Southeast Data, Assessment, and Review

SEDAR 89

South Atlantic Tilefish

SECTION I: Introduction

SEDAR 4055 Faber Place Drive, Suite 201 North Charleston, SC 29405

Introduction

SEDAR 89 addressed the stock assessment for South Atlantic Tilefish. The process consisted of a series of data webinars with the Life History Topical Working Group from November 2023-February 2024.

The Stock Assessment Report (SAR) is organized into 2 sections. Section I – Introduction contains a brief description of the SEDAR Process, Assessment and Management Histories for the species of interest, and the management specifications requested by the Cooperator. The Assessment Report can be found in Section II.

The final SAR for South Atlantic Tilefish was disseminated to the public in July 2024. The South Atlantic Fishery Management Council's Scientific and Statistical Committee (SSC) will review the final SAR. The SSC is tasked with recommending whether the assessment represents Best Available Science, whether the results presented in the SARs are useful for providing management advice and developing fishing level recommendations for the Council. An SSC may request additional analyses be conducted or may use the information provided in the SAR as the basis for their Fishing Level Recommendations (e.g., Overfishing Limit and Acceptable Biological Catch). A review of the assessment will be conducted by the South Atlantic Fishery Management Council's SSC in October 2024, followed by the Council receiving that information at its December 2024.

SEDAR PROCESS DESCRIPTION

SouthEast Data, Assessment, and Review (**SEDAR**) is a cooperative Fishery Management Council process initiated in 2002 to improve the quality and reliability of fishery stock assessments in the South Atlantic, Gulf of Mexico, and US Caribbean. SEDAR seeks improvements in the scientific quality of stock assessments and the relevance of information available to address fishery management issues. SEDAR emphasizes constituent and stakeholder participation in assessment development, transparency in the assessment process, and a rigorous and independent scientific review of completed stock assessments.

SEDAR is managed by the Caribbean, Gulf of Mexico, and South Atlantic Regional Fishery Management Councils in coordination with NOAA Fisheries and the Atlantic and Gulf States Marine Fisheries Commissions. Oversight is provided by a Steering Committee composed of NOAA Fisheries representatives: Southeast Fisheries Science Center Director and the Southeast Regional Administrator; Regional Council representatives: Executive Directors and Chairs of the South Atlantic, Gulf of Mexico, and Caribbean Fishery Management Councils; a representative from the Highly Migratory Species Division of NOAA Fisheries, and Interstate Commission representatives: Executive Directors of the Atlantic States and Gulf States Marine Fisheries Commissions.

SEDAR is normally organized around two workshops and a series of webinars. First is the Data Workshop, during which fisheries, monitoring, and life history data are reviewed and compiled. The second stage is the Assessment Process, which is conducted via a workshop and/or a series

of webinars, during which assessment models are developed and population parameters are estimated using the information provided from the Data Workshop. The final step is the Review Workshop, during which independent experts review the input data, assessment methods, and assessment products. The completed assessment, including the reports of all 3 stages and all supporting documentation, is then forwarded to the Council SSC for certification as 'appropriate for management' and development of specific management recommendations.

SEDAR workshops are public meetings organized by SEDAR staff and the lead Cooperator. Workshop participants are drawn from state and federal agencies, non-government organizations, Council members, Council advisors, and the fishing industry with a goal of including a broad range of disciplines and perspectives. All participants are expected to contribute to the process by preparing working papers, contributing, providing assessment analyses, and completing the workshop report.

MANAGEMENT OVERVIEW

Fishery Management Plan and Amendments

The following summary describes only those management actions that likely affect golden tilefish fisheries and harvest.

Original Snapper Grouper FMP

The Fishery Management Plan (FMP), Regulatory Impact Review, and Final Environmental Impact Statement for the Snapper Grouper Fishery of the South Atlantic Region, approved in 1983 and implemented in August of 1983, established a management regime for the fishery for snappers, groupers and related demersal species of the Continental Shelf of the southeastern United States in the exclusive economic zone (EEZ) under the area of authority of the South Atlantic Fishery Management Council and the territorial seas of the states, extending from the North Carolina/Virginia border through the Atlantic side of the Florida Keys to 83^o W longitude. Regulations apply only to federal waters.

Measures in the original FMP that affected golden tilefish include data reporting and research needs. No regulations specific to golden tilefish were included.

SAFMC FMP Amendments affecting tilefish

Description of Action	FMP/Amendment	Effective Date
 Prohibit trawls to harvest snapper grouper species south of Cape Hatteras, NC and north of Cape Canaveral, FL. Defined directed fishery as vessel with trawl gear and at least 200 pounds of snapper grouper species on board. 	Amendment 1	1/12/1989
 Prohibit fish traps, entanglement nets, and longline gear within 50 fathoms. Requirement to land with heads & fins attached. Permits - income requirement & required to exceed bag limits. Established 5 grouper aggregate. 	Amendment 4	1/1/1992
 Establish Total Allowable Catch (TAC) for golden tilefish and adjust the annual TAC downward by reserving a portion based on bycatch. Phase-in reduction over 3 years; year 1=1994 fishing year (calendar year). Logbook 1992 landings (1,777,772 lbs) used as base year. Establish a 5,000 pound (gutted weight) golden tilefish trip limit while the directed golden tilefish quota is open, then reduce to 300 pounds Include all tilefish species in the current 5 grouper aggregate bag limit. Prohibited transfer at sea for snowy grouper and golden tilefish regardless of where the fish were caught (i.e., state vs. federal waters). 100% logbook coverage upon renewal of permit. Creation of the <i>Oculina</i> Experimental Closed Area. Data collection needs specified for evaluation of possible individual fishing quota system. 	Amendment 6	6/27/1994; trip limit effective 6/6/1994
 Prohibit engaging in a directed fishery for tilefish in the EEZ north of Cape Canaveral, Florida, aboard a vessel that does not have a permit for snapper grouper. Bottom longline gear is allowed only north of St. Lucie Inlet, FL (27°10'N latitude). 	Amendment 7	1/23/1995
• Limited entry program: transferable permits and 225-lb non-transferable permits.	Amendment 8	8/17/1998

 Vessels with longline gear aboard may only possess snowy, warsaw, yellowedge, and misty grouper, and golden, blueline and sand tilefish. Specify that within the 5-fish aggregate grouper bag limit (which currently includes tilefish and excludes goliath grouper and Nassau grouper), no more than 2 fish may be gag or black grouper (individually or in combination). 	Amendment 9	2/24/1999
 Maximum sustainable yield (MSY) proxy for sg species (other than Nassau and goliath) = 30% static spawning potential ratio (SPR) Optimum yield: hermaphroditic groupers = 45% static SPR; all other species = 40% static SPR Overfished/overfishing evaluations: Golden tilefish: overfished (couldn't update existing static SPR of 21% SPR). Council concluded measures in Amendments 7, 8 and 9 were sufficient to rebuild golden tilefish above the overfished level. Defined overfishing level for snapper grouper species other than Nassau and goliath as F>F30% static SPR. MSST = [(1-M) or 0.5 whichever is greater]*B_{MSY} MFMT = F_{MSY} 	Amendment 11	12/2/1999
• Extended prohibition on bottom fishing for snapper grouper species in the Oculina Experimental Closed Area and on retaining such species in or from the area.	Amendment 13A	4/26/2004
 Commercial quota for golden tilefish = 295,000 lbs gw Commercial trip limit for golden tilefish of 4,000 lbs gw until 75% of quota is taken then reduce to 300 lbs; do not adjust trip limit downwards unless 75% of quota is landed on or before September 1 Recreational bag limit of 1 golden tilefish/person/day and included within 5 grouper aggregate bag limit. 	Amendment 13C	10/23/2006
• Established eight deepwater marine protected areas (MPA) in which fishing for or possession of South Atlantic snapper grouper are prohibited	Amendment 14	2/12/2009

 Prohibited sale of bag-limit caught snapper grouper species Reduced the effects of incidental hooking on sea turtles and smalltooth sawfish Changed the commercial permit renewal period and transferability requirements Implemented a plan to monitor and address bycatch, and Established management reference points, such as MSY and OY for golden tilefish. MSY equals the yield produced by FMSY. MSY and FMSY are defined by the most recent SEDAR. F_{MSY} = 0.043 = 336,425 lbs whole weight. If a stock is overfished, F_{OY} equals the fishing mortality rate specified by the rebuilding plan designed to rebuild the stock to SSBMSY within the approved schedule. After the stock is rebuilt, F_{OY} = a fraction of F_{MSY}. Golden tilefish is not overfished. Therefore, F_{OY} = 75% F_{MSY} = 326,554 lbs whole weight. MSST equals 75% SSB_{MSY} = 1,454,063 lbs whole weight. 	Amendment 15B	12/16/2009
 Reduced grouper aggregate bag limit (including tilefishes) from 5 to 3. Required possession of dehooking tools when catching snapper grouper species to reduce recreational and commercial bycatch mortality. 	Amendment 16	7/29/2009
• Required use of non-stainless steel circle hooks when fishing for snapper grouper species with hook-and-line gear and natural bait north of 28°N latitude in the South Atlantic EEZ.	Amendment 17A	3/3/2011

 following fishing season. Compare the recreational ACL with projected recreational landings over a range of years. For 2010, use only 2010 landings. For 2011, use the average landings of 2010 and 2011. For 2012 and beyond, use the most recent three-year running average. Implemented a closure to commercial and recreational harvest of 6 deepwater species (snowy grouper, blueline tilefish, yellowedge grouper, misty grouper, queen snapper, and silk snapper) seaward of 240 feet (73 m) to
--

		I
 Established a longline endorsement for the commercial component of the golden tilefish fishery, including eligibility and transferability requirements and appeals process. Allocated commercial ACL between gear groups: 75% to longline and 25% to hook-and-line. Established a commercial trip limit of 4,000 for longlines and 500 pounds for hook and line (longliners not eligible to fish under hook-and-line trip limit after longline quota is landed). 	Amendment 18B	5/23/2013
 Modified AMs for snapper grouper species, including golden tilefish 	Amendment 34 (Generic Accountability Measures and Dolphin Allocation Amendment)	2/22/2016
• Clarified regulations governing the use of Golden Tilefish Longline Endorsements.	Amendment 35	6/22/2016
• Established SMZs to enhance protection for snapper- grouper species in spawning condition including speckled hind and warsaw grouper.	Amendment 36	7/31/2017
Modification to sea turtle release gear and snapper grouper framework procedures	Amendment 42	1/8/2020
• Modify bycatch and discard reporting for commercial and for-hire vessels.	Amendment 26 (Bycatch Reporting Amendment) (2019a)	3/30/2020
 Weekly electronic reporting for charter vessel operators with a federal for-hire permit. Reduce the time allowed for headboat operators to complete electronic reports. Requires location reporting by charter vessels with the same detail currently required for headboat vessels. 	Amendment 39 (Generic For-Hire Reporting Amendment) (2017e)	1/4/2021

 Revises golden tilefish acceptable biological catch, annual catch limit (ACL), and annual optimum yield. Revises sector allocations (96.7% commercial; 3.3% recreational) and sector ACLs. Modifies the commercial longline season to begin on January 15. The fishing year remains the calendar year. Modifies recreational accountability measures for golden tilefish. NMFS will announce the recreational season each year based on catch rates from the previous season. The season will start on January 1 and end on the announced closing date. The recreational fishery does not close mid-season. 	Amendment 52	12/7/2023
--	--------------	-----------

Description of Action	FMP/Amendment	Effective Date
• Removed closure for deep water species (snowy grouper, blueline tilefish, yellowedge grouper, misty grouper, queen snapper, and silk snapper) beyond 240 ft (73 m) implemented through Amendment 17B	Regulatory Amendment 11	5/10/2012
 Revised ABC based on projections from SEFSC (January 27, 2012) Established ACL = yield at 75%Fmsy when stock is at equilibrium = 625,000 lbs ww (558,036 lbs gw) Revised commercial and recreational ACLs based on existing allocations: Commercial ACL = 606,250 lbs ww (541,295 lbs gw) Recreational ACL = 3,019 fish Revised rec ACT and AMs. Reopened commercial harvest under 300 lbs trip limit for 2012 fishing year. 	Regulatory Amendment 12	10/9/2012
• Ended overfishing of golden tilefish by reducing the ACL based on the most recent stock assessment.	Regulatory Amendment 28	1/4/2019
Best fishing practices & powerheads	Regulatory Amendment 29	7/15/2020
• 30 Special Management Zones off NC & 4 off SC were established at artificial reef sites	Regulatory Amendment 34	5/3/2021

Emergency and Interim Rules

Golden tilefish Interim Rule – effective 1/2/2018 through 7/1/2018 and 7/2/2018 through 1/3/2019 -- Reduced the golden tilefish total ACL, the commercial and recreational sector ACLs, and the quotas for the hook-and-line and longline components of the commercial sector.

Secretarial Amendments

None.

Control Date Notices

- 1. Notice of Control Date (07/30/91 56 FR 36052) Anyone entering **federal snapper grouper fishery (other than for wreckfish)** in the EEZ off S. Atlantic States after 07/30/91 was not assured of future access if limited entry program developed.
- 2. Notice of Control Date (10/14/05 70 FR 60058) Anyone entering **federal snapper grouper fishery** off S. Atlantic states after 10/14/05 was not assured of future access if limited entry program developed.
- 3. Notice of Control Date (2/20/09 74 FR 7849) Anyone entering federal golden tilefish segment of the snapper grouper fishery off S. Atlantic states after 12/4/08 was not assured of future access if limited entry program developed.
- 4. Notice of Control Date (01/31/11 76 FR 5325) Anyone entering federal snapper grouper fishery off S. Atlantic states after 09/17/10 was not assured of future access if limited entry program developed.
- 5. Notice of Control Date (6/15/16 76 FR 66244) Fishermen entering the **federal forhire recreational sector for the Snapper Grouper fishery** after June 15, 2016, will not be assured of future access should a management regime that limits participation in the sector be prepared and implemented.

The net effect of these various control dates is that there are two control dates:

- 1. Federal Snapper Grouper Fishery 1/31/2011
- 2. Federal Golden Tilefish Segment of the Snapper Grouper Fishery -2/20/2009

Management Program Specifications

General Management Information

Species	Golden Tilefish
Management Unit	Southeastern US
Management Unit Definition	All waters within South Atlantic Fishery Management Council Boundaries (VA/NC boundary south to the SAMFC/GMFMC boundary)
Management Entity	South Atlantic Fishery Management Council

Management Contacts Council/SERO	Michael Schmidtke / Rick DeVictor
Current stock exploitation status	Not Overfishing
Current stock biomass status	Not Overfished

Specific Management Criteria

Estimated status indicators, benchmarks, and related quantities from the Beaufort catch-age model applied in SEDAR 66 (2021). Rate estimates (F) are in units of y-1; status indicators are dimensionless; and biomass estimates are in units of metric tons or pounds, as indicated. Spawning stock biomass (SSB) and minimum stock size threshold (MSST) are measured by total gonad weight of mature females.

Criteria	South Atlantic – Current (SEDAR 66, 2021)		
Cinterna	Definition	Value	
MSST (metric tons)	75% SSB _{MSY}	14.9	
MFMT (per year)	F _{MSY}	0.282	
MSY (1000 pounds)	Yield at F _{MSY}	541.6	
F _{MSY} (per year)	Fmsy	0.282	
OY (1000 pounds)	Yield at Foy	OY (65% F _{MSY})= 525 OY (75% F _{MSY})= 534 OY (85% F _{MSY})= 539.4	
R _{MSY}	1000 age-1 fish	312.1	
Yield at F _{TARGET} (equilibrium)	Landings and discards, pounds and numbers		
Боу	F _{OY} = 65%,75%, 85% F _{MSY}	65% F _{MSY} = 0.183 75% F _{MSY} = 0.211 85% F _{MSY} = 0.24	
М	Scalar of Lorenzen M	0.1038	
Terminal F	Exploitation (per year)	0.2671	
Terminal Biomass ¹	Biomass (metric tons)	18	
Exploitation Status	F2016-2018/FMSY	0.947	
Biomass Status ¹	SSB ₂₀₁₈ /MSST ²	1.235	

2.5.2. Continued Specific Management Criteria

	South Atlantic – Proposed (Values from SEDAR 89)		
Criteria	Definition	Base Run Values	Median of Base Run MCBs
MSST ¹	75% SSB _{MSY}		
MFMT	F _{MSY}

F Target			
Yield at FTARGET (equilibrium)	Landings and discards, pounds and numbers		
Foy	F _{OY} = 65%,75%, 85% F _{MSY}		
М	М		
Terminal F	Exploitation		
Terminal Biomass ¹	Biomass		
Exploitation Status	F/MFMT		
Biomass Status ¹	SSB/MSST SSB/SSB _{MSY}		
Generation Time			
T _{REBUILD} (if appropriate)			

1. Biomass values reported for management parameters and status determinations should be based on the biomass metric recommended through the assessment process and Council's Scientific and Statistical Committee (SSC). This may be total, spawning stock or some measure thereof, and should be applied consistently in this table.

2. The SAFMC's definition of MSST for golden tilefish is (0.75*SSBmsy) which was established in Snapper Grouper Amendment 15B. The MSST value used in SEDAR 25 and the subsequent management actions was (1-M)*SSBmsy. Calculations for MSST in the 2015 update assessment used 0.75*SSBmsy.

NOTE: "Proposed" columns are for indicating any definitions that may exist in FMPs or amendments that are currently under development and should therefore be evaluated in the current assessment. Please clarify whether landings parameters are 'landings' or 'catch' (Landings + Discard). If 'landings', please indicate how discards are addressed.

Table 2.5.3. Stock Rebuilding Information

N/A

Table 2.5.4. Stock projection information

South Atlantic	
Requested Information	Value
First Year of Management	Assume management begins in 2027. However, if stock neither overfished or overfishing, a projection with the revised ABC and OFL should be provided assuming that landings limits are changed in the 2026 fishing year.
Interim basis	ACL, if landings are within 10% of the ACL; average landings otherwise. Assume the ratio of landings to discards remains the same and landings are constrained to the ACL.
Projection Outputs	
Landings	Pounds and numbers
Discards	Pounds and numbers
Exploitation	F & Probability F>MFMT
Biomass (total or SSB, as	B & Probability B>MSST
appropriate)	(and Prob. B>B _{MSY} if under rebuilding plan)
Recruits	Number

Table 2.5.5. Base Run Projections Specifications. Long Term and Equilibrium conditions.

	itali i i ojeenomo o			
Criteria	Definition	If overfished	If overfishing	Neither
				overfished nor
				overfishing
Projection Span	Years	T _{REBUILD}	10	10
	F _{CURRENT}	Х	Х	Х
Ducientian	F _{MSY}	Х	Х	Х
Projection Values	75% F _{MSY}	Х	Х	Х
values	F _{REBUILD}	Х		
	F=0	Х		

NOTE: Exploitation rates for projections may be based upon point estimates from the base run (current process) or upon the median of such values from the MCBs evaluation of uncertainty. The critical point is that the projections be based on the same criteria as the management specifications.

Table 2.5.6. P-star projections. Short term specifications for OFL and ABC
recommendations. Additional P-star projections may be requested by the SSC once the
ABC control rule is applied.

Criteria		Overfished	Not overfished
Projection Span	Years	Interim + 5	Interim + 5
Probability Values	50%	Probability of stock rebuild	Probability of overfishing
Flobability values	30%	Probability of stock rebuild	Probability of overfishing

Table 2.5.7. Quota Calculation Details

If the stock is managed by quota, please provide the following information.

The following quota values are pending approval of Snapper Grouper Amendment 52

	Commercial ACL (lbs gw)	Recreational ACL (numbers of fish)	Total ACL (lbs gw)
Current Quota Value	2023: 420,645 2024: 433,216 2025: 442,886 2026+: 450,622	2023: 2,559 2024: 2,635 2025: 2,694 2026+: 2,741	2023: 435,000 2024: 448,000 2025: 458,000 2026+: 466,000
Next Scheduled Quota Change	NA	NA	NA
Annual or averaged quota?	annual	annual	annual
If averaged, number of years to average	NA	NA	NA
Does the quota account for bycatch/discard?	No	No	No

How is the quota calculated - conditioned upon exploitation or average landings? Commercial ACL and Recreational ACL (as shown above) is based on yield at F_{OY} and assumes population biomass at equilibrium. Yield at F_{OY} is allocated to commercial and recreation sectors based on the following formula for each sector: Sector apportionment = (50% * average of long catch range (lbs) 1986-2008) + (50% * average of recent catch trend (lbs) 2006-2008). The allocation is 96.7% commercial and 3.3% recreational. This allocation was established in Amendment 52 (effective December 7, 2023).

Does the quota include bycatch/discard estimates? If so, what is the source of the bycatch/discard values? What are the bycatch/discard allowances?

Commercial and Recreational ACLs do not require monitoring of discards and are based on landed catch. Assessment takes into consideration bycatch and provides estimates of yield at F_{MSY} and F_{OY} as landed catch rather than landed catch plus dead discards.

Are there additional details of which the analysts should be aware to properly determine quotas for this stock?

No.

Management and Regulatory Timeline

The following tables provide a timeline of Federal management actions by fishery.

July 2024 Table 2.6.1 South Atlantic Golden Tilefish Recreational Regulatory History prepared by: Michael Schmidtke

Year	Quota/ Annual Catch Limit ^A (# fish)	Days Open	Fishing Season	Reason for Closure	Season Start Date (first day implemented)	Season End Date (last day effective)	Retention Limit	Retention Limit Start Date	Retention Limit End Date	Aggregate Retention Limit	Aggregate Retention Limit Start Date	Aggregate Retention Limit End Date

2023		168	closed	quota met	17-Jul	31-Dec						

* Fishing year is the calendar year. Size limits have not been used in management of the recreational sector of the golden tilefish fishery.

^A Aggregate grouper bag limit (includes gag, scamp, red grouper, black grouper, speckled hind, snowy grouper, rock hind, red hind, coney, graysby, misty grouper, yellowedge grouper, yellowmouth grouper, tiger grouper, golden tilefish, blueline tilefish, and sand tilefish) of 5/person/day; specifies 1 speckled hind and 1 warsaw grouper in 5 grouper aggregate. (Snapper Grouper [SG] Amendment 6; effective 6/27/1994)

^B Aggregate grouper bag limit specifies no more than 2 can be gag or black grouper. (SG Amendment 9; effective 2/24/1999)

^C Limit possesstion to 1 golden tilefish in aggregate grouper bag limit of 5/person/day. (SG Amendment 13C; effective 10/23/2006)

^D Limit possession to 1 golden tilefish in aggregate grouper bag limit of 3/person/day; no more than one fish in aggregate bag may be gag or black grouper; captain and crew may not retain bag limit. (SG Amendment 16; effective date 07/29/2009) ^E Prohibited sale of bag-limit caught snapper grouper species, including golden tilefish. (SG Amendment 15B; effective 12/16/2009)

F Recreational annual catch limit (ACL) established in numbers of fish (1,578 fish); Accountability Measure is if exceeded, Regional Administrator shall publish a notice to reduce the length of the following fishing season to ensure ACL is not exceeded. Harvest of speckled hind and warsaw grouper prohibited (e.g. removed from grouper aggregate bag limit). Prohibits harvest of 6 deepwater species seaward of 240' (yellow edge grouper, misty grouper, snowy grouper, blueline tilefish, queen snapper, silk snapper). (SG Amendment 17B; effective 1/31/2011)

^G Tiger grouper removed from FMU. (and therefore removed from aggregate bag limit; Comphrehensive ACL Amendment; effective date 4/16/2012)

^H Deepwater closure eliminated (Regulatory Amendment 11; effective date 5/10/2012)

July 2024

¹Recreational ACL in numbers of fish (3,019 fish); In-season closure if recreational ACL is met or projected to be met; if exceeded, monitor for persistence of increased landings and, if necessary, Regional Administrator shall publish a notice to reduce the length of the following fishing season to ensure ACL is not exceeded. (SG Regulatory Amendment 12; effective 10/9/2012)

^J Captain and crew on for-hire trips can retain bag limit of snapper grouper species. (Amendment 27; effective date 1/27/2014)

^K ACL was temporarily reduced while permanent adjustments were made through Regulatory Amendment 28. (Interim Rule effective on 1/2/2018 and extended through 1/3/2019)

^L Annual catch limits reduced to end overfishing. (SG Regulatory Amendment 28; effective 1/4/2019)

* Size limits and multispecies aggregate retention limits have not been used in management of the commercial sector of the golden tilefish fishery.

^A Annual catch limits (ACL) were first implemented for golden tilefish in 2011, replacing annual quotas. (SG Amendment 17B; effective 1/31/2011)

^B Commercial quota of 295,000 lb gw; 4,000 lb gw commercial trip limit until 75% of the commercial quota is taken, after which the trip limit is reduced to 300 lb gw. Trip limit is not reduced if 75% of the quota is reached after September 1. (SG Amendment 13C; effective 10/23/2006)

^C ACL established. (SG Amendment 17B; effective 1/31/2011)

^D ACL increased due to results of SEDAR 25 assessment; season re-opened Oct 9, 2012 with 300 lb gw trip limit. (SG Regulatory Amendment 12; effective 10/9/2012)

^E Commercial ACL allocated between gear groups: 75% to longline and 25% to hook and line; established 4000 lb gw trip limit for longliners and 500 lb gw trip limit for hook and line; longliners not eligible to fish under hook and line trip limit after longline quota is landed. (SG Amendment 18B; effective 5/23/2013)

^F ACL was temporarily reduced while permanent adjustments were made through Regulatory Amendment 28. (Interim Rule effective on 1/2/2018 and extended through 1/3/2019)

^G Annual catch limits reduced to end overfishing. (SG Regulatory Amendment 28; effective 1/4/2019)

State Regulatory History

North Carolina

There are currently no North Carolina state-specific regulations for golden tilefish. North Carolina has complemented federal regulations for all snapper grouper species via proclamation authority since 1991. Between 1992 and 2005, species-specific regulations were added to the proclamation authority contained in rule 15A NCAC 03M .0506. Specific to golden tilefish, this rule was amended effective May 24, 1999 (following Amendment 9 to the SAFMC Snapper-Grouper FMP, eff. 2/24/99) to include the following Sub-item: (q) It is unlawful to possess any species of the Snapper-grouper complex except snowy, warsaw, yellowedge, and misty groupers; blueline, **golden** and sand tilefishes; while having longline gear aboard a vessel.

In 2002, North Carolina adopted its Inter-Jurisdictional Fishery Management Plan (IJ FMP), which incorporates all ASMFC and council-managed species by reference, and adopts all federal regulations as minimum standards for management. In completing the 2008 update to the IJ FMP, all species-specific regulations were removed from rule 15A NCAC 03M .0506, and proclamation authority to implement changes in management was moved to rule 15A NCAC 03M .0512. Information updates to the IJ FMP were completed and approved in 2015 and 2022 and contained no additional regulatory changes. Since the 2008 IJ FMP update, all snapper grouper regulations were contained in a single proclamation, which was updated anytime an opening/closing of a particular species in the complex occurred, as well as any changes in allowable gear, required permits, etc. Beginning in 2015, commercial and recreational regulations are contained in separate proclamations. The most current Snapper Grouper proclamations (and all previous versions) can be found using this

link: <u>https://www.deq.nc.gov/about/divisions/marine-fisheries/rules-proclamations-and-size-and-bag-limits/fisheries-management-proclamations</u>.

15A NCAC 03M .0506 SNAPPER-GROUPER COMPLEX

(a) In the Atlantic Ocean, it is unlawful for an individual fishing under a Recreational Commercial Gear License with seines, shrimp trawls, pots, trotlines or gill nets to take any species of the Snapper-Grouper complex.

(b) The species of the snapper-grouper complex listed in the South Atlantic Fishery Management Council Fishery Management Plan for the Snapper-Grouper Fishery of the South Atlantic Region are hereby incorporated by reference and copies are available via the Federal Register posted on the Internet at <u>www.safmc.net</u> and at the Division of Marine Fisheries, P.O. Box 769, Morehead City, North Carolina 28557 at no cost. *History Note: Authority G.S. 113-134; 113-182; 113-221; 143B-289.52; Eff. January 1, 1991; Amended Eff. April 1, 1997; March 1, 1996; September 1, 1991; Temporary Amendment Eff. December 23, 1996; Amended Eff. August 1, 1998; April 1, 1997; Temporary Amendment Eff. January 1, 2002; August 29, 2000; January 1, 2000; May 24, 1999; Amended Eff. October 1, 2008; May 1, 2004; July 1, 2003; April 1, 2003; August 1, 2002; Readopted Eff. April 1, 2019.*

15A NCAC 03M .0512 COMPLIANCE WITH FISHERY MANAGEMENT PLANS

(a) In order to comply with management requirements incorporated in Federal Fishery Management Council Management Plans or Atlantic States Marine Fisheries Commission Management Plans or to implement state management measures, the Fisheries Director may, by proclamation, take any or all of the following actions for species listed in the Interjurisdictional Fisheries Management Plan:

(1) Specify size;

(2) Specify seasons;

(3) Specify areas;

(4) Specify quantity;

(5) Specify means and methods; and

(6) Require submission of statistical and biological data.

(b) Proclamations issued under this Rule shall be subject to approval, cancellation, or modification by the Marine Fisheries Commission at its next regularly scheduled meeting or an emergency meeting held pursuant to G.S. 113-221.1.

History Note: Authority G.S. 113-134; 113-182; 113-221; 113-221.1; 143B-289.4;

Eff. March 1, 1996;

Amended Eff. October 1, 2008;

Pursuant to G.S. 150B-21.3A, rule is necessary without substantive public interest Eff. January 9, 2018.

South Carolina

Sec. 50-5-2730 of the SC Code states:

"Unless otherwise provided by law, any regulations promulgated by the federal government under the Fishery Conservation and Management Act (PL94-265) or the Atlantic Tuna Conservation Act (PL 94-70) which establishes seasons, fishing periods, gear restrictions, sales restrictions, or bag, catch, size, or possession limits on fish are declared to be the law ofthis State and apply statewide including in state waters."

As such, South Carolina tilefish regulations are (and have been) derived directly from the federal regulations as promulgated under Magnuson-Stevens Fishery Conservation and Management Act. There are no known separate golden tilefish regulations that have been codified in the South Carolina Code.

Georgia

There are currently no Georgia state regulations for tilefish. However, the authority restswith the Georgia Board of Natural Resources to regulate this species if deemed necessary in the future.

2023	None	1 per person within the 3-fish grouper aggregate bag limit	Same as federal waters	Requires the possession or a descending device or venting tool that is rigged and ready for use on board a vessel when harvesting or attempting to harvest, including catch and release, of reef fish in state waters. Also, requires the use of such device/tool if a fish is exhibiting signs of barotrauma prior to release.	April 1, 2023

Florida Atlantic and Monroe County Golden Tilefish Regulation Changes by Date

July 1, 2007

- Added Golden Tilefish to the Reef Fish chapter, which established the following regulations for Golden Tilefish:
 - Allowable gear: hook and line, black sea bass trap, and spear (except powerheads, bangsticks or explosive devices);
 - Commercial harvest prohibited when adjacent federal waters are closed to commercial harvest;
 - Fish must be landed in whole condition; and
 - Two-day possession limit allowed for persons aboard charter and headboats on trips exceeding 24 hours provided that the vessel is equipped with a permanent berth for each passenger aboard, and each passenger has a receipt verifying the trip length.
- Set the recreational harvest limit at one Golden Tilefish within the five-fish daily aggregate grouper bag limit for Atlantic and Monroe County state waters.
- Designated Golden Tilefish a "restricted species" and required commercial harvesters to possess a Restricted Species endorsement on their Saltwater Products License as well as a federal South Atlantic Snapper Grouper commercial permit to sell Golden Tilefish or harvest Golden Tilefish in excess of the recreational bag limit.
- Set commercial trip limits in the Atlantic that are the same as trip limits in adjacent federal waters.
- Prohibited commercial fishermen from harvesting or possessing the recreational bag limit of reef fish species on commercial trips.

<u>January 19, 2010</u>

- Reduced recreational aggregate grouper bag limit to 3 fish per person per day in all Atlantic and Monroe County state waters.
- Prohibited the captain and crew of for-hire vessels from retaining any species in the aggregate grouper bag limit.
- Required dehooking tools to be aboard commercial and recreational vessels for anglers to use as needed to remove hooks from Atlantic reef fish.

March 13, 2014

• Eliminated prohibition on captain and crew of for-hire vessels from retaining recreational bag limits of Vermilion Snappers, groupers and Golden Tilefish on for-hire trips in state waters of the Atlantic (including Monroe County for grouper and Golden Tilefish).

September 13, 2016

• Created an exception allowing recreational anglers to land reef fish as fillets instead of as whole fish, provided the reef fish were recreationally harvested in The Bahamas and specific conditions are met.

<u>January 1, 2021</u>

• Requires non-stainless-steel, non-offset circle hooks north of 28 degrees north latitude and non-stainless-steel hooks south of 28 degrees north latitude when fishing for reef fish

with hook and line using natural bait.

<u>April 1, 2023</u>

• Requires the possession or a descending device or venting tool that is rigged and ready for use on board a vessel when harvesting or attempting to harvest, including catch and release, of reef fish in state waters. Also, requires the use of such device/tool if a fish is exhibiting signs of barotrauma prior to release.

ASSESSMENT HISTORY AND REVIEW

The benchmark assessment for Tilefish, SEDAR 04, was completed in 2004 with an assessment period 1961-2002 (SEDAR 04 2004). SEDAR 25 was a standard assessment completed in 2011 with an assessment period spanning 1962-2010 (SEDAR 25 2011). Several important changes were made during SEDAR 25 (e.g. M, h, SSB units) that make it somewhat difficult to compare SEDAR 04 with later assessments. An update assessment was completed in 2016 with an assessment period of 1962-2014 (SEDAR 25 2016). Current management of South Atlantic Tilefish is based on an assessment conducted in 2021 with data for the period 1962-2018 (SEDAR 66 2021).

As of 2002, the stock was not overfished (SSB₂₀₀₂/MSST = 1.27), but overfishing was occurring ($F_{2002}/F_{MSY} = 1.53$; SEDAR 04 2004). Terminal status estimates in SEDAR 25 found that the Tilefish stock was not overfished (SSB₂₀₁₀/MSST = 2.42), and it was also not undergoing overfishing ($F_{2008-2010}/F_{MSY} = 0.36$; SEDAR 25 2011). Terminal status estimates in the SEDAR 25 showed the stock was not overfished (SSB₂₀₁₄/MSST = 1.13), but overfishing was occurring ($F_{2008-2010}/F_{MSY} = 1.22$; SEDAR 25 2016).

Values from the SEDAR 66 assessment contrast with the stock status designation from SEDAR 04 (SSB₂₀₀₂/MSST =0.96) but concur with the not overfished status from SEDAR 25 (SSB₂₀₁₀/MSST = 1.69) and the SEDAR 25 (SSB₂₀₁₄/MSST = 1.49). However, the current assessment results suggest that overfishing was not occurring at the ends of any of the previous South Atlantic Tilefish assessments ($F_{2002} / F_{MSY} = 0.7, F_{2008-2010} / F_{MSY} = 0.47, F_{2012-2014} / F_{MSY} = 0.78$). The base model from SEDAR 66 ($F_{2016-2018} / F_{MSY} = 0.95$) suggested that South Atlantic Tilefish was not undergoing overfishing but the median of the uncertainty models suggested overfishing is occurring (median $F_{2016-2018} / F_{MSY} = 1.122$). Therefore, the overfishing status of this stock is highly uncertain but close to fully exploited.

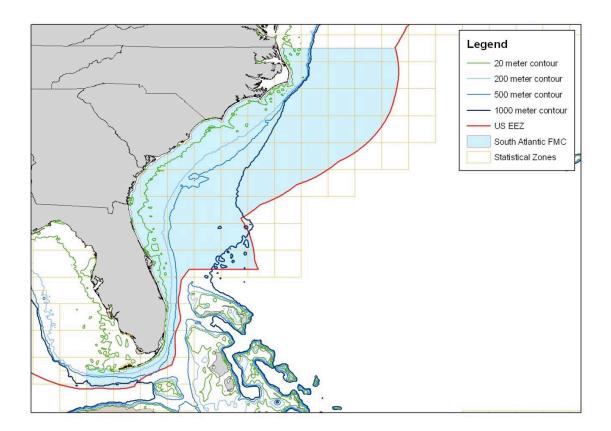

The general pattern in time series of SSB/MSST in SEDAR 66 was similar to the SEDAR 25, but was shifted upward so that it appears higher in all years. The trend and magnitude of SSB/MSST in SEDAR 25 were also similar up to 2003, but from 2004 to 2010 increased much more rapidly than what is reflected in the later assessments. The general pattern in the time series of F/F_{MSY} in SEDAR 66 was also similar to the SEDAR 25, but was shifted downward so that it appears lower in all years. This is particularly true of the period from approximately 1990-2005. The trend and magnitude of F/F_{MSY} in SEDAR 66.

Input values of constant M have been similar over the four Tilefish assessments (terminal years: 2002, 2010, 2014, 2018; M: 0.07, 0.1083, 0.1083, 0.1038), though M in SEDAR 04 was a little lower and was not used to scale age-varying M. Steepness has been fixed at similar values in all assessments (h: 0.72, 0.84, 0.84, 0.84) though again the value from

SEDAR 04 was a little lower. The estimate of F_{MSY} in SEDAR 04 was considerably lower than in later assessments (F_{MSY} : 0.043, 0.185, 0.236, 0.3). The estimate of MSY was also much lower in SEDAR 04 than in later assessments (MSY, klb: 335, 638, 560, 542). In SEDAR 04 SSB was measured in units of female biomass (MSST,mt: 659) and thus was not comparable to later assessments which were in units of gonad weight (MSST, mt W_{gonad} : 19.0, 16.4, 15).

1 Introduction

1.1 Executive Summary

This operational assessment evaluated the status of Tilefish (*Lopholatilus chamaeleonticeps*; a.k.a. Golden Tilefish, Great Northern Tilefish) off the Southeastern United States (i.e. the US South Atlantic stock). The primary objectives of this assessment were to build on previous assessments [SEDAR 04, SEDAR 25, and the SEDAR 66 (hereafter SEDAR 66)] to provide recent estimates of benchmarks and conduct updated stock projections.

Data compilation and assessment methods were guided by methods used in previous Tilefish assessments and other recent SEDAR assessments and output from the topical working group for this assessment. The benchmark assessment for Tilefish was completed in 2004 with an assessment period 1961-2002 (SEDAR 04 2004). SEDAR 25 was a standard assessment completed in 2011 with an assessment period spanning 1962-2010 (SEDAR 25 2011). An updated assessment of of South Atlantic Tilefish was completed in 2016 with an assessment period of 1962-2014 (SEDAR 25 2016). Management of Tilefish in the South Atlantic is currently based on an operational assessment conducted in 2021 with an assessment time period of 1972-2018. This assessment was conducted by the Southeast Fisheries Science Center in cooperation with regional data providers, for the time period 1972-2022.

Available data on this stock included indices of abundance, landings, and samples of annual length compositions and age compositions from fishery-dependent and fishery-independent sources. Two indices of abundance were developed during the SEDAR process and fit by the model: one fishery dependent index based on the commercial longline fleet logbooks and one fishery independent index based on the Marine Resources Monitoring, Assessment, and Prediction program 'long' bottom longline survey (MARMAP longline). These indices of abundance were not updated since the previous operational assessment as no new data were available or deemed usable due to management restrictions potentially influencing fishing behavior and catch rates. Landings data were available from all significant recreational and commercial sources.

The model used in all previous assessments of this stock—and updated here—was the Beaufort Assessment Model (BAM), an integrated statistical catch-age formulation (Williams and Shertzer 2015). A base run of BAM was configured and a mixed Monte Carlo/Bootstrap Ensemble (MCBE) analysis was conducted to provide estimates of key management quantities, such as stock and fishery status.

Estimated time series of stock status (SSB/MSST) showed a rapid decline during the 1980s and a slower decline during the 1990s, to a minimum value in 1996. From 1996 to 2010 stock status improved, but has been in decline again since 2011. This decline has slowed since 2020 to near SSB_{MSY} in 2022.

Current stock status was estimated in the base run to be $SSB_{2022}/MSST = 1.261$, indicating that the stock is not overfished. Through its history, SSB did not drop below MSST. Results from the MCBE suggested that the estimate of SSB relative to SSB_{MSY} and the status relative to MSST is highly uncertain (Figures 27 and 28). A small majority (54%) of MCBE runs agreed with the stock status result from the base assessment model. The base model, median and majority of the MCBE suggests that the stock is not overfished, but is below SSB_{MSY}.

The estimated time series of $F/F_{\rm MSY}$ from the assessment model suggests that although F has exceeded $F_{\rm MSY}$ sporadically for individual years during the assessment period, it has not been consistently above the limit since the period of overfishing during 1990-1995. However, fishing mortality has been increasing considerably since 2010 and is estimated to be above $F_{\rm MSY}$ in the terminal year of the model. There is considerable uncertainty in $F/F_{\rm MSY}$ as demonstrated by the MCBE, especially toward the end of the assessment period. Current fishery status in the terminal year, with current F represented by the geometric mean from 2020 - 2022 ($F_{\rm current} = F_{2020-2022} = 0.216$), was estimated by the base run to be $F_{2020-2022}/F_{\rm MSY} = 1$. Thus, at the end of the assessment Tilefish was fully exploited. However, results from the MCBE show that there is a lot of uncertainty in the fishing status of the species. Only 35% of MCBE runs agreed with the fishing status result from the base model, and the median value of $F_{2020-2022}/F_{\rm MSY}$ from the MCBE runs (1.16).

Compared to SEDAR 66, stock status has declined slightly and the stock is fully exploited in the base model but overfishing in the median of the MCBE. The estimated trends from this operational assessment are similar to those from the SEDAR 04, SEDAR 25, and SEDAR 66. However, this assessment did show some differences from previous assessments, which was not surprising, given modifications made to both the data and model (described throughout the report).

1.2 Workshop Time and Place

The SEDAR 89 South Atlantic Tilefish topical working group took place over a series of webinars held from November, 2023 to March, 2024.

1.3 Terms of Reference

- 1. Submit all data used in the SEDAR 66 South Atlantic Tilefish SEDAR process. Add all new and recent available data sufficient for use in the stock assessment through 2023. Data providers may decide to include additional preliminary or partial data that could be used in the stock assessment models or projection analyses (check with analysts if unsure about what could or could not be used).
- 2. Update the approved SEDAR 66 Atlantic Tilefish models with all provided and relevant data. Incorporate the latest and most appropriate BAM model methodologies, including relevant advances in fisheries science, biology, population dynamics, and stock assessment science.
- 3. Apply appropriate model diagnostics and make expert determinations for data and model changes as necessary to improve the accuracy and precision of population estimates.
- 4. Detail all the input data and model changes made between the SEDAR 66 South Atlantic Tilefish Operational assessment model and the proposed SEDAR 89 Operational assessment model. Write a final report describing all necessary details of the stock assessment model, data, and important issues. Include required management reference points and other important population dynamic information relevant for managers. Include a list of unresolved issues and research recommendations for future consideration.
- 5. Convene a topical working group including SSC representatives, industry representatives, and outside experts to meet via webinar or in-person. This group of specialists will evaluate the following subjects and document specific changes in input data or deviations from the SEDAR 66 South Atlantic Tilefish.
 - Review and explore the potential utility and incorporation of new life history information, including:
 - Data collected from expanded SCDNR SBLL survey, new cooperative SADLS survey, and SCDNR CRP pilot study (abundance, life history, etc). Examine spatial differences.
 - Evidence for hermaphroditism in the South Atlantic (specifically the interpretation and applicability of analyses conducted in Gulf of Mexico by Lombardi-Carlson (2012)).
 - Evidence for age or size dependence of spawning frequency and spawning season duration.
 - Genetic evidence of connectivity between northern and southern stocks (McDowell, VIMS).
 - Evidence for potential northward range shift.
- 6. Develop a stock assessment update report to address these ToRS and fully document the input data, methods, and results of the stock assessment update.

1.6 Statements Addressing Each Term of Reference

Note: Original ToRs are in normal font. Statements addressing ToRs are in italics and preceded by a dash (-).

- 1) Submit all data used in the SEDAR 66 South Atlantic Tilefish SEDAR process. Add all new and recent available data sufficient for use in the stock assessment through 2023. Data providers may decide to include additional preliminary or partial data that could be used in the stock assessment models or projection analyses (check with analysts if unsure about what could or could not be used).
- All data used in SEDAR 66 were collated and used in SEDAR 89. The assessment includes data through the end of 2022. Additional life history data were collected including ages, lengths, and weights. Conversion factors from length to whole weight, length to gutted weight and growth curves were updated with additional life history data. Additional date related to the reproductive biology of the species have become available since the previous assessment and have been incorporated into the assessment model. Recreational landings were calculated as the sum of MRIP and headboat (SRHS) estimates to better account for all sources of mortality. Estimates of longline discards were incorporated into the longline landings fit by the assessment model.
- 2) Update the approved SEDAR 66 Atlantic Tilefish models with all provided and relevant data. Incorporate the latest and most appropriate BAM model methodologies, including relevant advances in fisheries science, biology, population dynamics, and stock assessment science.
- SEDAR 89 updated the SEDAR 66 Atlantic Tilefish assessment model and incorporated data through the end of 2022 and included updated conversion factors and life history information. The current stock assessment incorporated numerous changes that were advances in fisheries science, the biology, and population dynamics of Atlantic tilefish. Recreational landings were modeled in numbers of fish to reduce some uncertainty in these estimates as the sample sizes for estimating weight were very small. Natural mortality relationships were updated using the most recent age data and the Hamel and Cope (2022) maximum age to natural mortality conversion. Natural mortality at age was modeled following Lorenzen (2022) as the inverse of length at age scaled to the constant M value. Natural mortality at age was coded into BAM so that the oldest age and youngest age over which to scale to the constant M could be changed to incorporate uncertainty in these values. The steepness parameter was estimated in this stock assessment after likelihood profiles and numerous testings suggested the parameter could be estimated. Biomass was reported in 1000 lb instead of metric tons to be more interpretable. Spawning stock biomass was calculated using age specific fecundity and is reported in units of trillions of eggs (see details below Terms of Reference 5 a. iii). In SEDAR 66, the last 7 years of the model did not estimate recruitment deviates. In SEDAR 89, likelihood profiling suggested that recruitment deviates could be extended so that only the last three terminal years were assumed to be driven solely by the stock recruitment function. A selectivity block in the commercial fisheries was implemented in 2009 for SEDAR 66, but this increase in number of parameters did not result in a sufficiently large change in the likelihood to warrant the increase in model complexity. Instead, a shift to smaller fish caught by the commercial fishery was observed to begin in 2020 and very few fish in the plus group were caught. To account for this drastic shift in the age composition, a dome-shaped time-block selectivity beginning in 2020 for the commercial fisheries was implemented in the model and resulted in an improvement in the likelihood. To account for the difficulty in ageing this species, an ageing error matrix was calculated from comparison of three readers from a reference set. The ageing error matrix was incorporated into the stock assessment model and resulted in a better likelihood and fit to the data.
- 3) Apply appropriate model diagnostics and make expert determinations for data and model changes as necessary to improve the accuracy and precision of population estimates.
- Changes to the SEDAR 66 BAM assessment model were made through the investigation of various diagnostics including likelihood profiles, likelihood value comparisons, runs tests, visual examination of residuals and onestep ahead residual of composition data. All model decisions resulted in better fits to the data in terms of the likelihood and accounted for a parsimonious model so as not to be overly complex. Model diagnostics are presented in the figures and the appendix.

- 4) Detail all the input data and model changes made between the SEDAR 66 South Atlantic Tilefish Operational assessment model and the proposed SEDAR 89 Operational assessment model. Write a final report describing all necessary details of the stock assessment model, data, and important issues. Include required management reference points and other important population dynamic information relevant for managers. Include a list of unresolved issues and research recommendations for future consideration.
- Changes to the model are described above in Terms of Reference 2 and are presented in further detail in the report. This report includes the necessary details of the stock assessment model, data, issues encountered and unresolved, research recommendations, management reference points, and population dynamics information relevant for managers.
- 5) Convene a topical working group including SSC representatives, industry representatives, and outside experts to meet via webinar or in-person. This group of specialists will evaluate the following subjects and document specific changes in input data or deviations from the SEDAR 66 South Atlantic Tilefish.
 - (a) Review and explore the potential utility and incorporation of new life history information, including:
 - i. Data collected from expanded SCDNR SBLL survey, new cooperative SADLS survey, and SCDNR CRP pilot study (abundance, life history, etc). Examine spatial differences.
 - SADLS: The South Atlantic Deepwater Longline Survey (SADLS) targets multiple deepwater species, with a focus on tilefishes and deepwater groupers. Catches of golden tilefish individuals by survey year were as follows: 2020: 166; 2021: 898; 2022: 434; 2023: 631. An SSC working group was convened in 2023 to assess the utility of the SADLS index in stock assessments. This working group determined that "at least 5 years of survey data should be available before an index of relative abundance should be considered for use in a stock assessment." For age compilations during the current assessment, the working group advised to "use age/biological information as available and appropriate." The compiled life history data for the current assessment contains 1179 samples collected from the SADLS. Age, weight, length and histology data collected by this survey were incorporated into the updated life history conversion equations. SCDNR SBLL survey/CRP pilot study: The expanded short bottom longline survey (SBLL) samples high relief bottom types, and catches relatively few golden tilefish. Compiled life history data for the current assessment had only 140 sampled individuals from the SBLL survey. The age, length, and weight samples from all available sources were incorporated into the updated growth models and length-weight models.
 - ii. Evidence for hermaphroditism in the South Atlantic (specifically the interpretation and applicability of analyses conducted in Gulf of Mexico by Lombardi-Carlson (2012)).
 - Analyses conducted by members of the SCDNR concluded that golden tilefish do not meet the criteria to be considered hermaphroditic in the South Atlantic. Findings from these analyses are reported in SEDAR89-WP-03 (Bubley et al. 2024).
 - iii. Evidence for age or size dependence of spawning frequency and spawning season duration.
 - As reported in SEDAR89-WP-03 (Bubley et al. 2024), spawning season duration was linearly related to total length and spawning fraction was logistically related to total length. Age specific fecundity estimates resulting from these models were incorporated into the stock assessment and used to calculate spawning stock.
 - iv. Genetic evidence of connectivity between northern and southern stocks (McDowell, VIMS).
 - The scientific literature was searched for any studies that investigated the stock structure of golden tilefish in the Atlantic Ocean and Gulf of Mexico. A single study was identified (Katz et al. 1983). This study included samples from a number of sites in the Mid-Atlantic Bight, Gulf of Mexico, and a single site off the coast of South Carolina. The study presented evidence that the morphological data for the South Carolina samples were contradictory with the electrophoretic analysis and the two showed conflicting results. Morphometric characteristics compared between the SC samples and the Mid-Atlantic Bight indicated no significant difference. However, there was a highly significant

difference between the Mid-Atlantic Bight and southern samples (Gulf of Mexico and SC) in the genotype distributions from liver electrophoresis. The authors state that the interpretation of the data may be hampered by the small sample sizes for the southern populations and the great distances between sampling sites. Jan McDowell was contacted to determine if she had conducted any studies on this species of tilefish. She confirmed that she had not conducted any genetic analysis for golden tilefish, but had conducted and published research for blueline tilefish. A study is currently being conducted by David Portnoy and Shannon O'Leary on golden tilefish genetics in the Gulf of Mexico and Atlantic Ocean. However, this research is not yet completed and has not been peer reviewed. Therefore, there is no information currently available to determine the genetic evidence of connectivity between the northern and southern stocks.

- v. Evidence for potential northward range shift.
- Tilefish were first discovered in 1879 just south of Nantucket, MA. Since then, the distribution of tilefish has been described as extending from Nova Scotia to Suriname (Doolet 1978). The South Atlantic population falls squarely within the middle of the latitudinal range of this species. Tilefish have been described as relatively sedentary as a result of a mark-recapture study that recaptured all fish within 2 km of the tagging site up to 1.6 years after release (Grimes et al. 1983). The northern extent of the South Atlantic population of tilefish has been delineated at Cape Hatteras, NC. The upper middle continental slope near Hatteras has been hypothesized as a potential barrier between the northern and southern stock of tilefish (Steimle et al. 1999). This area of the continental shelf has either continuous or episodic hypoxia in the benthic boundary layer, which would prove problematic for the burrowing tilefish (Sulak and Ross 1996). Additionally, the area was noted to be devoid of active benthopelagic foragers and species present were of smaller size than elsewhere on the shelf. The lack of movement in the adult phase of the species and the inhospitable habitat near Cape Hatteras make a northward shift of adults in the population unlikely. The other potential route of a northward range shift would be the dispersal of eggs and larvae and their eventual settlement in favorable habitats in northern regions. This would likely overlap with the current northern stock of tilefish. A plethora of information would be needed to prove such a phenomenon was occurring. First, evidence delineating the historical and current differences in stock structure and characteristics of the northern and southern stocks would need to be clearly defined through a multi-faceted approach (genetics, meristics, etc.). Second, a clear methodology to accurately classify individuals as either from the northern or southern stock would need to be developed. Third, a time series of the proportion of northern and southern stock individuals that occur north of Cape Hatteras would need to show an increase in the proportion of individuals from the southern stock. Currently, there is limited data available to delineate and classify the stock structure in the Atlantic Ocean (Katz et al. 1983), and no time series exists documenting northward movement of southern individuals. Anecdotal evidence from commercial fishermen during the Topical Working Group suggested that tilefish continue to be caught in the same areas that have historically been observed in both the northern and southern extent of the population. Therefore, there is no evidence suggesting a northward range shift.
- 6) Develop a stock assessment update report to address these ToRS and fully document the input data, methods, and results of the stock assessment update.
- Please see this report.

2 Data Review and Update

The benchmark assessment for Tilefish (*Lopholatilus chamaeleonticeps*) off the Southeastern United States (i.e. the US South Atlantic stock), SEDAR 04, was completed in 2004 with an assessment period 1961-2002 (SEDAR 04 2004). SEDAR 25 was a standard assessment completed in 2011 with an assessment period spanning 1962-2010 (SEDAR 25 2011). An update assessment of South Atlantic Tilefish was completed in 2016 with an assessment period of 1962-2014 (SEDAR 25 2016). Current management of Tilefish of the Southeastern United States is based on SEDAR 66 with an assessment period of 1972-2018 (SEDAR 66 2021).

In the current SEDAR 89 assessment, data through 2022 were considered. For most data sources, the data were simply updated with the additional years of data (2018-2022) using the same methods as in the prior assessments. However, for some sources, it was necessary to update data prior to 2019 as well. The input data for this assessment are described below, with emphasis on the data that required modification beyond just the addition of years. A summary timeline of data sources fit to in this assessment is plotted in Figure 1.

2.1 Data Review

In this operational assessment, the Beaufort assessment model (BAM) was fit to many of the same data sources as in SEDAR 04 and the SEDAR 25, SEDAR 66 (hereafter SEDAR 66).

- Landings: commercial handline, commercial longline, and general recreational
- Indices of abundance: commercial longline and Marine Resources Monitoring, Assessment, and Prediction program 'long' bottom longline survey (MARMAP longline)
- Length compositions of landings: general recreational
- Age compositions of landings: commercial handline, commercial longline, and MARMAP longline survey.

Contrasts to data used in the SEDAR 66 assessment include:

- Recreational landings were calculated as the sum of landings estimated from the Marine Recreational Information Program (MRIP) and Southeast Region Headboat Survey (SRHS). Landings were fit in number of fish caught. This was to remove the necessity of converting landings to pounds whole weight and then converting to pounds gutted weight as in SEDAR 66. For calculations of total landings, number of fish were converted directly to pound gutted weight using new conversion factors.
- Estimates of commercial longline discard were incorporated into the landings estimates for this fleet.
- Data on age estimates by multiple readers of a reference set of tilefish otoliths were used to create an ageing error matrix, which was used in the assessment model to characterize the uncertainty in this data source.
- Natural mortality was updated using recent maximum age data and the Hamel and Cope (2022) maximum age equation. Natural mortality at age (M_a) was calculated by scaling the inverse length to the constant M for a specified range of ages (Lorenzen 2022).
- All conversion factors were updated by fitting appropriate models to all currently available data from fisherydependent and -independent sources. These conversion factors include length-length conversions, von Bertalanffy growth, length to whole weight, and length to gutted weight.
- Length compositions used in the assessment and the age compositions that were weighted by the lengths were slightly different than previous assessments as a result of changes to the conversion factors.
- Maturity at age was fit as maturity at length and mean length at age from the von Bertalanffy growth curve was used to determine maturity at age. Fecundity at age was determined using a plateau model and batch fecundity model (Bubley et al. 2024), which were multiplied together and with the maturity at age to provide total reproductive output in trillions of eggs. Spawning stock biomass (SSB) was calculated based on this total reproductive output at age. SEDAR 66 had calculated SSB as gonad weight.

2.2 Data Update

2.2.1 Life History

Numerous changes to conversion equations of life history inputs were made compared to SEDAR 04 and SEDAR 66. It was discovered that in previous assessments, data providers had incorrectly assumed that the conversions of TL listed in SEDAR 4 were for natural TL. However, all samples from MARMAP are measured in maximum TL and therefore the conversion from SL and FL would be to maximum TL. Therefore, the order of conversion and preference for length type changed as a result of this understanding. To ensure that all life-history conversions factors were in the appropriate units and were up to date using new available information, regressions were performed using all currently available data.

Age was used to predict maximum total length using a von Bertalanffy growth curve fit to all available information for tilefish. Two growth curves were fit, one to both sexes that provided a population growth curve and the other to only females. The female growth curve was used in the calculations of spawning stock biomass, whereas the population growth curve was used to calculate total biomass and landings. Estimation of the t_0 parameter resulted in biologically unreasonable estimates that were less than -1. Therefore, the t_0 parameter was fixed at -0.5, but sensitivity to this parameter was incorporated into the Monte Carlo/Bootstrap Ensemble (MCBE) analysis by fitting numerous models to the data using values within the range of -1 to 0 (Figure 62). The mean length at age for the population was determined by the equation

Population
$$L_a = 830.18 * (1 - e^{0.20482 * (age + 0.5)}),$$
 (1)

while the mean length of females as determined by the equation:

Female
$$L_a = 731.53 * (1 - e^{0.25073 * (age + 0.5)}).$$
 (2)

Conversion factors for length to whole weight and gutted weight were obtained by fitting non-linear models to available fishery-independent and -dependent data. Whole weight (WW) was converted from maximum total length (TL) using the equation $WW = 3.966e - 06 * TL^{3.159}$ and gutted weight (GW) from maximum total length (TL) by the equation $GW = 3.113e - 06 * TL^{3.190}$.

Maturity at age and fecundity at age were estimated using recently available data (Bubley et al. 2024). These new life history relationships were used in combination with the female growth curve to calculate SSB. Additionally, the peak time of spawning in the assessment was changed to May 15^{th} (i.e., 0.37 fraction of the year or the 135^{th} day Bubley et al. 2024). Uncertainty in maturity at age, reproductive output at age, and peak spawning time were incorporated into the MCBE analysis by drawing parameter estimates from the covariance matrix of the respective models and recalculating the quantities of interest. Primary life-history information for the base model is summarized in Table 6.

Maximum age (t_{max}) remained age $t_{max} = 40$ for the base model. However, uncertainty in this value was incorporated in the MCBE analysis by applying values between the range of 37 and 45. Thirty-seven was chosen as the lower bound because is was the last age for which all previous ages had at least on age sample and forty-five was the oldest observed age in the dataset. Constant natural mortality (M) used for scaling age-varying natural mortality (M_a) was calculated using the equation from Hamel and Cope (2022, $M = 5.40/A_{max}$) such that M = 0.135. M_a was calculated by an inverse length scaled so that mortality from ages 6 to the maximum age was consistent with the constant natural mortality rate across these ages (Lorenzen 2022). Sensitivity to the youngest age used for the Lorenzen M_a was explored in the sensitivity analysis and the MCBE.

2.2.2 Landings

Landings estimates were combined into three fleets: commercial handline, commercial longline, and general recreational (Table 1). Commercial landings of Tilefish were compiled from 1950 through 2022 in gutted weight (GW). Only landings from 1972 to 2022 were included in this assessment as landings prior to 1972 were minimal. Sources for landings in the U.S. South Atlantic (Florida through North Carolina) included the Florida Trip Ticket program (FTT), South Carolina Department of Natural Resources (SCDNR), North Carolina Division of Marine Fisheries (NCDMF), and the Atlantic Coastal Cooperative Statistics Program (ACCSP). Commercial handline landings included gear types such as hook and line, bandit reels, and similar hook gear. Landings from gear types other than handline and longline were negligible and were not included in the assessment. Commercial landings include data from the North Carolina-Virginia border to the Florida Keys in Monroe County, Florida along US Highway 1. Landings in Monroe County were apportioned by data providers to exclude landings north of the Florida Keys, which are considered part of the Gulf of Mexico. Estimates of commercial discards from the longline fleet were obtained (Thompson et al. 2024) using new methodology. Since the estimates were minimal and no size composition were available for these discards, the landings and discards were summed by year to be fit by the model.

For this assessment, estimates of recreational landings from the private and charter modes were based on current Marine Recreational Information Program (MRIP) methodology. Estimates account for changes in the Fishing Effort Survey, the redesigned Access Point Angler Intercept Survey, and the For Hire Survey. A large value of recreational landings in 1981 (227,080 fish) was associated with one trip which reported 12 Tilefish (Nuttall and Matter 2020). The Southeast Region Headboat Survey (SRHS) also provided landings estimates for tilefish. Landings for the general recreational fleet were the sum of the MRIP and SRHS landings estimates. Years where landings were estimated as 0 were replaced with the next lowest value in the time series because years with no landings were not expected. This is similar to the methodology of SEDAR 66 (SEDAR 66 2021). Landings were provided in number of fish and whole weight. The number of landed fish for the recreational fleet were used in the assessment model as these estimates had slightly lower uncertainty compared to landed weight.

2.3 Discards

Commercial longline discards were estimated by new methodology (Thompson et al. 2024). Discards for this fleet were minimum and information regarding the size of discarded fish was not available. Therefore, discards were added to landings assuming complete mortality and fit as total landings for the commercial longline fleet. Discards estimates were not available for the commercial handline fleet or the SRHS and therefore were assumed to be zero. Discards estimates from MRIP were minimal and were not included in the stock assessment.

2.4 Indices of abundance

The indices of abundance used in SEDAR 66 included the fishery-independent MARMAP longline index and the fishery dependent longline logbook index (Table 5). These indices of abundance remained unchanged since the previous assessment as no new information were available or deemed usable in a standardized index.

2.5 Length Composition

Length compositions were developed from the commercial handline, commercial longline, and recreational sampling data. Sample sizes by year and fleet are reported in Table 3 (trips) and Table 4 (fish). Following the methodology of SEDAR 66, the contribution of each length was weighted by the landings associated by state, gear, and year.

2.6 Age Composition

Age data were available from the commercial handline, commercial longline, and MARMAP longline sampling programs. For commercial data, ages greater than 20 yr were pooled to age-20 creating a plus group. For the MARMAP age compositions, there were few ages > 16 yr, so ages \geq 16 yr were pooled as a plus group. Sample sizes by year and fleet are reported in Table 3 (trips) and Table 4 (number of fish).

An ageing error matrix was estimated from data from ageing of a reference set of otoliths by three readers. This ageing error matrix was applied to the age compositions in the BAM assessment model to represent uncertainty in the ageing process.

3 Stock Assessment Methods

This assessment updates the primary model applied during the SEDAR 04 and the SEDAR 66 for Tilefish (*Lopho-latilus chamaeleonticeps*) off the Southeastern United States (hereafter South Atlantic Tilefish). The methods are reviewed below, and any changes since the SEDAR 66 are emphasized.

3.1 Overview

This operational assessment updated the primary model applied in SEDAR 66, which was developed using the Beaufort Assessment Model (BAM) software (Williams and Shertzer 2015). BAM applies a statistical catch-age formulation, coded in AD Model Builder (Fournier et al. 2012). BAM is referred to as an integrated model because it uses multiple data sources relevant to population and fishery dynamics (e.g. removals, length and age compositions, and indices of abundance) in a single framework. In essence, the catch-age model simulates a population forward in time while including fishing processes (Quinn and Deriso 1999; Shertzer et al. 2008). Quantities to be estimated are systematically varied until characteristics of the simulated population match available data on the real population. The model is similar in structure to Stock Synthesis (Methot and Wetzel 2013) and other stock assessment models used in the United States (Dichmont et al. 2016; Li et al. 2021). Versions of BAM have been used in previous SEDAR assessments of reef fishes in the U.S. South Atlantic, such as Black Sea Bass, Blueline Tilefish, Gag, Greater Amberjack, Red Grouper, Red Porgy, Red Snapper, Snowy Grouper, Tilefish, and Vermilion Snapper, as well as in the previous SEDAR assessment of Tilefish (SEDAR 66 2021).

3.2 Data Sources

The catch-age model included data from the commercial longline logbook program, the fishery independent MAR-MAP longline survey, and three fleets that caught South Atlantic Tilefish: commercial handline, commercial longline, and the recreational fishery. The model was fit to annual landings and discards in gutted weight for commercial fleets and numbers for the recreational fleet (Table 1). Data providers also supplied coefficients of variation (CVs) associated with landings (Table 2), which were used to generate bootstrap data sets during the MCBE analysis. The model was also fit to annual length composition of recreational landings and annual age compositions from commercial handline and commercial longline landings and from the MARMAP longline survey. Samples sizes associated with composition data are provided in numbers of trips (Table 3) and numbers of fish (Table 4). The model was also fit to the fishery dependent commercial longline logbook standardized CPUE and the fishery independent MARMAP longline survey index of abundance (Table 5). Data used in the model are described in §2 of this report and in previous reports of South Atlantic Tilefish.

3.3 Model Configuration and Equations

Model structure and equations of the BAM are detailed in Williams and Shertzer (2015). The assessment time period for this assessment was 1972-2022. A general description of the assessment model follows.

3.3.1 Stock dynamics

In the assessment model, new biomass was acquired through growth and recruitment, while abundance of existing cohorts experienced mortality from fishing and natural sources. The population was assumed closed to immigration and emigration. The model included age classes $1-20^+$, where the oldest age class 20^+ allowed for the accumulation of fish (i.e., plus group).

3.3.2 Initialization

Initial (1972) abundance at age was estimated in the model as follows. The equilibrium age structure was computed for ages 1–20⁺ based on natural and fishing mortality (F_{init}), where F_{init} was set equal to a value that resulted in the 1972 biomass level equaling 90% of the unfished level. This was done in SEDAR 25 and the SEDAR 66 based on the assumption by the SEDAR 25 workshop panel that the stock was lightly exploited prior to the 1960's. In SEDAR 89, landings data showed minimal exploitation prior to 1972, and the same method was followed. Lognormal deviations around that equilibrium age structure were found not to deviate from zero during model development and thus were fixed at zero. Sensitivity of the assessment model to the assumed value of F_{init} were tested by randomly sampling a value of F between 0 and 0.2 as suggested by a change in 2 likelihood values by the profile of this parameter (Figure 53).

3.3.3 Natural mortality rate

The natural mortality rate (M) was assumed constant over time, but decreasing with age. Constant M was calculated by the Hamel and Cope (2022) relationship with a maximum age of 40, which yielded a value of M = 0.135. The form of M as a function of age was based on Lorenzen (2022) and are inversely related to length at age. The age-dependent estimates of M_a were rescaled to provide the same fraction of fish surviving from age-6 through the oldest observed age (40 yr) as would occur with constant M = 0.135. The starting age class for this calculation was chosen as the age of full selectivity to the fishery because most estimates of M in the database compiled by Then et al. (2014) are based on fully selected individuals of the population. For the MCBE analysis, the oldest observed age used to calculate the constant M and rescale M_a was randomly drawn between 37 and 45. Additionally, the minimum age used to scale M_a was randomly drawn age between 5 and 8 as possible ages of full selectivity.

3.3.4 Growth

Mean length at age in the population $[l_a; \text{total length (TL) in millimeters, (mm)}]$ was modeled with the von Bertalanffy function of age (a)

$$l_a = L_{\infty} (1 - exp[-K(a - t_0 + \tau)]) \tag{3}$$

where $L_{\infty} = 830.2$, K = 0.2048, and $t_0 = -0.5$, are parameters estimated external to the assessment model during the SEDAR 89 process and $\tau = 0.5$, representing a fraction of the year. Here, l_a is being computed at midyear. In the model fitting to the age and length data the t_0 was estimated to be a biologically unreasonable value much less than -1, thus, the parameter was fixed at -0.5 for the base model.

A similar von Bertalanffy equation was derived for female tilefish where $L_{\infty} = 731.5$, K = 0.2507, and $t_0 = -0.5$

All parameters in Equation (3) of the population and female growth curves were treated as fixed input to the assessment model. However, uncertainty in the t_0 parameter was incorporated into the stock assessment model through the MCBE procedure by randomly drawing a value between -1 and 0, then refitting both von Bertalanffy growth curves to the age and length data and using these new estimates in the stock assessment model. For fitting length composition data, the distribution of size at age was assumed normal with coefficient of variation estimated by the assessment model ($CV_l = 0.1397$). A constant CV, rather than constant standard deviation, was suggested by the size at age data.

Whole weight at age $[WW_a; WW$ in kilograms (kg)] was modeled as a power function of l_a maximum total length (TL in mm)

$$WW_a = \theta_1 l_a^{\theta_2} \tag{4}$$

where $\theta_1 = 3.966e - 06$ and $\theta_2 = 3.159$ are parameters estimated external to the assessment model during the current operational assessment and treated as fixed input to the assessment model (Table 6 and Figure 2). Where necessary (e.g. converting recreational landings to GW), total length at age (l_a) was converted to gutted weight (GW_a) with the power function

$$GW_a = \alpha l_a^\beta \tag{5}$$

where $\alpha = 3.113e - 06$ and $\beta = 3.19$ Uncertainty in the length to weight functions were incorporated into the MCBE analysis by drawing values using the covariance matrix of the parameters from the model fit.

3.3.5 Spawning stock

Spawning stock was modeled using total egg production measured at the time of peak spawning. For Tilefish, peak spawning was considered to occur in the middle of May (May 15^{th} ; $spawn_time_frac = 0.37$). Total egg production at age was calculated as the product of maturity at age, batch fecundity at age, and spawning frequency at age (Bubley et al. 2024). Total reproductive output at age (Table 6 and Figure 2) was multiplied by the female abundance at age and summed across ages to calculate the spawning stock biomass.

3.3.6 Recruitment

Expected annual recruitment (\bar{R}_y) of age-1 fish (i.e. recruits) was predicted from spawning stock in year $y(S_y)$ using the Beverton–Holt spawner-recruit model

$$\bar{R}_{y+1} = \frac{0.8R_0hS_y}{0.2R_0\phi_0(1-h) + S_y(h-0.2)} \tag{6}$$

where R_0 is virgin recruitment, h is steepness, and ϕ_0 is the unfished spawners per recruit (Williams and Shertzer 2015). In SEDAR 89 R_0 and h were estimated as likelihood profiling suggested these parameters were estimable for

this model. For years where data were considered useful for providing information on year-class strength, annual recruitment deviations (r_y) were estimated, assuming a lognormal distribution with standard deviation (σ_R)

$$N_{1,y} = \bar{R}_y exp(r_y) \tag{7}$$

In early runs of the model, σ_R had a tendency to be estimated at the lower bound and thus was fixed at a value of 0.6 from a meta-analysis based on Beddington and Cooke (1983) and Mertz and Myers (1996)

Annual variation in recruitment was assumed to occur with lognormal deviations for years 1982 – 2019 only. The start of recruitment residuals in 1982 was based on examination of a series of different starting years and the start of the age composition data that have information on year class strength. The first year of age composition data was 1992 from the commercial longline landings. In those early age compositions, the number of fish diminishes beyond age-10 (Figure 3) which is the approximate age at full selection (Figure 14). Thus, 1982 seemed to be about the earliest year that the composition data could reliably provide information on year class strength (i.e. estimate a recruitment residual) and is consistent with SEDAR 66. The ending year of estimated recruitment residuals (2019) was determined by conducting likelihood profiles of the recruitment in the terminal year for 2015-2020. The terminal year of 2019 was chosen because the likelihood profile of the following year suggested there was a wide range of values that had a change in total likelihood value of less than 2 (Figure 55 to 60).

3.3.7 Landings

The model included time series of landings from three fleets: commercial longlines (1972–2022), commercial handlines (1972–2022), and general recreational (1981–2022). Landings were modeled with the Baranov catch equation (Baranov 1918) and were fit in units of weight (1000 lb GW) for the commercial fishery and numbers for the recreational fleet.

3.3.8 Discards

As noted above, observed discards were only available for the longline fleet and were incorporated into the landings for this fleet assuming a 100% discard mortality due to the depth of capture and lack of other data.

3.3.9 Fishing Mortality

For each time series of landings, the assessment model estimated a separate full fishing mortality rate (F). Agespecific rates were then computed as the product of full F and selectivity at age. Apical F was computed as the maximum of F at age summed across fleets.

3.3.10 Selectivities

As in SEDAR 66, selectivity at age was estimated using a two-parameter, flat-topped, logistic model for years prior to 2020. However, in 2020 there was a marked increase in the proportion of fish less than age 5 and a decrease in the fish older than age 15. Therefore, a time block and domed selectivity were incorporated into the model to account for this change in the age composition. Likelihood profiling of the parameters controlling the dome shaped selectivity suggested that the model was able to estimate these parameters, though some tended to be close to the lower bound. The cause of this selectivity change is currently unknown, but is hypothesized to be in response to the decrease in quota in recent years. During the SEDAR 66 workshop multiple fishermen (appointed observers)

confirmed that decreases in the fishing season affected behavior of the commercial fleet in ways that might cause a change in selectivity. Age and size composition data were critical for estimating selectivity functions.

As in the SEDAR 66, seperate selectivity functions were estimated for commercial handline, commercial longline, and general recreational fleets, as well as for the MARMAP longline index. In contrast to the SEDAR 66, the time blocks occurred for different time periods. The break for the two time blocks for both commercial fisheries in SEDAR 66 occurred in 2009. For SEDAR 89 selectivity functions for both the commercial handline and commercial longline fleets were estimated for two time blocks (1972-2019, 2020-2022), where the later assumed a domed selectivity. The time block in 2009 was removed from the current assessment because it did not result in a significant improvement in the model fit to warrant the additional parameters.

No selectivity parameters are fixed in SEDAR 89, but a normal prior distribution was applied to the slope parameter for the general recreational fleet selectivity which was not well estimated. Values for this normal prior were based on SEDAR 66.

3.3.11 Indices of abundance

The model was fit to two indices of relative abundance: commercial longline (1993-2006) and MARMAP longline survey (discontinuous years from 1996 to 2016; Table 5). Predicted indices were conditional on selectivity of the corresponding fleet or survey and were computed from abundance (MARMAP) or biomass (commercial) at the midpoint of the year.

In this assessment, commercial CPUE units within the model code were converted from GW to WW to better match the population units of WW. This conversion does not affect model results, as the predicted index is ultimately scaled by the catchability parameter.

3.3.12 Catchability

In the BAM, catchability scales indices of relative abundance to the estimated vulnerable population at large. As in prior assessments, catchability coefficients of both indices were assumed constant through time.

3.3.13 Fitting criterion

The fitting criterion was a penalized negative log-likelihood approach in which observed landings were fit closely, and observed composition data and abundance indices were fit to the degree that they were compatible. Landings and index data were fit using lognormal likelihoods. Length and age composition data were fit using the Dirichlet-multinomial distribution, with sample size represented by the annual number of trips (Table 5), adjusted by an estimated variance inflation factor (i.e. one additional parameter for each fleet's composition data).

The assessment model fit composition data using the Dirichlet-multinomial distribution (Francis 2017; Thorson et al. 2017). This distribution is self-weighting through estimation of an additional variance inflation parameter for each composition component, making iterative re-weighting unnecessary. Another advantage is that it can better account for overdispersion, or, larger variance in the data than would be expected by the multinomial. Overdispersion can result from intra-haul correlation, which results when fish caught in the same set are more alike in length or age than fish caught in a different set (Pennington and Volstad 1994). The effectiveness of the Dirichlet-multinomial distribution for composition data has been demonstrated through simulation studies and applications (Fisch et al. 2021; 2022). The Dirichlet-multinomial has been implemented in Stock Synthesis (Methot and Wetzel 2013; Thorson et al. 2017) and in the BAM, and since SEDAR41 has become the standard likelihood for fitting composition data in assessments of South Atlantic reef fishes.

The model includes the capability for each component of the likelihood to be weighted by user-supplied values. When applied to landings and indices, these weights modify the effect of the input CVs. In this application to Tilefish, CVs of landings (in arithmetic space) were assumed equal to 0.05 to achieve a close fit to these data while allowing some imprecision. In practice, the small CVs are a matter of computational convenience, as they help achieve a close fit to the landings, while avoiding having to solve the Baranov equation iteratively (which is complex when there are multiple fisheries). Similar to SEDAR 66, data weights were all equal in the base model.

In addition, the compound objective function included several prior distributions, applied to the Dirichlet-multinomial variance inflation factor parameters associated with each set of composition data and the slope parameter for the selectivity function of the general recreational fleet. Priors were applied to maintain parameter estimates near reasonable values, and to prevent the optimization routine from drifting into parameter space with negligible gradient in the likelihood which can result in a non-positive definite Hessian matrix (an indication of incomplete or incorrect parameter solutions).

3.3.14 Parameters Estimated

The model estimated a total of 210 parameters including average fishing mortality rates (3 parameters) and annual fishing mortality rates (144 parameters) for each fleet, selectivity parameters (16 parameters), Dirichlet-multinomial variance inflation factors (4 parameters), a catchability coefficient associated with each index (2 parameters), coefficient of variation of length at age (CV_l ; 1 parameter), virgin recruitment (R_0 ; 1 parameter), Beverton–Holt stock recruitment steepness (h; 1 parameter), and annual recruitment deviations (38 parameters).

3.3.15 Biological reference points

Biological reference points (benchmarks) were calculated based on maximum sustainable yield (MSY) estimates in gutted pounds from the Beverton–Holt spawner-recruit model with bias correction (expected values in arithmetic space). Computed benchmarks included MSY, fishing mortality rate at MSY ($F_{\rm MSY}$), and spawning stock at MSY (SSB_{MSY}) by the method of Shepherd (1982). In this assessment spawning stock measures total egg production. These benchmarks are conditional on the estimated selectivity functions and the relative contributions of each fleet's fishing mortality. The selectivity pattern used here was the effort-weighted selectivities at age, with effort from each fishery estimated as the full F averaged over the last three years of the assessment (2020-2022).

Reference points are sensitive to changes in selectivity and ratios of F among the removal fleets. These reference points are based on the domed shaped selectivity which assumes that the oldest ages are not vulnerable to fishing. If the fishing behavior were to change such that the selectivity were to return to a logistic selectivity then the reference points based on the domed selectivity could result in overfishing of the species. Care must be taken in such scenarios so as not to reduce the population below sustainable levels.

3.3.16 Configuration of base run

The base run was configured as described above. However, the base run configuration was not considered to represent all uncertainty. Sensitivity analyses, retrospective analyses, and ensemble modeling was conducted to better characterize the uncertainty in base run point estimates.

3.4 Sensitivity Analysis

Sensitivity of results to some key model inputs and assumptions was examined through sensitivity analyses. Sensitivity runs were chosen to address specific questions that arose during the SEDAR 89 assessment process. They were intended to demonstrate directionality of results with changes in inputs or simply to explore model behavior. These model runs vary from the base run as follows.

- S1-S2: Low/high values of maximum age used to calculate constant natural mortality (M = 0.120, 0.146) and Lorenzen natural mortality at age (Maximum M age = 45, 37)
- S3-S4: Low/high values of minimum age used to calculate Lorenzen natural mortality at age (Minimum M age = 5, 8)
- S5-S6: Low/high values of steepness (h = 0.323, 0.975)
- S7-S8: Low/high values of initial F ($F_{init} = 0, 0.2$).
- S9-S10: Low/high values of fixed t_0 growth parameter ($t_0 = -1, 0$)

3.5 Retrospective Analysis

Retrospective analyses were run by reducing the terminal year of the model from 2022 to 2015-2021, thereby trimming all time series accordingly, and rerunning the assessment model. This analysis facilitates investigation of patterns in model results, particularly terminal status estimates, that may occur when recent data are excluded.

Retrospective analyses should be interpreted with caution because several data sources are not continuous between 2015 and 2022 (Figure 1). These include the MARMAP longline index and age compositions, commercial handline age compositions, and recreational length compositions. Additionally, the time block selectivity occurs in the last 3 years and has limited data as years are remove to estimate the domed selectivity parameters. The final year of recruitment deviations in each retrospective run was set to the terminal year minus 3 years to mirror the base run model configuration.

3.6 Per Recruit and Equilibrium Analysis

Yield per recruit and spawning potential ratio were computed as functions of F, as were equilibrium landings and spawning biomass. Equilibrium landings were also computed as functions of biomass B, which itself is a function of F. As in computation of MSY-related benchmarks (described in §3.7), per recruit and equilibrium analyses applied the most recent selectivity patterns averaged across fleets, weighted by each fleet's F from the last three years (2020-2022) of the assessment.

3.7 Benchmarks and Reference Points

In this assessment of Tilefish, the quantities $F_{\rm MSY}$, ${\rm SSB}_{\rm MSY}$, $B_{\rm MSY}$, and MSY were estimated by the method of Shepherd (1982). In that method, the point of maximum yield is calculated from the spawner-recruit curve and parameters describing growth, natural mortality, maturity, and selectivity. The value of $F_{\rm MSY}$ is the F that maximizes equilibrium landings.

On average, expected recruitment is higher than that estimated directly from the spawner-recruit curve, because of lognormal deviation in recruitment. Thus, in this assessment, the method of benchmark estimation accounted for lognormal deviation by including a bias correction in equilibrium recruitment. The bias correction (ς) was computed

J

from the variance (σ_R^2) of recruitment deviation in log space: $\varsigma = \exp(\sigma_R^2/2)$. Then, equilibrium recruitment (R_{eq}) associated with any F is,

$$R_{eq} = \frac{R_0 \left[\varsigma 0.8h\Phi_F - 0.2(1-h)\right]}{(h-0.2)\Phi_F} \tag{8}$$

where R_0 is median-unbiased virgin recruitment, h is steepness, and Φ_F is spawning potential ratio given growth, maturity, and total mortality at age. In BAM, the calculation of total mortality includes natural and fishing mortality rates. The R_{eq} and mortality schedule imply an equilibrium age structure and an average sustainable yield (ASY). The estimate of F_{MSY} is the F giving the highest ASY, and the estimate of MSY is that ASY. The estimate of SSB_{MSY} follows from the corresponding equilibrium age structure

Estimates of MSY and related benchmarks are conditional on the selectivity pattern. The selectivity pattern used here was an average of terminal-year selectivities from each fleet, where each fleet-specific selectivity was weighted in proportion to its corresponding estimate of F averaged over the last three years (2020-2022) of the assessment. If the selectivities or relative fishing mortalities among fleets were to change, so would the estimates of MSY and related benchmarks.

The maximum fishing mortality threshold (MFMT) is defined as F_{MSY} , and the minimum stock size threshold (MSST) is defined by the SAFMC as 75%SSB_{MSY} (Restreption et al. 1998). Overfishing is defined as F > MFMT and overfished as SSB < MSST. Current stock size is represented as SSB in the last assessment year (2022), and current fishing mortality (F_{current}) is represented by the geometric mean of F from the last three years of the assessment (2020-2022). Thus, $F_{\text{current}} = F_{2020-2022}$.

3.8 Comparison to Previous Assessments

This SEDAR 89 operational assessment builds upon the SEDAR 66 with an additional 4 years of data, substantial improvements to the structure of the BAM, updates to most life history parameters, and minor changes to the configuration of the model. No new data sources were included. See §2 for changes to data included in SEDAR 89 compared with the SEDAR 66.

Changes to the life history information used in the model included:

- 1. constant natural mortality calculated by Hamel and Cope (2022),
- 2. M_a calculated proportional to inverse length following Lorenzen (2022),
- 3. population and female growth curves were updated using available length and age data,
- 4. maximum total length to whole weight and gutted weight were estimated using additional data,
- 5. maturity-at-age was estimated from a logistic model fit to length and converted to age using the mean length at age from the von Bertalanffy growth curve,
- 6. reproductive output was calculated as the number of eggs produced at age,
- 7. peak spawning time was derived from the plateau model of fecundity (Bubley et al. 2024),
- 8. uncertainty in all parameters fixed within the stock assessment were incorporated into the MCBE analysis by drawing parameters from the estimated covariance matrix or refitting the model across the range of reasonable fixed parameters (i.e., t_0).

Changes to model configuration include:

- 1. natural mortality at age calculated internally within the model to allow for changes in maximum and minimum age for Lorenzen M_a ,
- 2. biomass calculated in 1000 lb instead of metric tons,
- 3. recreational landings were modeled in numbers of fish and incorporated MRIP and SRHS data,
- 4. selectivity of commercial longline and handline included two time blocks with the break occurring after 2019 instead of after 2009,
- 5. selectivity of commercial longline and handline in the terminal time block was modeled as a domed shape,
- 6. an ageing error matrix was incorporated into the stock assessment model,
- 7. Beverton-Holt steepness was estimated within the model, while previously it was fixed,
- 8. the last year of recruitment deviates was set to 2019 based on likelihood profiling of the terminal year recruitment parameter,
- 9. commercial longline landings incorporated discard estimates, and
- 10. spawning stock biomass was calculated in trillions of eggs.

3.9 Monte Carlo/Bootstrap Ensemble (MCBE) Analysis

For the base run of the catch-age model (BAM), uncertainty in results and precision of estimates was computed through an ensemble modeling approach (Scott et al. 2016; Jardim et al. 2021) using a mixed Monte Carlo and bootstrap framework (Efron and Tibshirani 1993; Manly 1997). Monte Carlo and bootstrap methods are often used to characterize uncertainty in ecological studies, and the mixed approach has been applied successfully in stock assessment (Restrepo et al. 1992; Legault et al. 2001; SEDAR4 2004; SEDAR19 2009; SEDAR24 2010; SEDAR 66 2021). The approach is among those recommended for use in SEDAR assessments (SEDAR Procedural Guidance 2010).

The approach translates uncertainty in model input into uncertainty in model output, by fitting the model many times with different values of "observed" data and key input parameters. A chief advantage of the approach is that the results describe a range of possible outcomes, so that uncertainty is characterized more thoroughly than it could be by any single fit or small set of sensitivity runs. A minor disadvantage of the approach is that computation times can be long, though current parallel computing techniques largely mitigate those demands (i.e. computing results many times as fast as a single processor).

In this assessment, the BAM was re-fit in n = 4000 trials that differed from the original inputs by bootstrapping on data sources, and by Monte Carlo sampling of several key input parameters. Of the 4000 trials, 3018 were ultimately retained in the uncertainty analysis. The remaining runs were discarded because of lack of model convergence (hessian was not invertible) or unrealistic values of R_0 , steepness, or the slopes of the domed shaped selectivity curves estimated at the upper bound. Similar filtering procedure was also done in SEDAR 66, though the criterion used were different.

The MCBE should be interpreted as providing an approximation to the uncertainty associated with each output. The results are approximate for two related reasons. First, not all combinations of Monte Carlo parameter inputs are equally likely, as biological parameters might be correlated. Second, all runs are given equal weight in the results, yet some might provide better fits to data than others. Additionally, given the large CV of the recreational landings some Monte Carlo datasets are more likely than others.

3.9.1 Bootstrapping of Observed Data

To include uncertainty in time series of observed landings, and indices of abundance, multiplicative lognormal errors were applied through a parametric bootstrap. To implement this approach in the MCBE trials, random variables $(x_{s,y})$ were drawn for each year y of time series s from a normal distribution with mean 0 and variance $\sigma_{s,y}^2$ [that is, $x_{s,y} \sim N(0, \sigma_{s,y}^2)$]. Annual observations were then perturbed from their original values $(\hat{O}_{s,y})$,

$$O_{s,y} = \hat{O}_{s,y} [\exp(x_{s,y} - \sigma_{s,y}^2/2)]$$
(9)

The term $\sigma_{s,y}^2/2$ is a bias correction that centers the multiplicative error on the value of 1.0. Standard deviations in log space were computed from CVs in arithmetic space, $\sigma_{s,y} = \sqrt{\log(1.0 + CV_{s,y}^2)}$. The CVs used to generate bootstrap data sets of landings were supplied by the data providers (Table 2). Note that these values are different and generally higher than the CVs used to estimate landings when fitting the assessment model (i.e. 0.05 for all years and fleets). The CVs used to generate bootstrap data sets of indices of abundance were the same as those used when fitting the assessment model (Table 5).

Uncertainty in age and length compositions were included by drawing new distributions for each year of each data source, following a multinomial sampling process. Ages (or lengths) of individual fish (Table 4) were drawn at random with replacement using the cell probabilities of the original data. For each year of each data source, the number of fish sampled was the same as in the original data (Table 5).

3.9.2 Monte Carlo Sampling

In each successive fit of the model, several parameters were fixed (i.e., not estimated) at values drawn at random from distributions described below.

3.9.2.1 Maximum age for natural mortality calculation The maximum age of tilefish was randomly drawn from a uniform distribution between 37 and 45. The maximum age was used in conjunction with a bootstrap sampling of the Then et al. (2014) natural mortality dataset fit using the Hamel and Cope (2022) model to estimate constant natural mortality. The maximum age was also used to determine the oldest age over which the mortality should scale to the constant natural mortality rate.

3.9.2.2 Minimum age for natural mortality calculation The minimum age for determining the M_a re-weighting using the Lorenzen (2022) formulation was randomly drawn as an integer between ages 5 and 8. These values were input into the assessment model to calculate the natural mortality at age in conjunction with the growth parameters.

3.9.2.3 von Bertalanffy t_0 The t_0 parameter was a fixed value that was randomly sampled between -1 and 0. A von Bertalanffy growth model was fit to the age and length data with this fixed parameter. A growth curve for the population and for females only was determine for each fixed value of t_0 . The resulting growth curves were then input as fixed values into the stock assessment model.

3.9.2.4 Standard deviation of recruitment deviations (σ_R) In the base model, the standard deviation of recruitment deviations (σ_R) was fixed at 0.6. For each MCBE trial, a new value of σ_R was drawn from a truncated normal distribution defined by $\mu = 0.6$ and $\sigma = 0.15$ truncated to 0.3 to 1.0.

3.9.2.5 Length to weight relationship parameters Parameters for the length-weight relationship for gutted and whole weights were drawn from the covariance matrix of the respective model fits using a multivariate distribution. Parameter for these relationships were fixed within the assessment model.

3.9.2.6 Reproductive output ogive The reproductive output ogive was calculated through numerous models and uncertainty from each of the models was incorporated into the fixed ogive in the stock assessment model. Parameters for the logistic maturity at length were drawn from a multivariate distribution centered at the parameter estimates with the estimated covariance matrix. Mean length at age from the respective growth curve was used to determine proportion mature at age. Batch fecundity at age was calculated by randomly drawing parameters for the exponential relationship from the covariance matrix and run specific mean length at age. Number of batches at age were determined by the drawing parameters for the plateau model from the covariance matrix. These parameters were inserted into the function and integrated across the year to provide the number of batches per year for each model specific length at age (Bubley et al. 2024). Reproductive output was determined as the product of age specific maturity, batch fecundity, and number of batches (Figure 63)).

3.9.2.7 *Time of peak spawning* The parameter drawn from the plateau model for calculating the reproductive output ogive above were used to derive the peak spawning time as described in Bubley et al. (2024). This date of peak spawning was fixed within the assessment model and had very little uncertainty in the values used in the MCBE.

3.9.2.8 Initial Fishing mortality rate (F_{init} Values of initial fishing mortality were randomly drawn from a uniform distribution between 0 and 0.2 based on similar likelihood values in a profile of the parameter (Figure 53)).

3.10 Projection Analysis

Projections were run to determine the overfishing limit (OFL) as requested in the ToRs. The structure of the projection model was the same as that of the assessment model, and parameter estimates were those from the assessment. Any time-varying quantities, such as selectivity, were fixed to the most recent values of the assessment period. A single selectivity curve was applied to calculate landings computed by averaging selectivities across fleets using geometric mean Fs from the last three years of the assessment period, similar to computation of MSY benchmarks (§3.7).

Expected values of SSB (time of peak spawning), F, recruits, and landings were represented by deterministic projections using parameter estimates from the base run. These projections were built on the estimated spawner-recruit relationship with bias correction, and were thus consistent with estimated benchmarks in the sense that long-term fishing at $F_{\rm MSY}$ would yield MSY from a stock size at SSB_{MSY}. Uncertainty in future time series was quantified through stochastic projections that extended the ensemble model fits of the stock assessment model.

3.10.1 Initialization of Projections

Although the terminal year of the assessment is 2022, the assessment model computes abundance at age (N_a) at the start of 2023. For projections, those estimates were used to initialize N_a . However, the assessment has no information to inform the strength of 2023 recruitment, and thus it computes 2023 recruits (N_1) as the expected value, that is, without deviation from the spawner-recruit curve, and corrected to be unbiased in arithmetic space. In the stochastic projections, log-normal stochasticity was applied to these abundances after adjusting them to be unbiased in log space, with variability based on the estimate of σ_R . Thus, the initial abundance in year one of projections (2023) included this variability in N_1 . Additionally, variability was added to the abundance of ages 2 through 4 to account for the lack or recruitment deviates in the last 3 years of the assessment. The deterministic projections were not adjusted in this manner, because deterministic recruitment follows Beverton-Holt expectation.

Fishing rates that define the projections were assumed to start in 2023. Because the assessment period ended in 2022, the projections required an interim period (2023–2024). Fishing mortality during this interim period was set at the estimate of F_{current} from the assessment model.

3.10.2 Uncertainty of Projections

To characterize uncertainty in future stock dynamics stochasticity was included in replicate projections, each an extension of a single assessment fit from the ensemble. Thus, projections carried forward uncertainties in natural mortality, life history relationships, as well as in estimated quantities such as spawner-recruit parameters (R_0 , h, and σ_R), selectivity curves, and in initial (start of 2023) abundance at age.

Initial and subsequent recruitment values were generated with stochasticity using a Monte Carlo procedure, in which the estimated Beverton-Holt model of each MCB fit within the ensemble is used to compute expected annual recruitment values (\bar{R}_y) . Variability is added to the mean values by choosing multiplicative deviations at random from a log-normal distribution,

$$R_y = \bar{R}_y \exp(\epsilon_y). \tag{10}$$

Here ϵ_y is drawn from a normal distribution with mean 0 and standard deviation σ_R , where σ_R is the standard deviation from the relevant ensemble model run.

The procedure generated 20,000 replicate projections of models within the ensemble drawn at random (with replacement) from the MCBE. In cases where the same model run was drawn, projections would still differ as a result of stochasticity in projected recruitment streams. Central tendencies were represented by the deterministic projections of the base run, as well as by medians of the stochastic projections. Precision of projections was represented graphically by the 5^{th} and 95^{th} percentiles of the replicate projections.

3.10.3 Projection Scenarios

Projections were run to determine the overfishing limit (OFL) as requested in the ToRs. In the projections, management started in 2023, the earliest year likely to implement management changes. Projections were carried forward to 2027. Scenarios 1 and 2 were considered to determine the OFL and scenarios 3 was considered to determine the ABC. A P^* of 32.5 is presented based on the projections from SEDAR 66, though a range of different values were run but were not presented for brevity. In all scenarios $F = F_{\text{current}}$ from 2023 to 2024:

- Scenario 1: $F = F_{P_{50\%}^*}$ from 2023 to 2027
- Scenario 2: $F = F_{MSY}$ from 2023 to 2027
- Scenario 3: $F = F_{P_{32,5\%}^*}$ from 2023 to 2027

4 Stock Assessment Results

4.1 Measures of Overall Model Fit

The Beaufort assessment model (BAM) generally fit well to the available data. Predicted age compositions from each fishery were reasonably close to observed data in most years (Figure 3). Fits to length compositions for the recreational fleet were not quite as good, but the data were also very variable, probably due to small sample sizes (often < 50 fish per year; Figure 3 and Tables 3 and 4). The model was configured to fit observed commercial and recreational landings closely (Figures 4 to 6). The fit to the commercial longline index captured the general trend well but not all annual fluctuations (Figure 7). The fit to the MARMAP longline survey index (Figure 8) did not capture the general trend very well due in part to the large CVs associated with the index (Table 5).

4.2 Parameter Estimates

Estimates of all parameters from the catch-age model are shown in §B. No parameters were hitting bounds (Figures 38 and 39). Estimates of management quantities and some key parameters, such as those of the spawner-recruit model, are reported in sections below.

4.3 Total Abundance, Spawning Biomass, and Recruitment

Total abundance shows a decline in the early 1980s (Figure 9 and Table 7) concurrent with large increase in landings, especially in the commercial longline fleet (Figures 18 and 19 and Tables 16 and 17). Abundance declined until the late 1990s and then rapidly increased around 2000. Since then, abundance has fluctuated between approximately 1.5-2 million fish peaking in the mid 2000s, but then declining until 2019 and slightly increase at the end of the assessment attributed to the recruitment determined by the stock recruitment without deviates. Older ages classes were truncated beginning in the 1980s; abundance in older ages declined through the mid 1990s and then expanded after the 2010s (Figure 9 and Table 7). Spawning stock biomass (SSB) declined in the early 1980s and continued to decline to a low point in 1995 and 2000. Since 2000, SSB increased until 2009 but has decreased gradually since then (Figure 12 and Table 10). Recruitment has fluctuated during the period when deviations were estimated (1982-2019) ranging from 194,685 to 914,761 fish with peaks in 1988, 1991, and 1999, but with little evidence of a long term trend (Figure 11 upper panel; Table 10). Similarly, recruitment deviations showed fluctuations over this same period with no evidence of a long-term trend (Figure 11 lower panel).

4.4 Selectivity

Selectivity of the MARMAP longline survey is shown in Figure 13, selectivities of landings from commercial and recreational fleets are shown in Figures 14 and 15. In the most recent years, full selection occurred near age-4 in the recreational fleet, age-6 in the commercial handline fleet, age-9 in the MARMAP longline survey, and age-7 in the commercial longline fleet. Logistic selectivity functions were used for all fleets prior to 2020, but domed selectivities were used for the commercial handline and longline fleets in the latter time block.

Average selectivities of landings were computed from F-weighted selectivities in the most recent period of regulations (Figure 16). These average selectivities were used to compute point estimates of benchmarks. All selectivities from the most recent period, including average selectivities, are tabulated in Table 11. In the average selectivity, full selection occurred near age-7, like the commercial longline fleet which is responsible for > 80% of the total F in most years (Figure 17).

4.5 Landings, Fishing Mortality, Quotas, and Biomass

From 1972 to 1980, total landings were low (< 200 klb; Figures 18 and 19 and Tables 16 and 17) and estimated fishing mortality rate (F) was very low (≤ 0.02 ; Figure 17 and Table 12), with stock biomass still near virgin (B_0). Since this early period of low exploitation, landings and F have occurred in about five main periods of exploitation, each lasting 5-10 years. The first period from 1981 to 1986 represents a set of years with the highest landings in the South Atlantic Tilefish stock, all of which were near or above 1000 klb, with peak landings in 1982 over 2600 klb. During this period F increased to range between 0.1 to nearly 0.4. Estimated biomass during this first period dropped dramatically, from 92 to about 45% of B_0 . The second period begins in 1987 with landings dropping sharply down below 300 klb, but quickly increasing again to a range of 600 to 900 klb for most years through 1995. Due to the decline in biomass during the first period, this second period exhibits lower landings but higher F than the first period, with most values of F 0.2 to above 0.4. During the second period, biomass continued to decline to 32%of B_0 . In the third period, from 1996 to 2002, landings decreased sharply again, remaining between 300-400 klb in most years through 2002. Total F also declined but remained within a range similar to the first period (0.1-0.3). Biomass in 1995 was the lowest in the history of the stock, but increased slightly over the period. In 2003 landings dropped to 235 klb, the lowest level in the history of the stock since 1980. This fourth period from 2003 to 2011 was characterized by a gradual increase back up to the mid-300 klb range, as F remained low (0.1-0.18). This fourth period marks a period of recovery from 32 to 47% of B_0 . In 2006 the commercial quota was substantially reduced from 1,001 klb to 295 klb, and resulted in a reduced fishing season from 365 to 295 days in 2006 (see §I. Table 2.6.2). The quota remained at this level through 2010, and was reduced slightly in 2011 (282 klb) resulting in the commercial fishery being open for only 67 days. In 2012, the commercial quota increased to 541 klb following results of SEDAR 25, and remained at this level through 2017. An increase in landings followed as the commercial fleets repeatedly reached the quota, and total landings remained in the 490-670 klb range again through 2017, until dropping back below 340 klb in 2018 when the quota was again reduced to 313 klb. Values of F generally increased during this period (0.16-0.22) while biomass was again in decline.

4.6 Spawner-Recruitment Parameters

The estimated Beverton–Holt spawner-recruit curve is shown in Figure 20, along with the effect of density dependence on recruitment, depicted graphically by recruits per spawner as a function of spawners (spawning biomass). Values of recruitment-related parameters were as follows: steepness h = 0.6, unfished age-1 recruitment $R_0 = 509,900$, unfished spawning biomass (1000 lb) per recruit $\phi_0 = 2.759$, and standard deviation of recruitment residuals in log space $\hat{\sigma}_R = 0.6$ (fixed; which resulted in bias correction of $\varsigma = 1.2$). Uncertainty in these quantities was estimated from the MCBE (Figure 21).

4.7 Per Recruit and Equilibrium Analyses

Yield per recruit and spawning potential ratio were computed as functions of F (Figure 22). As in computation of MSY-related benchmarks, per recruit analyses applied the most recent selectivity patterns averaged across fisheries, weighted by F from the last three years (2020 - 2022). The F that provides 40% SPR is $F_{40\%} = 0.213$, and 30% is $F_{30\%} = 0.306$.

As in per recruit analyses, equilibrium landings and spawning biomass were computed as functions of F (Figure 23). By definition, the F that maximizes equilibrium landings is F_{MSY} , and the corresponding landings and spawning biomass are MSY and SSB_{MSY}.

4.8 Benchmarks / Reference Points

As described in §3.7, biological reference points (benchmarks) were derived analytically assuming equilibrium dynamics, corresponding to the expected spawner-recruit curve (Figure 20). These benchmarks are conditional on the estimated selectivity functions and the relative contributions of each fleet's fishing mortality. Furthermore the selectivity pattern used here was the effort-weighted selectivities at age, with effort from each fishery estimated as the full F averaged over the last three years of the assessment (2020-2022).

Reference points estimated were F_{MSY} , MSY, B_{MSY} and SSB_{MSY} . Estimates of benchmarks are summarized in Table 18. Standard errors of benchmarks were approximated as those from the MCBE (§3.9).

Maximum likelihood estimates (base run) of benchmarks, as well as median values from MCBE, are summarized in Table 18. Point estimates of MSY-related quantities were $F_{\rm MSY} = 0.22$ (y⁻¹), MSY = 545 (1000 lb GW), $B_{\rm MSY} = 6191$ (1000 lb), MSST = 0.385 (trillion eggs), and SSB_{MSY} = 0.514 (trillion eggs). The estimate of SSB_{MSY} is about 37% of the unfished spawning biomass. Median estimates were $F_{\rm MSY} = 0.18$ (y⁻¹), MSY = 564 (1000 lb GW), GW), $B_{\rm MSY} = 7264$ (100 lb), MSST = 0.488 (trillion eggs), and SSB_{MSY} = 0.651 (trillion eggs). Distributions of these benchmarks from the MCBE are shown in Figure 24.

4.9 Status of the Stock and Fishery

Estimated time series of stock status (SSB/MSST) showed a rapid decline during the 1980s and a slower decline during the 1990s, to a minimum value in 1995. From 1995 through 2011 stock status improved, but has been in decline again since 2012 (Figure 25 and Table 10).

Current stock status was estimated in the base run to be $SSB_{2022}/MSST = 1.261$ (Table 18), indicating that the stock is not overfished. Throughout its history, the stock has not dropped below MSST but was below the SSB_{MSY} in the late 1990s. However, this result should be viewed with caution because the msst is based on the domed shaped selectivity at the end of the assessment, whereas the fishing during this time period exhibited a logistic selectivity curve. Results from the MCBE suggested that the estimate of SSB relative to SSB_{MSY} and the status relative to MSST is highly uncertain (Figures 27 and 28). The slight majority of MCBE runs (54%) agreed with the stock status result from the base model and the median of the MCBE analysis ($SSB_{2022}/MSST = SSBMSSTmedVal$). However, the majority of models in the MCBE analysis (74.4%), the base model, and the median of the MCBE models show that the SSB is below SSB_{MSY} . Therefore, the stock is technically not overfished but is likely below the spawning stock size that will yield MSY.

Age structure estimated by the base run during 2022 shows numbers of fish at all age classes declined over the assessment period but especially older age classes. Numbers of Tilefish ages-15 and older reached their lowest point in 2000. During the recovery of the stock in the late 2010s, numbers of older fish increased substantially back above the predicted numbers at $F_{\rm MSY}$ equilibrium by 2016. At the end of the assessment, the plus group was higher than in 2016, but ages 7-19 years older have declined (Figure 29).

 $F/F_{\rm MSY}$ has been continually increasing since 2008 and exceeds $F_{\rm MSY}$ in the terminal year (Figure 25 and Table 10). Additionally, there is considerable uncertainty in $F/F_{\rm MSY}$ as demonstrated by the MCBE, especially toward the end of the assessment period (Figure 25). Current fishery status in the terminal year, with current F represented by the geometric mean from 2020 to 2022 ($F_{\rm current} = F_{2020-2022} = 0.216$), was estimated by the base run to be $F_{2020-2022}/F_{\rm MSY} = 1$ (Table 18). However, the median from the MCBE was estimated as $F_{2020-2022}/F_{\rm MSY} = 1.16$ and the analysis shows that there is a lot of uncertainty in the status of the fishery (Figures 27 and 28). Only 35% of MCBE runs agreed with the fishing status result from the base model, while the majority of models agree with the fishing status of the median of the MCBE. Note that $F_{\rm MSY}$ is based on average Fs from last three years of the assessment and thus it is not the technically correct denominator for all years going back in time. Thus, caution should be applied when interpreting F status back in time. Additionally, $F_{\rm MSY}$ is based on the assumption that the domed shape selectivity means that older fish are not vulnerable to fishing mortality, which is likely only a transient artifact of management restrictions on harvest and not a limitation of the gear to catch these older fish.

4.10 Comparison to Previous Assessments

The benchmark assessment for Tilefish, SEDAR 04, was completed in 2004 with an assessment period 1961-2002 (SEDAR 04 2004). SEDAR 25 was a standard assessment completed in 2011 with an assessment period spanning 1962-2010 (SEDAR 25 2011). Several important changes were made during SEDAR 25 (e.g. M, h, SSB units) that make it somewhat difficult to compare SEDAR 04 with later assessments. An update assessment was completed in 2016 with an assessment period of 1962-2014 (SEDAR 25 2016). Current management of South Atlantic Tilefish is based on SEDAR 66 with an assessment period of 1972-2018 (SEDAR 66 2021).

As of 2002, the stock was not overfished (SSB₂₀₀₂/MSST = 1.27), but overfishing was occurring (F_{2002}/F_{MSY} = 1.53; SEDAR 04 2004). Terminal status estimates in SEDAR 25 found that the Tilefish stock was not overfished (SSB₂₀₁₀/MSST = 2.42), and it was also not undergoing overfishing ($F_{2008-2010}/F_{MSY}$ = 0.36; SEDAR 25 2011). Terminal status estimates in the SEDAR 25 showed the stock was not overfished (SSB₂₀₁₄/MSST = 1.13), but overfishing was occurring ($F_{2008-2010}/F_{MSY}$ = 1.22; SEDAR 25 2016). SEDAR 66 found that the status of the stock was not overfishing (SSB₂₀₁₈/MSST = 1.235) and was not undergoing overfishing ($F_{2016-2018}/F_{MSY}$ = 0.95; SEDAR 66 2021). However, SEDAR 66 showed there was considerable uncertainty in the fishing status and the stock in 2018 was below SSB_{MSY}.

Values from the current SEDAR 89 assessment contrast with the stock status designation from SEDAR 04 (SSB₂₀₀₂/MSST = 1.31) but concur with the not overfished status from SEDAR 25 (SSB₂₀₁₁/MSST = 1.93), the SEDAR 66 (SSB₂₀₁₈/MSST = 1.49; Table 10).

The general pattern in time series of SSB/MSST in SEDAR 89 was similar to the SEDAR 66. However, the stock did not start at as high of a value and the minimum value reached in the mid-1990s did not go below 1. The general pattern in the time series of $F/F_{\rm MSY}$ in SEDAR 89 was also similar to the SEDAR 66, but was shifted downward so that it appears lower in all years. This is particularly true of the period from approximately 1990-2005. The trend and magnitude of $F/F_{\rm MSY}$ in SEDAR 66 were quite similar to SEDAR 89, but there is much less uncertainty at the end of the time series in the current assessment.

Input values of constant M have been lower for the previous four Tilefish assessments (terminal years: 2002, 2010, 2014, 2018, 2022; M: 0.07, 0.1083, 0.1083, 0.1038, 0.135), where M in SEDAR 04 was the lowest value and was not used to scale age-varying M. Steepness was fixed in previous assessments at a value near that estimated in the current assessment (h: 0.72, 0.84, 0.84, 0.84, 0.6). The estimate of $F_{\rm MSY}$ in SEDAR 04 was considerably lower than in later assessments ($F_{\rm MSY}$: 0.043, 0.185, 0.236, 0.3, 0.22). The estimate of MSY was also much lower in SEDAR 04 than in later assessments (MSY, klb: 335, 638, 560, 518, 545). In SEDAR 04 SSB was measured in units of female biomass (MSST, mt: 659) and thus was not comparable to later assessments which were in units of gonad weight (MSST, mt $W_{\rm gonad}$: 19.0, 16.4, 14) and is not comparable to the current assessment in units of trillions of eggs (MSST =0.385).

4.11 Sensitivity Analyses

Sensitivity runs, described in §3.3, may be useful for evaluating implications of assumptions in the base model, and for interpreting MCBE results in terms of expected effects from input parameters. Time series of F/F_{MSY} and SSB/MSST are plotted to demonstrate sensitivity to natural mortality (Figure 30), the steepness of the stock-recruit relationship (Figure 31), the value of initial F (F_{init} ; Figure 32), and the fixed growth t_0 parameter and resulting growth curve and natural mortality (Figure 33).

The qualitative results on terminal stock and fishing status were the same for eight of the sensitivity runs (S1-S4: sensitivity to M, S6: high h, S7: low F_{init} , and S9-S10: both sensitivities to t_0 Figures 30 to 33).

However, the other two sensitivity runs disagreed, and suggested that the stock was overfished (SSB₂₀₂₂ < MSST) and undergoing overfishing ($F_{2020-2022} > F_{MSY}$). These exceptions were runs S5 (low h) and S8 (high F_{init}). Sensitivity analyses were in general agreement with those of the MCBE that there is considerable uncertainty in the stock and fishing status of South Atlantic Tilefish.

4.12 Retrospective Analyses

Retrospective analyses did not suggest any patterns of substantial over- or underestimation in terminal-year estimates of $F/F_{\rm MSY}$, SSB/MSST, or B (Figure 34). Recruitment plots show an increase through the entire time series as a result of estimating steepness at the upper bound once the terminal year is removed. The domed selectivity at the end of the time series also changed as a result of the loss of one of the three years of age compositions that informed these parameters. This suggests that there may be considerable uncertainty in the steepness parameter and estimation is data dependent, which is generally true of statical catch at age models. It appears that steepness is informed primarily by the age composition of the commercial longline in 2022 and the removal of this data source results in an unreasonable estimated value of 0.99 for all models in the retrospective analysis. Despite this, calculated Mohn's rho were within reasonable values for all parameters.

4.13 Projections

Projection results for Tilefish are shown in Figures 35 to 37 and Tables 19 to 21. Among all scenarios considered, the probability that SSB_{MSY} exceeds MSST [P(>MSST)] is at least 0.50 in all years of all projections. Thus, under no management prescription considered in the current projections is the South Atlantic Tilefish stock predicted to be overfished.

5 Discussion

5.1 Comments on Assessment Results

Estimated benchmarks played a central role in this assessment. Values of MSST and F_{MSY} were used to gauge the status of the stock and fishery. Computation of benchmarks was conditional on selectivity in the terminal year of the stock assessment. A significant change in the age composition of the commercial fisheries occurred in 2020. The cause of this drastic shift to younger ages and the absence of older fish is unclear. It is currently hypothesized that there has been a recent change in fishing behavior in response to the restriction implemented in 2017. However, if the change observed in the age composition is due to a change in the population dynamics of tilefish then the model will likely be misspecified and could be in a much worse status. If selectivity patterns change in the future, for example an increase in the catch of older fish resulting in a return to a logistic selectivity, estimates of benchmarks would likely change as well and could result in overfishing of the species.

The base run of the BAM indicated that the stock is not overfished (SSB₂₀₂₂/MSST = 1.261), and that overfishing is not occurring, but is fully exploited ($F_{2020-2022}/F_{MSY} = 1$). However, the median of the MCBE analysis indicates that the stock is barely not overfished (SSB₂₀₂₂/MSST = 1.04), is currently undergoing overfishing ($F_{2020-2022}/F_{MSY} = 1.16$) and is below SSB_{MSY} (SSB/SSB_{MSY}2022 = 0.78). MCBE analyses show that there is a lot of uncertainty in these status results (Figure 28).

The median of the MCBE analysis did not provide the same status as the base BAM model. Additionally, the base BAM model was not generally in the center of the distribution of stock status or benchmarks. The initial fishing mortality (F_{init}) was the only parameter fixed during the MCBE analysis where the value of the base model was not close to the median of the distribution and was not near the center. Therefore, this parameter likely causes the apparent difference between the MCBE median and the base model.

The current assessment lacked an index of abundance for years after 2016 (i.e., the last 6 years of the assessment). The likelihood profiles of model parameters indicated that the age composition was influential in the estimation of the stock recruitment parameters (R_0 and h, i.e., key parameters that set the scale of the population). Future assessments will likely benefit from the addition of SADLS data to provide a fishery-independent index of abundance. Future assessments should pay close attention to the age composition in the commercial fisheries for a potential return to logistic selectivity and potentially implement another time block in the selectivity.

5.2 Comments on Projections

As usual, projections should be interpreted in light of the model assumptions and key aspects of the data. Some major considerations are the following:

- In general, projections of fish stocks are highly uncertain, particularly in the long term (e.g., beyond 5–10 years).
- Although projections included many major sources of uncertainty, they did not include structural (model) uncertainty. That is, projection results are conditional on one set of functional forms used to describe population dynamics, selectivity, recruitment, etc.
- Fisheries were assumed to continue fishing at their estimated current proportions of total effort, using the estimated current selectivity patterns. Benchmarks (e.g. MSY) are conditional on the estimated selectivity functions and the relative contributions of each fleet's fishing mortality. New management regulations that reallocate harvest in a way that alters proportions of F by fleet or selectivity patterns would likely affect projection results.
- The projections assumed that the estimated spawner-recruit relationship applies in the future and that past residuals represent future uncertainty in recruitment. If future recruitment is characterized by runs of large or small year classes, possibly due to environmental or ecological conditions, stock trajectories may be affected.
- Projections apply the Baranov catch equation to relate F and landings using a one-year time step, as in the assessment. The catch equation implicitly assumes that mortality occurs throughout the year. This assumption is violated when seasonal closures are in effect, introducing additional and unquantified uncertainty into the projection results.

6 Research Recommendations

- 1. From the previous assessment (SEDAR 66)
 - (a) Re-examine the quantity and quality of biological samples collected by "Other" commercial gears. If adequate, consider methods for inclusion.
 - (b) Monitor the quantity of commercial and recreational discards and consider methods for inclusion if deemed necessary.
 - (c) More closely examine historical length composition data used in the assessment and consider alternate methods for incorporating this information in the model.
 - (d) Collect data to investigate the stock structure of tilefish in the Atlantic ocean through a multifaceted approach (e.g., genetics, meristics, diet, otolith chemistry, life history characteristics, etc.)
 - (e) Increase age sampling to improve composition data
- 2. From the current assessment (SEDAR 89)
 - (a) following the guidance of the SADLS review, incorporate the fishery-independent standardized index of abundance and associated age composition
 - (b) Investigate potential mechanisms for the domed selectivity that started in 2020
 - (c) Collect and process more histological samples to reduce the uncertainty in the batch fecundity estimates to provide better estimates of SSB.

Table 5. Observed indices of abundance and CVs from commercial longline (cL) and the MARMAP longline survey (sM).

Table 6. Life-history characteristics at age. Variables include total length (TL) in millimeters (mm) and inches (in), the coefficient of variation (CV) of TL, whole weight (WW) in kilograms (kg) and pounds (lb), gutted weight (GW) in pounds (lb), proportion female [P(fem.)] and proportion of females mature [P(fem. mat.)], Egg production (EP; product of the proportion of females mature and total fecundity), and natural mortality. All values were fixed model input, but most had different values in the MCBE analysis.

Age	TL (mm)	TL (in)	TL CV	WW (kg)	WW (lb)	GW (lb)	P(fem.)	P(fem. mat.)	EP (million eggs)	М

Table 10. Estimated time series of status indicators. Fishing mortality rate is apical F (F_{apical}). Total biomass (B, 1000 lb) is at the start of the year, while spawning stock biomass (SSB, trillion eggs) is at peak spawning. The MSST is defined by MSST = 75%SSB_{MSY}. SPR is static spawning potential ratio and R_y is expected annual recruitment in million fish.

Year	F_{apical}	$F/F_{\rm MSY}$	В	$B/B_{\rm unfished}$	SSB	$\mathrm{SSB}/\mathrm{SSB}_{\mathrm{MSY}}$	SSB/MSST	SPR	R_y

Table 11. Selectivity at age for landings from commercial handline (cH), commercial longline (cL), and recreational (rA) fleets, selectivity for the MARMAP longline (sM) survey, selectivity of landings averaged across fisheries (L.avg), and selectivity of total removals (Total = L.avg). For time-varying selectivities, values shown are from the first year of each constant selectivity time period.

Age	$_{(mm)}^{TL}$	$_{(in)}^{TL}$	cH- 1972	cH- 2020	cL- 1972	cL- 2020	rA	sM	L.avg	Total

Table 18. Estimated status indicators, benchmarks, and related quantities from the base run of the BAM, conditional on estimated current selectivities averaged across fleets. Also presented are median values and measures of precision (standard errors, SE) from the Monte Carlo/Bootstrap ensemble analysis. Rate estimates (F) are in units of y^{-1} ; status indicators are dimensionless; biomass estimates are in units of thousands of pounds, as indicated; and recruits are in millions of age-1 fish. Spawning stock biomass (SSB) is measured as fecundity of mature females (trillion eggs). $L_{current}$ are the average landings from 2020–2022.

Quantity	Units	Estimate	Median	SE
F _{MSY}	y ⁻¹	0.22	0.18	0.06
$75\%F_{\rm MSY}$	y^{-1}	0.16	0.14	0.04
$B_{\rm MSY}$	1000 lb whole	6191.07	7263.71	2446.69
SSB_{MSY}	Trillions of Eggs	0.514	0.651	1.738

9 Figures

Figure 1. Timeline of data available to fit to in this assessment by source, data type, and year. Data sources include the commercial handline (cH), commercial longline (cL), and general recreational (rec all; rA) fleets, and the MARMAP longline survey (survey MARMAP; sM).

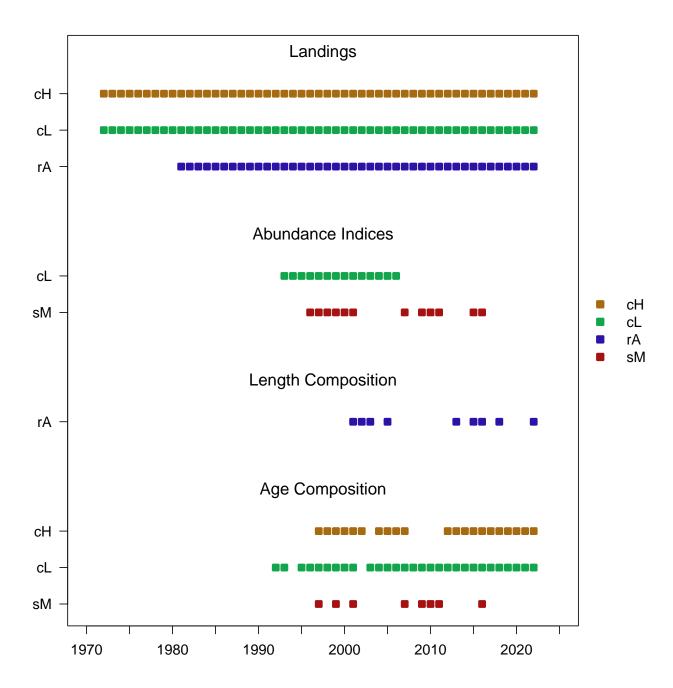

Figure 2. Length, female maturity, and reproductive output at age. Top panel: Mean length at age (mm) and estimated 90% confidence interval of the population. Middle panel: Female maturity by age. Bottom panel: Reproductive output (millions eggs) by age.

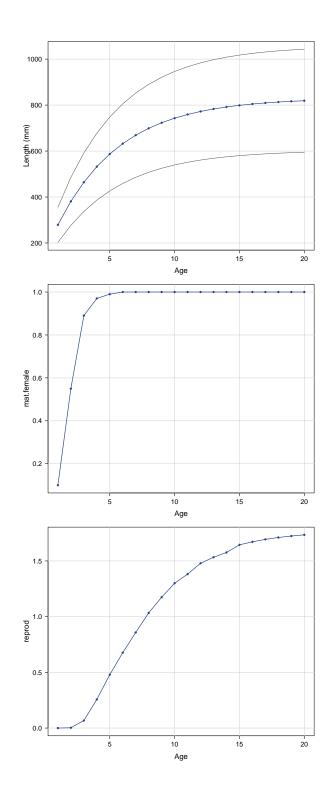

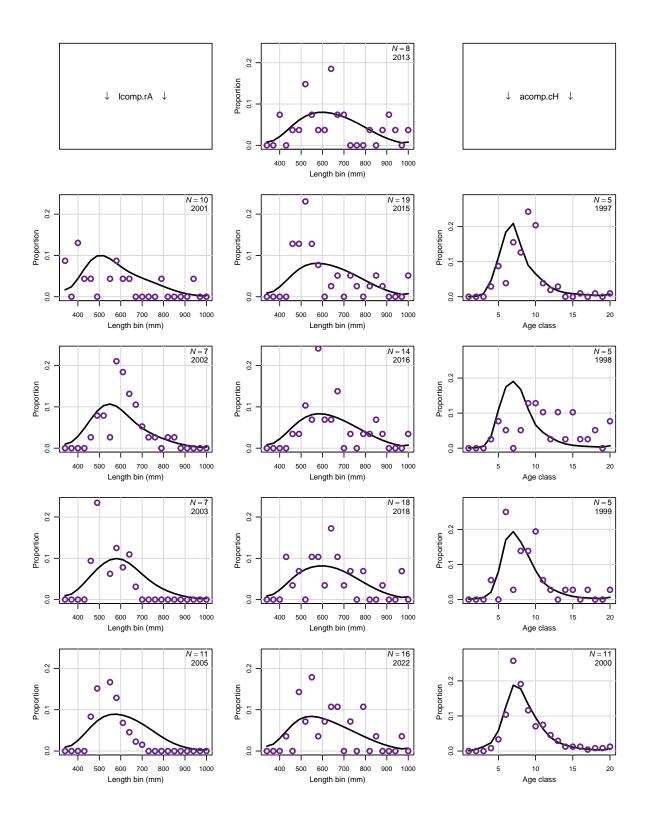

Figure 3. Observed (open circles) and estimated (solid line) annual age and length compositions by fleet. In panels indicating the data set: acomp = age compositions, lcomp = length compositions, cH = commercial handline, cL = commercial longline, sM = MARMAP longline survey, rA = general recreational. N indicates the number of trips from which individual fish samples were taken. The four digit number in upper right corner of each panel indicates year of sampling (e.g. 1997, 1998).

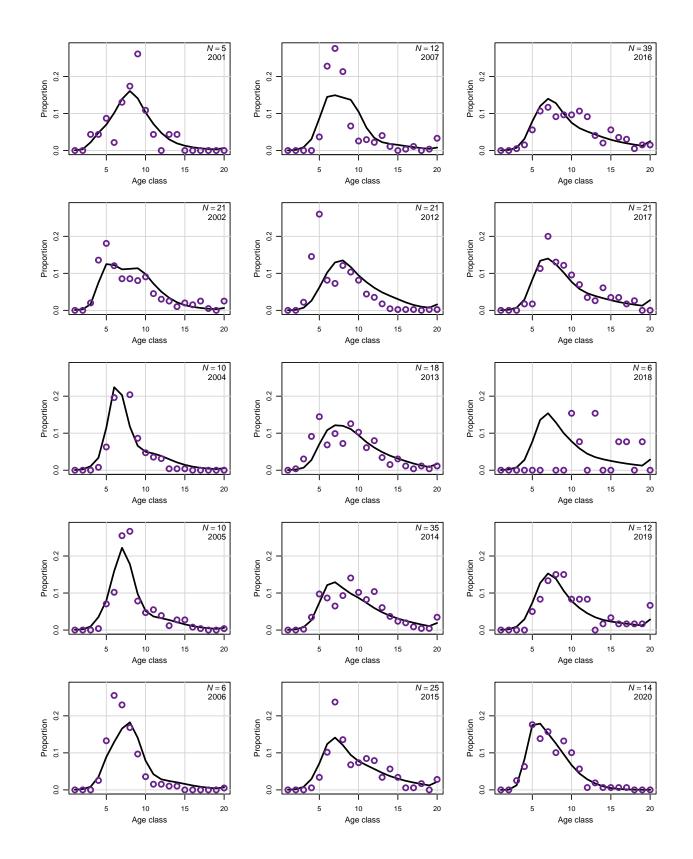

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual age and length compositions by fleet.

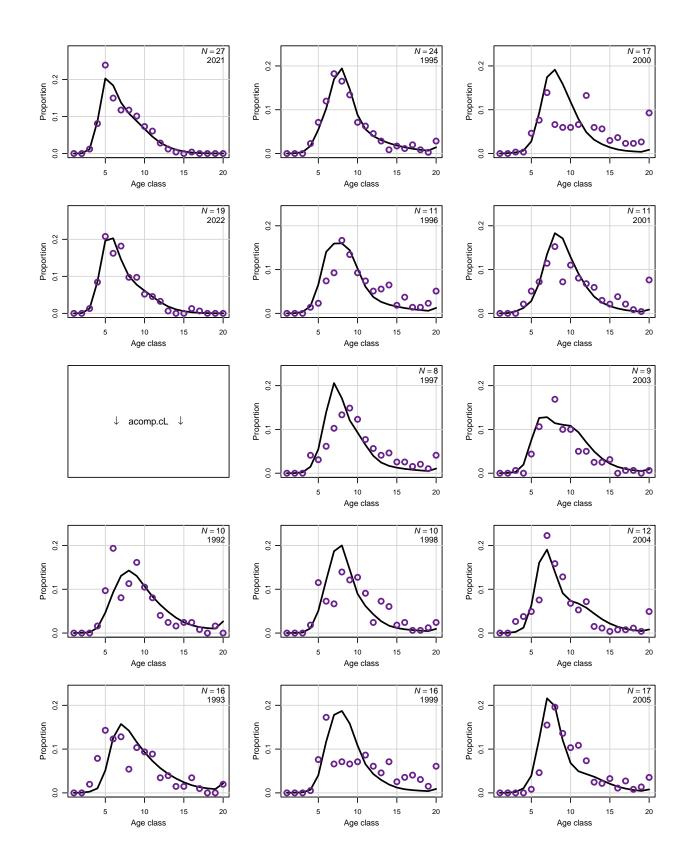

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual age and length compositions by fleet.

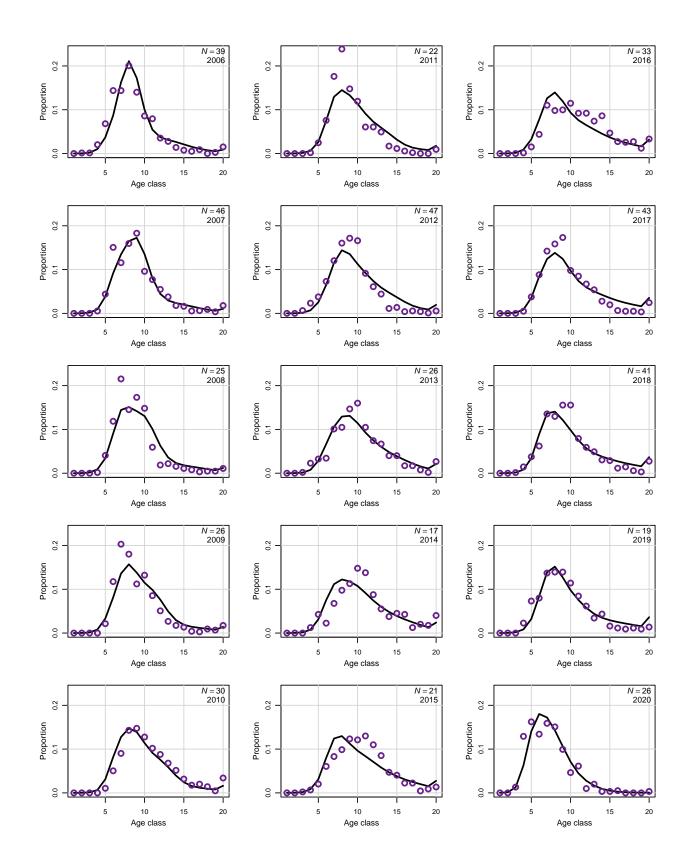

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual age and length compositions by fleet.

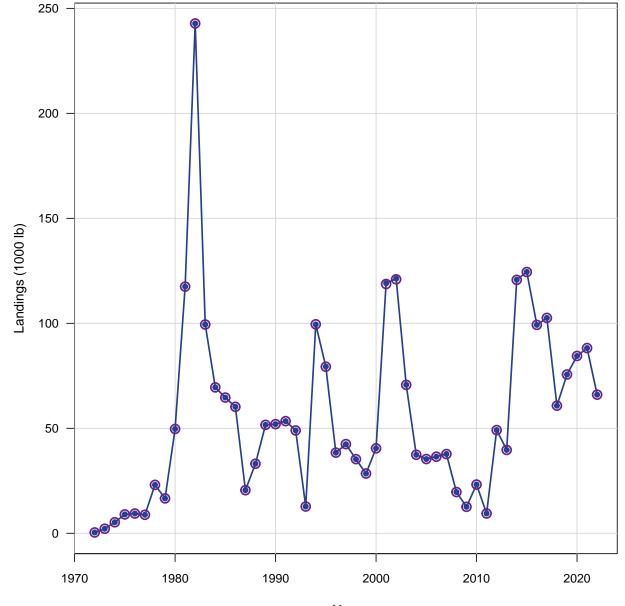

Figure 4. Observed (open circles) and estimated (line, solid circles) commercial handline landings (1000 lb gutted weight).

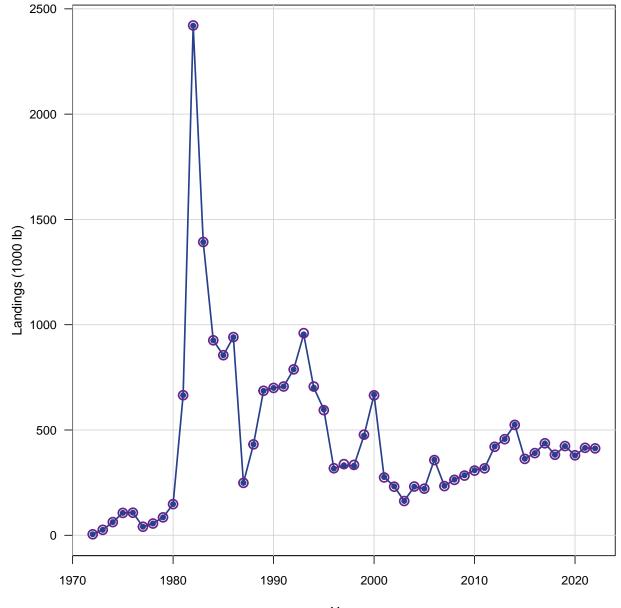

Figure 5. Observed (open circles) and estimated (line, solid circles) commercial longline landings (1000 lb gutted weight).

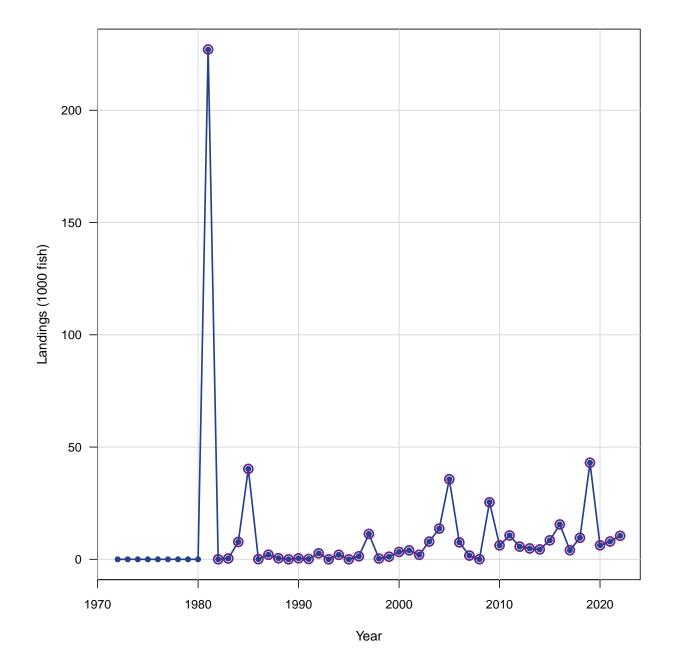

Figure 7. Observed (open circles) and estimated (line, solid circles) index of abundance from commercial longline. The bottom panel are the log residuals of the fit to the index and the color of the box indicates the p-value of the runs test (green > 0.05, orange ≤ 0.05 and >0.01, red < 0.01) and the width of the box is 3 times the standard error. Points that fall outside 3 standard errors are plotted in red.

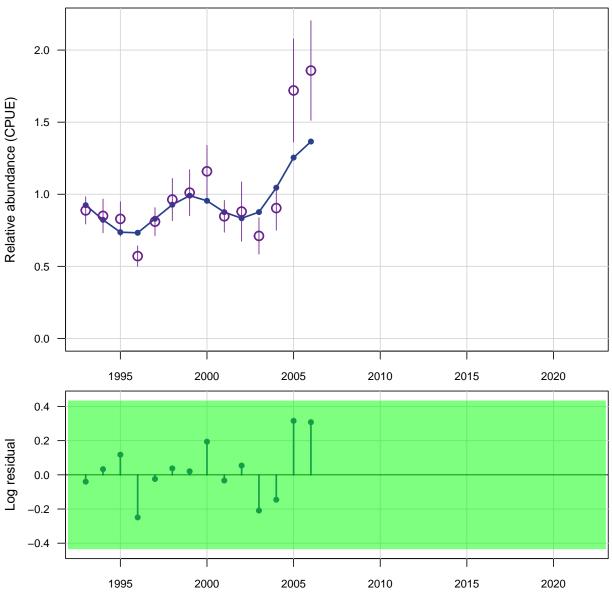

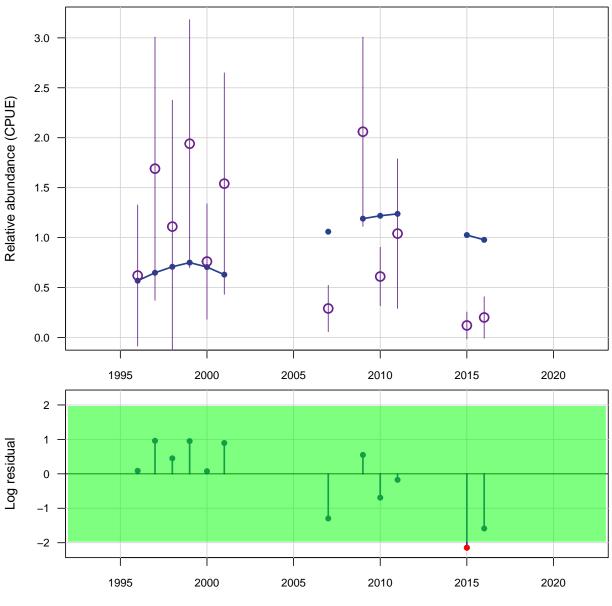

Figure 8. Observed (open circles) and estimated (line, solid circles) index of abundance from MARMAP longline survey. The bottom panel are the log residuals of the fit to the index and the color of the box indicates the p-value of the runs test (green > 0.05, orange ≤ 0.05 and >0.01, red < 0.01) and the width of the box is 3 times the standard error. Points that fall outside 3 standard errors are plotted in red.

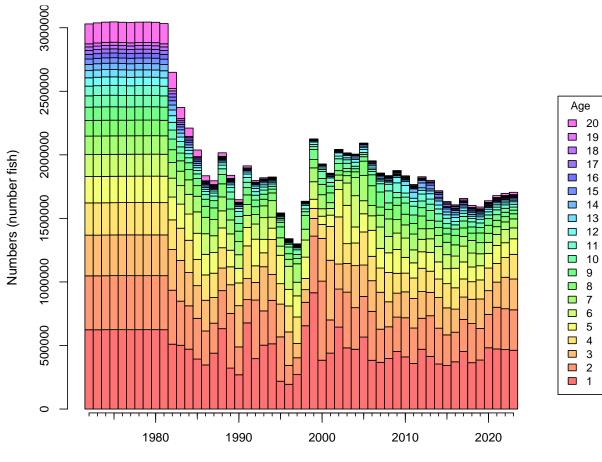

Figure 9. Estimated abundance at age at start of year

Year

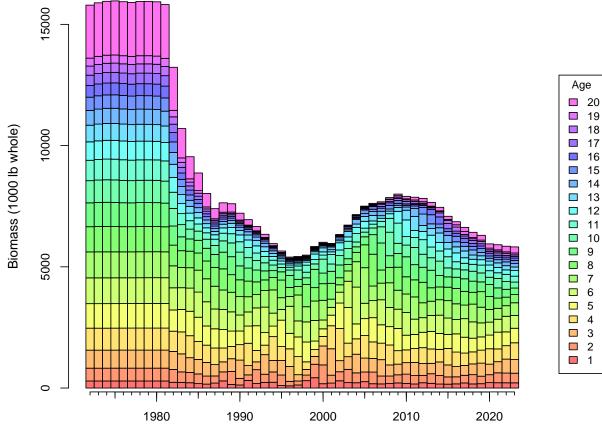

Figure 10. Estimated biomass at age at start of year.

Year

Figure 11. Estimated recruitment time series. Top panel: Estimated recruitment of age-1 fish. Horizontal dashed line indicates R_{MSY} . Bottom panel: log recruitment residuals (open circles). These are annual recruitment deviations (r_y) estimated within the model. The solid line is a lowess smoother fit to the residuals.

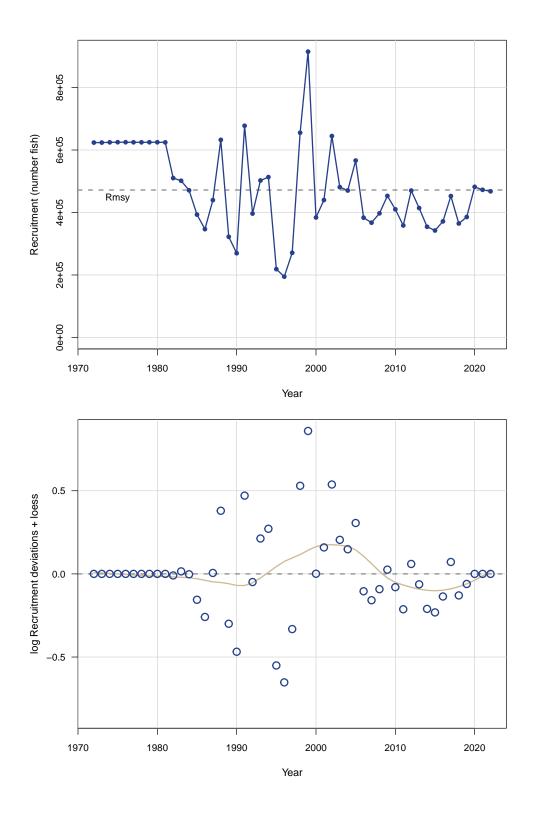

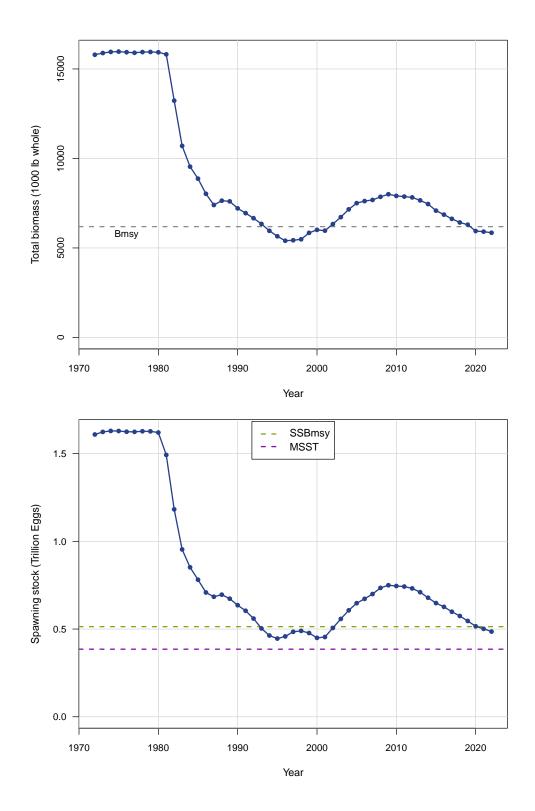

Figure 12. Estimated total biomass and spawning stock time series. Top panel: Estimated total biomass (1000 lb) at start of year. Horizontal dashed line indicates B_{MSY} . Bottom panel: Estimated spawning stock (trillion eggs) at time of peak spawning (May 15th; 0.37 yr). Note that B_{MSY} and MSST should only be compared to the last 3 years of the trend because of changes in selectivity in the time series.

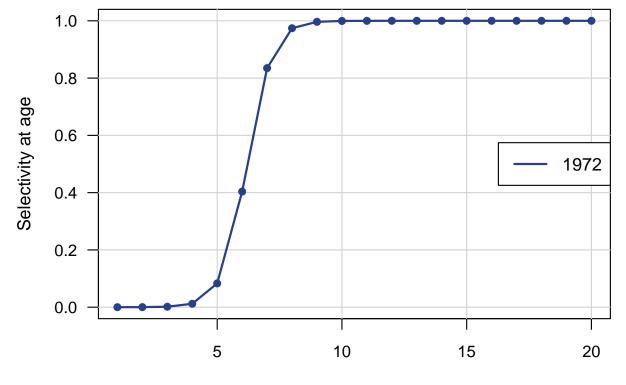

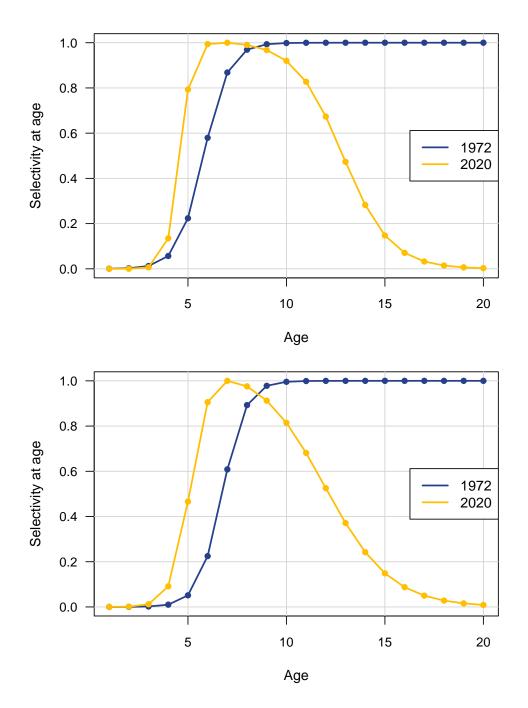

Figure 13. Selectivity of MARMAP longline index.

Age

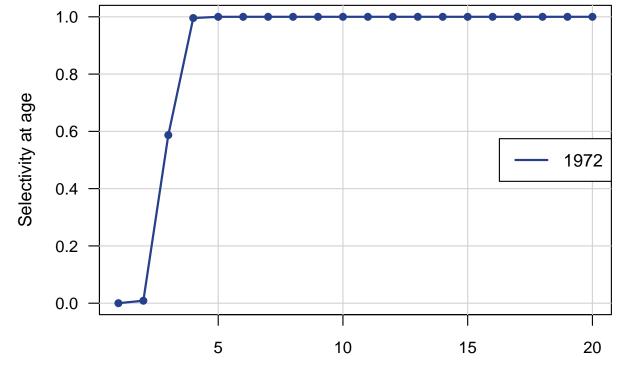

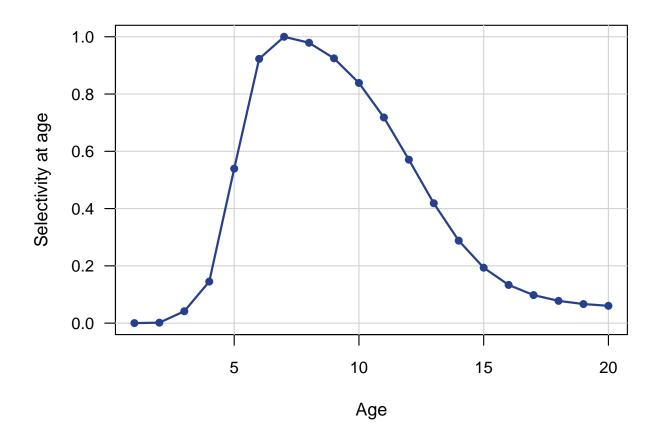

Figure 15. Selectivity of recreational landings.

Age

Figure 16. Average selectivity from the terminal assessment year weighted by geometric mean Fs from the last three assessment years, for landings. This selectivity is used in computation of benchmarks and central-tendency projections.

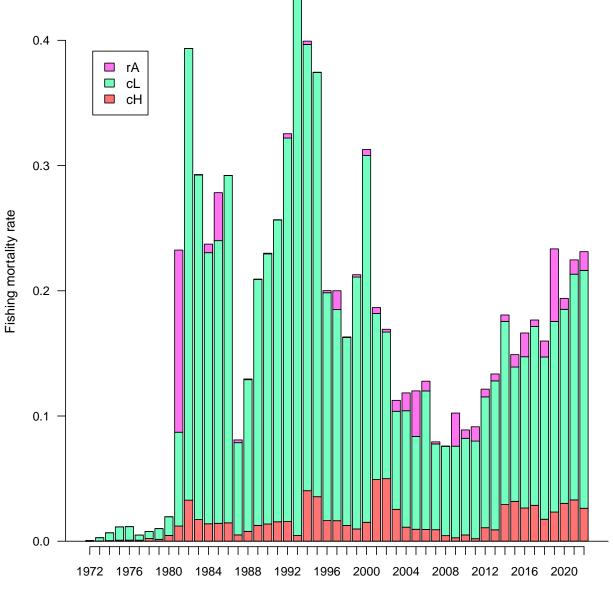

Figure 18. Estimated landings in absolute numbers (top) and proportion of total numbers (bottom) by fleet from the catch-at-age model. rA = recreational landings, cL = commercial longline landings, and cH = commercial handline landings

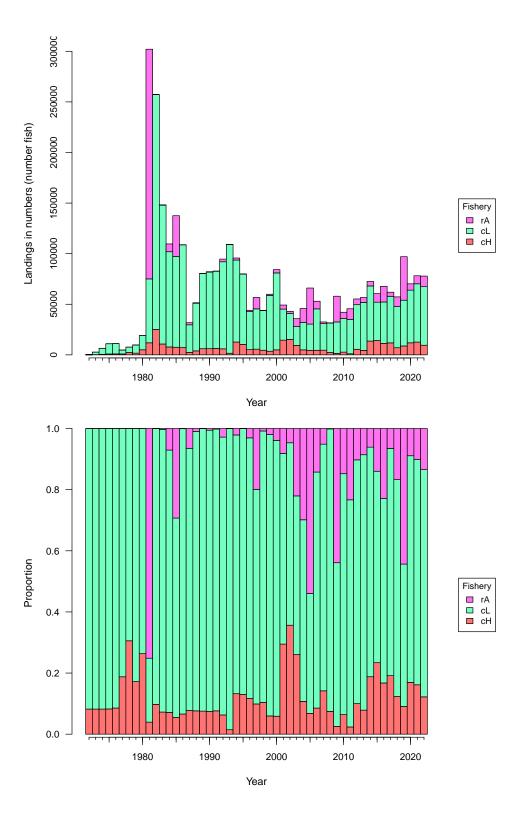

Figure 19. Estimated landings in absolute weight (top) and proportion of total weight (bottom) by fleet from the catch-at-age model. rA = recreational landings, cL = commercial longline landings, and cH = commercial handline landings

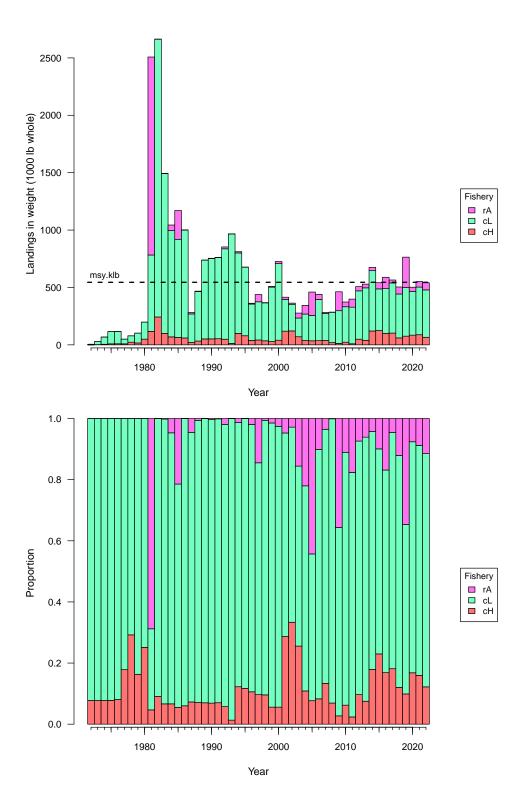

Figure 20. Beverton-Holt spawner-recruit curve (top) with and without lognormal bias correction. The expected (upper) curve was used for computing management benchmarks. Years within panel indicate year of recruitment generated from spawning biomass. Natural log of recruits (number of age-1 fish) per spawner is also plotted as function of the spawning stock (lower).

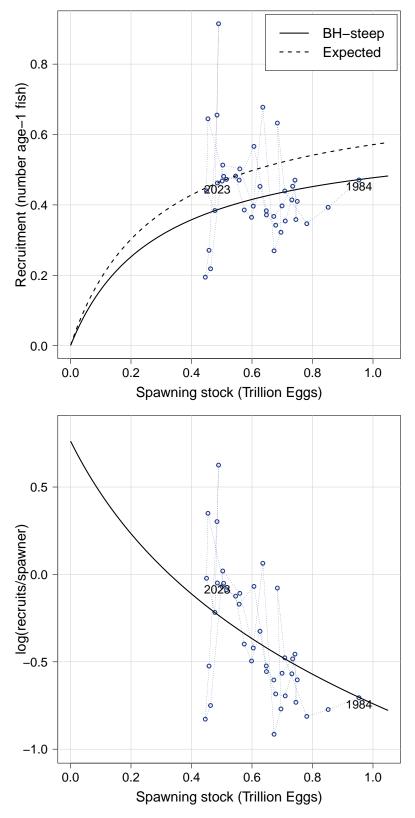

Figure 21. Probability densities of spawner-recruit quantities R0 (unfished recruitment of age-1 fish), steepness, unfished spawners per recruit (million of eggs), and standard deviation of recruitment residuals in log space. Solid blue vertical lines represent point estimates or values from the BAM base run; dashed green vertical lines represent medians from the MCBE runs (n = 3018).

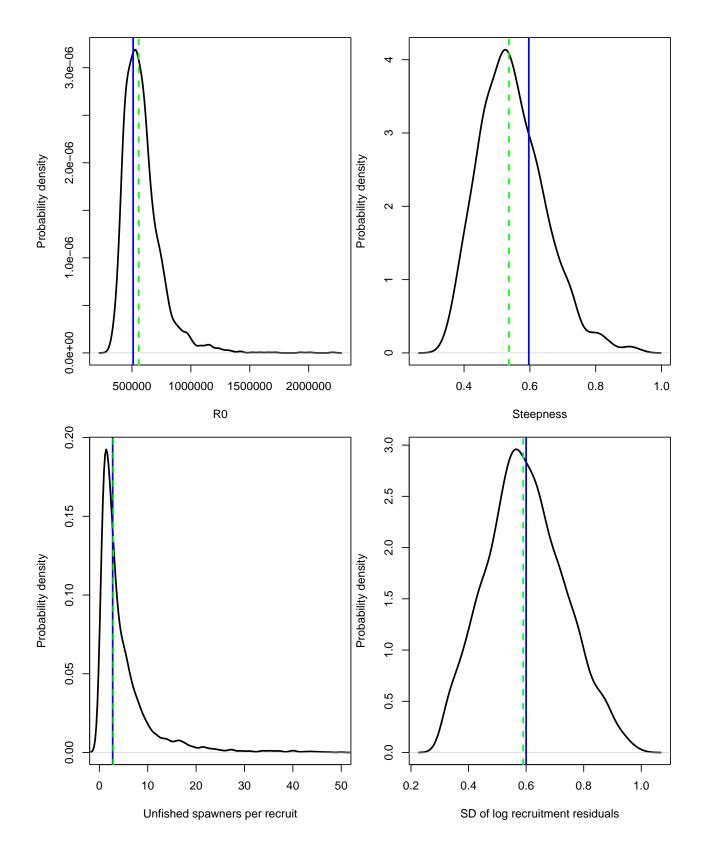

Figure 22. Yield per recruit (top; lb GW) and spawning potential ratio (bottom; spawning biomass per recruit relative to that at the unfished level) over a range of F. Both curves are based on average selectivity from the end of the assessment period.

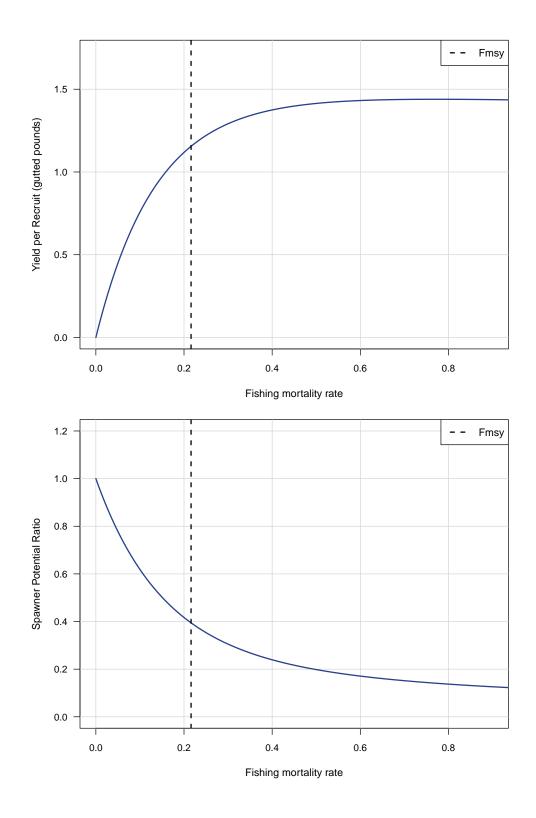

Figure 23. The top panel shows equilibrium landings at F. The peak occurs where fishing rate is $F_{MSY} = 0.22$ and equilibrium landings are MSY = 545 (1000 lb GW). The bottom panel shows equilibrium spawning biomass at F. Both curves are based on average selectivity from the end of the assessment period.

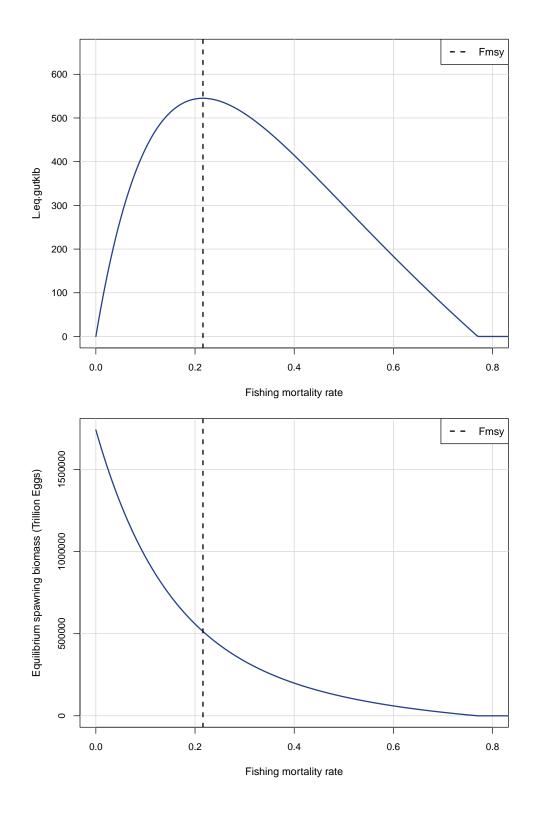

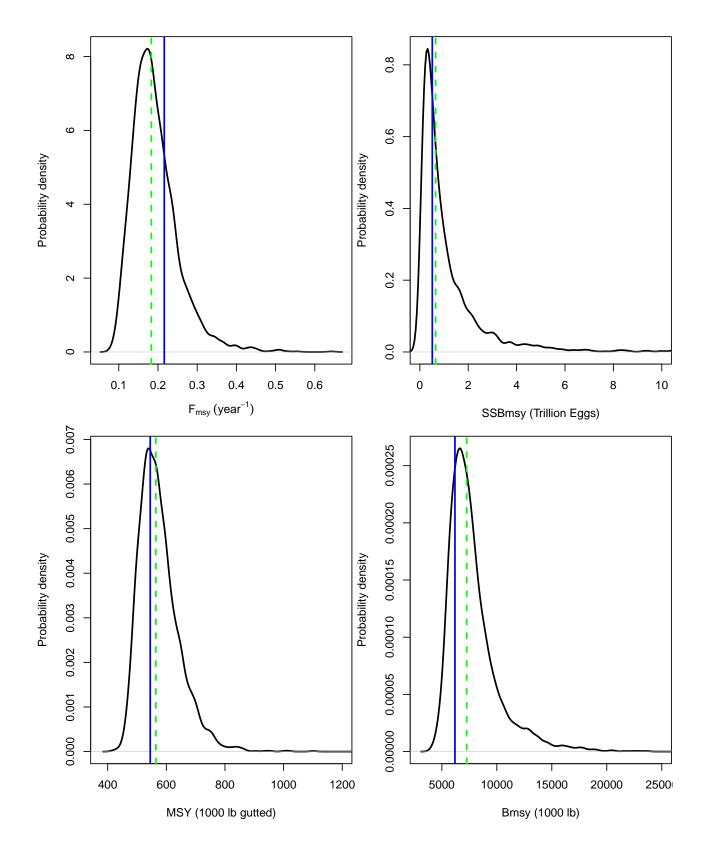

Figure 24. Probability densities of MSY-related benchmarks from MCBE analysis (n = 3018). The solid blue vertical line represent point estimates from the BAM base run; green dashed vertical line represent medians from the MCBE runs.

SEDAR 89 SAR Section II

Figure 25. Estimated time series of SSB and F relative to benchmarks: (top) spawning biomass relative to the minimum stock size threshold (MSST), (middle) spawning biomass relative to the spawning stock as MSY (SSB_{MSY}), (bottom) F relative to F_{MSY} . Shaded region represents 90% confidence bands from the MCBE runs (n = 3018). The blue solid dotted line represents the estimate from the BAM base run, while the green dashed line represents the median across the MCBE runs for each year.

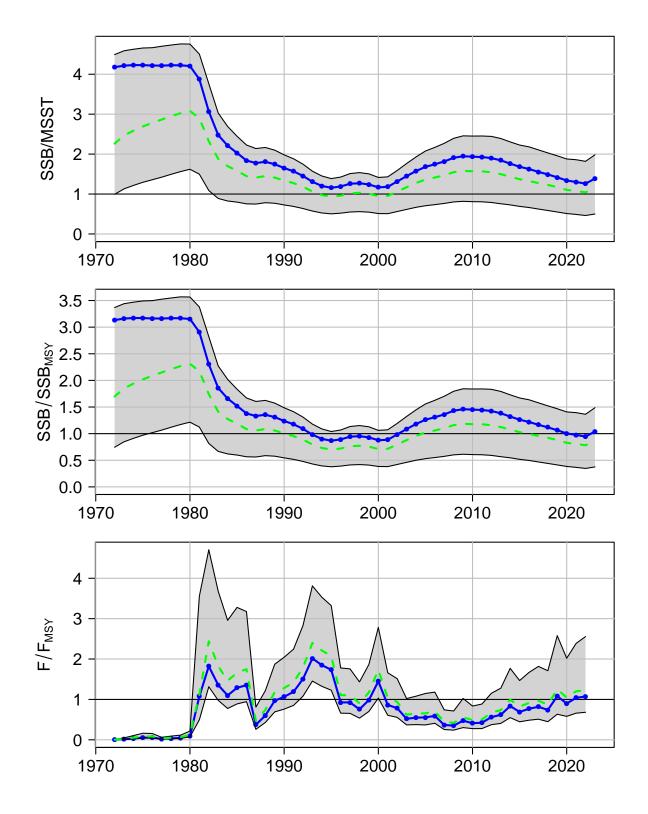

Figure 26. Estimated time series of SSB in million eggs at peak spawning. The solid blue dotted line is the estimate from the base BAM model, the dashed green line is the median of each year of the MCBE runs and the shaded region represents 90% confidence bands from the MCBE runs (n = 3018).

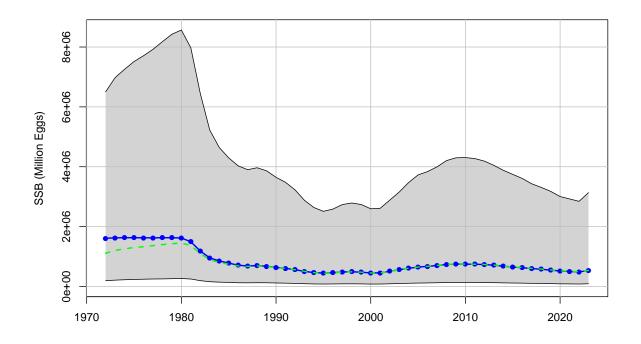

Figure 27. Probability densities of terminal status estimates from MCBE analysis of the Beaufort Assessment Model (n = 3018). The solid blue vertical line represent point estimates from the BAM base run; the dashed green vertical line represent medians from the MCBE runs.

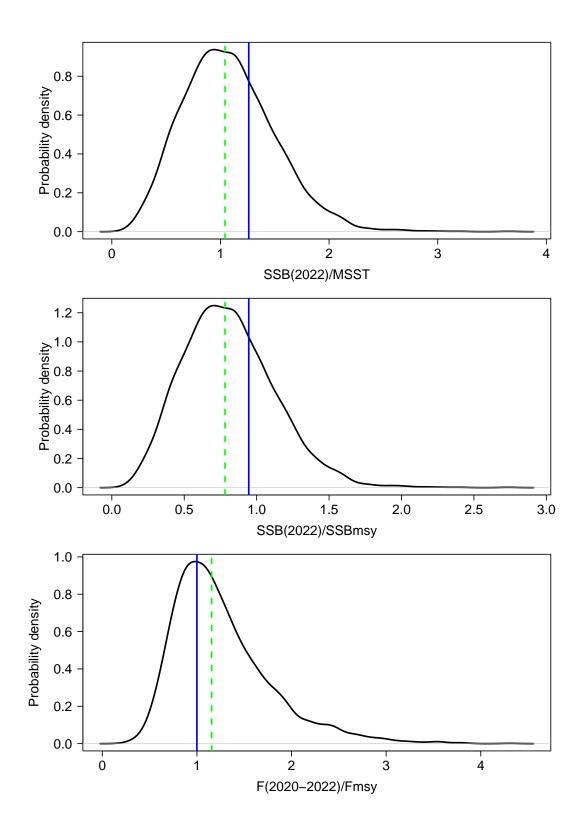

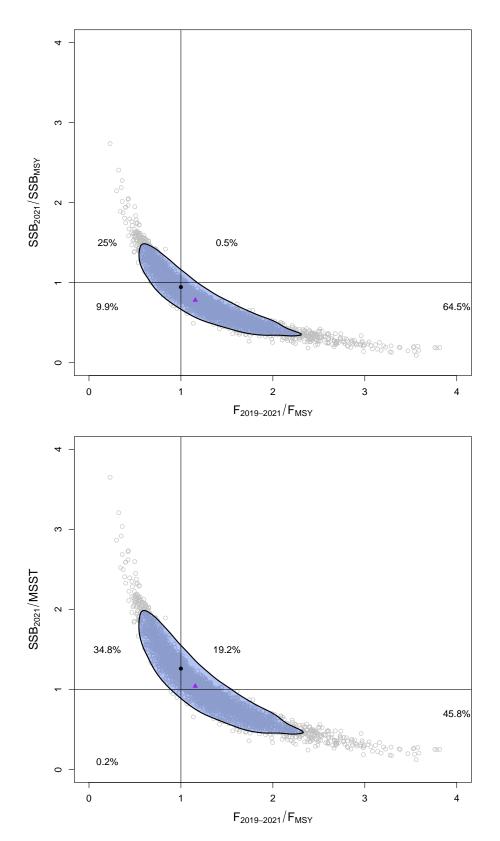

Figure 28. Phase plots of terminal status estimates from the MCBE of the Beaufort Assessment Model. Top panel is status relative to MSST, and the bottom panel is status relative to MSY. The filled black dot indicates the estimate from the base run; the purple filled triangle is the median of the MCBE analysis (n = 3018); the grey points indicate estimates from the MCBE runs and the shaded region is the 90th percentile of the two parameters.

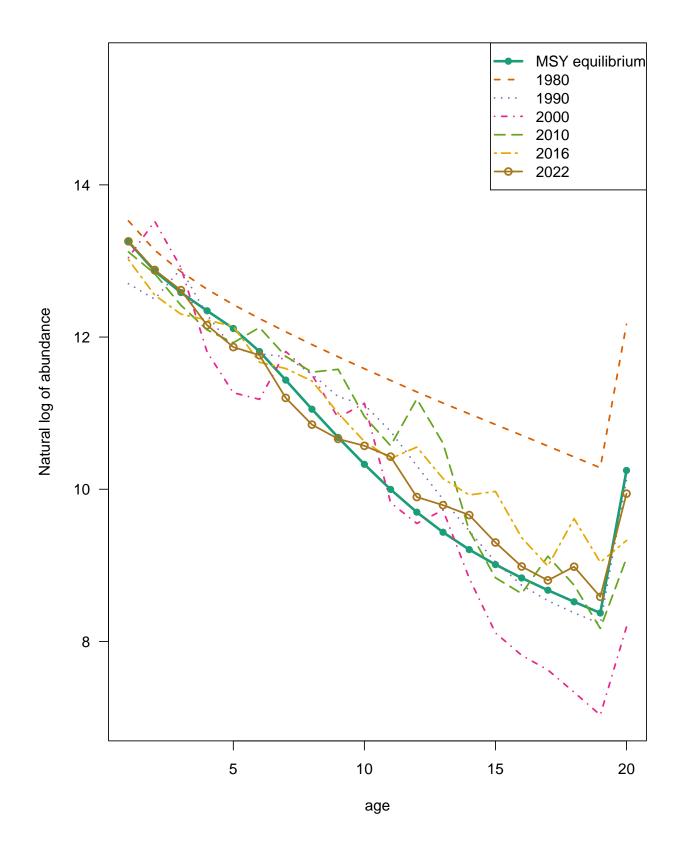

Figure 29. Estimated age structure from a series of individual years during the assessment, relative to the equilibrium expected at $F_{\rm MSY}$.

Figure 30. Sensitivity to low and high values of oldest and youngest ages used to calculate natural mortality at age: (S1-S4). Estimated time series of F and SSB relative to benchmarks. Sensitivity runs are indicated by colored broken lines, represented in the legend. Top panel: spawning stock biomass (SSB) relative to MSST. Bottom panel: F relative to F_{MSY} .

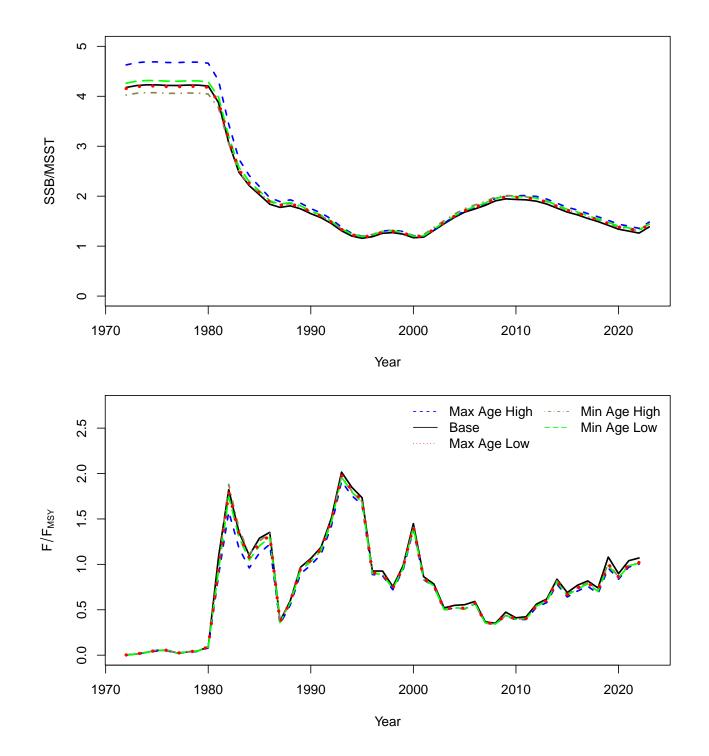

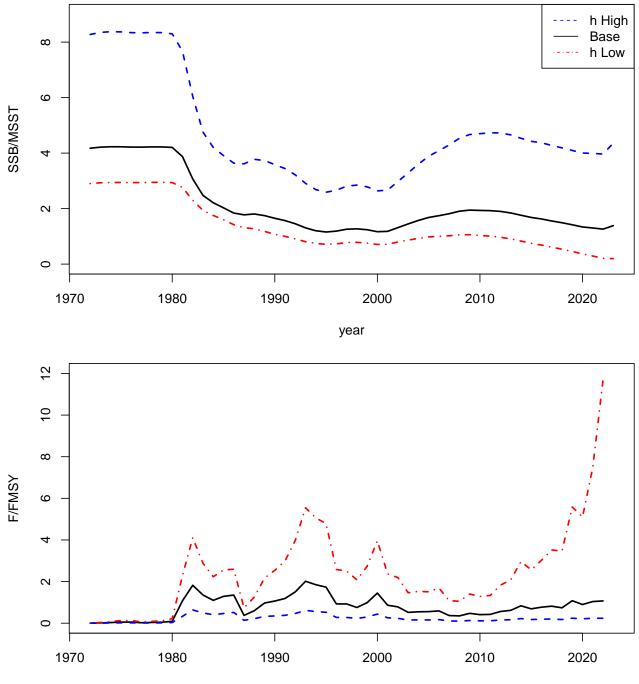

Figure 31. Sensitivity to low and high fixed values of steepness: (S5-S6). Estimated time series of F and SSB relative to benchmarks. Sensitivity runs are indicated by colored broken lines, represented in the legend. Top panel: spawning stock biomass (SSB) relative to MSST. Bottom panel: F relative to F_{MSY} .

year

Figure 32. Sensitivity to low and high values of F_{init} : (S7-S8). Estimated time series of F and SSB relative to benchmarks. Sensitivity runs are indicated by colored broken lines, represented in the legend. Top panel: spawning stock biomass (SSB) relative to MSST. Bottom panel: F relative to F_{MSY} .

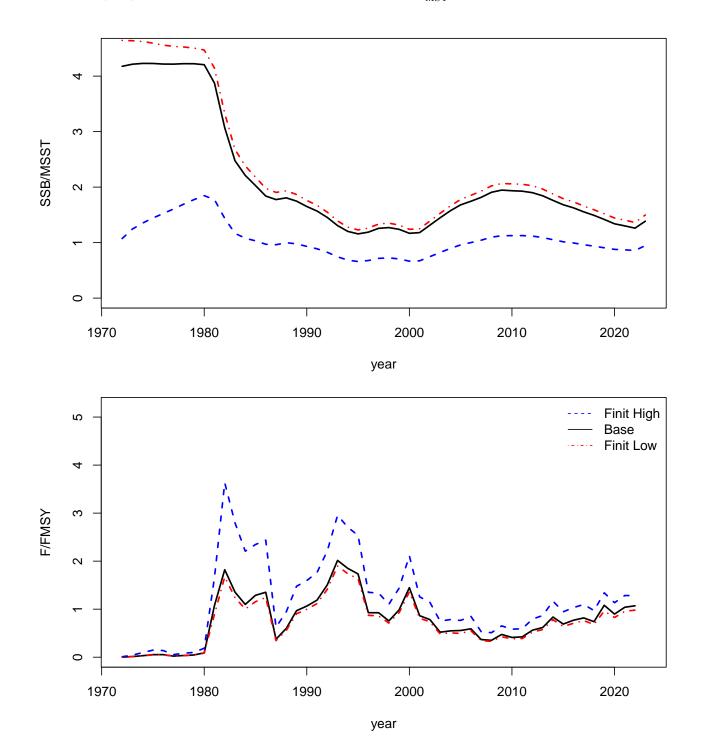

Figure 33. Sensitivity to low and high fixed t_0 values and estimated growth curves: (S9-S10). Estimated time series of F and SSB relative to benchmarks. Sensitivity runs are indicated by colored broken lines, represented in the legend. Top panel: spawning stock biomass (SSB) relative to MSST. Bottom panel: F relative to F_{MSY}.

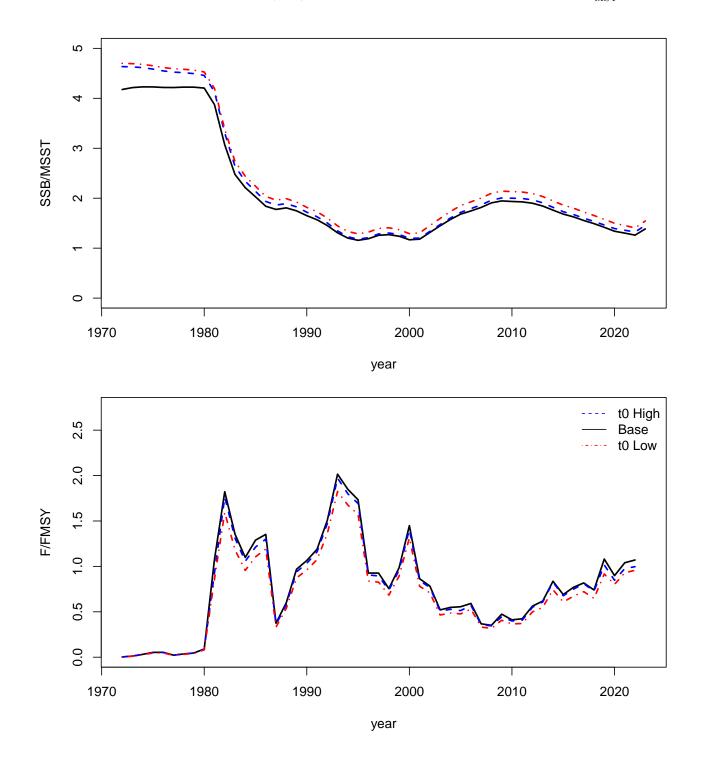

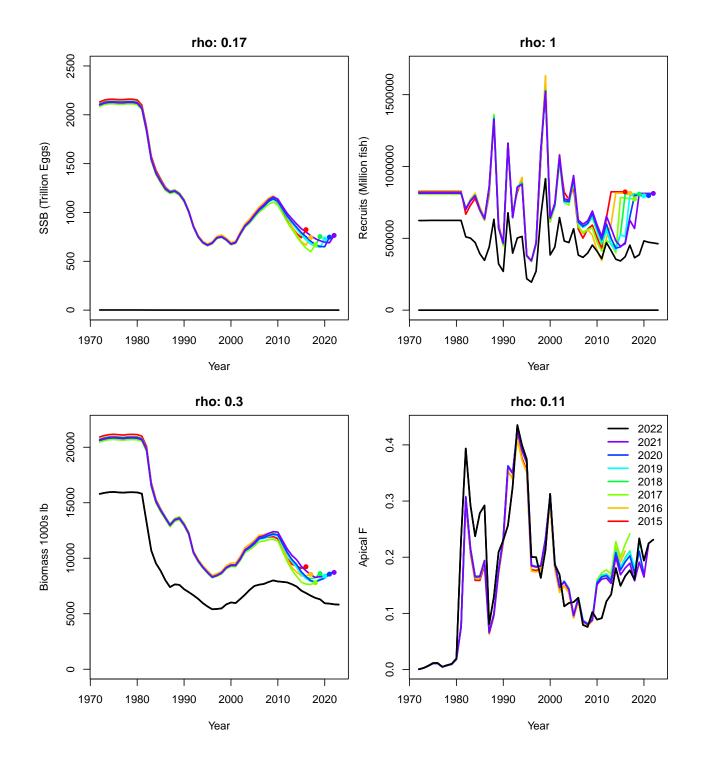

Figure 34. Retrospective analysis reducing the terminal year of the assessment from 2022 to values over a range from 2015 to 2021. Value at the top of each plot indicate the Mohn's rho value. Top left panel: Spawning Stock Biomass. Top right panel: Recruits. Bottom left panel: Biomass. Bottom right: Fishing mortality rates. Closed circles show terminal-year estimates.

July, 2024

Figure 35. Plots of SSB, landings, recruits, F, and the probability that SSB > MSST for projections with fishing mortality rate at fixed F that provides $P^* = 0.50$. In all panels except the bottom right, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5th and 95th percentiles of replicate projections. Solid horizontal blue lines mark MSY-related quantities from the base model; dashed horizontal green lines represent corresponding medians from the MCBE analysis. Spawning stock (SSB) is at time of peak spawning. In the bottom right panel, the curve represents the proportion of projection replicates for which SSB exceeds the replicate-specific MSST.

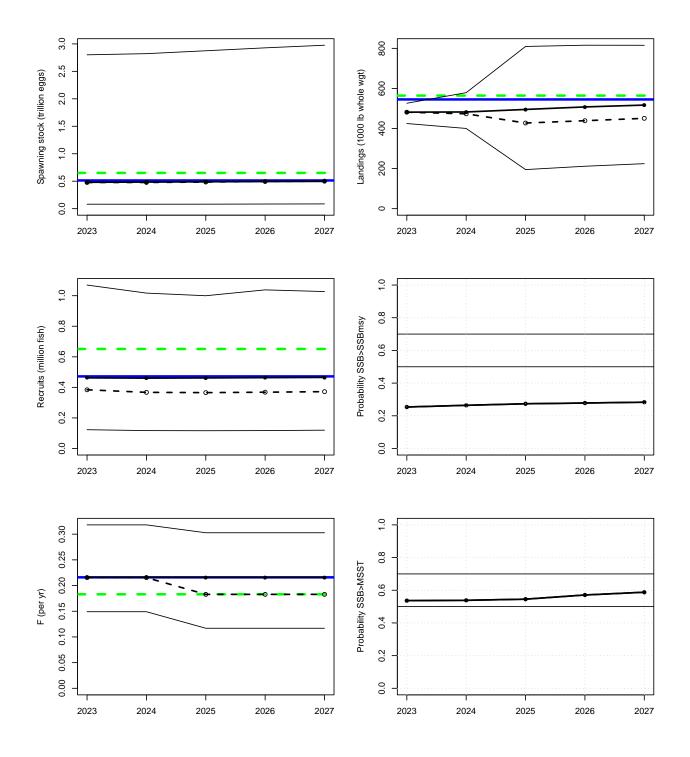

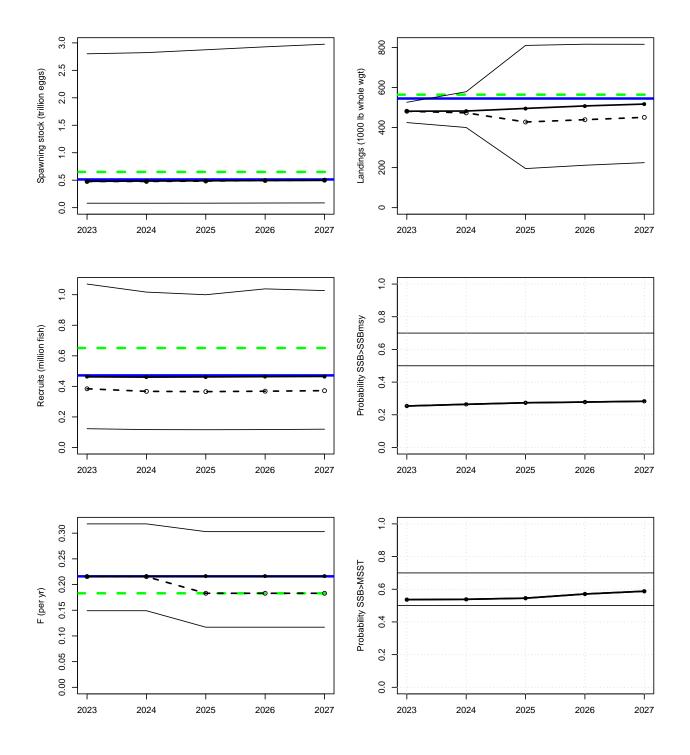

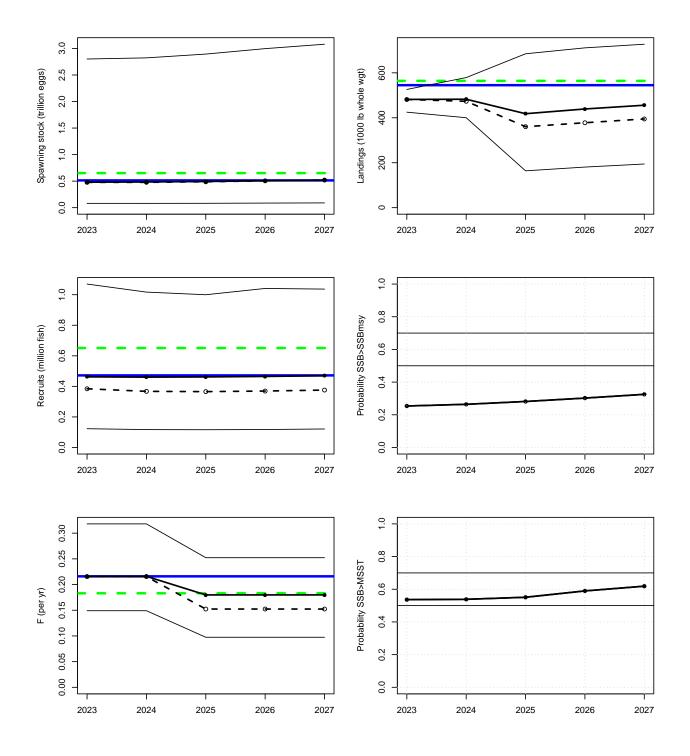

Figure 36. Plots of SSB, landings, recruits, F, and the probability that SSB > MSST for projections with fishing mortality rate fixed at $F = F_{MSY}$. In all panels except the bottom right, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5th and 95th percentiles of replicate projections. Solid horizontal blue lines mark MSY-related quantities from the base model; dashed horizontal green lines represent corresponding medians from the MCBE analysis. Spawning stock (SSB) is at time of peak spawning. In the bottom right panel, the curve represents the proportion of projection replicates for which SSB exceeds the replicate-specific MSST.

July, 2024

Figure 37. Plots of SSB, landings, recruits, F, and the probability that SSB > MSST for projections with fishing mortality rate at fixed F that provides $P^* = 0.325$. In all panels except the bottom right, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5th and 95th percentiles of replicate projections. Solid horizontal blue lines mark MSY-related quantities from the base model; dashed horizontal green lines represent corresponding medians from the MCBE analysis. Spawning stock (SSB) is at time of peak spawning. In the bottom right panel, the curve represents the proportion of projection replicates for which SSB exceeds the replicate-specific MSST.

Appendix A Abbreviations and symbols

Table 22. Acronyms and abbreviations used in this report

Symbol	Meaning
ABC	Acceptable Biological Catch
AW	Assessment Workshop (here, for tilefish)
ASY	Average Sustainable Yield
B	Total biomass of stock, conventionally on January 1
BAM	Beaufort Assessment Model (a statistical catch-age formulation)
CPUE	Catch per unit effort; used after adjustment as an index of abundance
CV	Coefficient of variation
CI	Confidence Interval
CVID	SERFS index combining sampling from chevron traps and video gear
DW	Data Workshop (here, for tilefish)
F	Instantaneous rate of fishing mortality
$F_{\rm MSY}$	Fishing mortality rate at which MSY can be attained
FL	State of Florida
GA	State of Georgia
GLM	Generalized linear model
K	Average size of stock when not exploited by man; carrying capacity
kg	Kilogram(s); 1 kg is about 2.2 lb.
klb	Thousand pounds; thousands of pounds
lb	Pound(s); 1 lb is about 0.454 kg
m	Meter(s); 1 m is about 3.28 feet.
M	Instantaneous rate of natural (non-fishing) mortality
MARMAP	Marine Resources Monitoring, Assessment, and Prediction Program, a fishery-independent data collection program
	of SCDNR
MCBE	Monte Carlo/Bootstrap ensemble, an approach to quantifying uncertainty in model results
MFMT	Maximum fishing-mortality threshold, a limit reference point used in U.S. fishery management; often based on
	F _{MSY}
mm	$\overset{MST}{\text{Millimeter}(s): 1 \text{ inch} = 25.4 \text{ mm}$
MRFSS	Marine Recreational Fisheries Statistics Survey, a data-collection program of NMFS, predecessor of MRIP
MRIP	Marine Recreational Information Program, a data-collection program of NMFS, descended from MRFSS
MSST	Minimum stock-size threshold; a limit reference point used in U.S. fishery management. The SAFMC has defined
MSY	MSST for tilefish as $(1 - M)$ SSB _{MSY} = 0.7SSB _{MSY} . Maximum sustainable yield (per year)
mt	Maximum sustainable yield (per year) Metric ton(s). One mt is 1000 kg, or about 2205 lb.
N	Number of fish in a stock, conventionally on January 1
NC	State of North Carolina
NMFS	National Marine Fisheries Service, same as "NOAA Fisheries Service"
NOAA	National Oceanic and Atmospheric Administration; parent agency of NMFS
OY	Optimum yield; SFA specifies that $OY \leq MSY$.
PSE	Proportional standard error $\leq MST$.
R	Recruitment
SAFMC	South Atlantic Fishery Management Council (also, Council)
SC	State of South Carolina
SCDNR	Department of Natural Resources of SC
SDNR	Standard deviation of normalized residuals
SEDAR	SouthEast Data Assessment and Review process
SEFIS	SouthEast Fishery-Independent Survey
	SouthEast Reef Fish Survey
$\begin{array}{c} \mathrm{SERFS} \\ \mathrm{SFA} \end{array}$	SouthEast Reef Fish Survey Sustainable Fisheries Act; the Magnuson–Stevens Act, as amended
SL	
	Standard length (of a fish)
$_{ m SPR}^{ m SPR}$	Spawning potential ratio
	Spawning stock biomass; mature biomass of males and females
SSB_{MSY}	Level of SSB at which MSY can be attained Trip Interview Program a federar dependent biodate collection program of NMES
TIP	Trip Interview Program, a fishery-dependent biodata collection program of NMFS
TL VDA	Total length (of a fish), as opposed to FL (fork length) or SL (standard length)
VPA	Virtual population analysis, an age-structured assessment
WW	Whole weight, as opposed to GW (gutted weight)
yr	Year(s)

Appendix C Additional diagnostic plots for the base model

C.1 Parameter bounding plots

Figure 38. Diagnostic plot of parameter estimates to check for bounding issues, where the red lines indicate the upper and lower parameter bounds, orange is the initial model parameter starting value and blue is the final model estimate.

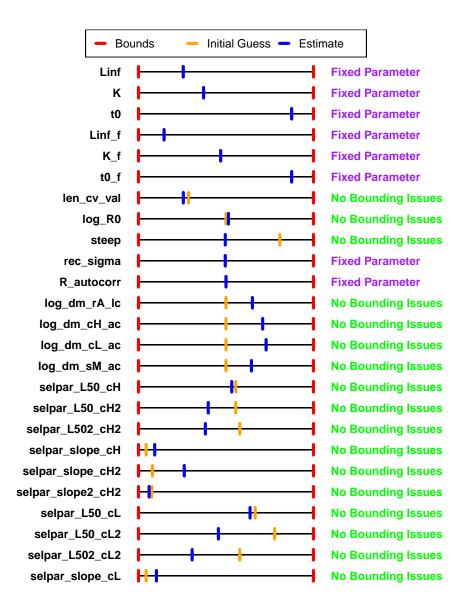

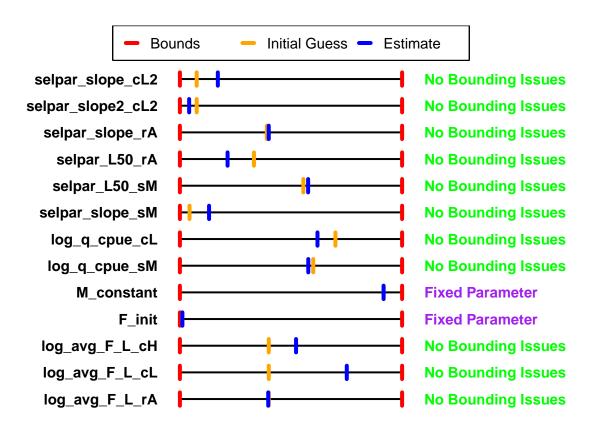

Figure 39. Continued: Diagnostic plot of parameter estimates to check for bounding issues, where the red lines indicate the upper and lower parameter bounds, orange is the initial model parameter starting value and blue is the final model estimate.

C.2 Composition fit plots

Figure 40. Top panel: One Step Ahead (OSA) residuals for the commercial handline age composition, where orange indicates an underestimate and blue is an overestimate and the size of the circle is the magnitude. Bottom panel: correlation between vectors of estimated and observed values.

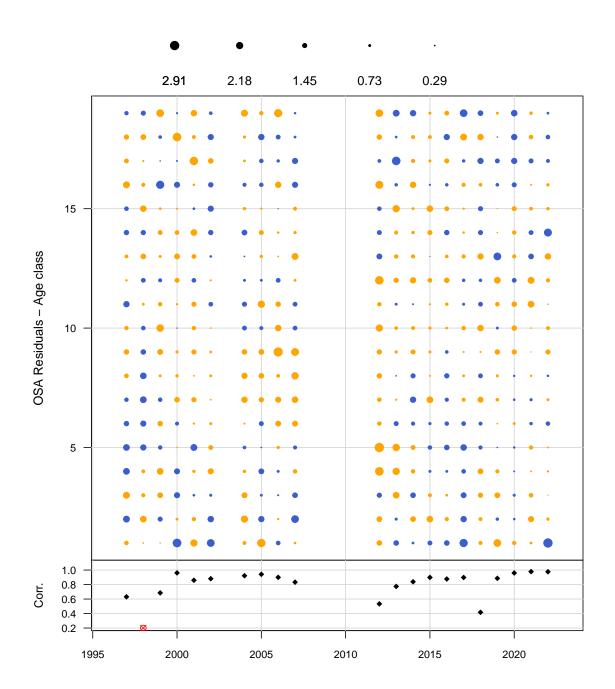

Figure 41. Top panel: One Step Ahead (OSA) residuals for the commercial longline age composition, where orange indicates an underestimate and blue is an overestimate and the size of the circle is the magnitude. Bottom panel: correlation between vectors of estimated and observed values.

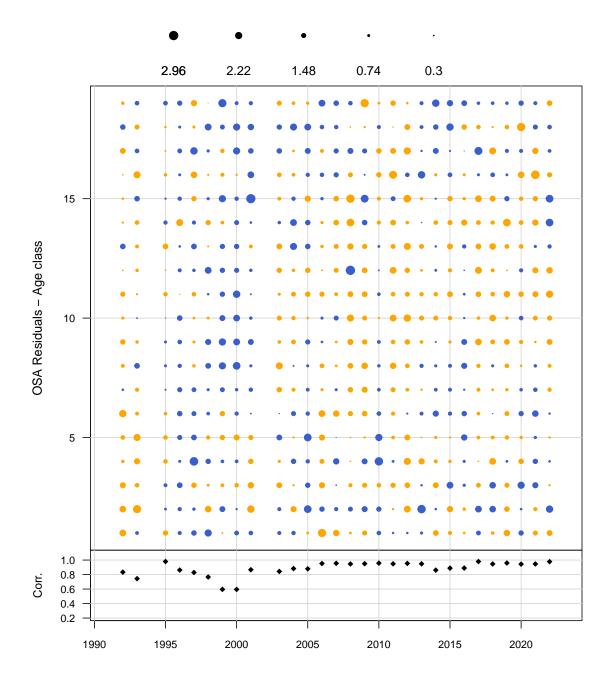

Figure 42. Top panel: One Step Ahead (OSA) residuals for the MARMAP survey age composition, where orange indicates an underestimate and blue is an overestimate and the size of the circle is the magnitude. Bottom panel: correlation between vectors of estimated and observed values.

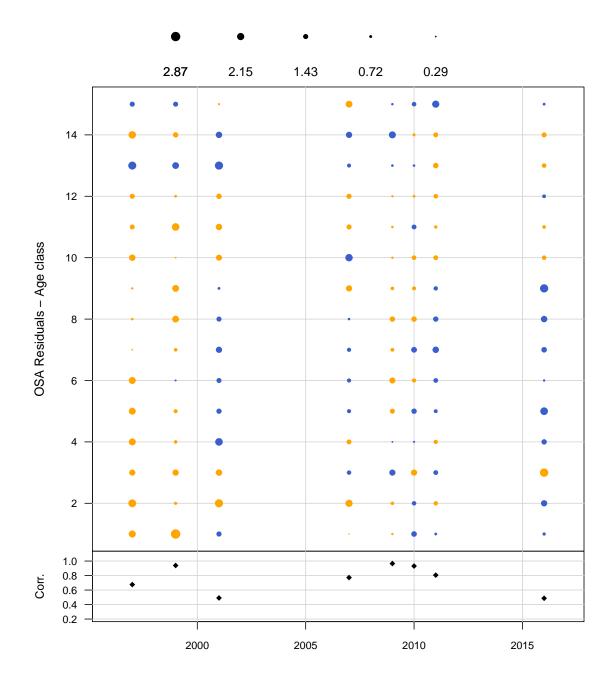

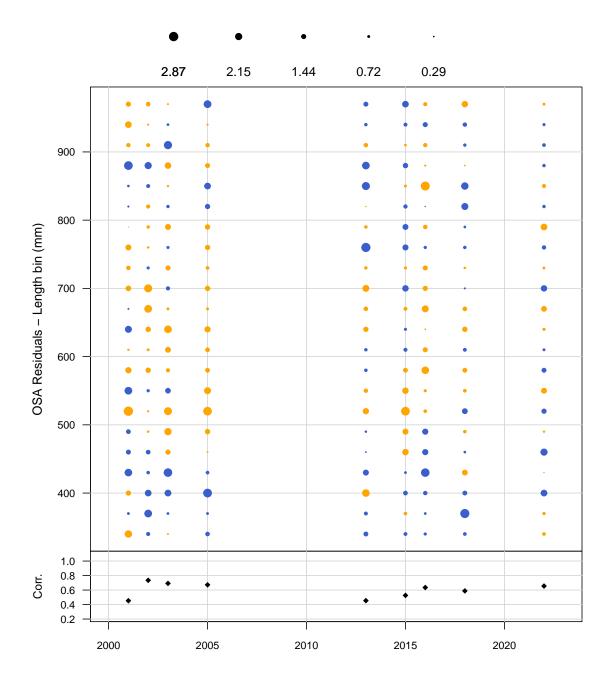

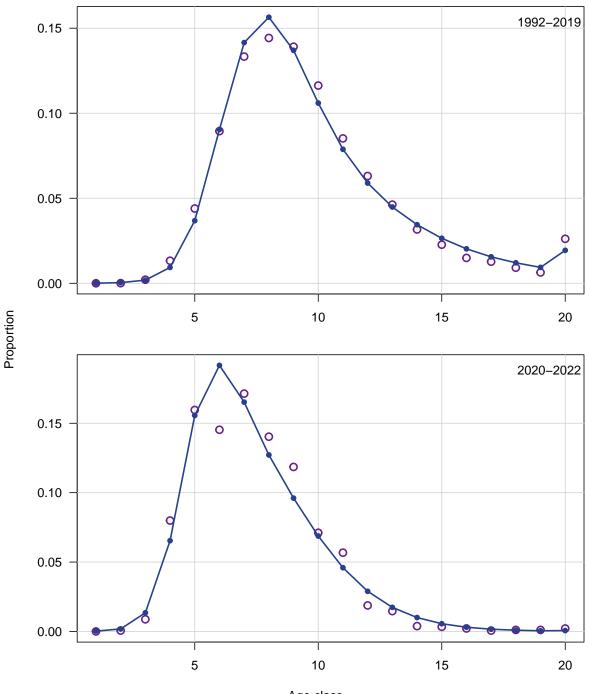

Figure 43. Top panel: One Step Ahead (OSA) residuals for the general recreation length composition, where orange indicates an underestimate and blue is an overestimate and the size of the circle is the magnitude. Bottom panel: correlation between vectors of estimated and observed values.

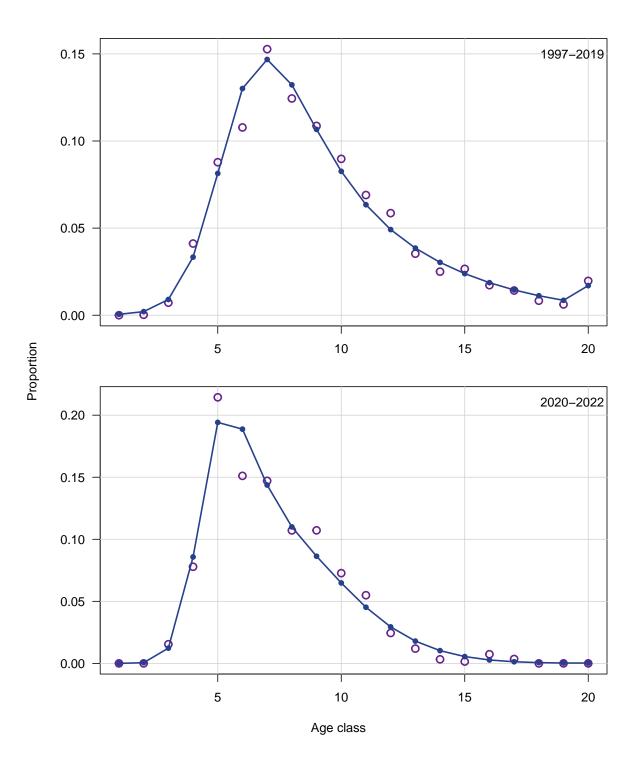

C.3 Pooled Composition fits

Figure 44. Observed (open circles) and estimated (solid line) pooled age compositions for the commercial longline fleet weighted by the effective sample size from the base run separated by the time block selectivities where the year range of the time block is in the top right corner of the plot.

Age class

Figure 45. Observed (open circles) and estimated (solid line) pooled age compositions for the commerical handline flee weighted by the effective sample size from the base run separated by the time block selectivities where the year range of the time block is in the top right corner of the plot.

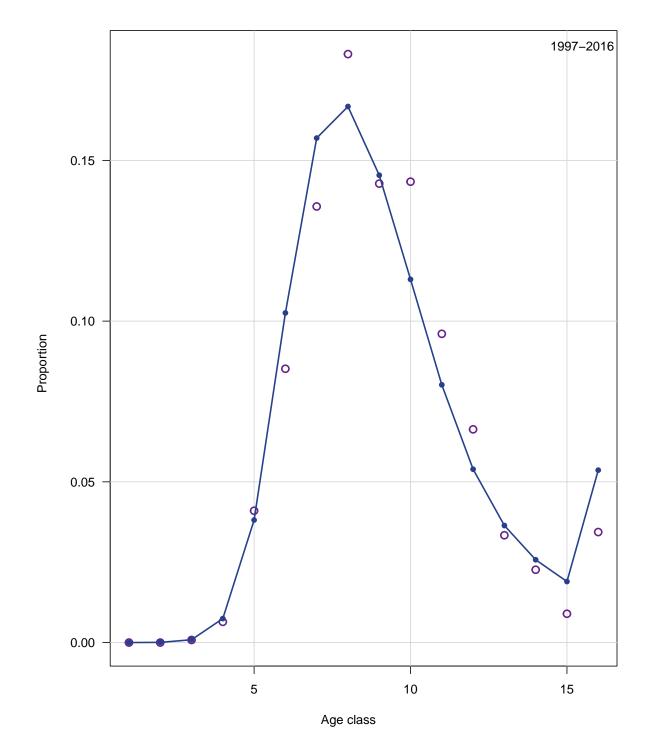

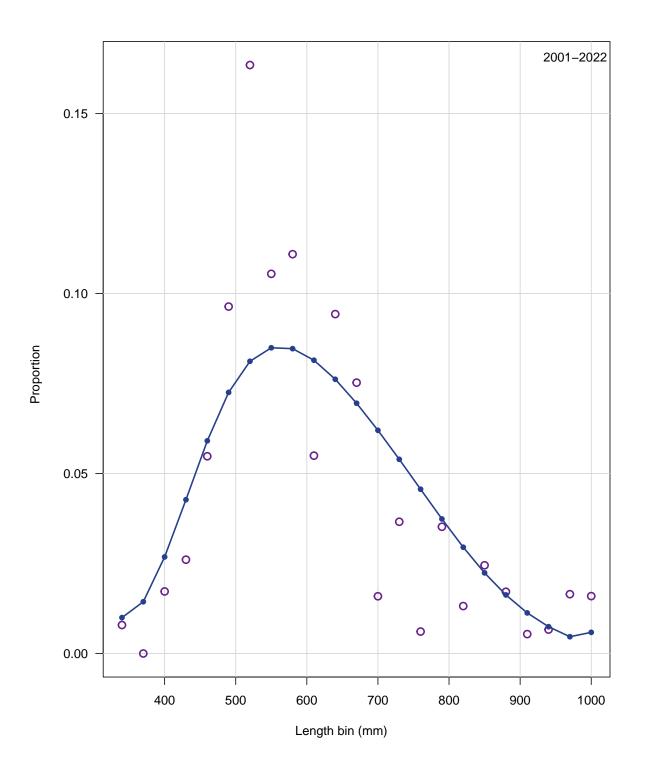

Figure 46. Observed (open circles) and estimated (solid line) age compositions for the MARMAP bottom long line survey from the base run.

Figure 47. Observed (open circles) and estimated (solid line) pooled length compositions for the general recreational fleet weighted by the effective sample size from the base run separated by the time block selectivities where the year range of the time block is in the top right corner of the plot.

C.4 Likelihood Profiles

Figure 48. Scaled likelihood profile for Age 50 descending limb of commercial handline domed selectivity where the change in likelihood from the lowest observed value among values tested for each component. The color of the line indicates the data source of the change in likelihood where the black line is all data sources and prior penalties, the red line is from age compositions, the light green line is from indices of abundance, the dark green line is from landings, the brown line is from length composition, the orange line is from prior penalties, and the grey line is the recruitment deviate penalties and other stock recruitment related penalties.

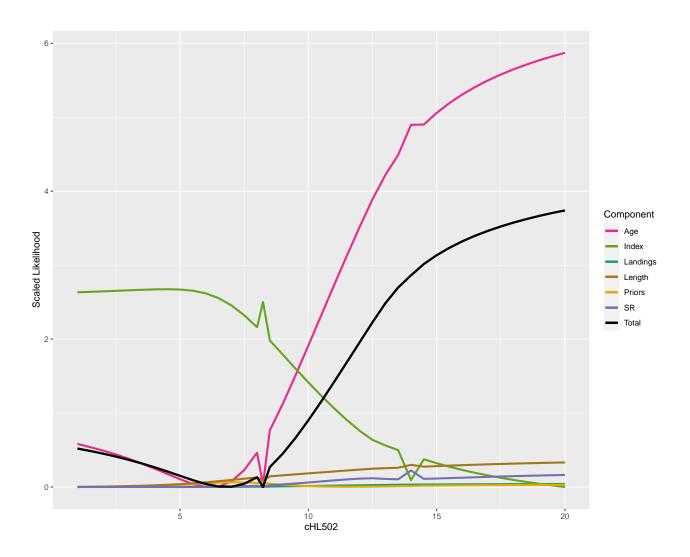

Figure 49. Scaled likelihood profile for Age 50 descending limb of commercial longline domed selectivity where the change in likelihood from the lowest observed value among values tested for each component. The color of the line indicates the data source of the change in likelihood where the black line is all data sources and prior penalties, the red line is from age compositions, the light green line is from indices of abundance, the dark green line is from landings, the brown line is from length composition, the orange line is from prior penalties, and the grey line is the recruitment deviate penalties and other stock recruitment related penalties.

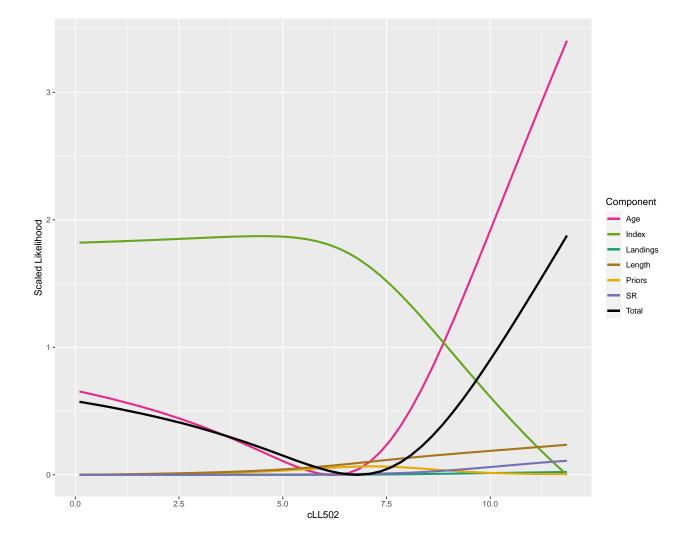

Figure 50. Scaled likelihood profile for slope descending limb of commercial handline domed selectivity where the change in likelihood from the lowest observed value among values tested for each component. The color of the line indicates the data source of the change in likelihood where the black line is all data sources and prior penalties, the red line is from age compositions, the light green line is from indices of abundance, the dark green line is from landings, the brown line is from length composition, the orange line is from prior penalties, and the grey line is the recruitment deviate penalties and other stock recruitment related penalties.

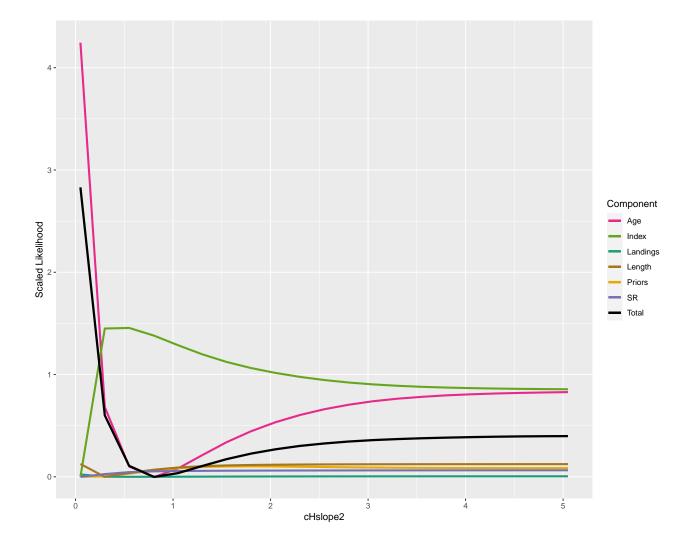

Figure 51. Scaled likelihood profile for slope descending limb of commercial longline domed selectivity where the change in likelihood from the lowest observed value among values tested for each component. The color of the line indicates the data source of the change in likelihood where the black line is all data sources and prior penalties, the red line is from age compositions, the light green line is from indices of abundance, the dark green line is from landings, the brown line is from length composition, the orange line is from prior penalties, and the grey line is the recruitment deviate penalties and other stock recruitment related penalties.

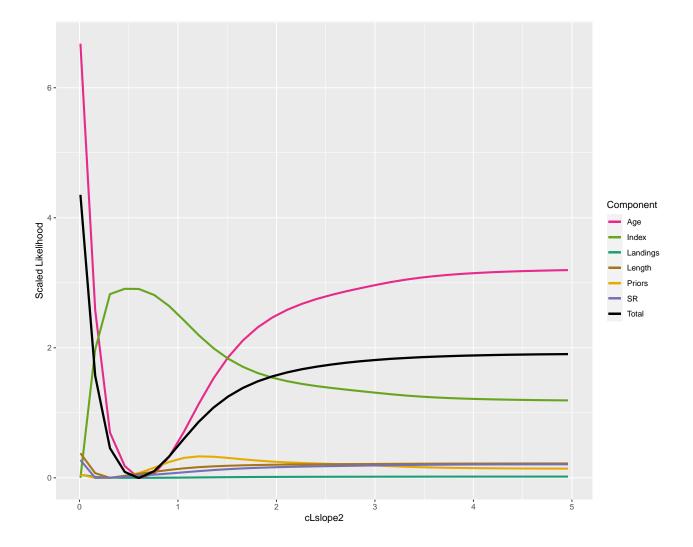

Figure 52. Scaled likelihood profile for Beverton-Holt steepness where the change in likelihood from the lowest observed value among values tested for each component. The color of the line indicates the data source of the change in likelihood where the black line is all data sources and prior penalties, the red line is from age compositions, the light green line is from indices of abundance, the dark green line is from landings, the brown line is from length composition, the orange line is from prior penalties, and the grey line is the recruitment deviate penalties and other stock recruitment related penalties.

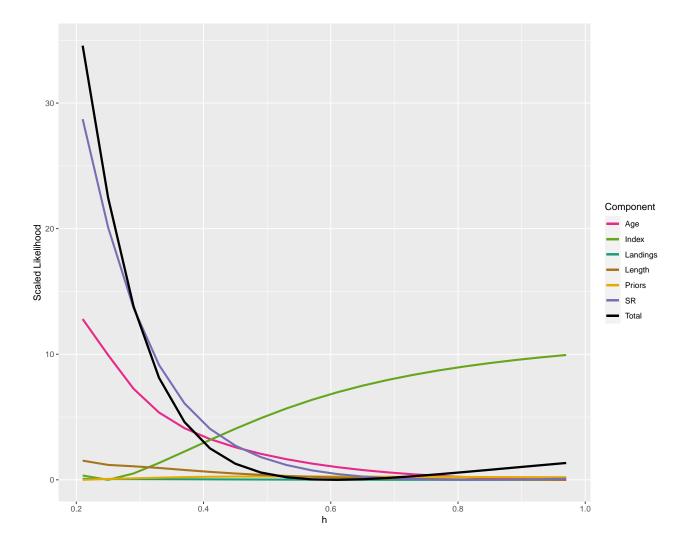

Figure 53. Scaled likelihood profile for initial fishing mortality rate F_{init} where the change in likelihood from the lowest observed value among values tested for each component. The color of the line indicates the data source of the change in likelihood where the black line is all data sources and prior penalties, the red line is from age compositions, the light green line is from indices of abundance, the dark green line is from landings, the brown line is from length composition, the orange line is from prior penalties, and the grey line is the recruitment deviate penalties and other stock recruitment related penalties.

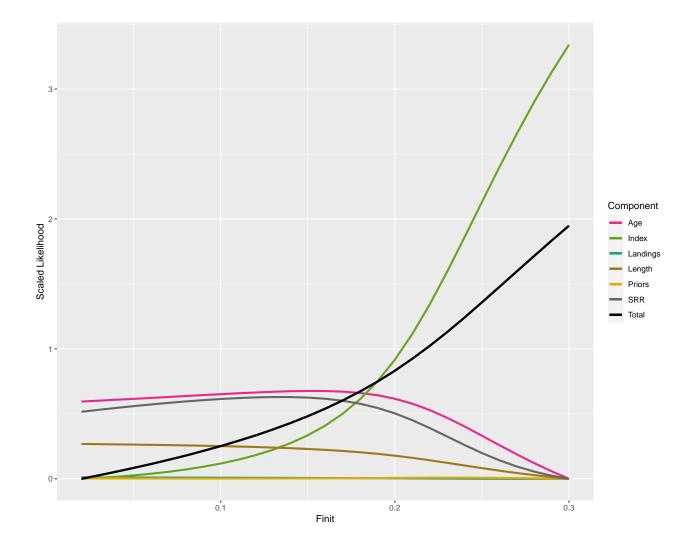

Figure 54. Scaled likelihood profile for Beverton-Holt R_0 where the change in likelihood from the lowest observed value among values tested for each component. The color of the line indicates the data source of the change in likelihood where the black line is all data sources and prior penalties, the red line is from age compositions, the light green line is from indices of abundance, the dark green line is from landings, the brown line is from length composition, the orange line is from prior penalties, and the grey line is the recruitment deviate penalties and other stock recruitment related penalties.

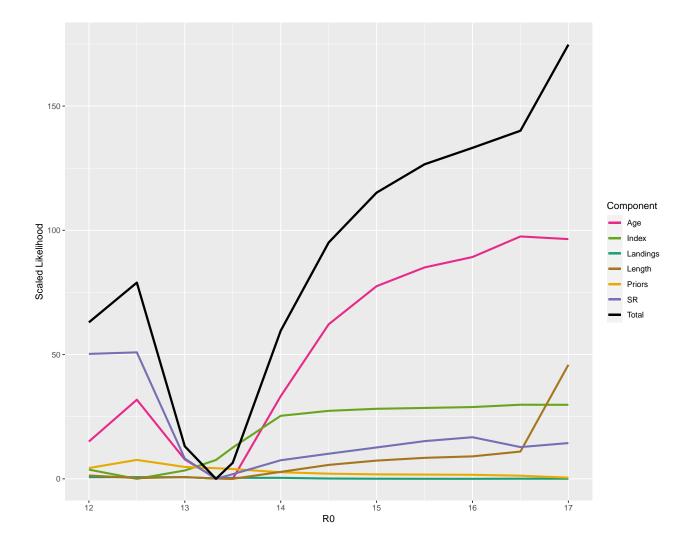

Figure 55. Scaled likelihood profile for the recruitment deviate in 2015, where the change in likelihood from the lowest observed value among values tested for each component. The color of the line indicates the data source of the change in likelihood where the black line is all data sources and prior penalties, the red line is from age compositions, the light green line is from indices of abundance, the dark green line is from landings, the brown line is from length composition, the orange line is from prior penalties, and the grey line is the recruitment deviate penalties and other stock recruitment related penalties.

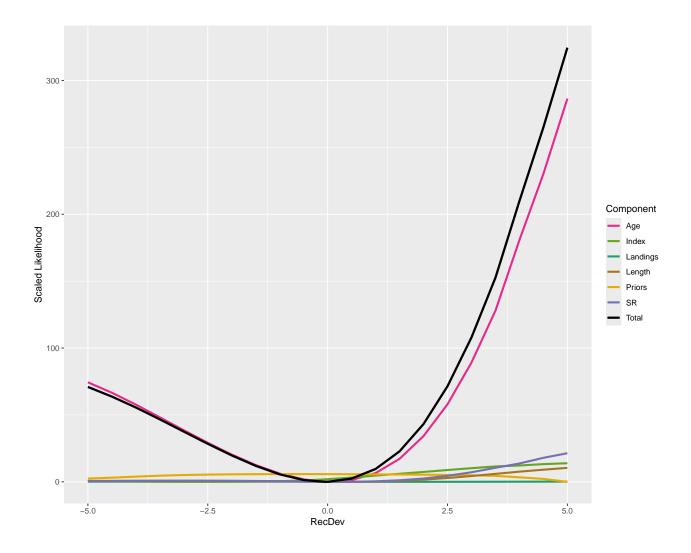

Figure 56. Scaled likelihood profile for the recruitment deviate in 2016, where the change in likelihood from the lowest observed value among values tested for each component. The color of the line indicates the data source of the change in likelihood where the black line is all data sources and prior penalties, the red line is from age compositions, the light green line is from indices of abundance, the dark green line is from landings, the brown line is from length composition, the orange line is from prior penalties, and the grey line is the recruitment deviate penalties and other stock recruitment related penalties.

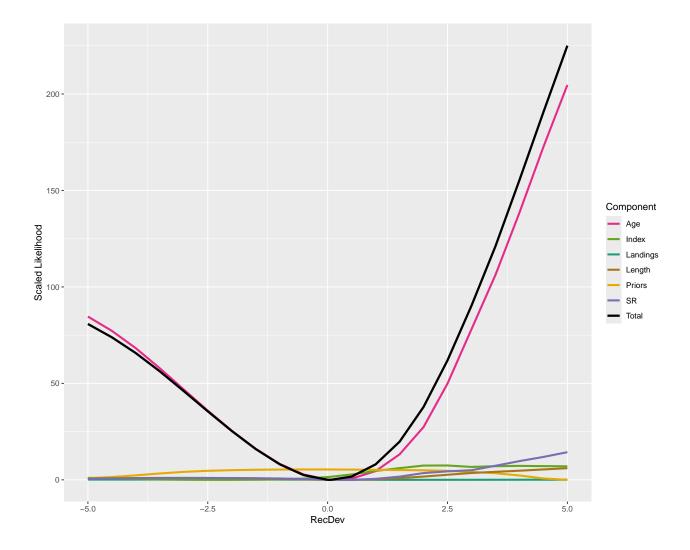

Figure 57. Scaled likelihood profile for the recruitment deviate in 2017, where the change in likelihood from the lowest observed value among values tested for each component. The color of the line indicates the data source of the change in likelihood where the black line is all data sources and prior penalties, the red line is from age compositions, the light green line is from indices of abundance, the dark green line is from landings, the brown line is from length composition, the orange line is from prior penalties, and the grey line is the recruitment deviate penalties and other stock recruitment related penalties.

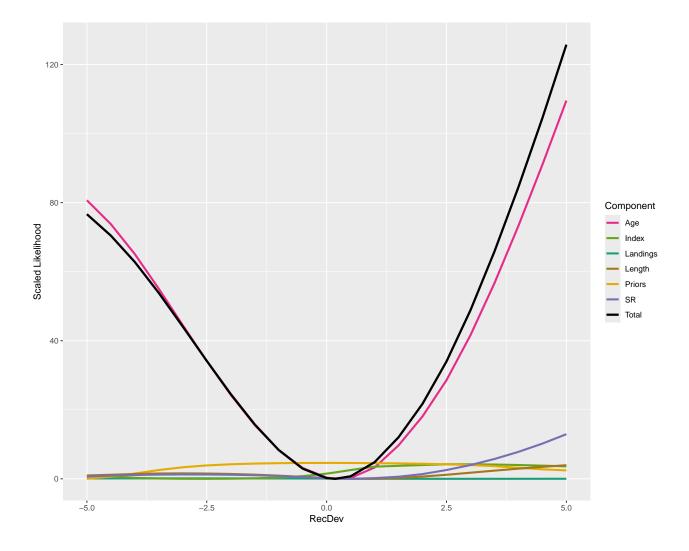

Figure 58. Scaled likelihood profile for the recruitment deviate in 2018, where the change in likelihood from the lowest observed value among values tested for each component. The color of the line indicates the data source of the change in likelihood where the black line is all data sources and prior penalties, the red line is from age compositions, the light green line is from indices of abundance, the dark green line is from landings, the brown line is from length composition, the orange line is from prior penalties, and the grey line is the recruitment deviate penalties and other stock recruitment related penalties.

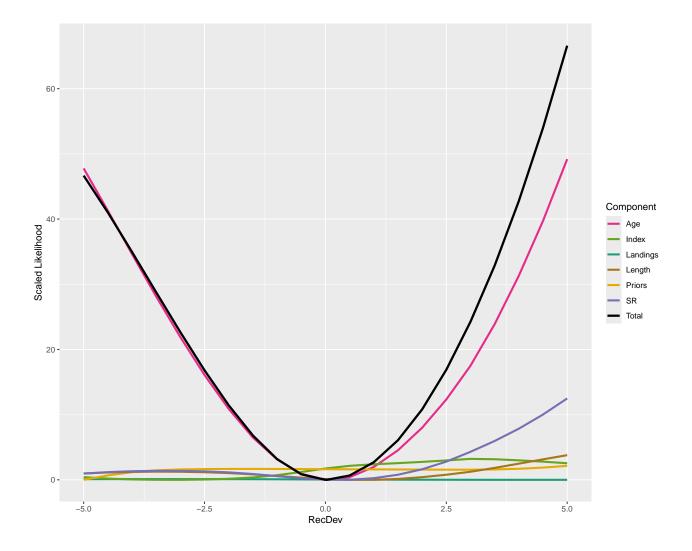

Figure 59. Scaled likelihood profile for the recruitment deviate in 2019, where the change in likelihood from the lowest observed value among values tested for each component. The color of the line indicates the data source of the change in likelihood where the black line is all data sources and prior penalties, the red line is from age compositions, the light green line is from indices of abundance, the dark green line is from landings, the brown line is from length composition, the orange line is from prior penalties, and the grey line is the recruitment deviate penalties and other stock recruitment related penalties.

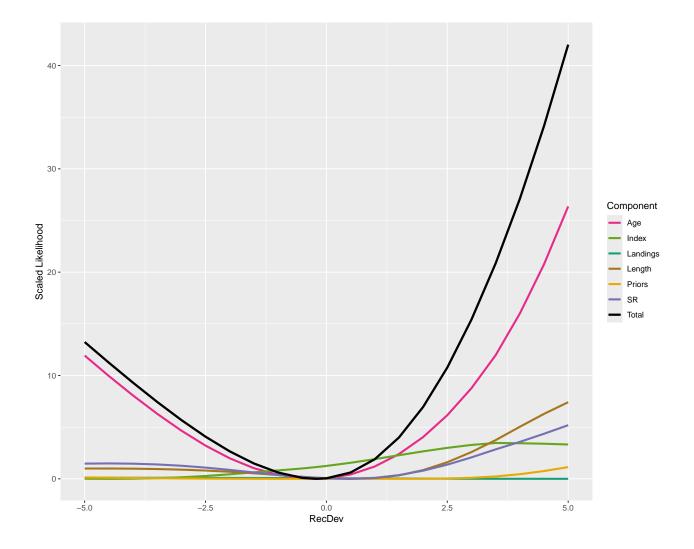

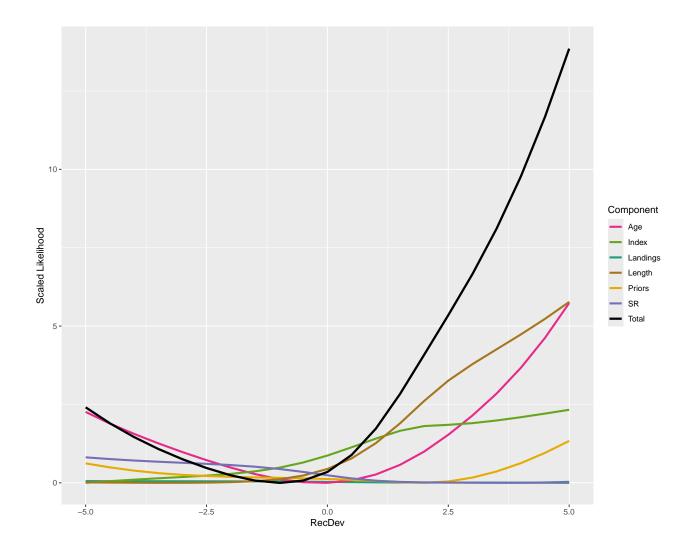

Figure 60. Scaled likelihood profile for the recruitment deviate in 2020, where the change in likelihood from the lowest observed value among values tested for each component. The color of the line indicates the data source of the change in likelihood where the black line is all data sources and prior penalties, the red line is from age compositions, the light green line is from indices of abundance, the dark green line is from landings, the brown line is from length composition, the orange line is from prior penalties, and the grey line is the recruitment deviate penalties and other stock recruitment related penalties.

C.5 Fixed MCBE parameters

Figure 61. Density plots of fixed parameters in the MCBE models where the solid blue vertical lines are the value in the base BAM model, the green vertical lines are the median of the MCBE model runs (n = 3018). Top left panel: fixed constant natural mortality used to calculate M_a , Top right panel: Fishing mortality in the initial year, Bottom left panel: fraction of year of peak spawning, Bottom right panel: standard deviation of recruitment deviates.

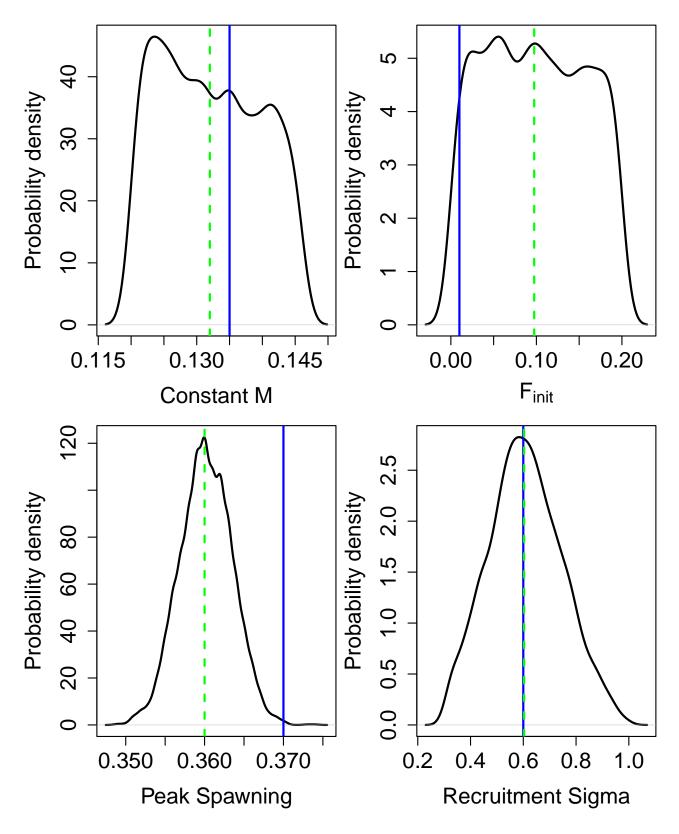

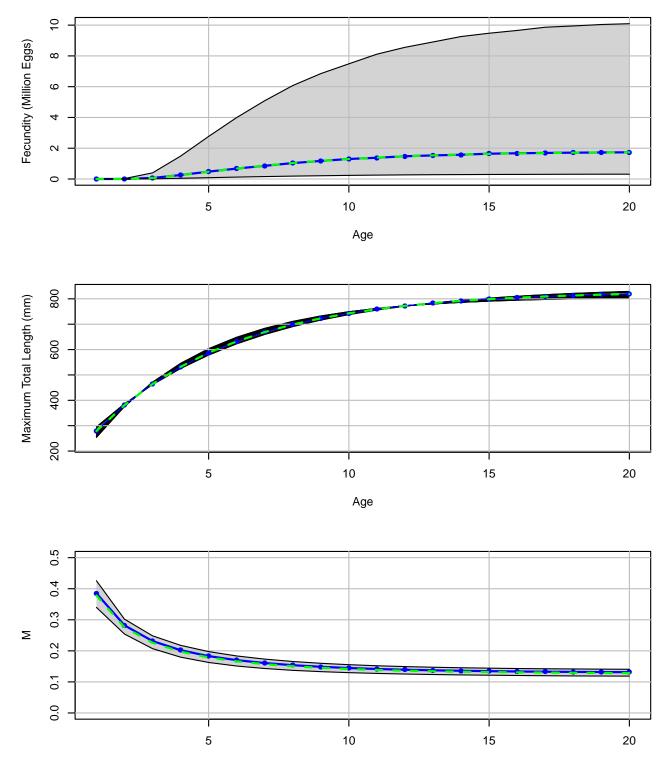

Figure 62. Density plots of fixed age vectors in the MCBE models where the solid blue lines are the value in the base BAM model, the green lines are the median of the MCBE model runs and the shaded region represents 90% confidence bands from the MCBE runs (n = 3018). Top panel: Total reproductive output at age in millions of eggs produced (is the product of batch fecundity at age, number of batches at age and maturity at age), Middle panel: Maximum total length in millimeters, Bottom panel: natural mortality at age.

Age

Figure 63. Density plots of fixed age vectors used to calculate reproductive output (i.e., fecundity) in the MCBE models where the solid blue lines are the value in the base BAM model, the green lines are the median of the MCBE model runs and the shaded region represents 90% confidence bands from the MCBE runs (n = 3018). Top panel: Proportion mature at age, Middle panel: Batch fecundity at age, Bottom panel: number of spawns per year by age.

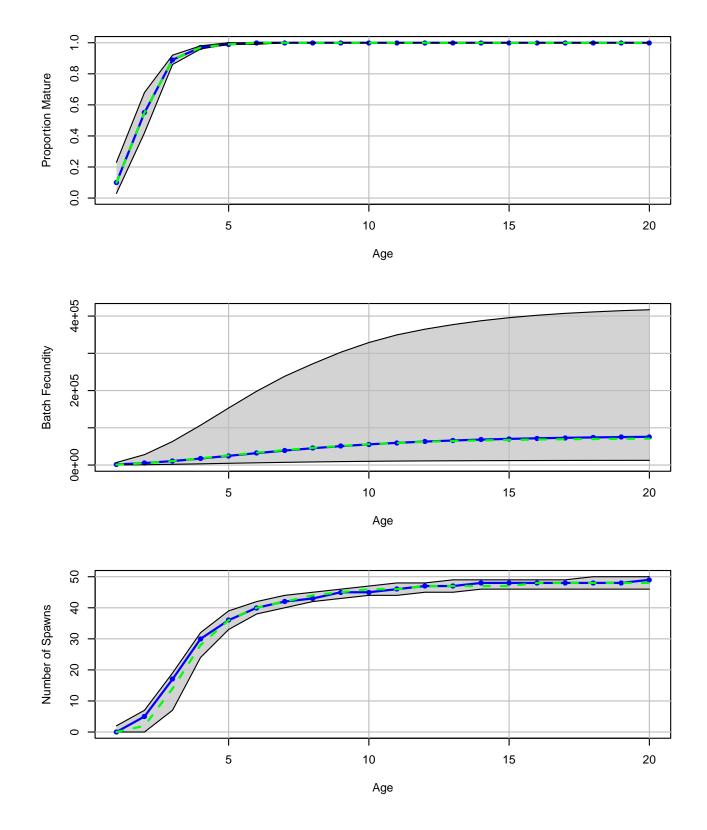

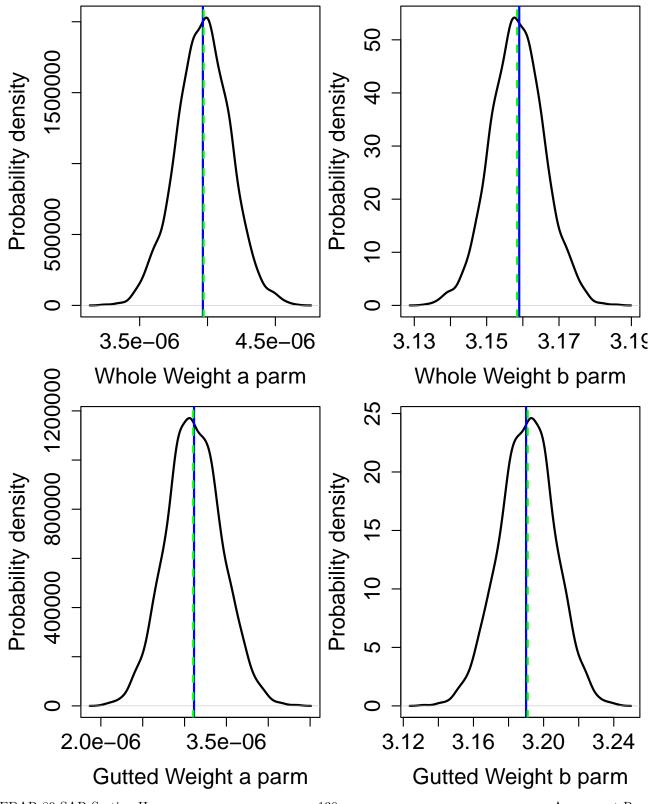

Figure 64. Density plots of fixed parameters in the MCBE models where the solid blue vertical lines are the value in the base BAM model, the green vertical lines are the median of the MCBE model runs (n = 3018). Top left panel: a parameter of total length to whole weight relationship, Top right panel: b parameter of total length to whole weight relationship, Bottom left panel: a parameter of total length to gutted weight relationship, Bottom right panel: b parameter of total length to gutted weight relationship.
