Table of Contents

Red snapper working group for ABC definition

Members: Rob Ahrens, Luiz Barbieri, Scott Crosson, Eric Johnson, Genny Nesslage, Amy Schueller (Chair), Katie Siegfried, Erik Williams

**Note: Can consult outside sources as needed

Task: To collate data, analyses, stock assessments, and any other background information on red snapper in order to determine an Acceptable Biological Catch (ABC). If necessary, work on additional analyses for providing an ABC or tracking an ABC.

ToRs:

1. Collate and evaluate existing information on red snapper
2. Determine if an ABC can be determined from existing information
3. If an ABC cannot be determined from existing information, provide a plan of action for moving forward to determine an ABC
    a. Plan of action should include evaluation of index based methods for tracking ABC, as well as consideration of the index based method can be used to determine an ABC
4. Assess to the extent possible newly developed methods providing strengths and weaknesses of each method
5. Provide a final ABC recommendation and also include any viable alternatives in priority order based on the science and data available

<u>Timeline (approximate):</u>
<u>Council review the ToRs at the November 6 meeting – see John's email</u>

2nd or 3rd week of November – scoping call

2nd week of December – All current information pulled together and vetted; brainstorm ABC determination ideas; brainstorm ideas for tracking the ABC; assign ideas to workgroup members

3-4th week of January – Vet all analyses and ideas assigned to the workgroup members; determine which are sufficient for providing an ABC; prioritize a list of best possible options for providing an ABC

2nd week of February – Continue work from January

2nd week of March – Finalize work from January and prepare materials for distribution to the SSC

April 1 – all materials provided to SSC for sufficient time for review

**Note that additional webinars can be scheduled as needed by the group.

Scope of Work

Analysis Type: Vetting and prioritization of potential methods for determining a Red Snapper Acceptable Biological Catch (ABC)

Justification: Terms of Reference (ToRs):

1. Collate and evaluate existing information on red snapper
2. Determine if an ABC can be determined from existing information
3. If an ABC cannot be determined from existing information, provide a plan of action for moving forward to determine an ABC
    a. Plan of action should include evaluation of index based methods for tracking ABC, as well as consideration of the index based method can be used to determine an ABC
4. Assess to the extent possible newly developed methods providing strengths and weaknesses of each method
5. Provide a final ABC recommendation and also include any viable alternatives in priority order based on the science and data available

Analyst: Work group members include: Rob Ahrens, Luiz Barbieri, Scott Crosson, Eric Johnson, Genny Nesslage, Amy Schueller (chair)

Support has also been provided by both Council staff and SEFSC staff.

Tasks and Timeline: Task: To collate data, analyses, stock assessments, and any other background information on red snapper in order to determine an Acceptable Biological Catch (ABC). If necessary, work on additional analyses for providing an ABC or tracking an ABC.

The work group is currently midway through the work toward achieving the stated terms of reference.

Council reviewed the ToRs – November 6, 2017

Scoping call where methods were reviewed and assignments were made to address each method – November 17, 2017

Second call where the first set of potential methods was reviewed and vetted – December 14, 2017

Third call where the second set of potential methods was reviewed and vetted; action items remaining from the December call were also addressed – January 31, 2018

Fourth call where the action items remaining from the January call will be addressed; will start to create a prioritized list of best possible options for providing an ABC – February 27, 2018

Final call or calls where a prioritized list of best possible options for providing an ABC will be finalized – March of 2018

All draft materials due to chair of working group – April 1, 2018

Final workgroup review – by April 13, 2018

Completion of workgroup report and delivery of report to the SSC – April 16, 2018

Final presentation and review by the SSC – May 1-3, 2018 meeting

Final Report to the Council – June 11-15, 2018

Agenda

Red Snapper ABC work group
Thursday, March 29, 2018
1:00 PM - 3:00 PM EST

1. Welcome and attendance

Genny Nesslage, Eric Johnson, Scott Crosson, Marcel Reichert, Mike Errigo, Erik Williams, Amy Schueller

2. Review of timeline and tasks; review the ToRs

Reviewed timeline and tasks

3. Review and prioritize methods; please review the introduction on the Google Drive - *ALL*
4. Documentation of process; writing due March 30 - *ALL*
5. Writing timeline

Summary of outstanding writing assignments:

1. *Write up summary of projections compared to Amendment 43 including landings versus discards (Katie and Eric)*
2. *Write up of discussion on index based methods (Amy and Genny)*
3. *Validity of indices at low population size (Genny)*
4. *Examples of interpreting data (e.g., catch increases, SSB decreases, but recruitment increases - can lead to an increasing index with high recruitment, but doesn't mean the SSB is increasing) (Genny)*
5. *Write up ACL monitoring information (Scott)*
6. *Add Table 2.1.2 to Amendment 43 summary (Eric)*
7. *Write up DLM discussion regarding applicability to red snapper (Luiz)*

Agenda

Red Snapper ABC work group
Tuesday, March 20, 2018
9:00 AM - 11:00 AM EST

1. Welcome and attendance

Scott Crosson, Mike Errigo, Marcel Reichert, Kyle Shertzer, Erik Williams, Amy Schueller, Rob Ahrens, Genny Nesslage, Eric Johnson (had microphone problems, so didn't contribute verbally)

2. Review of timeline and tasks; review the ToRs
3. Methods that were vetted with remaining action items:
    a. Center Interim Analysis based method (*Kyle and Erik*)
        i. ACTION: Present progress. Write up the methodology for the group's review. Run analysis.

The power point on this topic has been put onto the Google Drive. Kyle Shertzer presented on the Center Interim Analysis, and a discussion followed. The documentation includes a comparison with the status quo projections that were provided via SEDAR 41. The question of how 2017 age compositions compared to the 2017 projections came up, but this hasn't been looked at. This comparison would be useful for planning purposes. Discussed whether the index or the age compositions had a stronger influence on the outcomes, but it seems that both offer some information for recruitment estimation (see scenarios IA1 and IA2). This method isn't as quick as projection analyses, but is quicker than an update assessment; and similarly provides an intermediate level of information on the stock projection. Key assumptions for the stock assessment are maintained in this analysis in order to keep benchmarks the same. The discard ratios are the same as in the stock assessment; the group discussed that the ratios would change over time, but in order for the benchmarks to be consistent, this assumption is reasonable. This method addresses some of the original uncertainties in the stock assessment and projections, which we need to highlight. Additionally, the Interim Analysis is dependent upon the CVID index, so the group should work to highlight the pros and cons of the index. After much discussion, the group agreed that this method provides the best available science for determining an ABC and should be prioritized high.

4. Documentation of process; writing due March 30 - *All*
5. Review and prioritize methods - *ALL*

This will be the task for the second call that we hold in March (March 29 1-3 EST). A strawman prioritization will be put together before the meeting and will be found in the introductory documentation.

6. Assign and review tasks for next meeting
7. Schedule next meeting, if needed. Writing timeline.

Agenda

Red Snapper ABC work group
Tuesday, February 27, 2018
10:00 AM - 12:00 PM EST

1. Welcome and attendance

Amy Schueller, Mike Errigo, Marcel Reichert, Eric Johnson, Genny Nesslage, Scott Crosson, Rob Ahrens, Katie Siegfried, Erik Williams

2. Review of timeline and tasks; review the ToRs; view scope of work

Viewed scope of work document in main directory on the google drive. Note that at this point we have ~month left to finish our work to have time to collate a document and provide it to the SSC.

3. Methods that were vetted with remaining action items:
   a. Red snapper stock assessment and projections (*Katie*)
      i. ACTION: Provide updated projections with 2016 actual landings and discards with current projection methodology (what the Council requested previously plus 2016 data updated)

Documents were provided in the scoping materials folder on the google drive. Projections were run at Frebuild, which was F=0.14. The total ABC in numbers with landings (12,000) and discards (28,000) was 40,000 fish. This ABC option was similar in scale to some of the Amendment 43 ACLs listed in Table 2.1.2; however, these ACLs included landed individuals only and didn't include discards. Discards have been included in the ABC determination for red snapper in the past, as specified by the SSC. Even with no fishing season for red snapper, there are still background discards. There is no information available on how discards change when a season opens. ACTION: Write up summary of these analyses with a comparison to the ACL in Amendment 43. When writing, provide information on landings versus discards.

   b. Center Interim Analysis based method (*Erik and Katie*)
      i. ACTION: Present progress. Write up the methodology for the group's review. Run analysis.

Age comps not ready yet. Marcel will get these to Erik by Friday or early next week. The next call that this group has will be to specifically go over the Center Interim Analysis method. The written documentation will be put on the google drive in advance of the meeting in order to allow sufficient time to read the materials. An email will go out when the materials have been put on the drive.

c. Methods used at other Centers (*Amy and Genny*)

    i. ACTION: Review materials on drive and come to next meeting prepared to discuss whether any index/indices meet the necessary criteria - *ALL need to review*

Indices could be used in one of two ways to set an ABC: 1) if the scale is known, then the index could be related to population size directly or 2) in an ad hoc way where catch is set and then you watch whether the index is increasing, stable, or decreasing and then adjust catch accordingly. Each of these options is currently unavailable for red snapper. For the first option, to know the scale of the index, you would need an absolute index of abundance (for red snapper, we have relative indices of abundance) or you would need to know the catchability of the index (which can not be estimated outside of the stock assessment with the available data). For the second option, management would need to be in place long enough to account for the time lag in management and recruitment of fish to the fishery versus index in order to determine if the management had impacted the population dynamics such that the population size was increasing, stable, or decreasing. The overall consensus of the discussion was that none of the indices for red snapper had a long time series for use and that none of the indices had the auxiliary information available to make then useful in an index based method. The work group did want to note that the indices are useful on a relative scale and have been used for the red snapper stock assessment (and have been used for many other stock assessments in the South Atlantic). Additionally, the increase in the indices for red snapper at the end of the time series may not be actual increases and could be the result of observation error. The work group did recognize that the Headboat index could be useful for comparative evidence in that the ABC should not be set larger than the catch observed during the 1970s. Finally, the work group also wanted to ensure that the following topics were discussed in the report in order to address as many potential questions as possible - usefulness of the fishery-independent data in general *versus the usefulness for red snapper, validity of indices at low population size, fine scale shifts in spatial targeting and the inability to track them, the use of the chevron trap index from 1990 to the present (document why assessments haven't used this index during last two benchmark assessments), and examples of interpreting data (e.g., catch increases, SSB decreases, but recruitment increases - can lead to an increasing index with high recruitment, but doesn't mean the SSB is increasing).*

d. Monitoring of the ACL - current and future - report from SEP (*Scott*)

   i. ACTION: Additional questions to be addressed - What about discards? Any discussion on how to monitor discards without using MRIP? Phone app and logbooks - what data are being collected from this and how are those data intended to be used, has the SSC been consulted on data collection/utility? Any info on rare event workshop?

Scott provided documentation in the scoping materials folder on the google drive. The materials addressed how the ACL is currently tracked given the mini seasons, as well as the new app and what information is being collected. The rare event workshop was canceled. While this isn't part of the ToRs for the work group, we still felt that this information would be useful to the Council when deciding how to move forward with monitoring option for the ACL. Scott agreed to write this up into a section for the report.

4. Documentation of process; writing due February 26 - *All*

Several documents were placed in the folder labeled draft of sections on the google drive. Each of these documents is available for reading and editing by the entire work group. Eric placed a document on the drive summarizing Amendment 43. Eric agreed to add Table 2.1.2 to the document regarding Amendment 43, as well as include information on Amendment 46. Rob placed a document on the drive summarizing the DLMs. Luiz offered in an email to add to the document on DLM a discussion regarding the applicability of DLM to red snapper. Genny and Amy added two documents to the drive, one that is a summary of the available index data for red snapper and the other is documentation of the other methods used at other Science Centers to determine ABC. Finally, an introduction section was added to the drive, which will be the start of the main document resulting from this group's work.

5. Review and prioritize methods - *ALL*

This will be the task for the second call that we hold in March. A strawman prioritization will be put together before the meeting and will be found in the introductory documentation.

6. Assign and review tasks for next meeting

Tasks include:

1. *Write up summary of projections compared to Amendment 43 including landings versus discards (Katie and Eric)*
2. *Finish red snapper ages and provide to SEFSC (Marcel)*
3. *Run Center Interim Analysis and write up (Erik)*
4. *Write up of discussion on index based methods (Amy and Genny)*
5. *Write ups on the following topics to address potential questions from the SSC and Council:*
    a. *Process versus observation error (Rob)*

Interpreting changes in stock abundance from indices of abundance must consider the potential relative impact of both the expected variation in abundance (process error) and variation in sampling (observation error). Previous work has shown that understanding the ratio of process to observation error is a critical for appropriately filtering/smoothing time series data to extract changes in biomass (see Freeman and Kirkwood 1995, Walters and Hilborn 2005). Common approaches are to apply a Kalman filtering (Kalman 1960) and/or Rauch–Tung–Striebel smoothing (Rauch et al. 1965). While most index methods have associated standard error estimates, providing insight into observation error, understanding of process error is limited to the length of the index, as in many instances, process error is estimated as the difference between the apparent total variance in the index and the estimated observation error. In instances where short time series are used the estimation of the process error are poor.

Freeman, S.N., and Kirkwood, G.P. (1995). On a structural time series method for estimating stock biomass and recruitment from catch and effort data. Fish. Res. 22: 77–98.

R. E. Kalman. (1960). A New Approach to Linear Filtering and Prediction Problems. Transaction of the ASME—Journal of Basic Engineering, pp. 35-45

Rauch, H.E., Tung, F., and Striebel, C.T. 1965. Maximum likelihood estimates of linear dynamic systems. AIAA J. 3: 1445–1450.

Walters, C. J., & Hilborn, R. (2005). Exploratory assessment of historical recruitment patterns using relative abundance and catch data. Canadian Journal of Fisheries and Aquatic Sciences, 62: 1985-1990.

b. *Fine scale shifts in spatial targeting and the inability to track them (Rob)*

Changes in the spatial distribution of fisheries and/or research surveys has the potential to obscure changes in stock abundance when catch and effort information are not geospatially referenced at spatial scales at which the assumption of representative sampling can be made. The resulting catch per effort that is commonly used to generate relative abundance trends will tend to not be proportional to stock abundance (hyperstable or hyperdeplete). In general the issue of non-proportionality is greater with fishery dependent data that is documented at broad spatial scales.

c. *Usefulness of the fishery-independent data in general versus the usefulness for red snapper (Amy)*
d. *Use of the chevron trap index from 1990 to the present (last two benchmark assessments) (Amy)*
e. *Validity of indices at low population size (Genny)*
f. *Examples of interpreting data (e.g., catch increases, SSB decreases, but recruitment increases - can lead to an increasing index with high recruitment, but doesn't mean the SSB is increasing) (Genny)*

6. *Write up ACL monitoring information (Scott)*
7. *Add Table 2.1.2 to Amendment 43 summary (Eric)*
8. *Write up DLM discussion regarding applicability to red snapper (Luiz and Rob)*
9. *Create a strawman prioritization for discussion at the second March call (Amy)*
10. *Doodle poll for 2 meetings in March (Amy)*

7. Schedule next meeting

Amy will send 2 doodle polls out for meetings during the weeks of March 19th and 26th. The first meeting date will be to specifically discuss the Center Interim Methods, and the second meeting date will be to prioritize the available methods.

Agenda

Red Snapper ABC work group
Wednesday, January 31, 2018
1:00 - 3:00 PM EST

1. Welcome and attendance

    Mike Errigo, Amy Schueller, Genny Nesslage, Erik Williams, Eric Johnson, Luiz Barbieri, Scott Crosson, Rob Ahrens
2. Review of timeline and tasks
3. Discussion of data, analyses, stock assessments, and any other background information available for red snapper ABC determination and consideration of methods/analyses that could be completed in time
    a. Questions to consider:
        i. Has the method been vetted through the SAFMC SSC?
        ii. What are the pros and cons of each method?
        iii. Are the data for red snapper sufficient for the method?
    b. Methods (Need to finalize review from December):
        i. Amendments 43 and 46 (*Eric and Marcel*)

        Originally one Amendment. Amendment 43 provides an alternative methodology for determining an ACL - based on index increase at end of time series, assumed sustainable, harvest could be set at average harvest or a multiplier (1.88) of that average harvest or at highest level of catch during 2012-2014. Amendment 46 is in scoping.

        SSC did not comment on final Amendment 43.

        Comments on Index based method contained in Amendment 43:

        - *Not been through any peer review.*
        - *Age structure of indices and the age structure of the catch potentially do not match up. Might be a mismatch between increasing indices and what can be caught. Not considering time lags.*
        - *simple, rough estimate that does not consider important demographic factors*

- *Assumes a linear relationship between index and catch, which is unlikely to exist*
- *Assuming 2012-2014 was at a sustainable fishing level*
- *Suffer from some of the same problems the other index based methods suffer from*
- *A change of 1.88 can simple be measurement error. We don't have a good understanding of the relationship between the index and harvest. Concerns about the level of noise contained within the index itself.*
- *Concerns that if the index decreased that there is no accountability to decrease the catch in the current Amendment*
- *Overall, currently data are unavailable to determine if this method is sufficient to provide a sustainable ABC or ACL*
- *ACTION ITEM: summarize Amendment 43 and the methods contained within it, summarize our comments, and provide in the drafts folder on the drive*

ii. Data Limited Approaches (*Luiz and Rob*)

- *Started work on the document. DLM is not best available science and doesn't use best data. These types of methods do not work when you have a recovering stock. DLM method requires similar data to stock assessment, but would go down a Tier in control rule. ACTION: Write up methods, comments from workgroup, and provide in the drafts folder on the drive.*
- *Discussion of memos leading to this working group. Statement that the memos have been unclear. Need to make clear that projections can be provided. Need to include this as a discussion or maybe intro in final document (maybe as background). ACTION: (Amy) add this information to the background/intro for document to go to the SSC.*
- *Note that the PSEs are around ~25%, which is fairly low, given the species that the SE manages.*

iii. Summary of call on Rago's work on Rcrit (*Katie/Amy*)

Summary on drive for inclusion into draft document.

4. Methods that were vetted in December and associated action items:
    a. Red snapper stock assessment and projections (*Katie*)
        i. ACTION: Provide updated projections with 2016 actual landings and discards with current projection methodology (what the Council requested previously plus 2016 data updated)
    b. Center Interim Analysis based method (*Erik and Katie*)
        i. ACTION: *Erik* - Provide documentation from the West Coast and North Pacific regions on this method. *Erik and Katie* - Present progress.

        Talked with Methot, Ianelli, Lynch - West Coast and North Pacific do not do this method, rather they do update assessments. What we are presenting to do is unique. Data sets can be fairly quickly updated - index from MARMAP; ages from MARMAP; and removals. Allowing Rec devs to be estimated to provide a more accurate projection. Status - have code done, have updated removals and index values, waiting on ages (needs about another 10 days). Then, they can run the analysis and write it up. ACTION: Write up the methodology for the group's review. Run analysis.
    c. Methods used at other Centers (*Amy and Genny*)
        i. Need to make sure that OFL and ABC are linked.
        ii. ACTION: *Amy* - Does PIFSC do P* for rebuilding species?

    No, but they only have 1 species in rebuilding and it doesn't have a rebuilding plan...currently a moratorium on catch and part of its range is within a national monument.

        iii. ACTION: Assessment of the appropriateness of the indices available for red snapper; do any indices cross MSY or BMSY, have catch at MSY, or catch that is not impacting MSY; Provide a table - *Genny and Amy*.

    ACTION (ALL): Review materials on drive and come to next meeting prepared to discuss whether any index/indices meet the necessary criteria.
    d. Monitoring of the ACL - current and future (*Scott*)

i. ACTION: Additional questions to be addressed - What about discards? Any discussion on how to monitor discards without using MRIP? Phone app and logbooks - what data are being collected from this and how are those data intended to be used, has the SSC been consulted on data collection/utility? Any info on rare event workshop?

Started working on this. Socio-economic panel (SEP) will be discussing this next week. ACTION: Scott will report back from SEP meeting.

5. IPT development - Who is on Amendment 46 IPT? (*Mike*) - *Scott and Katie are on IPT*
6. Documentation of process - *All*
7. Assign and review tasks for next meeting
8. Schedule next meeting - *Amy send Doodle to schedule for Week of Feb 26*

Deadline for writing assignments - Feb 26

Agenda

Red Snapper ABC work group
Thursday, December 14, 2017
10:00 AM – 12:00 PM

1. Welcome and attendance

   Amy Schueller, Mike Errigo, Erik Williams, Katie Siegfried, Scott Crosson, Genny Nesslage

2. Discussion of data, analyses, stock assessments, and any other background information available for red snapper ABC determination and consideration of methods/analyses that could be completed in time
   a. Questions to consider:
      i. Has the method been vetted through the SAFMC SSC?
      ii. What are the pros and cons of each method?
      iii. Are the data for red snapper sufficient for the method?
   b. Methods:
      i. Red snapper stock assessment and projections (*Katie*)
         1. Reference documents are on the drive in the scoping materials folder.
         2. Yes, vetted through SSC. Pros and Cons available from SSC and reviewers. Largest concern was monitoring of ABC as projected. Assessment was deemed Best Available Science.
         3. On Drive - an overview of assessment results and projections was provided, as well as the updated, corrected assessment. Updated projections need to be requested.
         4. Discussion of MRIP numbers - new numbers will not be available until mid-2018 at the earliest, current MRIP numbers are uncertain but not biased, *setting ABC versus monitoring of the ABC [2 separate issues that we need to take care to separate]*, we have methods to handle uncertain discard data, MRIP data already included in assessment, which was deemed best available science

by reviewers and SSC, uncertainty in terminal year was investigated thoroughly,

5. ACTION: Request for updated projections with 2016 actual landings and discards with current projection methodology (what the Council requested previously plus 2016 data updated) - *Katie*

ii. Amendments 43 and 46 (*Eric and Marcel*) - not in attendance, will come back to this in January

iii. Center Interim Analysis based method (*Erik and Katie*)

1. No, this hasn't been vetted by SAFMC SSC. Data are almost available (waiting on ages, landings and discards are coming in tomorrow). Pros and Cons will be addressed when the method is up and running and we can see how it performs. Some questions include: how well can we update these parameters? Would like to do simulation analyses to test performance. SSC will be first to vet method. West Coast and North Pacific does these types of analyses already. Is documentation available in those regions? This is an ABC determination tool. Can do direct comparison with projections and any differences are expected to be due to index and age data.
2. ACTION: *Erik* - Look into documentation from the West Coast and North Pacific regions. *Katie and Erik* - Present progress at next meeting.
3. As an aside, this could serve as an intermediary assessment in the future; thus this could be useful for all of our stock in the SAtlantic.

iv. Methods used at other Centers (*Amy and Genny*)

1. NEFSC Index based method
2. Other methods?
   a. Reference documents are on the drive in the scoping materials folder in the Methods from other centers folder.

b. Need to take care to make sure that OFL and ABC are linked.
c. Does PIFSC do P* for rebuilding species?
d. ACTION: Need to assess appropriateness of the indices available for red snapper [index working group report from DW and some discussion in AW report]; do we have any indices that cross MSY or BMSY, is catch at MSY or not impacting MSY; a table would be useful - *Amy and Genny*. *Mike* - will find S41 DW working papers on topic.

v. Data Limited Approaches (*Luiz and Rob*) - not in attendance, will come back to this in January

vi. Monitoring of the ACL - current and future (*Scott*)
1. Reference ppt is on the drive in the scoping materials folder.
2. What about discards? Ask if there is any discussion on how to monitor discards without using MRIP? Phone app and logbooks - what data are being collected from this and how are those data intended to be used, has the SSC been consulted on data collection/utility; Any info on rare event workshop?

3. Can anyone attend a webinar Monday, December 18 at 1:30? *Katie*
4. Assign and review tasks for next meeting
5. Schedule next meeting - Doodle poll for Jan meeting (not Jan 17-19 national SSC); Amy will touch base with those not on the call.

NOTE: Need to work on documentation as we move through these discussions. *All*

Amendment 46 is on hold waiting for this group to present to SSC. Who is on the IPT from SEFSC? *Mike* - find out who is on IPT from SEFSC.

Agenda

Red Snapper ABC work group
Friday, November 17, 2017
10:00 AM – 12:00 PM

1. Welcome and attendance

Amy Schueller, Katie Siegfried, Erik Williams, Mike Errigo, Eric Johnson, Luiz Barbieri, Scott Crosson, Marcel Reichert, George Sedberry

2. Review of the tasks and timeline to occur between scoping call and April SSC meeting

3. Discussion of data, analyses, stock assessments, and any other background information available for collation for red snapper and consideration of methods/analyses that could be completed in time (based on timeline above) to determine an ABC for red snapper (including methods used by other Centers or Councils and index based methods)

- *Katie: Red snapper stock assessment (corrected base run is in the appended part of the document) - this includes all projections with the corrected run*
- *Marcel and Eric: Amendment 43 Index based method*
- *Marcel and Eric: Amendment 46 Index based method (determine if the same as Amendment 43)*
- *Erik and Katie: Center Interim Analysis based method - landings, discards, and index will be folded into projections*
- *Amy and Genny: NEFSC Index based method - needs investigation; Contact other Centers to see if they are using any similar methods*
- *Luiz and Rob: Data Limited Approaches (DLM)*
- *Scott: How ABC is currently monitored? How can the ABC be monitored in the future? - Contact Regional Office for current methods; brainstorm additional ideas for monitoring*

Which of these have been vetted through the SSC already?

Expectations: Collate all available information, come to December webinar ready to present the information and discuss options; pros and cons

   a. Assignments for compilation and collation of existing materials
   b. Assignments of new analyses to be completed

4. Review of tasks for next meeting
5. Schedule next meeting

Looking at the week of December 11. Amy will send a Doodle poll. If members are unable to attend, please hand off analysis, info to chair. Amy will contact Rob and Genny.

6. Outline agenda for the next meeting

Interim Analysis and Projections of Red Snapper in the US South Atlantic Region

Sustainable Fisheries Branch, Beaufort Laboratory, SEFSC

22 March 2018

Summary

In the U.S. South Atlantic region, stock assessments are typically several years out of date by the time regulations based on them are implemented. This occurs for numerous reasons, including the length of time to complete an assessment from data provision to SSC review, the length of time for managers to develop new regulations, and the time between assessments themselves (at least 5 years for many species). Consequently, ABC advice is based on uncertain projections several years into the future. These status quo projections include, when available, the latest information on removals (landings, discards), but must make assumptions about annual recruitment. For example, they commonly assume that future recruitment occurs at the long-term, average value.

In this document, we propose an Interim Analysis approach to provide updated ABCs between stock assessments. The application of Interim Analysis is consistent with national guidance from a soon-to-be-released NOAA report, Implementing a Next Generation Stock Assessment Enterprise[1] (eds. Lynch, Methot, and Link). The Interim Analysis approach described here is hybrid between the status quo projection methodology and an update assessment. In short, the approach advances the assessment model beyond the terminal year, fitting to the latest data on removals as well as other key data sources (e.g., index of abundance, age compositions) that might provide information on recent year-class strength. In this way, projections on which ABCs are based utilize more up-to-date information than does the status quo approach, without the need to re-do the full assessment. The approach holds potential for application to numerous stocks in the South Atlantic, increasing throughput of SEDAR in general. Here we focus on red snapper, which was last assessed through SEDAR-41 with a terminal year of 2014. The Interim Analysis updates recruitment estimates through 2016.

Methods

The Interim Analysis (IA) applies the latest assessment model and current projection model, but extends the assessment to include additional, more recent years. In this report, we

[1] A draft version is available from https://www.st.nmfs.noaa.gov/Assets/stock/documents/SAIPCompleteDraft_2-16-17_ExSumm.pdf

describe how the assessment is extended, but rely on previous documentation for more complete descriptions of the assessment and projection models (SEDAR-41 2017[2]).

In the SEDAR-41 red snapper assessment, the terminal year was T1=2014. The IA includes two more years of data, extending the terminal year to T2=2016. However, the IA differs from an Update assessment in two key ways:

- Unlike an Update assessment, not all data sources are updated through the new terminal year T2. Updated data sources include landings by fleet, discards by fleet, an index of abundance, and age compositions associated with that index.
- Unlike an Update assessment, the IA does not attempt to estimate all parameters of the assessment model. Instead, it fixes all parameters at their previously estimated values, with limited exception (described below). Thus, the Interim Analysis does not attempt to modify previous estimates of fishing mortality rate through year T1, selectivity ogives, the spawner-recruit relationship, or catchability applied to indices of abundance. Consequently, estimates of benchmarks remain unaltered from the previous assessment.

Most updated data sources include only the two additional years. The exception is the SERFS fishery independent index of abundance (CVID, combined chevron trap and video survey). Because the index is standardized, it was computed over its full time series (2010–T2) using identical methodology as in SEDAR-41 (2017), but with the two additional years. Specifically, the new data are the following:

- Landings in 2015 and 2016 for each fleet—commercial, headboat, general recreational (Table 1)
- Discards in 2015 and 2016 for each fleet—commercial, headboat, general recreational (Table 1)
- SERFS fishery independent index of abundance for 2010–2016. After standardization, the index was re-scaled such that values in the years 2010–T1 had the same mean as the SEDAR-41 index that spanned those same years. This way, the estimate of catchability from the assessment could be fixed, and the additional two years reflected population trends relative to the previous, SEDAR-41 index.
- Age compositions in 2015 and 2016 collected by SERFS chevron traps.

The intent of including an updated index of abundance and associated age compositions is to better inform recent year-class strength in the projections. Ideally, an index of recruitment would be available for this purpose. Such a focused index is not available for red snapper,

[2] SEDAR-41. 2017. SEDAR 41 – South Atlantic Red Snapper Assessment Report – Revision 1. SEDAR, North Charleston SC. 805 pp. available online at: http://sedarweb.org/sedar-41

however the SERFS did capture young red snapper (age 1+) and is therefore believed to contain information on recent, age-1 recruitment (in addition to older ages).

Only a limited number of parameters are estimated in the IA. These include parameters for each interim year describing fishing mortality associated with landings (3 fleets × 2 years = 6 parameters), fishing mortality associated with discards (3 fleets × 2 years = 6 parameters), and annual recruitment deviations (2 years = 2 parameters). Likelihood formulations for estimating these parameters were the same as for SEDAR-41. The additional years of data also have potential to inform year-class strength prior to the terminal year (T1=2014) of the assessment. We allow for this possibility by estimating an annual multiplier (m_y) on previously estimated recruitment deviations (r_y) in years immediately prior to T1, such that lognormal recruitment deviations in the IA equal $m_y \times r_y$. The MARMAP age compositions included ages 1–13+, and thus we estimated the multipliers starting in year T0=T2–13+1=2004, which is the year age-13 fish in year 2016 would have been age-1. The multipliers were estimated for years T0 through T1 (11 years = 11 parameters). A penalty term to constrain estimates of m_y was added to the total likelihood,

$$\Lambda^m = \sum_{y=T0}^{T1} (m_y - 1)^2$$

Thus, the likelihood was penalized for deviations away from 1, shrinking IA recruitment estimates toward the SEDAR-41 estimates unless informed by the new data.

Uncertainty

Uncertainty in the IA was quantified using MCB analysis. This was done by applying the IA to each MCB run from SEDAR-41. The primary reason for quantifying uncertainty in the IA was to carry that uncertainty forward into projections that may form the basis of ABC advice.

Effect of new data on interim recruitment estimates

To evaluate the effect of new data sources on estimating recruitment deviations and terminal-year (T2) age structure, we incrementally removed sources. For this evaluation, we label the analyses as follows:

- IA1: Interim analysis with all new data sets as described above
- IA2: Interim analysis without age composition data (index and removals only)
- IA3: Interim analysis without age composition or index data (removals only). In this analysis, the data cannot inform recent recruitment, and thus we turned off estimation of recruitment deviations through 2016, by fixing m_y=1 and by using expected, long-term values for 2015–2016 recruitment.

We consider model IA1, with all new data, to be the primary model and use it as the basis for subsequent projections. Model IA2 is a sensitivity analysis to investigate the importance of the new age composition data. Model IA3 is also a sensitivity analysis; it is analogous to the approach used in status quo projections.

Projections

To compute ABCs beyond the new terminal year T2, projections based on Model IA1 were run for 2017–2044. The projection methodology was identical to that from SEDAR-41. The primary difference is that the SEDAR-41 status quo projections started in 2015, and thus had to make assumptions about recruitment in 2015–2016. On the other hand, IA projections start in 2017 with an initial age structure that reflects recent recruitment as estimated from data.

In theory, IA could be performed without any lag between T2 and projections. However, in this application to red snapper, we have a one-year lag between T2=2016 and the earliest possible start of any new management implementation (2018). For the one year in between (2017), we assumed that landings were equal to the average level from 2012–2014, chosen because those years had red snapper season openings similar to 2017. Uncertainty in those landings was carried forward from the bootstrap of landings data performed as part of the SEDAR-41 MCB analysis.

We computed projections for two different levels of fishing mortality, $F=F_{30\%}$ (Scenario 1) and $F=F_{rebuild}$ (Scenario 2), starting in 2018. $F=F_{rebuild}$ was defined to be the fishing mortality rate that provides a 50% chance of rebuilding SSB to SSB_{MSY} by 2044.

Results

The primary model (IA1) fit reasonably well to the new age composition data (Figure 1A,B). It under-fit age-1 fish in 2015, but then fit that same cohort nearly perfectly in 2016. The information content from age composition data must be interpreted in the context of selectivity (Figure 1C).

Model IA1 predicted that the spawning stock continued to increase in 2015 and 2016, and that overfishing continued (Figure 2). These results appear to be robust, based on the MCB uncertainty analysis (Figure 2). The overfishing result comes almost entirely from discard mortalities, especially from the general recreational fleet (Table 1). Although the model estimates that spawning biomass remains below its threshold, it also estimates that total abundance of age-2+ fish is near its highest level since 1970 (Figure 2). The age structure remains truncated relative to that expected at $F_{30\%}$, but this result of relatively high abundance is consistent with reports from anglers and with observations from the SERFS.

Models IA1 and IA2 both captured the recent increasing trend in the SERFS index of abundance, however IA3 did not (Figure 3). Although AI3 was not fit to the index, the model can still generate predictions for comparison to the observed index.

The increasing trend in the index was explained by higher than expected recruitment in recent years (Figure 4A). Compared to IA3, which depicts the SEDAR-41 recruitment estimates through 2014 and the status quo assumption in 2015–2016, the primary model IA1 predicted considerably higher recruitment in 2014–2016, and slightly higher values in years prior. Model IA2 predicted similarly higher values, except for year 2016. That exception underscores the importance of including age composition data for estimating recruitment. However, even with age composition data (as in IA1), the terminal year recruitment estimates are typically very uncertain, especially when selectivity of age-1 fish is low.

Estimated recent recruitment values determine the initial abundance at age in projections (Figure 4B). Estimated initial abundances (in 2017) of ages 2–4 were nearly twice as high for IA1 than for the status quo approach of IA3. These higher values affect projections, including catch levels and the rate of rebuilding, particularly in the short term.

In Scenario 1 projections based on IA1, with fishing rate at the limit reference point of $F=F_{30\%}$, the stock is not projected to recover with a 50% probability by 2044 (Figure 5, Table 2). However, the short-term catch levels are substantially higher than those calculated with status quo projections[3], a consequence of the initial abundance at age. For the same reason, Scenario 2 projections, with $F=F_{rebuild}$, allows for higher short-term catch levels than status quo rebuilding projections (Figure 6, Table 3).

Discussion

On the spectrum of complexity, Interim Analysis falls in between an Update Assessment and a stock projection. IA is less complex than an Update Assessment, because it does not update all of the data sources, nor does it re-estimate all model parameters. IA is more complex than a stock projection because it attempts to estimate year-class strength, in addition to fishing mortality, in years between the terminal year of the assessment and implementation of new management. For some stocks, this gap can span five years or more. If a goal of SEDAR is to provide up-to-date catch advice with more throughput than is currently possible, adopting more frequent IA in place of full assessments could be an efficient approach.

Since the terminal year (2014) of SEDAR-41, the abundance of red snapper has continued to increase, as evidenced by the CVID index of abundance. The IA accounts for this trend by estimating high recruitment in recent years, and these estimates form the basis of the initial age structure projected forward from year 2017. In this way, projections stemming from

[3] Report: SEDAR 41 Red Snapper: Projection Supplement for SSC's ABC Working Group. Available upon request.

the IA are better informed by recent data than are those stemming from the SEDAR-41 Benchmark Assessment. We view this as an improvement, particularly for short-term forecasts. Nonetheless, the IA simply fills the gap of years since the last assessment. Forecasting future dynamics of fish stocks remains a highly uncertain endeavor, with all of the same caveats described in the SEDAR-41 AW report.

Table 1. Estimates of landings and discards for red snapper in the South Atlantic by fleet in 2015 and 2016.

	Commercial		Headboat		General recreational	
	Landings (lb)	Discards (fish)	Landings (fish)	Discards (fish)	Landings (fish)	Discards (fish)
2015	4,762	31,565	750	54,405	1,111	508,196
2016	4,151	34,568	331	66,511	72	788,460

Table 2. Projection results based on IA1 under Scenario 1, with fishing mortality rate fixed at $F = F_{30\%}$ starting in 2018. R = number of age-1 recruits (in 1000s), F = fishing mortality rate (per year), B = biomass (mt), S = spawning stock (1E8 eggs), L = landings expressed in numbers (1000s) or whole weight (1000 lb), and D = dead discards expressed in numbers (1000s) or whole weight (1000 lb), pr.rebuild = proportion of stochastic projection replicates with SSB greater than or equal to $SSB_{F30\%}$. The extension .base indicates expected values (deterministic) from the base run; the extension .med indicates median values from the stochastic projections.

Figure 1. Fits of Model IA1 to the interim years of SERFS age compositions (top two panels). Selectivity of the SERFS gear, as estimated by the SEDAR-41 assessment model (bottom panel).

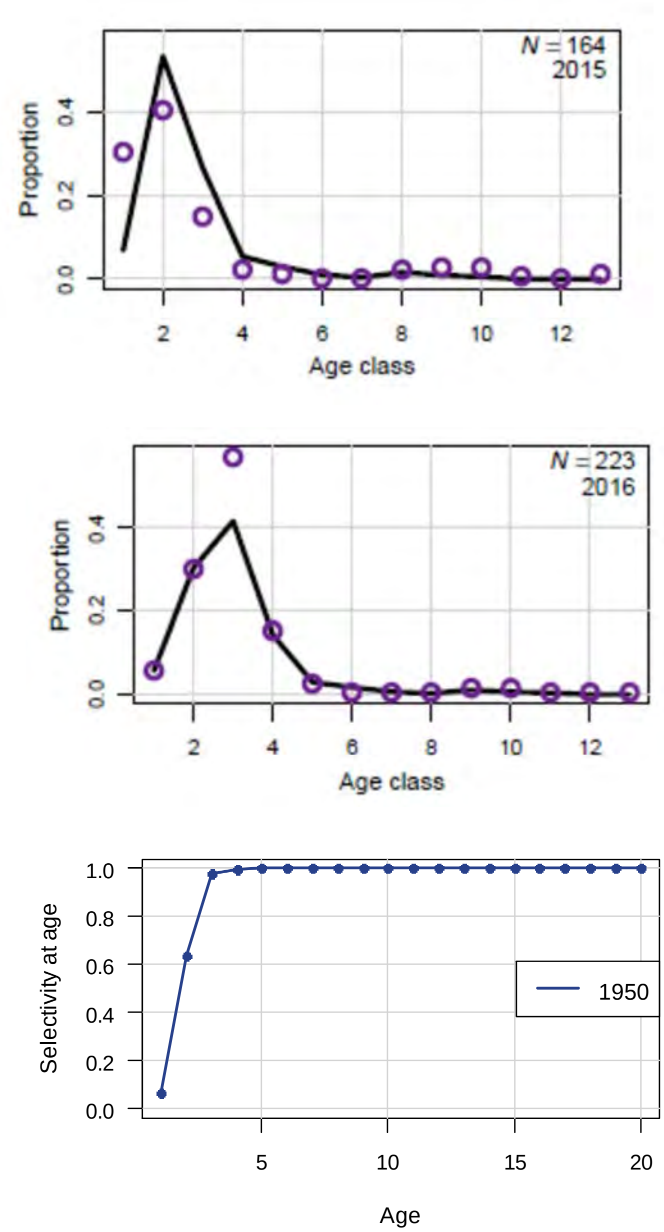

Figure 2. Results from model IA1: spawning biomass relative to that at $F_{30\%}$ (top panel), total abundance of age-2+ fish (middle panel), and F relative to $F_{30\%}$ (bottom panel). In each panel, the solid curve with filled circles represents base-run results, and the dashed line and gray bounds represent median and 95% intervals from the MCB analysis.

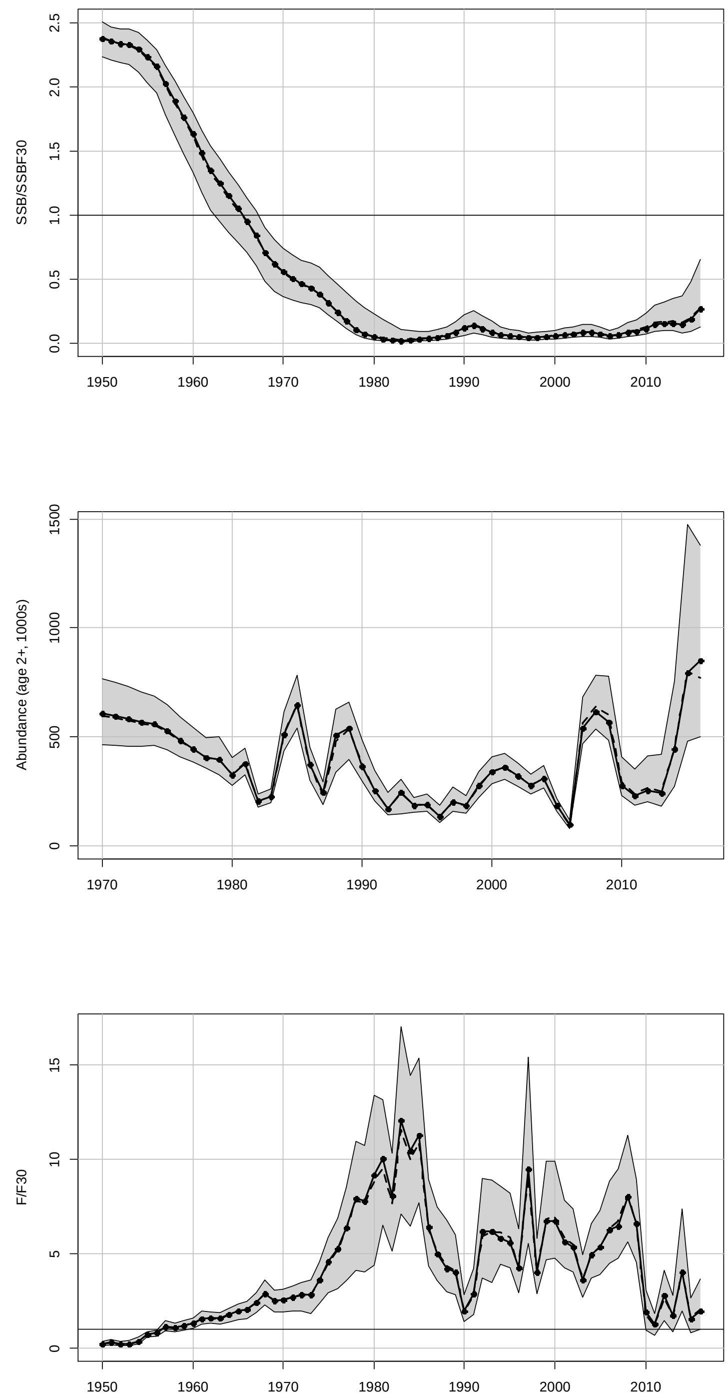

Figure 3. SERFS index of abundance fitted by Models IA1 (top) and IA2 (middle), and generated by Model IA3 (bottom). Model IA3 did not include the index in the objective function.

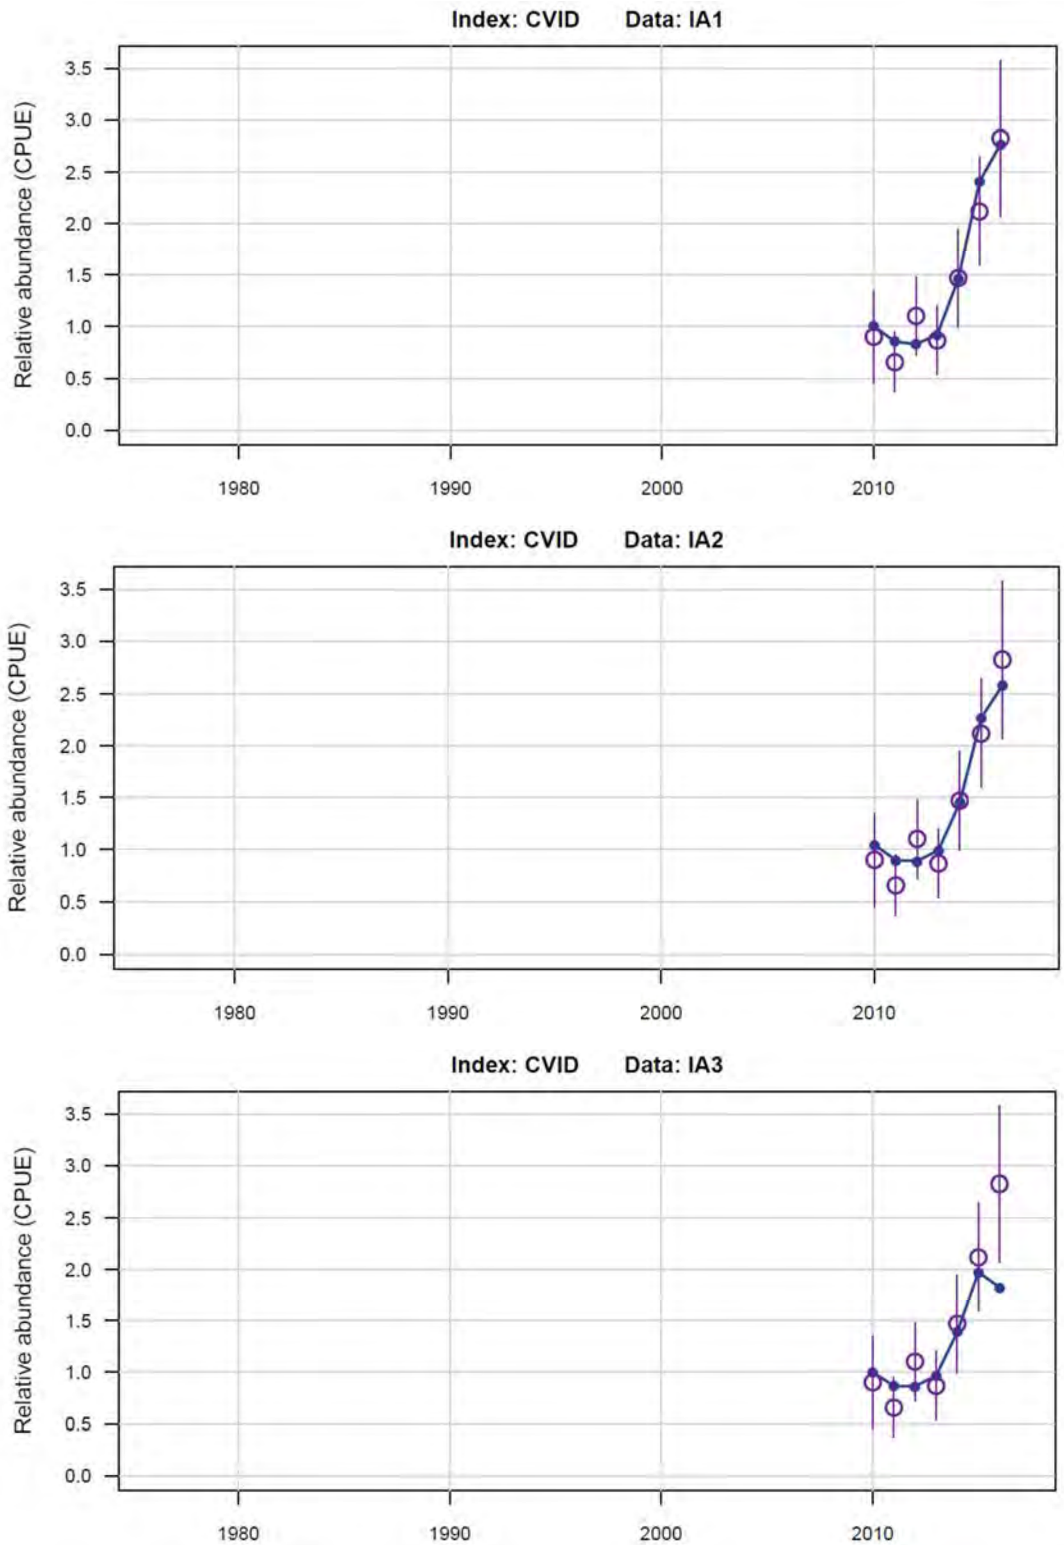

Figure 4. Predicted recruitment since the year 2000 from models IA1, IA2, and IA3 (top panel). Age structure (ages 2–10) in year 2017, as used to initialize population projections (bottom panel).

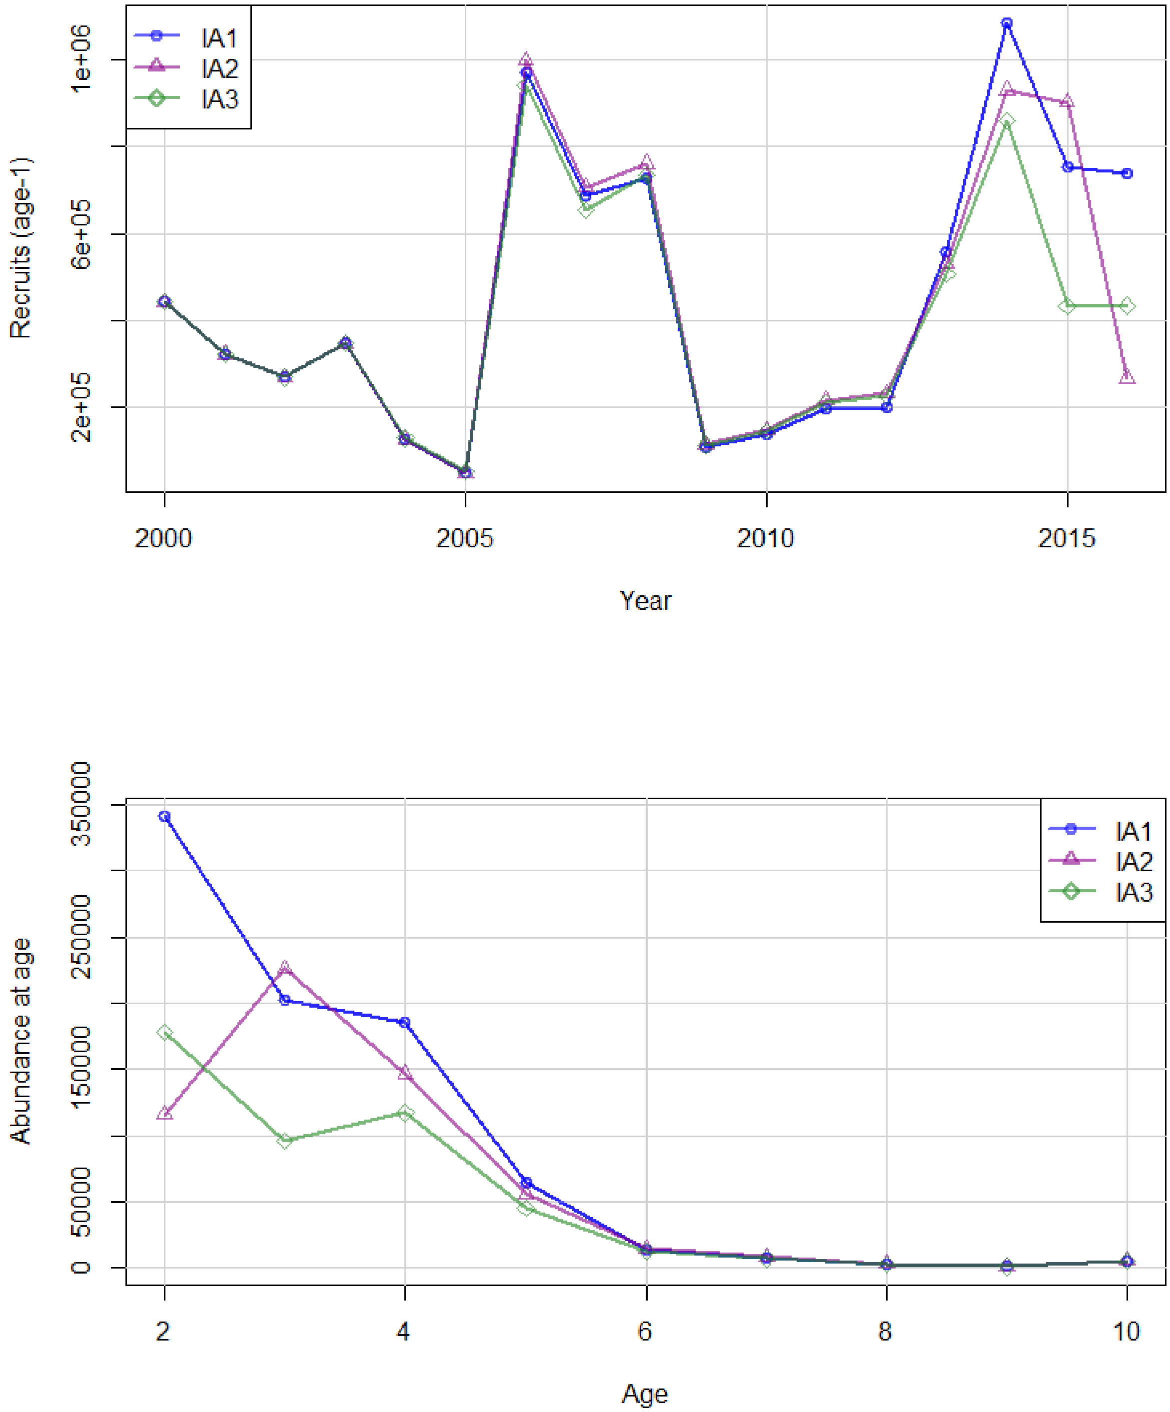

Figure 5. Projection results based on IA1 under Scenario 1, with fishing mortality rate at $F = F_{30\%}$ starting in 2018. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5th and 95th percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $SSB_{F30\%}$.

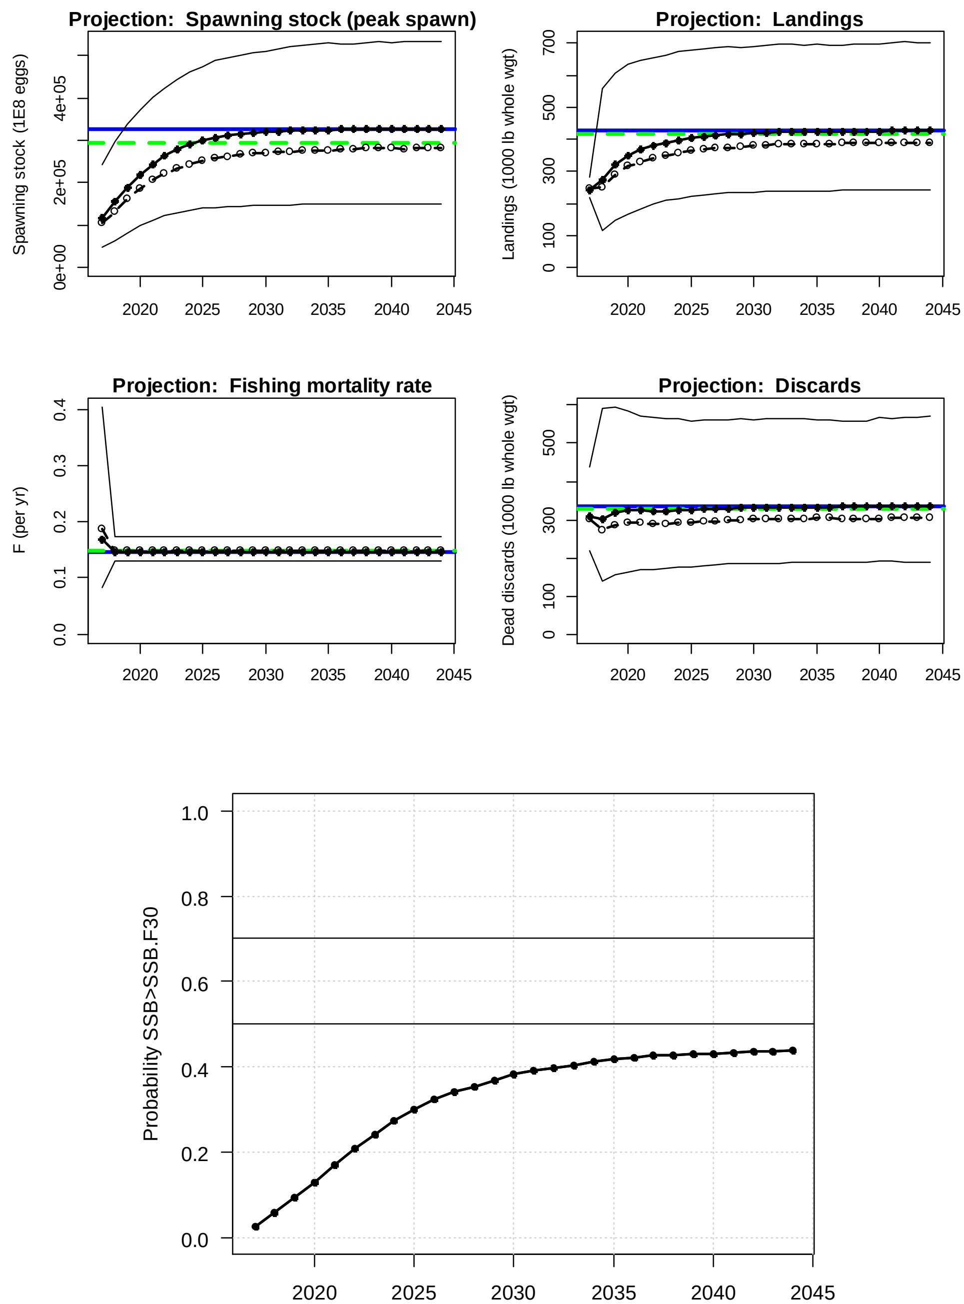

Figure 6. Projection results based on IA1 under Scenario 2, with fishing mortality rate at F = $F_{rebuild}$ starting in 2018. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5th and 95th percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $SSB_{F30\%}$.

SEDAR 41

South Atlantic Red Snapper

SECTION I: Introduction

April 2016

SEDAR
4055 Faber Place Drive, Suite 201
North Charleston, SC 29405

Executive Summary

SEDAR 41 addressed the stock assessments for South Atlantic gray triggerfish and red snapper. The assessments consisted of four in-person workshops, as well as a series of webinars. Two Data Workshops (DW) were held in Charleston, SC, the first August 4-8, 2014 and the second August 4-6, 2015. The SEDAR 41 Assessment Process was conducted through a combination of an in-person workshop, held December 14-17, 2015 in Morehead City, NC, and a series of webinars held from October 2015 to February 2016. The Review Workshop (RW) took place March 15-18, 2016 in North Charleston, SC.

The Stock Assessment Report is organized into six sections. Section I is the Introduction which contains a brief description of the SEDAR Process, Assessment, and Management Histories for the species of interest, and the management specifications requested by the Cooperator. Section II is the Data Workshop Report. It documents the discussions and data recommendations from the Data Workshop Panel. Section III is the Assessment Report. This section details the assessment model, as well as documents any changes to the data recommendations that may have occurred after the Data Workshop. Consolidated Research Recommendations from all three stages of the process (data, assessment, and review) can be found in Section IV for easy reference. Section V documents the discussions and findings of the Review Workshop. Finally, Section VI is the Addenda and Post-Review Workshop Documentation which consists of any analyses conducted during or after the RW to address reviewer concerns or requests. It may also contain documentation of the final RW-recommended base model, should it differ from the model put forward in the Assessment Report for review.

The final Stock Assessment Report (SAR) for South Atlantic Red Snapper was disseminated to the public in April 2016. The Council's Scientific and Statistical Committee (SSC) will review the SAR for its stock. The SSCs are tasked with recommending whether assessments represent Best Available Science, whether the results presented in the SARs are useful for providing management advice, and developing fishing level recommendations for the Council. An SSC may request additional analyses be conducted or may use the information provided in the SAR as the basis for their fishing level recommendations (e.g. Overfishing Limit and Acceptable Biological Catch). The South Atlantic Fishery Management Council's SSC will review the assessment at its May 2016 meeting, followed by the Council receiving that information at its June 2016 meeting. Documentation on SSC recommendations is not part of the SEDAR process and is handled through each Council.

During the March 2016 RW, the RW Panel evaluated outputs and results from the Beaufort Assessment Model (BAM), the primary assessment model that implements a statistical catch-at-age framework; and a secondary, surplus-production model (ASPIC) which provided a comparison of model results. The RW Panel accepted the new BAM base model with the corrected age compositions for the Southeast Reef Fish Survey (SERFS) combined chevron trap and video (CVID) survey index as the best available model to provide catch or management advice for the South Atlantic red snapper fishery. The RW Panel concluded that the data used in the assessment were generally sound and robust. Likewise, data generally were applied properly, and uncertainty in data inputs was appropriately acknowledged. Numerous sensitivity analyses and exploration of alternative scenarios of the BAM model were also presented during the RW, all of which agreed with the base model run conclusions of stock status. Based on these results, the Review Panel concluded that the stock is overfished and overfishing is occurring. Although the Review Panel concluded that assessment results represent the best available science, there were significant areas of uncertainty identified in both the data and in components to the model. The most significant sources of this uncertainty included: the composition and magnitude of recreational discards, the stock-recruitment relationship, potential changes in CPUE catchability, and the selectivities for the different fishery fleets. The Review Panel recognized that the perception of current selectivity used to derive reference points and projections is conditional on poorly-informed assumptions regarding recent fishing behavior. During the most recent years of the stock assessment series (i.e., the 2010-2014 moratorium), recreational discards were one of the most important and most uncertain sources of information. Also, a retrospective pattern in apical F indicated the base BAM model was very sensitive to the terminal year of data and suggests higher uncertainty in exploitation status.

During the assessment process several data and modeling topics received a lot of discussion. Some of these topics included:

- *Southeast Region Headboat Survey (SRHS) Data Evaluation*: After the 2014 DW, a working paper was submitted questioning the validity of data collected during the early years of the SRHS. The assessment was delayed in order to investigate these potential issues. Prior to the 2015 DW, the SEFSC did a comprehensive evaluation of the SRHS program that indicated no evidence of chronic, widespread misreporting, no evidence of an apparent temporal pattern in potentially misreported data, and minimal spatial patterns in potentially misreported data.
- *Marine Recreational Information Program (MRIP) Access Point Angler Intercept Survey (APAIS) adjustment:* Starting in wave 2 of 2013, the MRIP APAIS implemented a revised sampling design. To address this new survey design change, a Calibration Workshop was held in 2014. The final report recommended an additional calibration for catch estimates and recommended an interim ‘simple ratio’ method using 2013 data. SEDAR 41 was the first time this method was used in a South Atlantic SEDAR assessment.
- *Recreational Red Snapper Charter and Private Mini Season Landings and Discard Estimates*: In 2012 through emergency action and 2013 and 2014 through a process developed in Amendment 28 to the Snapper Grouper Fishery, the red snapper fishery was opened for a very short duration. MRIP was not designed to capture short pulses of fishing. State partners in the South Atlantic supplied data from studies conducted in each state during the mini-seasons as an attempt to supplement the MRIP data. The DW Panel

developed a set of rules in order to determine which dataset (MRIP vs. state partners) was more appropriate for landings and discards by state, mode, and wave.

- *Natural Mortality*: Both the DW and Assessment Workshop (AW) panels had lengthy discussions about natural mortality. The final recommendation was to use the Charnov et al. (2013) age-varying natural mortality curve scaled to the Then et al. (2015) point estimate for those ages fully recruited to the fishery. SEDAR 41 was the first time the Then et al. (2015) estimator has been used in a South Atlantic SEDAR assessment.
- *SERFS Chevron Trap Index Time Series:* The DW Panel recommended using the SERFS trap index from 2010-2014. Chevron trap survey data were available prior to 2010, and the Panel discussed potentially starting the trap index in 2005. However, due to the low incidence of red snapper catches prior to 2010, the Panel recommended using the trap index starting in 2010 and exploring the effect of the longer time series through a sensitivity run.
- *SERFS Chevron Trap and Video Indices – Independence and Selectivity:* The AW Panel recommended combining the trap and video indices into one index (CVID) since the data are collected from the same sampling platform (e.g. cameras are mounted on the traps). Age composition data were not available for the video index, so the selectivity for the combined CVID index was informed by age composition of red snapper caught in chevron traps.
- *Stock Recruitment Curve and Steepness:* Many initial attempts were made to estimate steepness resulting in a value near its upper bound. The AW Panel discussed whether to fix steepness or assume an average annual recruitment while estimating lognormal deviations around that average by setting steepness to 0.99. The AW Panel opted for the latter, acknowledging this would require using spawning potential ratio (SPR) benchmarks to determine stock status rather than MSY-benchmarks.
- *Start Year of Model*: The AW Panel had discussions regarding the start year of the assessment. They weighed the options of starting in 1950 vs. 1978. Only landings data were available for the historic time period (1950 – mid-1970's). No age or length composition data were available. The AW Panel recommended 1950 as the starting year and included a model run with the 1978 start year as a sensitivity run.
- *SERFS Revised Chevron Trap Age Compositions:* An error with the chevron trap survey age composition data was discovered during the RW. The age compositions used at the AW were based on the number of annuli and the corrected data were based on calendar-year age. Revised age compositions along with preliminary assessment results were presented at the RW and accepted for use in the base run of the model.
- *Selectivity for General Recreational Fleet from 2010-2014*: Selectivity of the general recreational fleet was assumed to be flat-topped for the 2010-2014 time block. The RW Panel could not agree on whether the flat-topped assumption was well justified and requested a sensitivity analysis where the selectivity for this time period mirrored the headboat dome-shaped selectivity.
- *Recreational Discard Estimates:* The RW Panel noted that during the most recent years of the assessment (2010-2014 moratorium period), recreational discards were one of the most important sources of information for the assessment. Recreational discards were

also noted as one of the most uncertain sources of information. Despite the uncertainty of recreational catch estimates, the BAM base configuration is conditional on catch estimates. The impact of the uncertainty in discards and landings on stock status was explored through the MCB uncertainty analysis and sensitivity runs.

- *Evaluating Trends of Fishing Mortality (F) Over Time:* The RW Panel noted that evaluating trends in F across time requires a metric that is comparable among years and reflects exploitation across a range of ages. In this assessment, apical F (maximum F at age) is based on a different range of ages among years because of changing fleet contributions and fleet selectivities. The RW Panel discussed other potential F metrics and noted deciding on a more appropriate metric of F was challenging due to the complexity of patterns in estimated F at age. The RW Panel noted the potential large uncertainty in the F estimates including the terminal year of the assessment (2014).

I. Introduction

1. SEDAR Process Description

SouthEast Data, Assessment, and Review (SEDAR) is a cooperative Fishery Management Council process initiated in 2002 to improve the quality and reliability of fishery stock assessments in the South Atlantic, Gulf of Mexico, and US Caribbean. The improved stock assessments from the SEDAR process provide higher quality information to address fishery management issues. SEDAR emphasizes constituent and stakeholder participation in assessment development, transparency in the assessment process, and a rigorous and independent scientific review of completed stock assessments.

SEDAR is managed by the Caribbean, Gulf of Mexico, and South Atlantic Regional Fishery Management Councils in coordination with NOAA Fisheries and the Atlantic and Gulf States Marine Fisheries Commissions. Oversight is provided by a Steering Committee composed of NOAA Fisheries representatives: Southeast Fisheries Science Center Director and the Southeast Regional Administrator; Regional Council representatives: Executive Directors and Chairs of the South Atlantic, Gulf of Mexico, and Caribbean Fishery Management Councils; a representative from the Highly Migratory Species Division of NOAA Fisheries; and Interstate Commission representatives: Executive Directors of the Atlantic States and Gulf States Marine Fisheries Commissions.

SEDAR is typically organized around three stages. First is the Data Stage, where a workshop is held during which fisheries, monitoring, and life history data are reviewed and compiled. Second is the Assessment Stage, which is conducted via a workshop and/or series of webinars, during which assessment models are developed and population parameters are estimated using the information provided from the Data Workshop. The final stage is the Review Workshop, during which independent experts review the input data, assessment methods, and assessment products. The completed assessment, including the reports of all 3 workshops and all supporting documentation, is then forwarded to the Council SSC for certification as 'appropriate for management' and development of specific management recommendations.

SEDAR workshops are public meetings organized by SEDAR staff and the lead Council. Workshop participants are drawn from state and federal agencies, non-government organizations, Council members, Council advisors, and the fishing industry with a goal of including a broad range of disciplines and perspectives. All participants are expected to contribute to the process by preparing working papers, contributing, providing assessment analyses, and completing the workshop report.

SEDAR Review Workshop Panels consist of a chair, three reviewers appointed by the Center for Independent Experts (CIE), and one or more SSC representatives appointed by each council having jurisdiction over the stocks assessed. The Review Workshop Chair is appointed by the council having jurisdiction over the stocks assessed and is a member of that council's SSC. Participating councils may appoint representatives of their SSC, Advisory, and other panels as observers.

2. Management Overview

2.1 Fishery Management Plan and Amendments

The following summary describes only those management actions that likely affect red snapper fisheries and harvest.

Original Snapper Grouper Fishery Management Plan

The Fishery Management Plan (FMP), Regulatory Impact Review, and Final Environmental Impact Statement for the Snapper Grouper Fishery of the South Atlantic Region, approved in 1983 and implemented in August of 1983, establishes a management regime for the fishery for snappers, groupers and related demersal species of the continental shelf of the southeastern United States in the exclusive economic zone (EEZ) under the area of authority of the South Atlantic Fishery Management Council (Council) and the territorial seas of the states, extending from the North Carolina/Virginia border through the Atlantic side of the Florida Keys to 83º W longitude. In the case of the sea basses and scup, the management regime applies only to south of Cape Hatteras, North Carolina. Regulations apply only to federal waters.

SAFMC FMP Amendments affecting red snapper

Description of Action	FMP/Amendment	Effective Date
4" Trawl mesh size and a 12" TL minimum size limit for red snapper.	Snapper Grouper FMP	8/31/1983
Prohibit trawls.	Amendment # 1	1/12/1989
Required permit to fish for, land or sell snapper grouper species.	Amendment # 3	1/31/1991
Prohibited gear: fish traps except bsb traps north of Cape Canaveral, FL; entanglement nets; longline gear inside 50 fathoms; bottom longlines to harvest wreckfish; powerheads and bangsticks in designated SMZs off S. Carolina. Established 20" TL minimum size for red snapper and a 10 snapper/person/day bag limit, excluding vermilion snapper, and allowing no more than 2 red snapper.	Amendment # 4	1/1/1992
Oculina Experimental Closed Area.	Amendment # 6	6/27/1994
Limited entry program; transferable permits and 225 lb non-transferable permits.	Amendment # 8	12/14/1998

Vessels with longline gear aboard may only possess snowy grouper, warsaw grouper, yellowedge grouper, misty grouper, golden tilefish, blueline tilefish, and sand tilefish.	Amendment # 9	2/24/1999
Approved definitions for overfished and overfishing. MSST = [(1-M) or 0.5 whichever is greater]* B_{MSY}. MFMT = F_{MSY}	Amendment # 11	12/2/1999
Extended for an indefinite period the regulation prohibiting fishing for and possessing snapper grouper species within the *Oculina* Experimental Closed Area.	Amendment # 13A	4/26/2004
Established eight deepwater Type II marine protected areas to protect a portion of the population and habitat of long-lived deepwater snapper grouper species. Also protected known spawning areas of many snapper grouper species including red snapper.	Amendment #14 (2007)	2/12/09
Prohibited harvest and possession of red snapper from January 4, 2010 to June 2, 2010. Was extended for 186 days.	Red Snapper Interim Rule	12/4/2009
Specified an ACL=0 for red snapper. Specified a rebuilding plan for red snapper. Specified status determination criteria for red snapper. Specified a monitoring program for red snapper. Required use of non-stainless steel circle hooks when fishing for snapper grouper species with hook-and-line gear north of 28 deg. N latitude in the South Atlantic EEZ. Implemented an area closure for South Atlantic snapper grouper extending from southern Georgia to northern Florida where harvest and possession of all snapper grouper species was prohibited (except when fishing with black sea bass pots or spearfishing gear for species other than red snapper).	Amendment # 17A	12/3/2010 red snapper closure; circle hooks 3/3/2011

Established red snapper seasons for the commercial and recreational sectors in South Atlantic federal waters in 2012. The commercial and recreational annual catch limits for 2012 were 20,818 pounds gutted weight and 9,399 fish, respectively. During the open season, the commercial trip limit was 50 pounds gutted weight, the recreational bag limit was 1 fish per person per day, and there was no minimum size limit for red snapper for either sector. The fishing seasons in 2012 for the commercial and recreational sectors were 14 and 6 days, respectively.	Red Snapper Emergency Rule	8/28/2012
Established regulations to allow limited harvest of red snapper on an annual basis. Also specified the commercial and recreational annual catch limits for red snapper in 2013. The commercial and recreational annual catch limits were 21,447 pounds gutted weight and 9,585 fish, respectively. During the open season, the commercial trip limit was 75 pounds gutted weight, the recreational bag limit was 1 fish per person per day, and there is no minimum size limit for red snapper for either sector. The fishing seasons in 2013 for the commercial and recreational sectors were 43 and 3 days, respectively. The fishing seasons in 2014 for the commercial and recreational sectors were 57 and 8 days, respectively.	Amendment # 28	8/23/2013

SAFMC Regulatory Amendments affecting red snapper

Description of Action	FMP/Amendment	Effective Date
Prohibited fishing in SMZs except with hand-held hook-and-line and spearfishing gear.	Regulatory Amendment # 1	3/27/1987
Established 2 artificial reefs off Ft. Pierce, FL as SMZs.	Regulatory Amendment # 2	3/30/1989
Established artificial reef at Key Biscayne, FL as SMZ.	Regulatory Amendment # 3	11/02/1990
Established 8 SMZs off S. Carolina, where only hand-held, hook-and-line gear and spearfishing (excluding powerheads) was allowed.	Regulatory Amendment # 5	7/31/1993
Established 10 SMZs at artificial reefs off South Carolina,	Regulatory Amendment # 7	1/29/1999
Established 12 SMZs at artificial	Regulatory Amendment # 8	11/15/2000

reefs off Georgia; revised boundaries of 7 existing SMZs off Georgia to meet CG permit specs; restricted fishing in new and revised SMZs.		
Eliminated closed area for snapper grouper species approved in Amendment 17A.	Regulatory Amendment # 10	5/31/2011
Change MSST for 8 snapper grouper species including red snapper from MSST = [(1-M) or 0.5 whichever is greater]*B_{MSY} to 0.75*B_{MSY}	Regulatory Amendment #21	11/6/2014

2.2 Emergency and Interim Rules (if any)

Emergency Rule effective 9/3/1999: Reopened the Amendment 8 permit application process.

Interim Rule effective 12/4/2009: Prohibited harvest and possession of red snapper from January 4, 2010 to June 2, 2010. Was extended for 186 days.

Emergency Rule effective 12/3/2010: Delay the effective date of the area closure for snapper grouper species implemented through Amendment 17A.

Emergency Rule effective 8/28/2012: Established red snapper seasons for the commercial and recreational sectors in South Atlantic federal waters. The commercial and recreational annual catch limits for 2012 were 20,818 pounds gutted weight and 9,399 fish, respectively. During the open season, the commercial trip limit was 50 pounds gutted weight, the recreational bag limit was 1 fish per person per day, and there was no minimum size limit for red snapper for either sector. The fishing seasons in 2012 for the commercial and recreational sectors were 14 and six days, respectively.

2.3 Secretarial Amendments (if any)

None

2.4 Control Date Notices (if any)

Notice of Control Date effective July 30, 1991: Anyone entering federal snapper grouper fishery (other than for wreckfish) in the EEZ off S. Atlantic states after 7/30/91 was not assured of future access if limited entry program developed.

Notice of Control Date effective October 14, 2005: The Council is considering management measures to further limit participation or effort in the commercial fishery for snapper grouper species (excluding Wreckfish).

Notice of Control Date effective March 8, 2007: The Council may consider measures to limit participation in the snapper grouper for-hire fishery.

Notice of Control Date effective January 31, 2011: Anyone entering federal snapper grouper fishery off South Atlantic states after 9/17/10 was not assured of future access if limited entry program is developed.

2.5 Management Program Specifications

Table 2.5.1. General Management Information

South Atlantic

Species	Red Snapper
Management Unit	Southeastern US
Management Unit Definition	All waters within South Atlantic Fishery Management Council Boundaries
Management Entity	South Atlantic Fishery Management Council
Management Contacts SERO / Council	SAFMC: Myra Brouwer/Gregg Waugh SERO: Jack McGovern/Rick DeVictor
Current stock exploitation status	Overfishing
Current stock biomass status	Overfished

Table 2.5.2 Management Parameters

See November 2010 SEFSC report (SEDAR41-RD09) **for updated values from SEDAR 24 based on headboat weight of 0.30.**

Criteria	South Atlantic – Current (SEDAR 24)	
	Definition	Value
MSST[1]	MSST = [(1-M) or 0.5 whichever is greater]*SSB_{MSY}	317,465 lbs ww
	Regulatory Amendment # 21 (effective 11/6/2014) changed definition to MSST = 75%*SSB_{MSY}	258,000 lbs ww
MFMT	$F_{30\%SPR}$ proxy for F_{MSY}	0.204

MSY	Yield at F_{MSY}		
F_{MSY}	F_{MAX}		
OY	Yield at F_{OY} (defined as 98%F30%SPR)		
R_{MSY}	Recruits as MSY		
F Target			
Yield at F_{TARGET} (equilibrium)	Landings and discards, pounds and numbers		
F_{OY}	F_{OY} = 65%,75%, 85% F_{MSY} F_{OY} = 98%$F_{30\%SPR}$		
M	M		
Terminal F	Exploitation		

Terminal Biomass[1]	Biomass		
Exploitation Status	F/MFMT		
Biomass Status[1]	SSB/MSST SSB/SSB_{MSY}		
Generation Time			
$T_{REBUILD}$ (if appropriate)			

1. Biomass values reported for management parameters and status determinations should be based on the biomass metric recommended through the assessment process and Council's Scientific and Statistical Committee (SSC). This may be total, spawning stock or some measure thereof, and should be applied consistently in this table.

2. SAFMC defined $F_{MSY}=F_{30\%SPR}$ (or stated $F_{OY}=98\%F_{30\%SPR}$). SEDAR 24 determined $F_{MSY}=0.178$. SEFSC projections were completed (see Table 1 in SEDAR41-RD09) and determined the following: $F_{30\%SPR}=0.204$, $F_{MSY}=0.206$. (Both of these values use a headboat weight of 0.30). The SAFMC determined that $F_{30\%SPR}$ is used as a proxy for F_{MSY}.

NOTE: "Proposed" columns are for indicating any definitions that may exist in FMPs or amendments that are currently under development and should therefore be evaluated in the current assessment. Please clarify whether landings parameters are 'landings' or 'catch' (Landings + Discard). If 'landings', please indicate how discards are addressed.

Table 2.5.3. Stock Rebuilding Information

Amendment 17A to the FMP specified a 35 year rebuilding schedule with the rebuilding time period ending in 2044. The rebuilding schedule is based on T_{MIN} + one generation Time; SEDAR 15 2008 was the source of the generation time.

Table 2.5.4. General Projection Specifications

South Atlantic

Requested Information	Value
First Year of Management	Assume management begins in 2018. However, if there are no changes to reference points and rebuilding plan, a projection with the revised ABC and OFL should be provided assuming that landings limits are changed in the 2017 fishing year.
Interim basis	ABC, if landings are within 10% of the ABC; average landings since 2012 (implementation of emergency rule and Amendment 28) otherwise.
Current Acceptable Biological (ABC) Value (1,000 fish (landings + dead discards))	2014: 106 2015: 114 2016: 121 2017: 128

	2018: 135 2019: 142
Projection Outputs	
Landings	Pounds and numbers
Discards	Pounds and numbers
Exploitation	F & Probability F>MFMT
Biomass (total or SSB, as appropriate)	B & Probability B>MSST (and Prob. B>B_{MSY} if under rebuilding plan)
Recruits	Number

Table 2.5.5. Base Run Projections Specifications. Long Term and Equilibrium conditions.

Red snapper is currently in a rebuilding plan, implemented in Snapper Grouper Amendment 17A. The rebuilding period is 35 years, ending in 2044. Rebuilding is based on fixed exploitation at F=98% of F30%SPR.

Criteria	Definition	If overfished	If rebuilt
Projection Span	Years	to 2044	10
Projection Values	$F_{CURRENT}$	X	X
	F_{MSY}	X	X
	75% F_{MSY}	X	X
	$F_{REBUILD = 98\%F30\%SPR}$	X	

NOTE: Exploitation rates for projections may be based upon point estimates from the base run (current process) or upon the median of such values from the MCBs evaluation of uncertainty. The critical point is that the projections be based on the same criteria as the management specifications.

Table 2.5.6. Short term projections (P* or exploitation based). Short term specifications for OFL and ABC recommendations. Additional P-star projections may be requested by the SSC once the ABC control rule is applied. Projections based on exploitation rates should provide probabilities of both overfishing and overfished conditions.

Basis	Value	Years to Project	P* applies to
P*	50%	Interim + 5	Probability of overfishing
Exploitation	98% of F30%SPR	Interim + 5	NA

Table 2.5.7. Quota Calculation Details

If the stock is managed by quota, please provide the following information.

Red snapper is managed by catch limits that are established annually, after the results of the prior fishing year are evaluated. Calculation of these catch limits is specified in Snapper Grouper Amendment 28, values are not required to be calculated in this assessment.

2.6 Management and Regulatory Timeline

The following tables provide a timeline of federal management actions by fishery.

Table 2.6.1. Annual Commercial Red Snapper Regulatory Summary (please fill out as appropriate)

Year	Fishing Year	Size Limit	Possession Limit	Open Date	Close Date	Other
1992	Calendar	20”	None	January 1		
1993	Calendar	20”	None	January 1		
1994	Calendar	20”	None	January 1		
1995	Calendar	20”	None	January 1		
1996	Calendar	20”	None	January 1		
1997	Calendar	20”	None	January 1		
1998	Calendar	20”	None	January 1		
1999	Calendar	20”	None	January 1		
2000	Calendar	20”	None	January 1		
2001	Calendar	20”	None	January 1		
2002	Calendar	20”	None	January 1		
2003	Calendar	20”	None	January 1		
2004	Calendar	20”	None	January 1		
2005	Calendar	20”	None	January 1		
2006	Calendar	20”	None	January 1		
2007	Calendar	20”	None	January 1		
2008	Calendar	20”	None	January 1		
2009	Calendar	20”	None	January 1		
2010	Calendar	20”	Zero	January 1	December 3	** see note below
2011	Calendar	No Harvest				
2012	Calendar	No min size limit	50 lb per trip	September 17	September 24	Reopened November 13-21 and December 12-19
2013	Calendar	No min size limit	75 lb per trip	August 26	October 8	
2014	Calendar	No min size limit	75 lb per trip	July 14	September 9	

**Red snapper interim rule prohibited harvest and possession of red snapper from January 4, 2010 to June 2, 2010 and was extended for 186 days. Existing size limits were not changed in the interim rule, but the prohibition of harvest trumped these regulations.

Table 2.6.2. Annual Recreational Red Snapper Regulatory Summary (Please fill out as appropriate)

Year	Fishing Year	Size Limit	Bag Limit	Open Date	Close Date	Other
1992	Calendar	20”	aggregate snapper bag limit – 10/person/day, excluding vermilion snapper and allowing no more than 2 red snappers	January 1		
1993	Calendar	20”	aggregate snapper bag limit – 10/person/day, excluding vermilion snapper and allowing no more than 2 red snappers	January 1		
1994	Calendar	20”	2	January 1

2004	Calendar	20”	2	January 1		
2005	Calendar	20”	2	January 1		
2006	Calendar	20”	2	January 1		
2007	Calendar	20”	2	January 1		
2008	Calendar	20”	2	January 1		
2009	Calendar	20”	2	January 1		
2010	Calendar	20”	2	January 1	December 3	** see note below
2011	Calendar	No harvest				
2012	Calendar	No min size limit	1	Sept 14-17, and Sept 21-24	Sept 17; Sept 24	Two 3-day weekends
2013	Calendar	No min size limit	1	August 23	August 26	One 3-day weekend
2014	Calendar	No Min size limit	1	Jul 11-14, Jul 18-21, Jul 25-27	Jul 14; Jul 21; Jul 27	Two 3-day weekends and 1 two-day weekend

**Red snapper interim rule prohibited harvest and possession of red snapper from January 4, 2010 to June 2, 2010 and was extended for 186 days. Existing size and bag limits were not changed in the interim rule, but the prohibition of harvest trumped these regulations.

2.6.3 Closures due to Meeting Commercial Quota or Commercial/Recreational ACL

Commercial: See Table 2.6.1

Recreational: See Table 2.6.2

Table 7. State Regulatory History

North Carolina:

There are currently no North Carolina state-specific regulations for red snapper. North Carolina has complemented federal regulations for all snapper grouper species via proclamation authority since 1991. Between 1992 and 2005, species-specific regulations were added to the proclamation authority contained in rule 15A NCAC 03M .0506. In 2002, North Carolina adopted its Inter-Jurisdictional Fishery Management Plan (IJ FMP), which incorporates all Atlantic States Marine Fisheries Commission and Council-managed species by reference, and adopts all federal regulations as minimum standards for management. In completing the 2008 update to the IJ FMP, all species-specific regulations were removed from rule 15A NCAC 03M .0506, and proclamation authority to implement changes in management was moved to rule 15A NCAC 03M .0512. Since this time, all snapper grouper regulations have been contained in a single proclamation, which is updated anytime an opening/closing of a particular species in the complex occurs, as well as any changes in allowable gear, required permits, etc. Beginning in 2015, commercial and recreational regulations are contained in separate proclamations. The most current snapper grouper proclamations (and all previous versions) can be found using this link: http://portal.ncdenr.org/web/mf/proclamations.

15A NCAC 03M .0506 SNAPPER-GROUPER COMPLEX

(a) In the Atlantic Ocean, it is unlawful for an individual fishing under a Recreational Commercial Gear License with seines, shrimp trawls, pots, trotlines or gill nets to take any species of the Snapper-Grouper complex.

(b) The species of the snapper-grouper complex listed in the South Atlantic Fishery Management Council Fishery Management Plan for the Snapper-Grouper Fishery of the South Atlantic Region are hereby incorporated by reference and copies are available via the Federal Register posted on the Internet at www.safmc.net and at the Division of Marine Fisheries, P.O. Box 769, Morehead City, North Carolina 28557 at no cost.

15A NCAC 03M .0512 COMPLIANCE WITH FISHERY MANAGEMENT PLANS
(a) In order to comply with management requirements incorporated in Federal Fishery Management Council Management Plans or Atlantic States Marine Fisheries Commission Management Plans or to implement state management measures, the Fisheries Director may, by proclamation, take any or all of the following actions for species listed in the Interjurisdictional Fisheries Management Plan:
(1) Specify size;
(2) Specify seasons;
(3) Specify areas;
(4) Specify quantity;
(5) Specify means and methods; and
(6) Require submission of statistical and biological data.
(b) Proclamations issued under this Rule shall be subject to approval, cancellation, or modification by the Marine Fisheries Commission at its next regularly scheduled meeting or an emergency meeting held pursuant to G.S. 113-221.1.
History Note: Authority G.S. 113-134; 113-182; 113-221; 113-221.1; 143B-289.4;
Eff. March 1, 1996;
Amended Eff. October 1, 2008.

South Carolina:
Sec. 50-5-2730 of the SC Code states:
"Unless otherwise provided by law, any regulations promulgated by the federal government under the Fishery Conservation and Management Act (PL94-265) or the Atlantic Tuna Conservation Act (PL 94-70) which establishes seasons, fishing periods, gear restrictions, sales restrictions, or bag, catch, size, or possession limits on fish are declared to be the law of this State and apply statewide including in state waters."

As such, South Carolina red snapper regulations are (and have been) pulled directly from the federal regulations as promulgated under the Magnuson-Stevens Fishery Conservation and Management Act. There are no know separate red snapper regulations that have been codified in the South Carolina Code.

Georgia:
Georgia state regulations for red snapper are currently:
- 2 fish per person daily creel limit
- 20 inch TL minimum size limit
- Season open year round

The law with these measures was originally enacted on July 1, 1989 with regulations following on September 13, 1989. The Official Code of Georgia Annotated (O.C.G.A.) and regulations sections have changed over time, but management measures have not. The current regulations are found in O.C.G.A 27-4-10 and DNR Rule 391-2-4-.04. Both documents are available upon request.

Florida:

Florida Atlantic Red Snapper Regulatory History

Year	Size Limit	Possession Limit	Other Regulation Changes
1985	12” TL		
1986	12” TL	10 per person per day aggregate snapper bag limit; off-the-water possession limit of 20 per person	Commercial longline gear prohibited; stab or sink nets prohibited off Monroe county; 5% of grouper in possession may be smaller than minimum size; all snappers must be landed in whole condition.

[1985]

SNAPPER, CH 46-14, F.A.C. (Effective July 29, 1985)

- Implements 12 inch minimum size limits for red snapper, mutton snapper, and yellowtail snapper

[1986]

REEF FISH, CH 46-14, F.A.C. (Effective December 11, 1986)

- Establishes snapper bag limit: 10 per person daily, with an off-the-water possession limit of 20 per person, for any combination of snapper, excluding lane, vermillion, and yelloweye

- Prohibits the use of long line gear in state waters for harvesting snapper, but allowed a 5% bycatch allowance under specific circumstances
- Prohibits use of stab nets (or sink nets) to take snapper in Atlantic waters of Monroe County
- Allows 5% of snapper in possession of harvester to be smaller than the minimum size limit
- Must be landed in whole condition (head and tail intact)

[1990]

REEF FISH, CH 46-14, F.A.C. (Effective February 1, 1990)

- Designates all **snapper** as "restricted species"
- Designates **red snapper** as protected species
- Establishes minimum size limits:
    - Red snapper - 13 inches
- Recreational bag limits: 10 daily per person for any combination of snapper, not including lane and vermillion (no more than 5 may be gray/mangrove snapper and no more than 2 may be red snapper)
- Off-the-water recreational possession limits: 20 per person for any combination of snapper, not including lane and vermillion (no more than 10 may be gray/mangrove snapper and no more than 4 may be red snapper)
- Establishes the following allowable gear: Hook and line, black sea bass trap, spear, gig, or lance (except powerheads, bangsticks, or explosive devices) for snapper
- Prohibits all commercial harvest of any species of snapper in state waters whenever harvest of that species is prohibited in adjacent federal waters
- Requires snapper to be landed in whole condition

[1992]

REEF FISH, CH 46-14, F.A.C. (Effective December 31, 1992)

- Requires the appropriate federal permit in order to exceed **snapper/grouper** bag limits and to purchase or sell snapper/grouper on the state's Gulf coast
- Establishes a minimum size limit of 20 inches for **red snapper** on the state's Atlantic coast

[1994]

REEF FISH, CH 46-14, F.A.C. (Effective March 1, 1994)

- Allows a two-day possession limit for reef fish statewide for persons aboard charter and headboats on trips exceeding 24 hours provided that the vessel is equipped with a permanent berth for each passenger aboard, and each passenger has a receipt verifying the trip length

[2003]

REEF FISH, CH 68B-14, F.A.C. (Effective January 1, 2003)

- Clarifies that imported reef fishes must comply with Florida's legal minimum size limits
- Deletes the rule designation of **red snapper** as protected species

[2007]

REEF FISH, CH 68B-14, F.A.C. (Effective July 1, 2007)

- Sets commercial trip limits in the Atlantic that are the same as trip limits in federal waters

[2010]

REEF FISH, CH 68B-14, F.A.C. (Effective January 19, 2010)

- Requires dehooking tools to be aboard commercial and recreational vessels for anglers to use as needed to remove hooks from Atlantic reef fish

None provided.

3. Assessment History and Review

In the early 1990s, a series of reports were prepared by the SAFMC Plan Development Team (in 1990) and by the NOAA-Beaufort Reef Fish Team (in 1991 and 1992), intended for prioritizing stocks for assessment. Those reports described "snapshot" analyses conducted on several snapper-grouper species, including red snapper. The analyses included the estimation of SPR (spawning potential ratio) based on a single year of data.

The first formal assessment of red snapper in the U.S. Atlantic was conducted by Manooch et al. (1998; abstract below). In that assessment, two age-structured models were used: an un-calibrated separable VPA and FADAPT. The results from FADAPT were downplayed because the model was calibrated to an abundance index derived from MARMAP chevron trap data, which had very low sample sizes. Manooch et al. (1998) concluded that "the status is less than desirable, but does appear to be responsive to recent management actions." They found that the fishing mortality rate (F) should be reduced by 33% to 68%, depending on the natural mortality rate and desired SPR. Prior to publication, a report of that assessment was submitted to the SAFMC. After publication, the results were revisited by Potts and Brennan (2001) in a trends report, also prepared for the SAFMC. Potts and Brennan (2001) repeated the findings of Manooch et al. (1998), but suggested a broader range of reduction in F, from 30% to 80%.

This stock of red snapper was first assessed through the SEDAR process in 2007 (SEDAR review held Jan. 28 – Feb. 1, 2008). That assessment applied a statistical catch-age model using data through 2006 (SEDAR 15, 2008). Because the spawner-recruit parameter of steepness was not estimable (hit its upper bound), the SEDAR review panel recommended using proxies for MSY-related benchmarks based on $SPR_{40\%}$. Relative to those benchmarks, the assessment found that since the 1960s, overfishing had been occurring and the stock had been overfished. In the terminal year, the assessment estimated $F_{2006}/F_{40\%}=7.7$ and $SSB_{2006}/SSB_{F40\%}=0.03$. Although quantitative results varied, these qualitative results of overfishing a depleted stock were consistent across all catch-age model configurations examined during and after the assessment process (~40 sensitivity runs), as well as with an alternative model formulation (surplus-production model). SEDAR24–AW–012.

SEDAR 24 (concluded October, 2010) was a benchmark assessment using the Beaufort Assessment Model (BAM) with data through 2009. BAM is a statistical catch-age model developed by the analysts at the Beaufort, NC NMFS laboratory, and is customizable to the data available. A surplus production model called ASPIC (Prager 1994, Prager 2004) was used as a complement for comparison purposes. Based on the assessment provided from the BAM, the Review Panel concluded that the stock was overfished with overfishing occurring. The SSB in the terminal year was estimate to be about 9% of MSST ($SSB_{2009}/MSST = 0.09$) and the fishing level at more than four times F_{MSY} ($F_{2007\text{-}2009}/F_{MSY} = 4.12$). Similar to SEDAR 15, more than 40 sensitivities were run, all of which resulted in the same status determinations.

Abstract from Manooch et al. (1998): Changes in the age structure and population size of red snapper, ***Lutjanus campechanus***, from North Carolina through the Florida Keys were examined using records of landings and size frequencies of fish from commercial, recreational, and headboat fisheries from 1986 to 1995. Population size in numbers at age was estimated for each year by applying separable virtual population analysis (SVPA) to the landings in numbers at age. SVPA was used to estimate annual, age- specific fishing mortality (***F***) for four levels of natural mortality (***M***=0.15, 0.20, 0.25, and 0.30). Although landings of red snapper for the three fisheries have declined, minimum fish size regulations have also resulted in an increase in the mean size of red snapper landed. Age at entry and age at full recruitment were age-1 for 1986-1991, compared with age-2 and age-6, respectively, for 1992-1995. Levels of mortality from fishing (***F***) ranged from 0.31 to 0.69 for the entire period. Spawning potential ratio (SPR) increased from 0.09 to 0.24 (***M***=0.25) from 1986 to 1995. The SPR level could be improved with a decrease in ***F***, or an increase in age at entry to the fisheries. The latter could be enhanced now if fishermen, particularly recreational fishermen, comply with minimum size regulations.

SEDAR 41

South Atlantic Red Snapper

SECTION II: Data Workshop Report

September 12, 2015

SEDAR
4055 Faber Place Drive, Suite 201
North Charleston, SC 29405

1. Introduction

1.1 Workshop Time and Place

The initial SEDAR 41 Data Workshop (DW) was held August 4 – 8, 2014 in Charleston, South Carolina. A data scoping call was held May 28, 2014 and webinars were held July 2, 2014, August 15, 2014 September 11, 2014, and September 26, 2014.

A working paper submitted after the DW questioned the validity of data collected during the early years of the Southeast Region Headboat Survey (SRHS). The Data Workshop Panel discussed this issue on a post-DW webinar and recommended stopping the SEDAR 41 assessments for both species to investigate the headboat issues and delaying both assessments until the issues are resolved. The SAFMC and SEDAR Steering Committee were briefed on this recommendation in fall 2014. A new schedule was approved in December 2014 delaying the assessment approximately one year and the terminal year of the assessment was changed to 2014.

The second abbreviated DW was held August 4-6, 2015 in Charleston, SC. This workshop built on the work done at the 2014 DW, revisiting decisions only if new information or analyses were available. Otherwise datasets were updated with 2014 data using decisions from the 2014 DW. Two data webinars were held before the workshop on April 15 and July 1, 2015 and a post-DW webinar was held August 20, 2015.

Between the 2014 and 2015 DW's, the Southeast Fisheries Science Center conducted a headboat data evaluation and submitted a working paper (SEDAR41-DW46) for review at the 2015 DW.

1.2 Terms of Reference

1. Review stock structure and unit stock definitions and consider whether changes are required.
2. Review, discuss, and tabulate available life history information.
    - Evaluate age, growth, natural mortality, and reproductive characteristics.
    - Provide appropriate models to describe growth, maturation, and fecundity by age, sex, or length as applicable.
    - Evaluate the adequacy of available life-history information for conducting stock assessments and recommend life history information for use in population modeling.
    - Evaluate, discuss, and characterize the sources of uncertainty, and data limitations (such as temporal and spatial coverage) for each data source. Provide ranges and/or distributions of uncertainty for data sources used in the stock assessment models[1].

3. Compare and contrast life history traits between the Gulf of Mexico and South Atlantic stocks.
4. Recommend discard mortality rates.
   - Review available research and published literature.
   - Consider research directed at these species as well as similar species from the SE and other areas.
   - Provide estimates of discard mortality rate by fishery, gear type, depth, and other feasible or appropriate strata.
   - Include thorough rationale for recommended discard mortality rates.
   - Provide justification for any recommendations that deviate from the range of discard mortality provided in the last benchmark or other prior assessment.
   - Evaluate, discuss, and characterize the sources of uncertainty, and data limitations (such as temporal and spatial coverage) for each data source. Provide ranges and/or distributions of uncertainty for data sources used in the stock assessment models[1].
5. Provide measures of population abundance that are appropriate for stock assessment.
   - Consider and discuss all available and relevant fishery dependent and independent data sources.
   - Document all programs evaluated; address program objectives, methods, coverage, sampling intensity, and other relevant characteristics.
   - Provide maps of fishery and survey coverage.
   - Develop fishery and survey CPUE indices by appropriate strata (e.g., age, size, area, and fishery) and include measures of precision and accuracy.
   - Discuss the degree to which available indices adequately represent fishery and population conditions.
   - Recommend which data sources adequately and reliably represent population abundance for use in assessment modeling.
   - Evaluate, discuss, and characterize the sources of uncertainty, and data limitations (such as temporal and spatial coverage) for each data source. Provide ranges and/or distributions of uncertainty for data sources used in the stock assessment models[1].
   - Complete the SEDAR index evaluation worksheet for each index considered.
   - Rank the available indices with regard to their reliability and adequacy for use in assessment modeling.
6. Provide commercial catch statistics, including both landings and discards in both pounds and number.

- Evaluate and discuss the adequacy of available data for accurately characterizing harvest and discard by species and fishery sector or gear.
- Evaluate, discuss, and characterize the sources of uncertainty, and data limitations (such as temporal and spatial coverage) for each data source. Provide ranges and/or distributions of uncertainty for data sources used in the stock assessment models[1].
- Provide length and age distributions for both landings and discards if feasible.
- Provide maps of fishery effort and harvest by species and fishery sector or gear.

7. Provide recreational catch statistics, including both landings and discards in both pounds and number.
   - Evaluate and discuss the adequacy of available data for accurately characterizing harvest and discard by species and fishery sector or gear.
   - Evaluate, discuss, and characterize the sources of uncertainty, and data limitations (such as temporal and spatial coverage) for each data source. Provide ranges and/or distributions of uncertainty for data sources used in the stock assessment models[1].
   - Provide length and age distributions for both landings and discards if feasible.
   - Provide maps of fishery effort and harvest by species and fishery sector or gear.
8. Provide recommendations for future research in areas such as sampling, fishery monitoring, and stock assessment. Include specific guidance on sampling intensity (number of samples including age and length structures) and appropriate strata and coverage.
9. Prepare the Data Workshop report providing complete documentation of workshop actions and decisions in accordance with project schedule deadlines (Section II. of the SEDAR assessment report).

[1.] In providing ranges for uncertain or incomplete information, data workshop groups should consider and distinguish between those ranges and bounds that represent probable values (i.e., likely alternative states) to be included in structured uncertainty analyses, and those that represent extreme values to be considered in evaluating model performance through sensitivity analyses.

1.3 List of Participants

2014 Data Workshop Panelists

Nate Bacheler, SEFSC/NMFS
Neil Baertlein, SEFSC/NMFS
Joey Ballenger, SCDNR
Peter Barile, SFA
Ken Brennan, SEFSC/NMFS
Russel Brodie, FL FWCC
Mark Brown, SC For-hire
Steve Brown, FL FWCC*
Amanda Kelly, SCDNR
Kathy Knowlton, GADNR*
Kevin Kolmos, SCDNR*
Susan Lowerre-Barbieri, FL FWCC
Adam Lytton, SCDNR
Vivian Matter, SEFSC/NMFS
Kevin McCarthy, SEFSC/NMFS
Stephanie McInerny, NCDMF

Wally Bubley, SCDNR
Julie Califf, GADNR*
Roz Camp, NCDMF
Rob Cheshire, SEFSC/NMFS
Michael Cooper, SEFSC/NMFS
Kevin Craig, SEFSC/NMFS
Tanya Darden, SCDNR
Sonny Davis, NC For-hire
Julie DeFilippi, ACCSP
Amy Dukes, SCDNR
Michelle Falk, SCDNR
Kenny Fex, NC Commercial
Eric Fitzpatrick, SEFSC/NMFS
Kelly Fitzpatrick, SEFSC/NMFS*
Dawn Franco, GADNR
Cameron Guenther, FL FWCC
Eric Hiltz, SCDNR
Rusty Hudson, FL For-hire/Commercial
Robert Johnson, FL For-hire
Todd Kellison, SEFSC/NMFS
Barbara Muhling, RSMAS*
David Nelson, FL For-Hire/Commercial
Refik Ohrun, SEFSC/NMFS*
Jack Perrett, GA Recreational*
Jennifer Potts, SEFSC/NMFS
Kevin Purcell, SEFSC/NMFS
Marcel Reichert, SCDNR/SAFMC SSC
Mitch Roffer, ROFFS*
Beverly Sauls, FL FWCC
Christina Schobernd, SEFSC/NMFS
George Sedberry, SAFMC SSC
Bill Shearin, GA Recreational
Kyle Shertzer, SEFSC/NMFS
Katie Siegfried, SEFSC/NMFS
Tracey Smart, SCDNR
Ted Switzer, FL FWCC
Byron White, SCDNR
Erik Williams, SEFSC/NMFS
Chris Wilson, NCDMF*
David Wyanski, SCDNR

* Appointees marked with an * were appointed to the workshop panel but did not attend the workshop. They provided data and reviewed the use of the data, and were available via email or phone for questions as needed.

2015 Data Workshop Panelists

Nate Bacheler, SEFSC/NMFS
Joey Ballenger, SCDNR
Nick Ballew, SEFSC
Neil Baertlein, SEFSC/NMFS*
Peter Barile, SFA
Ken Brennan, SEFSC/NMFS
Russel Brodie, FL FWCC
Steve Brown, FL FWCC*
Wally Bubley, SCDNR
Julie Califf, GADNR
Rob Cheshire, SEFSC/NMFS
Kevin Craig, SEFSC/NMFS
Julie DeFilippi, ACCSP
Amy Dukes, SCDNR
Kathy Knowlton, GADNR*
Kevin Kolmos, SCDNR*
Susan Lowerre-Barbieri, FL FWCC*
Vivian Matter, SEFSC/NMFS
Kevin McCarthy, SEFSC/NMFS
Stephanie McInerny, NCDMF*
David Nelson, FL For-Hire/Commercial
Refik Ohrun, SEFSC/NMFS*
Jennifer Potts, SEFSC/NMFS
Marcel Reichert, SCDNR/SAFMC SSC
Mitch Roffer, ROFFS*
Beverly Sauls, FL FWCC
Christina Schobernd, SEFSC/NMFS
George Sedberry, SAFMC SSC

Kenny Fex, NC Commercial
Eric Fitzpatrick, SEFSC/NMFS
Kelly Fitzpatrick, SEFSC/NMFS*
Dawn Franco, GADNR
Eric Hiltz, SCDNR
Rusty Hudson, FL For-hire/Commercial
Robert Johnson, FL For-hire
Nikolai Klibansky, SEFSC/NMFS
Bill Shearin, GA Recreational
Kyle Shertzer, SEFSC/NMFS
Katie Siegfried, SEFSC/NMFS
Tracey Smart, SCDNR
Ted Switzer, FL FWCC*
Erik Williams, SEFSC/NMFS
Chris Wilson, NCDMF
David Wyanski, SCDNR

* Appointees marked with an * were appointed to the workshop panel but did not attend the workshop. They provided data and reviewed the use of the data, and were available via email or phone for questions as needed.

2014 Council Representatives
Zack Bowen, SAFMC
Jack Cox, SAFMC
Chris Conklin, SAFMC

2015 Council Representatives
Zack Bowen, SAFMC
Mark Brown, SAFMC
Chris Conklin, SAFMC

2014 Council and Agency Staff
Julia Byrd, SEDAR Coordinator
John Carmichael, SEDAR/SAFMC Staff
Chip Collier, SAFMC Staff
Mike Errigo, SAFMC Staff *
Nick Farmer, SERO*
Patrick Gilles, NMFS/SEFSC
Nikolai Klibanski, NMFS/SEFSC*
Julie O'Dell/Andrea Grabman, SAFMC Staff
Tom Sminkey, NMFS*
Andy Strelcheck, SERO*

2015 Council and Agency Staff
Julia Byrd, SEDAR Coordinator
John Carmichael, SEDAR/SAFMC Staff
Chip Collier, SAFMC Staff
Mike Errigo, SAFMC Staff
Nick Farmer, SERO*
Mike Larkin, SERO
Julie O'Dell, SAFMC Staff
Tom Sminkey, NMFS*

*Participated in webinars but did not attend the data workshop.

2014 Data Workshop Observers
Liese Carlton, VIMS
Dawn Glasgow, SCDNR
Jimmy Hull, SG AP/SFA
Jessica Lewis, SEFSC/NMFS
Carl Miller, SEFSC/NMFS
Paul Nelson, SFA

2014 Webinar Observers
Barrett Colby, FL
Charles Driggers, MI
Frank Helies, GSAFF
Jimmy Hull, SG AP/SFA
Daniel Parshley, GA

Kevin Spanik, SCDNR
C. Michelle Willis, SCDNR

2015 Data Workshop Observers
Myra Brouwer, SAFMC Staff
Brian Cheuvront, SAFMC Staff
Lora Clarke, PEW
Jimmy Hull, SG AP/SFA
Wally Jenkins, SCDNR
Kari Maclauchlin, SAFMC Staff
Joe Myers, ACCSP
Paul Nelson, FL
Amber VonHarten, SAFMC Staff
Gregg Waugh, SAFMC Staff
David Westfall, SC

2015 Webinar Observers
Mel Bell, SAFMC / SCDNR
Lora Clarke, PEW
Alisha Gray, FL FWCC
Frank Helies, GSAFF
Jimmy Hull, SG AP/ SFA
Victor Lloyd, FL
Jean-Jacques Maguire, SCeMFis
Chris McDonough, SCDNR
Ken Stump, Ocean Foundation
Byron White, SCDNR
Michelle Willis, SCDNR

1.4 List of Data Workshop Working Papers

South Atlantic red snapper and gray triggerfish data workshop document list. Working papers that were updated from the 2014 DW or were new for the 2015 DW are labeled as such.

Document #	Title	Authors
	Documents Prepared for the Data Workshop (DW)	
SEDAR41-DW01	**UPDATED:** Georgia Headboat Red Snapper Catch and Effort Data, 1983-2013	Amick and Knowlton 2014
SEDAR41-DW02	**UPDATED:** Georgia Red Snapper Catch & Effort Collection during Mini-Seasons, 2012-2014	Knowlton 2015
SEDAR41-DW03	Standardized video counts of Southeast U.S. Atlantic gray triggerfish (*Balistes capriscus*) from the Southeast Reef Fish Survey ****See SEDAR41-DW44 for index updated through 2014**	Purcell et al. 2014
SEDAR41-DW04	Standardized video counts of Southeast U.S. Atlantic red snapper (*Lutjanus campechanus*) from the Southeast Reef Fish Survey ****See SEDAR41-DW45 for index updated through 2014**	Purcell et al. 2014
SEDAR41-DW05	Gray Triggerfish Fishery-Independent Indices of Abundance in US South Atlantic Waters Based on a Chevron Trap Survey	Ballenger et al. 2014

	****See SEDAR41-DW52 for index recommended from 2015 DW**	
SEDAR41-DW06	Red Snapper Fishery-Independent Indices of Abundance in US South Atlantic Waters Based on a Chevron Trap Survey ****See SEDAR41-DW53 and SEDAR41-DW54 for index recommendations from 2015 DW**	Ballenger et al. 2014
SEDAR41-DW07	Age Truncation and Reproductive Resilience of Red Snapper (*Lutjanus campechanus*) Along the East Coast of Florida **(has since been published – see SEDAR41-RD57)**	Lowerre-Barbieri et al. 2014
SEDAR41-DW08	The utility of a hooked gear survey in developing a fisheries-independent index of abundance for red snapper along Florida's Atlantic coast	Guenther et al. 2014
SEDAR41-DW09	Size and age composition of red snapper, *Lutjanus campechanus*, collected in association with fishery-independent and fishery-dependent projects off of Florida's Atlantic coast during 2012 and 2013	Switzer et al. 2014
SEDAR41-DW10	Overview of Florida's Cooperative East Coast Red Snapper Tagging Program, 2011-2013	Brodie et al. 2014
SEDAR41-DW11	Habitat models for Gray Triggerfish collected in fishery-independent trap surveys off the southeastern United States	Muhling et al. 2014
SEDAR41-DW12	**UPDATED:** Preliminary standardized catch rates of Southeast US Atlantic red snapper (*Lutjanus campechanus*) from headboat logbook data	SFB-NMFS 2015
SEDAR41-DW13	**UPDATED:** Preliminary standardized catch rates of Southeast US Atlantic gray triggerfish (*Balistes capriscus*) from headboat logbook data	SFB-NMFS 2015
SEDAR41-DW14	**UPDATED:** Standardized catch rates of red snapper (*Lutjanus campechanus*) from headboat at-sea-observer data	SFB-NMFS 2015
SEDAR41-DW15	Standardized catch rates of gray triggerfish (*Balistes capriscus*) from headboat at-sea-observer data	SFB-NMFS 2014
SEDAR41-DW16	**UPDATED:** Report on Life History of South Atlantic Gray Triggerfish, *Balistes capriscus*, from Fishery-Independent Sources	Kolmos et al. 2015
SEDAR41-DW17	**UPDATED:** Estimates of Historic Recreational	Brennan 2015

	Landings of Red Snapper in the South Atlantic Using the FHWAR Census Method	
SEDAR41-DW18	**UPDATED**: South Carolina Red Snapper Catch and Biological Data Collection during Mini-Seasons, 2012-2014	Dukes & Hiltz 2015
SEDAR41-DW19	**UPDATED**: Standardized catch rates of red snapper (*Lutjanus campechanus*) in the southeast U.S. from commercial logbook data	SFB-NMFS 2015
SEDAR41-DW20	**UPDATED**: Standardized catch rates of gray triggerfish (*Balistes capriscus*) in the southeast U.S. from commercial logbook data	SFB-NMFS 2015
SEDAR41-DW21	North Carolina Division of Marine Fisheries Red Snapper Carcass Collections, 2012-2013	NCDMF 2014
SEDAR41-DW22	SEDAR 41 Red snapper stock assessment must utilize “direct” estimates of gear selectivity	Barile and Nelson 2014
SEDAR41-DW23	Atlantic Red Snapper (*Lutjanus campechanus*) Fishing History Timeline	Hudson 2014
SEDAR41-DW24	Atlantic Red Snapper (*Lutjanus campechanus*) Historical Fishing Pictures	Hudson 2014
SEDAR41-DW25	Historical For-Hire Fishing Vessels: South Atlantic Fishery Management Council, 1930’s to 1985	Hudson 2014
SEDAR41-DW26	SEDAR 41 Atlantic Red Snapper and Gray Triggerfish Data Workshop Historical Photographs of For-Hire Vessels 1930’s to 1985	Hudson 2014
SEDAR41-DW27	Red snapper mini season ad-hoc working group report	Red Snapper Mini Season Ad-hoc Group 2014
SEDAR41-DW28	Red Snapper *Lutjanus campechanus* in Gulf of Mexico versus southeast US Atlantic Ocean waters: gaps in knowledge and implications for management	Rindone et al. 2014
SEDAR41-DW29	Discards of red snapper (*Lutjanus campechanus*) for the headboat fishery in the US South Atlantic ****See SEDAR41-AW01 for updated HB discards WP**	FEB-NMFS 2014
SEDAR41-DW30	Discards of gray triggerfish (*Balistes capriscus*) for the headboat fishery in the US South Atlantic ****See SEDAR41-AW02 for updated HB discards WP**	FEB-NMFS 2014

SEDAR41-DW31	Red Snapper Preliminary Genetic Analysis Temporal Genetic Diversity Trends in the South Atlantic Bight	O'Donnell and Darden 2014
SEDAR41-DW32	SCDNR Charterboat Logbook Program Data, 1993-2013	Hiltz 2014
SEDAR41-DW33	**UPDATED:** Size Distribution, Release Condition, and Estimated Discard Mortality of Red Snapper Observed in For-Hire Recreational Fisheries in the South Atlantic	Sauls et al. 2015
SEDAR41-DW34	**UPDATED:** Size Distribution, Release Condition, and Estimated Discard Mortality of Gray Triggerfish Observed in For-Hire Recreational Fisheries in the South Atlantic	Sauls et al. 2015
SEDAR41-DW35	**UPDATED:** Marine Resources Monitoring, Assessment and Prediction Program: Report on Atlantic Red Snapper, *Lutjanus campechanus*, Life History for the SEDAR 41 Data Workshop	White et al. 2014 Wyanski et al. 2015
SEDAR41-DW36	**UPDATED:** Discards of Red Snapper Calculated for Commercial Vessels with Federal Fishing Permits in the US South Atlantic	McCarthy 2015
SEDAR41-DW37	**UPDATED:** Calculated Discards of Gray Triggerfish from US South Atlantic Commercial Fishing Vessels	McCarthy 2015
SEDAR41-DW38	Historic catch of red snapper by headboats through historic photograph analysis	Gray et al. 2014
SEDAR41-DW39	Index report cards	Index Working Group 2014
SEDAR41-DW40	Problems with Headboat Index of Abundance Confounds Use in SEDAR 41 Red Snapper	Nelson et al. 2014
SEDAR41-DW41	Commercial Fishing Targeting Changes	Fex 2014
SEDAR41-DW42	**NEW:** South Atlantic Red Snapper (*Lutjanus campechanus*) monitoring in Florida: Revised recreational private boat mode estimates for 2012 and 2013 mini-seasons, and new private boat mode estimates for the 2014 mini-season	Sauls 2015
SEDAR41-DW43	**NEW:** Hook Selectivity in gray triggerfish observed in the for-hire fishery off the Atlantic coast of Florida	Gray and Sauls 2015
SEDAR41-DW44	**NEW:** Standardized video counts of Southeast U.S. Atlantic gray triggerfish (*Balistes capriscus*)	Ballew et al. 2015

	from the Southeast Reef Fish Survey	
SEDAR41-DW45	**NEW:** Standardized video counts of Southeast U.S. Atlantic red snapper (*Lutjanus campechanus*) from the Southeast Reef Fish Survey	Ballew et al. 2015
SEDAR41-DW46	**NEW:** Headboat Data Evaluation	NMFS-SEFSC 2015
SEDAR41-DW47	**NEW:** Development of an ageing error matrix for U.S. gray triggerfish *(Balistes capriscus)*	SFB-NMFS 2015
SEDAR41-DW48	**NEW:** Development of an ageing error matrix for U.S. red snapper *(Lutjanus campechanus)*	SFB-NMFS 2015
SEDAR41-DW49	**NEW:** Estimates of reproductive activity in red snapper by size, season, and time of day with nonlinear models	Klibansky 2015
SEDAR41-DW50	**NEW:** Hook Selectivity in red snapper observed in the for-hire fishery off the Atlantic coast of Florida	Gray and Sauls 2015
SEDAR41-DW51	**NEW:** SERFS Chevron Trap Red Snapper Index of Abundance: An Investigation of the Utility of Historical (1990-2009) Chevron Trap Catch Data	Ballenger 2015
SEDAR41-DW52	**NEW:** Gray Triggerfish Fishery-Independent Index of Abundance in US South Atlantic Waters Based on a Chevron Trap Survey (1990-2014)	Ballenger and Smart 2015
SEDAR41-DW53	**NEW:** Red Snapper Fishery-Independent Index of Abundance in US South Atlantic Waters Based on a Chevron Trap Survey (2005-2014)	Ballenger and Smart 2015
SEDAR41-DW54	**NEW:** Red Snapper Fishery-Independent Index of Abundance in US South Atlantic Waters Based on a Chevron Trap Survey (2010-2014)	Ballenger and Smart 2015

2. Life History

2.1 Overview (Group Membership, Leader, Issues)

The life history working group (LHWG) was tasked with reviewing the new data and analysis available (mostly as a result of adding the 2014 data) since the 2014 DW, and combining data from the South East Fisheries Science Center Beaufort Laboratory (SEFSC, NOAA/NMFS-Beaufort), South Carolina Department of Natural Resources (SCDNR), North Carolina Division of Marine Fisheries (NCDMF), Florida Wildlife Research Institute (FWRI), and Georgia Department of Natural Resources (GA-DNR). This combined data set could then be used for analysis of life history parameters for Red Snapper. Note that the collaborative fishery independent snapper grouper monitoring conducted by the Marine Resources Monitoring, Assessment, and Prediction Program (MARMAP), the South East Area Monitoring and Assessment Program-South Atlantic (SEAMAP-SA) (both housed at SC-DNR's Marine Resources Research Institute), and the South East Fishery Independent Survey (SEFIS) (NMFS project housed at SEFSC, Beaufort, NC) are now collectively referred to as the South East Reef Fish Survey (SERFS). Data from all SERFS components were combined for analyses. The SEFSC data predominantly came from various fishery dependent sources. Discussions involved age, growth, reproduction, stock structure, natural mortality, movements, and discard mortality of Atlantic Red Snapper and comparison with Gulf of Mexico (GoM) Red Snapper.
The LHG was tasked with reviewing the data age from the different labs, develop models that describe growth and reproduction most appropriately, determine the biological unit stock based on literature, develop estimates of natural mortality and select a preferred estimate, describe the migration and movements of Red Snapper, and develop a model or point estimate of discard mortality. Additionally the LHWG provided a comparison between estimates/methods proposed for use in SEDAR 41 with estimates/methods used in SEDAR 31for Gulf of Mexico Red Snapper. Note that the development of estimates for discard mortality was discussed by an ad hoc working group formed prior to the 2014 DW.

Life History Work Group (LHWG) Membership for the Data Workshop in August 2014
Panel members
Marcel Reichert - SCDNR/SA-SSC (LH Working Group Leader)
Jennifer Potts - NMFS (Red Snapper Subgroup Leader)
Walter Bubley - SCDNR
Michael Cooper - NMFS
Tanya Darden - SCDNR
Shelly Falk - SCDNR
Cameron Guenther - FWRI
Susan Lowerre - Barbieri - FWRI
Adam Lytton - SCDNR
Todd Kellison - NMFS

Amanda Kelly - SCDNR
Kevin Kolmos - SCDNR*
George Sedberry - NOAA/SSC
Byron White - SCDNR
David Wyanski - SCDNR (Gray Triggerfish Subgroup Leader)
Chip Collier - SAFMC (Bycatch Mortality Subgroup Leader)
Kevin Craig – SEFSC Assessment staff
David Nelson – DW Panel member

* Denotes that Panel Member was not present at the Data Workshop, but participated in data collection, analyses, pre- and post-DW calls and webinars, and report preparation.

Observers
Jessica Lewis - NMFS
Kevin Spanik – SCDNR
Michelle Willis - SCDNR

Note that the Observers played a very active role in assisting with the data compilation and analysis, and their help was much appreciated by the panel members.

LHWG Membership for the Data Workshop in August 2015
Panel members
Marcel Reichert - SCDNR/SA-SSC (LH Working Group Leader)
David Wyanski - SCDNR

2.2 Review of Working Papers

SEDAR41-DW02
Georgia Red Snapper Catch & Effort Collection during Mini-Seasons, 2012-2014. Knowlton 2015.

Synopsis
The reviewed paper discusses the methods and results from opportunistic sampling of Red Snapper for biological data and trip survey information via telephone calls and other electronic means during the so-called "mini-seasons" in 2012, 2013 and 2014 in Georgia by GA DNR. Biological sampling included GA DNR staff working dockside as well as donated carcasses deposited into freezers at various locations throughout coastal Georgia . The scope of data collection expanded each year. Initially, dockside sampling targeted one headboat and five charter boats trips, and 24 carcasses were left primarily by private recreational fishers. In 2013, sampling was expanded to intercept commercial fishing trips, for a total of 2 headboat trips, 2 charter boat trips and 6 commercial trips. A total of 42 carcasses were donated, of which 14 came from private recreational fishers. By 2014, GA DNR staff intercepted 6 headboat trips, 10 charter boat trips and 3 commercial trips. An additional 124 carcasses, of which 89 were donated from private recreational fishers.

Critique
The biological data and information are pertinent to SEDAR 41. The details of biological sampling methodology is sufficient to determine which samples with age data are usable in growth modeling and age composition of the recreational and commercial fisheries.

SEDAR41-DW07
Age Truncation and Reproductive Resilience of Red Snapper (*Lutjanus campechanus*) Along the East Coast of Florida. Lowerre-Barbieri, et al. 2014.

Synopsis:
The document describes the assessment of the age structure of red snapper off the east coast of Florida and demographic trends in reproductive traits which might be impacted by age truncation. The population exhibited age truncation, as the maximum sampled age (21 y) was less than half the expected life span (50+ y) and 84% of the sampled fish were < age 7. Virtually all females sampled (99%, n=696) were mature and although two-year-olds were not fully-recruited, 94% (n= 119) were mature. The population spawning season was from April through September, but the probability of being spawning capable within this time differed significantly by size and age, with June being the only month with predicted probabilities > 90% for all fish. Similarly, spawning fraction peaked in June, although older fish had more temporally distributed spawning activity. Red snapper spawned throughout the day and at multiple sites, with relatively few spawning females collected per site (maximum=13 fish). Batch fecundity increased significantly with size and in more northern zones but was highly variable. Egg dry weight did not differ significantly with size or age. Red snapper reproductive physiology suggests they are resilient and highly adaptive. However, age truncation appears to have restricted the time period over which spawning occurs and potentially has caused earlier maturation. Thus, recovery rates

are expected to be affected by environmental conditions in June and if the observed early maturation is due to fisheries-induced evolution.

Critique:
The document contains relevant information and some information, in particular combined with other studies, was included in the LHWG analyses. Note that the report does not identify the length, but the used length was MaxTL (Pers. Comm. by authors).The methodology used to conduct this study was well planned and executed. The analyses were very informative to the reproductive biology of the South Atlantic stock. Two drawbacks to the study include the one year duration of sampling and the range of samples was limited, though did target the center of abundance of the population. For these reasons, some caution should be taken when making inferences to the stock as a whole and to possible changes over time. This study does point out a much needed data inputs to improve the stock assessment and that is to collect routine, annual reproductive tissue samples from red snapper landed in the fishery and in fishery-independent surveys.

SEDAR41-DW09
Size and age composition of Red Snapper, *Lutjanus campechanus*, collected in association with fishery-independent and fishery-dependent projects off of Florida's Atlantic coast during 2012 and 2013. Switzer, et al. 2014.

Synopsis:
The South East Reef Fish Survey, which utilizes chevron traps, has been able to provide some life-history data for Red Snapper during the closure (since 2010). The mini seasons in 2012-13 provided the only fishery-dependent data available since the 2010 Red Snapper closure. Florida's Fish and Wildlife Conservation Commission (FFWCC) collected life history samples from Red Snapper during fishery-independent and fishery-dependent research and monitoring activities along the Atlantic coast of Florida. (A) Most fishery-independent samples were collected in 2012 in association with a one-year pilot study to explore the utility of various fishery-independent, hooked-gear methods. Additional samples were collected in 2012 and 2013 in association with a three-year tagging study to examine movement of Red Snapper. During both studies Red Snapper were culled for life history analyses using random culls with the additional selection of some larger individuals to better characterize the age distribution of larger Red Snapper. (B) Fishery-dependent samples were collected during the limited recreational and commercial harvest seasons in 2012 and 2013. Collections were derived from recreational private boats, charterboats, headboats, and the commercial TIP. During the 2012 and 2013 Red Snapper mini-seasons, parties returning from offshore recreational trips were sampled (random intercept locations). In addition, Red Snapper were targeted for biological sampling at private boat landing sites (not random). Private recreational anglers also donated Red Snapper carcasses at select locations on the east coast of Florida during the 2012 and 2013 season (sample bias unknown),

and Red Snapper were sampled at charter and headboat landing sites (not random). In 2013, FFWCC observers on random charter vessels measured all Red Snapper caught and fish houses were sampled during the commercial season.

Ages of fishery-independent (sampling and tagging) individuals ranged from 1 to 21 years of age, although 90% of individuals were six years old or younger. The age distribution was bimodal, with exceptionally high numbers of age-3 and age-5 Red Snapper, corresponding to the 2009 and 2007 year classes, respectively. Maximum size at age was just over 800 mm TL at approximately 8 – 10 years of age. No notable differences in age distribution or size at age were evident between males and females. An examination of age-specific depths of capture did not identify a significant increase in depth with age. Overall, the results from the fishery-dependent sources mirrored those from the fishery-independent sources.

Critique:
SEDAR41-DW09 was reviewed and deemed pertinent for the SEDAR process. Although each of these data sets contains their own set of biases (as identified by the authors), these are the best available data sources. When sampled in a standardized manner, as has been done over this short period, they can be useful and indicative of changes in the Red Snapper population under management. We recommend the data be incorporated into the SEDAR process as appropriate and the biases considered in their interpretation – the fishery-dependent data are not representative of the population, but the fishery-dependent data are useful for characterizing the size and age of the harvested population.

SEDAR41-DW10
Overview of Florida's Cooperative East Coast Red Snapper Tagging Program, 2011-2013. FWRI, 2014.

Synopsis:
In an effort to better understand red snapper population dynamics off the east coast of Florida, the Florida Fish and Wildlife Conservation Commission (FWC) with federal and industry funding worked cooperatively with various sectors of the recreational, for-hire, and commercial fisheries to initiate a Cooperative East Coast Red Snapper Tagging program in 2011.The program was designed to aid fishery managers in better understanding patterns of distribution, seasonal and spatial dynamics of movement patterns, ontogenetic changes in habitat selectivity, and site fidelity of Red Snapper based on recapture rates throughout the study area. This angler-based tagging program was overseen by FWC personnel who were responsible for coordinating regional training workshops for interested participants, distribution of tagging kits, tagging database management, responding to tag returns, and all aspects of public outreach associated with this project. All Red Snapper released by participating fishermen were tagged externally with a 100-mm Hallprint dart tag. Additional information recorded by the fisher to aid in the

understanding of Red Snapper population dynamics included the coordinates of capture, water depth, and associated catch-specific information (e.g., total length, release condition). A total of 3,441 Red Snapper were tagged by all participating sectors of the Cooperative East Coast Red Snapper Tagging program from 2011 through 2013. There were a total of 211 Red Snapper recaptured from 2011 through 2013, for an overall tag return rate of 6.1%. The time-at-large (days between initial tagging and recapture) of tagged fish ranged from 0 to 887 days. The distance traveled of tagged fish from the initial tag location ranged from 0 to 237 km. Eight fish were recaptured twice and one fish was recaptured three times. The majority of recaptured fish with confirmed location information were caught <1 km from where they were initially tagged, which is indicative of high site fidelity. Analysis of distance traveled in regards to direction of movement (bearing) from initial tag position for fish that moved 3-16 km (n=36) showed no clear ontogenetic movement patterns. Fish were seen to travel in all directions from their initial tag locations. These relatively small movement patterns are most likely a result of fish moving short distances within similar depth strata to nearby available habitat. Generally speaking, water depths and habitat types within the study area, over relatively short distances (3-16 km), change very little. Analysis of fish that moved >16 km from their initial tagging location (n=14), showed a general north-south movement pattern.

Critique:
This document is very relevant and information was considered by the LHWG. The relevance will increase with increasing returns and possible continuation of tagging efforts. Data from this study should be considered in future Red Snapper assessments.

SEDAR41-DW18
South Carolina Red Snapper Catch and Biological Data Collection during Mini-Seasons, 2012-2013. Dukes & Hiltz, 2014.

Synopsis:
This document reviews the collection of biological samples for Red Snapper by the South Carolina DNR during the 2012 and 2013 mini seasons. The SCDNR collected samples from three sources; private recreational vessels, for-hire vessels, and from an online survey. The majority of samples during both years were collected from the private recreational sector (N=43 and 39, respectively), followed by the for-hire sector (N=10 and 14, respectively), and lastly, from the online survey (N=6 and 1 respectively). Private sector samples were obtained through a combination of dockside sampling and carcass donations from participating anglers. For-hire samples were collected through cooperation between SCDNR staff and participating charter/headboats that fish primarily offshore waters. Online survey samples were completed by participating anglers that targeted Red Snapper and included trips where Red Snapper where not caught but were targeted.

Critique:
The document is brief and does not include any information on spatial coverage of the samples from any of the sectors or if there was overlap with other surveys including the SC finfish survey or MRIP sampling. Other concerns include a lack of description on how biological measurements were taken, or by whom they were taken. The samples sizes from the private and for-hire sectors are small. In the absence of more information, is not possible to assess whether or not the length and weight samples were reliably measured, and whether or not the samples are representative of the population. The samples from the online survey are very small and there is concern over the reliability of any reported measurements.

The LHWG reviewers recommend that the biological samples could possibly be included for biological characterization of the population, but due to concerns regarding small sample size, possible overlap between sampling, and non-random nature of the collections, it is not recommended these data are used for catch characterization during the mini-seasons.

SEDAR41-DW21
North Carolina Division of Marine Fisheries Red Snapper Carcass Collections, 2012-2013. NCDMF, 2014.

Synopsis
North Carolina Department of Marine Fisheries attempted to obtain biological sampling of recreational fisherman during the Red Snapper mini-season to supplement existing fishery-dependent sampling which focused on sampling from the commercial sector in 2012 and 2013. Two methods were used to accomplish this: 1. Carcass collection using freezers placed at strategic locations along the coast. 2. Online survey for those fishermen unable or unwilling to donate, but still report their catch. Less than 85 samples were obtained both years and many of the headboat samples were obtained after port samplers had already extracted one of the otoliths and obtained measurements, further decreasing the sample size. The online survey had low levels and none of the submitted data were included in harvest reports.

Critique
There was some concern about the overlap with port samplers due to possibility of duplication of biological samples and measurements. The privately donated fish from the freezers cannot be considered randomly sampled, are likely subject to selectivity biases, and should not be used to characterize the catch. As only otoliths were removed no other biological information such as for reproduction was available.

The data could possibly be used to characterize the biological samples as they may be under-represented size classes at the tails of the distribution, but due to non-random sampling, small sample size, and duplication with other sampling methods, the data should not be considered for catch characterization during the Red Snapper mini-season.

SEDAR41-DW28
Red Snapper *Lutjanus campechanus* in GoM versus southeast US Atlantic Ocean waters: gaps in knowledge and implications for management. Rindone et al., 2014.

Synopsis
This document reviews the relative availability of information supporting Red Snapper assessment and management between the Gulf of Mexico (GoM) and southeastern US Atlantic Ocean (SA). The authors conducted a comprehensive review of available literature and historical records for both mature and juvenile Red Snapper. Of the 110 peer reviewed publications found, 94% were GoM centric. Of the twenty eight available manuscripts focusing on juvenile (<150 mm), none were identified from the SA. Queries of all fisheries independent survey databases from North Carolina through Florida identified only 132 juvenile Red Snapper records out of >75,000 gear deployments and institutional collections. For reference, in a single GoM trawl database, more than 50,000 records of juvenile Red Snapper were found. The results of this review serve to highlight the paucity and need for additional data on Red Snapper (juvenile and mature) in the US south Atlantic.

Critique
While this document does not directly provide any biological information to the life history group, it does serve to highlight and document the severe paucity of data for Red Snapper in the US south Atlantic, especially for juveniles, and provides suggestions for future research directives. The LHWG recommends this working paper for acceptance as it serves as a point of reference for the lack of available data, especially in comparison to Red Snapper in the GoM.

SEDAR41-DW31
Red Snapper Preliminary Genetic Analysis Temporal Genetic Diversity Trends in the South Atlantic Bight. O'Donnell and Darden, 2014.

Synopsis:
There has been only slight fluctuation in genetic diversity of Red Snapper from 1975 to 2012, thus indicating a lack of a population bottleneck or severe reduction in abundance. However, estimates of effective population size from the same samples suggest that Red Snapper experienced a genetic bottleneck that was not detected in genetic diversity estimates due to a lack of samples prior to 1975 (i.e., before the population experienced overfishing). Contemporary estimates of effective population size and inbreeding coefficients provide genetic evidence of population recovery in the Atlantic. Inbreeding coefficient estimates were substantially higher in

the 1970s and 1980s, but have been decreasing (i.e., improving) since 2005, indicating a larger breeding population in recent years.

Critique:
Sample sizes are somewhat small for some years, and do not equally represent all states (however they do reflect state-by-state landings and abundance indices). All samples analyzed were collected after the largest reduction in population abundance (hence relatively stable values within the sample period). There was good agreement in effective population size index in the genetic data and census size (SEDAR), providing support for validity of detected trends. This paper should be used in the assessment.

SEDAR41-DW33
Size Distribution, Release Condition, and Estimated Discard Mortality of Red Snapper Observed in For-Hire Recreational Fisheries in the South Atlantic. Sauls et al., 2014.

Synopsis
The working paper provides a description of the size distribution, release condition, and estimated discard mortality of Red Snapper in for-hire recreational fishery. The paper includes the time series and the geographic coverage of the data collected and methods used to develop the estimates from the at-sea observer program for the south Atlantic.

The At-sea observer program started in 2004 for headboats in the South Atlantic and 2010 for charter boats in Florida. Florida has slightly different methodology than other states and collects more information on the observer trips than other states collect. This allowed for estimates of hook type usage, description of depth for released fish, and an overall estimate of discard mortality for the recreational for-hire fishery in the Red Snapper fishery off Florida.

Critique
The working paper is acceptable for use in the stock assessment. The paper provides needed information on the methods used to estimate the number and lengths of discarded fish and the potential fate of the fish. Additionally this working paper provided the estimate of discard mortality that was recommended for use in the stock assessment for the recreational fishery.

SEDAR41-DW35
Marine Resources Monitoring, Assessment and Prediction Program: Report on Atlantic Red Snapper, *Lutjanus campechanus*, Life History for the SEDAR 41 Data Workshop. White et al., 2014.

Synopsis
This working paper summarizes the data and analyses of Red Snapper as collected by fishery independent monitoring effort in waters off the southeastern US to prepare for the SEDAR 41 Data Workshop. It describes aspects of Red Snapper life history, including depth of capture in fishery-independent and fishery-dependent surveys, length-length and length-weight conversions, length at age, age- and length-at-maturity, sex ratio, spawning seasonality, and spawning frequency.

Critique
SEDAR 41 Reference Document 35 was reviewed and deemed pertinent for the SEDAR process. Data and analyses from this DW were discussed and used during the DW, and are reported in the LHWG DW report. Comments and updated analyses were incorporated I an updated WD.

SEDAR41-DW48
Development of an ageing error matrix for U.S. red snapper (*Lutjanus campechanus*)
Sustainable Fisheries Branch, National Marine Fisheries Service, Eric Fitzpatrick.

Synopsis
The WD describes the age error matrix for use in the SEDAR41 assessment. This analysis was done after the 2014 DW and no update was needed for the 2015 DW.

Critique
The LHWG reviewed the data and analysis and agreed that the presented information should be used to characterize the uncertainty in age estimates based on the variability in age readings between readers and labs. Note that the additional information on the age determination process is provided in section 2.6 of this LHWG report.

SEDAR41-DW49
Estimates of reproductive activity in red snapper by size, season, and time of day with nonlinear models. N. Klibansky

Synopsis
This paper describes a modeling approach to address the spawning season and spawning fraction that may result in more realistic estimates of both.

Critique
The novel modeling approach presented in this WD was considered to be more appropriate than that used in previous assessments. This approach does not assume that all fish start and stop spawning at the same date, and does not assume that fish of all sizes have an equally long spawning season. The presented analysis provides estimates of the proportion spawners by

length (age) during the spawning season. As such, the estimates derived using the approach presented in this paper represent a more realistic evaluation of the reproductive output.

2.3 Stock Definition and Description

Red Snapper are known to utilize both low- and high-relief hard bottom habitats in depths typically ranging from 50-100 m of water. Geographically, Red Snapper distribution ranges from the Yucatan Peninsula throughout the GoM and along the U.S. Atlantic coast north to North Carolina, with occasional occurrences north to Massachusetts (Manooch et al., 1998). Additionally, a disparate portion of the distribution occurs along the north coast of South American (Figure 2.1).

Genetic stock structure of Red Snapper between the GoM and western Atlantic was initially evaluated by Garber et al. (2004) using the mitochondrial control region identified homogeneity in haplotype frequencies among all locations included (four in GoM and one in Atlantic), suggesting Red Snapper in U.S. waters represented a single, panmictic population.

Additional studies limited to GoM collections using both mitochondrial and nuclear markers failed to identify any significant genetic structure (Gold et al., 1997; Pruett et al., 2005; Sallient and Gold, 2006); however, Sallient et al. (2010) evaluating microsatellite genotypes of young of year fish collected from the GoM detected significant spatial autocorrelations indicating small-scale genetic heterogeneity. The authors suggest Red Snapper in the GoM may represent metapopulation population dynamics. Numerous otolith microchemistry studies also provide evidence of regional patterns in the GoM (Patterson et al., 1998; 2001; Nowling et al., 2011; Sluis, 2011).

The most recent genetic evaluation (Gold and Portnoy, 2013 MARFIN Final Report) used both microsatellite and mtND4 data to evaluate gene flow patterns of Red Snapper within and between the U.S. Atlantic and GoM waters. All conventional data analyses failed to identify any level of genetic structuring, but a very weak pattern of isolation by distance was detected only in the mitochondrial data. They conducted an alternative Bayesian analysis which detected significant genetic heterogeneity within the Atlantic (5 locations), within the GoM (3 locations), and between the Atlantic and GoM. However, the new analyses (or at least it is not reported) does not identify locations of gene flow breaks and is in contradiction to all prior results.

During the SEDAR 24 Data Workshop, the Life History Working Group investigated the potential for spatial differences in maturity, growth, and length at age of U.S. Atlantic Red Snapper. They determined that fish in the Florida-Georgia (South) region may mature younger and at smaller sizes than fish in the Carolinas (North) region (See section 2.8 of the SEDAR 24 Data Workshop Report). They detected no difference in mean length-at-age or growth rates between the two regions (SEDAR 24 Data Workshop Report, Figure 2.7.1).

Tagging studies do not provide any additional evidence that suggests movement between GoM and Atlantic stocks, other than one fish tagged off Pensacola, FL was recaptured off St. Augustine, FL (Burns et al. 2008). Fishermen have suggested seasonal migration of fish occurs among regions of the South Atlantic.

During the 2015 DW, no new information was available, therefore, there are no indications from conventional methods that U.S. Red Snapper represent multiple stocks, either between the western Atlantic and GoM or regionally within the western Atlantic. Therefore, the continuation of single stock management of U.S. Atlantic Red Snapper appears to be biologically appropriate based on population genetics and life history trait patterns. However, for the purposes of this assessment, Red Snapper stock definition is from the Florida Keys (Atlantic side) to as for north as landings are recorded.

Recommendation

The Red Snapper stock be defined as the SAFMC jurisdiction of the Florida Keys north to as far as landings are recorded.

2.4 Natural Mortality

2.4.1 Juvenile (YOY)

Juvenile Red Snapper are rarely encountered in a nearshore (<30 ft) fishery-independent trawling program (SEAMAP-SA Coastal Trawl Survey) in the Atlantic. Estimates of juvenile Red Snapper mortality have been developed in the Gulf of Mexico (SEDAR-31), however, little information is available for the US South Atlantic. As with previous Red Snapper assessments from the South Atlantic region off the coast of the United States (SEDAR-32), age 0 fish will not be included as inputs into the stock assessment model and so all calculations regarding natural mortality will involve fish aged 1+.

2.4.2 Adult

Natural mortality (M) of Red Snapper was estimated using several methods. The LHWG also discussed the likelihood that natural mortality rate varies by age and an age-varying approach was advocated (e.g., SEDAR 32). Two methods for estimating age-dependent natural mortality using fitted von Bertalanffy growth models were discussed - Lorenzen (1996), a weight based estimator using length-weight conversions to provide values, and Charnov et al. (2013), using lengths directly from the growth model. Charnov et al. (2013) provides an equation which is an improvement to the empirical equation in Gislason et al. (2010), as well as meta-analyses of other estimators of M, including Lorenzen (1996). They also take into account various aspects of life history traits and habitat of a wide variety of exploited marine and brackish water fishes, leading the LHWG to recommend the Charnov et al. (2013) equation, which utilizes von Bertalanffy growth parameters L_∞ and k, as the best initial estimate of M-at-age:

$$M = ((\text{Length-at-age}/L_\infty)^\wedge(-1.5))*k$$

To apply the Charnov et al. (2013) method, the von Bertalanffy growth model was fit as the population growth model was, but with t_0 fixed at 0. The von Bertalanffy parameters used were:

L_∞ = 883.41 mm
k = 0.279
fixed $t_0 = 0$

The Charnov model provided an age-specific estimate of natural mortality that ranged from 1.395 – 0.279 for fish aged 1 to 51, respectively (Table 2.1). The survivorship to the oldest age using the Charnov et al. (2013) age varying method was unrealistically low ($1.082 * 10^{-6}$), considering the amount of fish caught at older ages. Because the age data, limited as they are at the upper tail, do include fish that are in their 30s, 40s, and 50s, it is more biologically reasonable to assume survivorship to these older ages is greater than zero. Considering the longevity of the species, as well as consistency with past SEDARs, the Charnov M curve was scaled to a point estimate based on the survivorship of the fully recruited ages (4+). Point estimates were generated using empirical models based on maximum observed age (t_{max} = 51 years). The LHWG determined the Then et al. (2015) method ($M = 4.899*t_{max}^{-0.916}$) was the most appropriate means for estimating a point estimate for natural mortality in Red Snapper. It should be noted that the Hoenig (1983) method had been used previously, but Hoenig (a co-author on Then et al. 2015) conceded that Then et al. 2015 is a superior means of obtaining a point estimate of natural mortality. The point estimate is applicable only to those ages that were fully recruited to the fishery. Because the point estimate does not vary with age, it is assumed that the estimate is the average mortality per year from the time at full recruitment. Age at full recruitment was 4+ years, as determined by the mode of the age in the fishery-dependent catch (3 years) and adding 1. The annual instantaneous mortality rate calculated for Red Snapper using the empirical estimator from Then et al. (2015) was 0.134. This resulted in a scaled estimate of natural mortality at age ranging from 0.625 to 0.125 for ages 1-51, respectively (Table 2.1), with the cumulative survival to maximum age at 0.2%.

To incorporate variance around the age-varying natural mortality estimate, the standard deviation (2.89 yr; n = 3) was calculated around the inter-reader variability for the fish with the maximum observed age. Confidence intervals (95%) around the maximum age were calculated from the variance. This, in turn, was used with the Then et al. (2015) method to create natural mortality point estimates based on the upper maximum age (Age = 54.3 yr; M = 0.126) and the lower maximum age (Age = 47.7 yr; M = 0.142). The age-varying natural mortality curve was then scaled to the point estimates calculated from these upper and lower maximum ages, resulting in natural mortality estimates at age for the low end (range = 0.603 - 0.121; cumulative survival = 0.3%) and for the high end (0.678 - 0.136; cumulative survival = 0.1%) for ages 1-51 (Table 2.1).

Recommendations

1. The LHWG recommends using the Charnov age-varying natural mortality curve scaled to the Then et al (2015) point estimate for those ages fully recruited to the fishery (4+).
2. The LHWG recommends that variance about the M age-varying curve be investigated using the inter-reader variation of the oldest aged fish, with 95% confidence intervals being produced to provide an upper and lower maximum age, which in turn is used in the Then et al. (2015) point estimate. The age-varying natural mortality curve was then scaled to these natural mortality point estimates calculated from the upper and lower maximum age estimates.

2.5 Discard Mortality

Note: Discard mortality estimates were developed during the 2014 DW. No new information or analyses were available, so discard mortality estimates were not revisited at the 2015 DW.

Rusty Hudson	Erik Williams

Discard mortality is an important estimation included in stock assessments and should be considered in evaluating the effectiveness of regulatory actions to reduce harvest. Several studies have been conducted to estimate a discard mortality rate for Red Snapper with values varying from 1 to 93% (see SEDAR 24 and 31 for reviews). Most of these studies have focused on Red Snapper in the GoM where the commercial Red Snapper fishery operates much differently from the snapper grouper fishery off the US South Atlantic both in depths fished and gear used to target Red Snapper (gear differences were displayed at the data workshop). Additionally, other factors that influence discard mortality likely vary between the South Atlantic and GoM including: depths fished by fishing sectors and fishing areas, fishing behavior between sectors and areas, bottom and surface temperature, and usage of circle hooks and dehooking devices.

Therefore, the stock assessments in the South Atlantic have used different discard mortality rates than what has been used in the GoM (Table 2.2).

The estimates of discard mortality used in SEDAR 15 were 90% for the commercial fishery and 40% for the recreational fishery. The SEDAR 15 discard mortality estimates for the recreational (40%) and commercial (90%) fleets were based on the discard mortality estimate for Red Snapper from the GoM for fish caught in waters deeper than 20 meters (SEDAR 7). The values used in SEDAR 24 were 39 to 41% for the recreational sector which was similar to the SEDAR 15 estimate and 48% for the commercial sector. These estimates were based on a depth related discard mortality model developed by Burns et al. (2002). A formal working paper (SEDAR 24 DW-12) was developed for SEDAR 24 and includes a more in depth discussion of discard mortality.

Consideration of Depth Effects

Several studies have focused on depth as an important factor in determining discard mortality due to the visible impact of barotrauma. Studies conducted in depth of less than 35 meters (115 feet) estimated discard mortality rates of 20% or less (Parker 1985, Render and Wilson 1994, Patterson et al. 2002, Burns et al. 2006). Studies conducted in greater than 35 meters generally estimated higher discard mortality rates ranging from 17% to 93% (Gitschlag and Renaud 1994, Burns et al. 2004, Nieland et al. 2007, Burns 2009, Diamond and Campbell 2009, Stephen and Harris 2009). This increase in discard mortality rate with increasing depth is an expected result and has been described for Red Snapper and other snapper grouper species (Patterson et al. 2001, Burns et al. 2002, Patterson et al. 2002, Rudershausen et al. 2007, Stephen and Harris 2009).

To account for increasing discard mortality rate with increasing depth, three models were reviewed in SEDAR 24. Two of the models (Burns et al. 2002, Diamond et al. unpublished data) used a logistic regression function to model the mortality rate (Figure 2.2) and one used a linear trend (Nieland et al. 2007). All three of the models had overlap in the estimation of discard mortality particularly between 50 and 90 meters (see SEDAR 24 DW 12 reference for plots). The linear model had a higher discard mortality rate for Red Snapper caught in depths less than 40 meters than the other two studies (Nieland et al. 2007), likely due to commercial fishing practices observed in the GoM. These fishermen were fishing bandit fishing reels with terminal gear consisting of 20 hooks spread over 4.5 to 6 meters (S. Baker, Jr, personal communication). Typical recreational fishermen in the South Atlantic and GoM as well as commercial fishermen in the South Atlantic fish for snapper/grouper species with terminal gear having less than 5 hooks (Gulf and South Atlantic Fisheries Foundation 2008). The other two models describing discard mortality also included delayed discard mortality in their discard mortality estimate. Koenig (Burns et al. 2002) used a cage study to determine the effects of depth on Red Snapper. Additionally, Red Snapper and gag grouper data were combined in the model since there was no significant difference in the percent mortality at depth. The Diamond et al. (unpublished) combined data from several different studies including the Burns et al. (2002) and Nieland et al. (2007). The discard mortality curves from these two studies were similar with less than 20% discard mortality for fish caught in less than 20 meters increasing to 100% mortality for fish caught in greater than 90 meters.

Consideration of Hook Effects

Hooking related injuries are also important when trying to determine discard mortality (Rummer 2007, Burns et al. 2008). Necropsy results from headboat caught fish showed Red Snapper suffered greatest from acute hook trauma (49.1%), almost equaling all other sources of Red Snapper mortality combined in the headboat fishery in waters less than 42 meters (50.9%, Burns et al. 2008). These hook related injuries caused both immediate and delayed mortality in Red Snapper. The delayed mortality was a result of the hook nicking an internal organ, causing the fish to slowly bleed internally eventually leading to death after a few days (Burns et al. 2004). Circle hooks are generally thought to reduce the discard mortality rate for Red Snapper (SEDAR 7; Rummer 2007); however, Burns et al. (2004) did not observe decreased discard mortality rate when comparing recapture rates of Red Snapper caught on circle and j-hooks. Recent work by Sauls et al. indicated that circle hooks reduced discard mortality for Red Snapper and SEDAR 31 used a discount for regulations that were established in 2008 for the GoM (circle hooks, dehooking devices, and venting). In SEDAR 31, it was stated that the requirement to vent was not quantifiable, but it was included in their model (SEDAR 31).

Consideration of Additional Factors

Additional factors that influence discard mortality rate, such as size of the fish, temperature, and predation, have been considered for Red Snapper but currently data are too limited to include these parameters in a quantifiable estimation of discard mortality. Temperature has been noted in some studies as a significant factor determining discard mortality rate for Red Snapper (Render and Wilson 1994, Rummer 2007, Diamond and Campbell 2009). In these studies, the discard mortality rate increased with increasing temperature. More importantly, both Rummer (2007) and Diamond and Campbell (2009) found the temperature differential between surface and bottom water was more important in determining the discard mortality rate than water temperature alone. A greater differential between the surface and bottom temperature resulted in a higher discard mortality rate.

Red Snapper are preyed upon by several different species including barracuda, sharks, and amberjack (Parker 1985). Dolphins have been listed as a predator in the GoM but this behavior has not been observed in the South Atlantic. In the South Atlantic, the predators of Red Snapper are generally present during months when water temperatures are warmer (personal communication with commercial fishermen).

Descending Devices

Descending devices were mentioned as a potential tool to reduce discard mortality. One fisherman brought in his homemade descending device which he started using in 2014. Currently, the change in discard mortality rate due to descending devices is unknown. There is some research being conducted to determine if descending devices reduce discard mortality. The fishermen pointed out that very few people are using descending devices. Descending devices were not considered for the discard mortality rate.

SEDAR 41 DW Comments and Recommendations

The ad hoc Discard Mortality group's first task was to review the decisions of SEDAR 24. The SEDAR 24 DW recommended using an estimate that included delayed mortality since this would be a better estimate of discard mortality than just surface release information. Immediate mortality is easier to quantify and can be observed at the surface but this value is unlikely to be an accurate estimate of discard mortality for Red Snapper. Delayed mortality is able to incorporate mortality due to hook related injuries, predation, and barotraumas that are not observed at the surface or on board boats. The group felt that delayed mortality rate was more appropriate to describe the fate of discarded Red Snapper.

The SEDAR 24 DW further recommended using a discard mortality model since depth is an important factor in determining discard mortality rate. Some of the participants mentioned that few fish die in the shallow water typically fished for Red Snapper. The plenary decided on using the depth model presented in Burns et al. (2002) to estimate discard mortality (Table 2.3). This model included information on Red Snapper in the South Atlantic and GoM and Gag in the South Atlantic. The model was based on several pieces of information including tag/return data, barotrauma and surface observations. To use the model, depth of discards was developed for each sector. The commercial discard mortality depth estimates came from observer data from the Gulf and South Atlantic Observer study (2008) since this study had depth information combined with catch information. The discard mortality rate estimate of the commercial fishery was 48%. The headboat at sea observer program and logbook data was used to estimate the headboat and charter boat depth distribution. The discard mortality rate estimate for these two sectors was 41%. Private boat depth data was very limited but used depth information from South Carolina DNR tagging study and depths recorded from biological samples from Florida and Georgia fishermen. The private boat discard mortality rate estimate was 39%.

The ad hoc Discard Mortality Working group for this SEDAR agreed with many of the decisions from SEDAR 24. The discard mortality value should include information on delayed mortality and information on depth should be incorporated into the estimate.

Recreational

New methodology using a tag/return model described in Sauls et al. 2014 (SEDAR 41 DW33) was used to condition a model that estimated discard mortality based on release condition and would include information on delayed mortality. The conditions included not impaired/not vented, not impaired/ vented, and impaired for 1,892 Red Snapper. The fish included in this study were post regulation (circle hook requirement and dehooking tool in both areas and venting in the GoM only). The tag/return discard mortality model includes delayed mortality based on the recapture information and a proxy for depth based on condition of the fish. This method was the preferred method to estimate the discard mortality for recreational Red Snapper.

The tag/return condition model estimate was 26.7% for the charter boat fishery and 28.5% for the headboat fishery (Table 2.3). Since the depth profiles were similar among the recreational fisheries (Figure 2.3), a single estimate of discard mortality was recommended. The estimate of discard mortality from the headboat fishery was the preferred estimate (28.5%) because of the higher sample number compared to the charter boat sample number (1,445 headboat, 447 charter boat).

Since this estimate was made based on post-regulation data for circle hooks and dehooking tools in the South Atlantic, an estimate of pre-regulation discard mortality was developed. An estimate of the proportion of discard mortality due to regulation was projected using a regression model from data in SEDAR 31 (data from SEDAR 31 Stock Assessment Report). In general, when discard mortality was low, the proportion of discard mortality due to hooking and releasing was greater than when discard mortality was high, where most of the discard mortality would be associated with barotrauma. This model assumes compliance with the regulations. However, based on observer work and communication with fishermen, compliance with circle hook regulations varied by area (state) and sector. The only compliance data recreational available at the workshop was for the recreational fisheries in Florida. It was estimated that approximately 50% of the trips targeting snapper/grouper were using circle hooks since 2011 (Sauls et al. 2014, SEDAR 41 DW 33). The reduction in discard mortality due to regulations was reduced by 50% based on compliance. The usage of circle hooks prior to 2011 is unknown, but Burns et al. (2002) reported that circle hook usage while snapper/ grouper fishing was minimal in the South Atlantic prior to their study. Using the equation in Figure 2.4 and reducing by 50% for compliance, the pre-regulation discard mortality was 36%.

In an effort to corroborate the method used to calculate discard mortality for the recreational sector, the depth information for the recreational sector was placed into the Burns et al. (2002) model to compare with the results from the tag/return condition model. The Burns et al (2002) model was considered the pre-regulation estimate and the depth related estimate was decreased for a post-regulation estimate due to the limited usage of circle hooks reported in the Burns et al. study. Depth information was obtained from the Florida fishery because this is the only state with depth specific information on discards and is the heart of the Red Snapper fishery. The depth model estimated that post-regulation discard mortality ranged between 23% and 28%. These estimates of post-regulation discard mortality were very similar to the tag/return model estimates and are in the range of sensitivities recommended for use in the assessment.

Commercial

The commercial fishery did not have information on condition of discarded fish; and, therefore the tag/return model based on fish condition could not be used. Instead the depth model (Burns et al. 2002) used in SEDAR 24 was the preferred model. Observer information was used to estimate the depth of discards. Similar to SEDAR 24, the commercial discard mortality was estimate to be 48%. This estimate was developed primarily with information on fish caught with j-hooks which have a significantly higher proportion of potentially lethal hooking interactions (Sauls et al. 2014). To account for the usage of circle hooks, an estimate of post-regulation discard mortality was developed. Observers reported commercial fishermen using circle hooks on approximately 50% of the drops from 2007 to 2011. No other reports were available since 2011 but fishermen at the data workshop indicated the compliance with the circle hook regulation varied by area (state) and sector. They indicated the compliance of 50% was possible but should be investigated before use in other assessments. Using the same method to increase the recreational sector for pre-regulation discard mortality, reduced discard mortality was developed for post 2007 due to the usage of circle hooks. The commercial sector discard mortality rate for 2007 to present was 38%.

The discard mortality for the commercial fishery is much less than the GoM's commercial discard mortality for two main reasons: depth fished and handling time. The modal depth fished for the commercial fishery in the South Atlantic was 31 to 40 meters. The average depth fished in the GoM ranged from 42 to 84 meters. Handling time was noted in SEDAR 31 in the GoM commercial fishery where the commercial fishermen averaged using seven hooks per rig (Scott-Denton et al. 2011). In the South Atlantic, commercial fishermen typically fish one to three hooks and up to five hooks on a rig (Gulf and South Atlantic Fisheries Foundation 2013, commercial fishermen at data workshop). The fewer number of hooks in the South Atlantic leads to less time fighting the fish and also less time dehooking on the deck of the boat.

Discard Mortality Values and Range of Plausible Estimates

Recreational 2011 to present – 28.5% (20% to 36%)
Recreational pre-2011 – 37% (27% to 45%)
Commercial 2007 to present – 38% (28% to 48%)
Commercial pre-2007 – 48% (38% to 58%)

2.6 Age

General introduction

For the 2015 DW, age data were updated and reanalyzed. Juvenile Red Snapper are rarely encountered in the U.S. South Atlantic. SEAMAPs fishery-independent trawling program captured three in 1999, two in 2000, seven in 2013 and four in 2014 in nearshore (<30 ft deep) habitat. One age-0 Red Snapper was landed by a headboat fisherman during the 2012 mini-season. One age-0 fish was landed in the commercial fishery in 1980. Fishermen have reported observing juvenile Red Snapper on artificial reefs in shallow water. Estimates of juvenile Red Snapper mortality have been developed in the Gulf of Mexico; however, little information is available for the US South Atlantic.

The SEFSC, the SCDNR, the GA-DNR, and the FWRI contributed both fishery-dependent and fishery-independent age data for this assessment. The final age data set included samples collected from 1977 – 2014. Most of the age samples were randomly collected by port agents intercepting fishing trips between 1977 and 2014: commercial n = 6,624; charter boat n = 4,025; private boat n = 4,470; headboat n = 6,355; unknown fishery type n = 57. (See Tables 2.4 and 2.5 for randomly collected commercial and recreational fishery age samples and number of trips intercepted.) Some age samples (n = 1,941) were collected from the commercial and recreational fisheries in a non-random way (GADNR and FWRI in 2009 and all states during mini-seasons in 2012 - 2014), and the decision on the treatment of the samples are discussed below. An additional 4,224 samples came from fishery-independent studies. All age data included an increment count, an adjusted calendar age based on timing of annulus formation and an estimate of the amount of translucent edge present, and the determined fractional age using a July 1 birth date.

Issues – 2009 sampling intensity and 2012-2014 mini-seasons

As noted in SEDAR24, sampling intensity for Red Snapper was greatly increased in 2009 for fish landed in Georgia. Also, fishermen donated large Red Snapper landed in Florida and Georgia to FWRI and GADNR during that year. The donated fish were considered non-random and were not used to characterize the landings, but were used in the population growth model. The other samples from GADNR were reviewed and the same conclusions made during SEDAR24 were accepted by the LHWG. The following excerpt from SEDAR24 report is included:

> *GADNR conducted a complete census of Red Snapper landed during May 2009 by three recreational vessels. Concern was raised that the high number of samples (nMay = 284) from one month in the year may bias the overall age structure of the Red Snapper landings for the entire year (nyear = 679). This issue was particularly noted by industry*

representatives who have commented that Red Snapper seem to move through the fishing grounds either latitudinally or longitudinally.
A few of the 2009 samples (n = 68) from the commercial and headboat fisheries were selected by fishermen for the largest fish in the catch.

Recommendations
1. GADNR May census data were plotted against the GADNR random samples for the entire year. No discernible difference was noted in the age frequency or the length distribution between the two sets of data. LHWG recommended keeping the May census data in the dataset used for age composition of the recreational fishery.
2. The fishermen selected samples were identified and will not be used in the age composition data to characterize the fishery, but will be used in the growth model and analysis of fishing by depth of water.

Other directed sampling efforts to obtain biological information on Red Snapper in 2012 - 2014 were undertaken by each state in the U.S. South Atlantic. Following the closure of the Red Snapper fishery in 2010 and 2011, the SAFMC re-opened the recreational fishery in 2012 - 2014 as “mini-seasons” and the commercial fishery as limited harvest. Each state agency provided documentation of methodology to collect Red Snapper samples through carcass collection programs and targeted intercepts of fishing trips by biologist (SEDAR41-DW02, SEDAR41-RD14, SEDAR-RS15, SEDAR41-DW18, and SEDAR41-DW21). These special collections were obtained outside of regular, routine sampling by the Southeast Region Headboat Survey (SRHS), MRIP, and TIP. The length data associated with these age samples would not be included in three fishery surveys, but may be made available to the Commercial and Recreational Work Groups for length composition of the respective fisheries. The LH group reviewed the documents, talked with the state agency representatives, and then assigned random or non-random to the age samples provided. Those samples deemed randomly collected during the directed effort were considered useable for characterizing the catch by fishery, gear, and mode. Those samples deemed non-random were used to model the fish growth at the population level, but were considered not useable for characterizing the catch. Samples considered non-random were those collected from donated fish carcasses into freezers or samples that were collected from tournaments. Tables 2.6 – 2.8 provide the number of samples by state, fishery, and mode, and include the designation of “random” or “not random”.

Recommendations

1. Use age samples from the state collections during the 2012-2014 mini-seasons and considered as randomly sampled to characterize the landings of the fishery and mode from which they came.

2. Age samples collected from a non-random sample or carcass can be used in the overall population growth analysis, but will not be used to characterize the catch.

Review of data collection of the "mini-season" and recommendations for data collection improvements.
Discussion by the LHWG, in particular relative to the relevant WDs reviews, resulted in several recommendations to potentially improve the data collection during possible future Red Snapper mini seasons. The LHWG reviewers recommended that if this program is to continue in the future, an exploration of methods to further incentivize angler participation is warranted, especially with such limited contribution from the private sector in some states. After brief interviews with participants from the recreational fishers group, the following suggestions were provided to increase participation in the private sector*:

- Free fish cleaning at donation site.
- Short questionnaire from a biologist on-site instead of them filling out a form. People are TIRED after being out all day, boat ramps are busy.
- Advertise at local bait & tackle shops.
- NOAA has announcement system on weather radio channel where they also announce season closures, etc. Since fishermen are frequently monitoring this channel for weather updates, it could be an effective communication route to announce the collection information (drop locations, reward information, etc.).
- Dry storage areas are a good place to sample fish as many people store boats there instead of trailering them home.
- Standardization of survey methods across states should be investigated.

*: Suggestions from various recreational fishermen and in particular, David Nelson (SEFA ECS).
The reviewers understand the cost and effort associated with some of these suggestions, making it difficult to implement all of them.

2.6.1 Age Reader Precision and Ageing Error Matrix

To combine age data from various labs, consistency in readings needed to be assessed. The age data were provided from readings by staff at three laboratories – SEFSC, SCDNR, and FWRI. All age readers have been involved in age workshops for Red Snapper from the U.S. South Atlantic. FWRI staff have the added benefit of yearly age workshops with experts from the Gulf of Mexico. Because the South Atlantic stock of Red Snapper were assessed in 2010, the age readers felt that it would be important to read a calibration set of otolith sections to insure consistency had been maintained. A set of 300 samples was created by SEFSC and exchanged between each of the labs.

The results of the calibration readings showed good consistency between labs. One measure of consistency is the Average Percent Error (APE) between paired readers and between all readers. Another consideration is whether one lab shows a bias in readings compared to the other labs.

APEs ranged from 8% between SEFSC and FWRI to 8.5% between FWRI and SCDNR to 11% between SCDNR and SEFSC. The overall APE amongst all readers was 11.4%. These values are higher than the desired level of ≤5%, but most of the variability in the age readings was from those fish aged 8+. Most of the life history parameters have met saturation by that age (maturity, maximum growth, etc.). The bias plots also indicate little bias in aging between the labs (Figure 2.5).

Accounting for error in age estimation is important for age composition data used in stock assessments (Punt et al. 2008). Thus, to account for any error associated with the age estimation process for South Atlantic Red Snapper and to get contemporary precision estimates, an aging error analysis will be completed for the assessment using a program called "agemat" provided by André Punt. Agemat can use age estimation data from multiple readers in order to estimate the coefficient of variation and standard deviation associated with age estimates and to provide an aging error matrix. This program has been used by other SEDAR assessments (ASFMC 2010).

The ageing error matrix was provided after the 2014 DW (SEDAR41-DW48) and reviewed during the 2015 DW (see above).

Recommendation

The age error matrix as provided in the working paper should be used to characterize the uncertainty in the age estimates as a result of the variability in age reading between readers and labs.

Research recommendation:

Continuing the age reading comparisons and calibrations between labs on a reference collection of known age fish would be beneficial for determining a more accurate aging error matrix and would provide accuracy to the age composition data.

2.6.2 Max Age

The 2014 age data did not yield older fish and the maximum observed age for Red Snapper remains 51 years in the combined data set. This fish was a 904 mm maximum TL female, and was caught in 2003 at 67 meters depth off Florida by a charter boat fisher. The maximum age of Red Snapper in SEDAR24 was 54 years. The otolith preparation from this fish was examined by multiple readers at the SEFSC, SCDNR, and FWRI labs. The age was adjusted to 48 years based on consensus by the readers. Note that there were 12 fish with an age of 40 years or more in the data base.

Recommendation

Use 51 years as the maximum age for Red Snapper in the Assessment. This is similar to the 48 years used in the Gulf of Mexico assessment and the 54 years used in SEDAR 24 assessment.

2.7 Growth

Since SEDAR 24, 14,700 additional aged samples were added to the data-set for a total of 27,696 fish for this workshop, thus increasing the temporal and regional coverage of each fishing mode (commercial, recreational, fishery-independent). For all growth models, fractional ages and maximum TL mm (pinched tail) were used, whether it was given with the data or converted using the determined meristics conversions (see Meristics sections). Growth models were constructed using a correction for the truncated normal distribution of size at age due to minimum size limit regulations across time (Diaz correction: Diaz et al. 2004; McGarvey and Fowler 2002).

Growth parameters were estimated on all available data, which represented the population and the fishery-dependent data separately (Table 2.9). Estimated von Bertalanffy growth parameters included L_∞ (the asymptotic fish length, mm maxTL), k (growth coefficient), and t_0 (birth date, yr). The von Bertalanffy population growth model was freely estimated and the Díaz correction was applied to fish restricted by a minimum size limit. The resulting parameter values were L_∞ = 911.36, k = 0.24, and t_0 = -0.33 (Figure 2.6). The model did not require any weighting scheme because sufficient samples at both tails of the data exist and the model was able to fit them well. The fishery-dependent growth model was also freely estimated and did not require inverse weighting of sample size at age, but no Diaz-correction was applied to the data in this model (Figure 2.7). This growth model will be used to estimate size of Red Snapper landed in the fisheries of the U.S. South Atlantic.

The potential of dimorphic growth in this species was investigated by comparing size-at-age analysis for both male and female fish, for fish in which the sex was determined. No discernible difference was found between male (n=4,976) and female (n=5,322) size-at-age (Figure 2.8), therefore spawning biomass should include all data and not discriminate between sex-based growth models.

Recommendation

1. Use combined data, unweighted, freely estimated, Diaz-corrected von Bertalanffy growth model to represent the population.
2. Use the fishery-dependent age data only, unweighted, and freely estimated, von Bertalanffy growth model to estimate the size of fish landed in the fishery.

2.8 Reproduction

2.8.1 Reproductive Strategy and Data Availability

Red Snapper are batch spawners with indeterminate fecundity that do not change sex during their lifetime (gonochorism). The MARMAP study by White and Palmer (2004 - SEDAR24-RD01) and additional samples collected by SERFS since 2001 provide extensive data on the South Atlantic Red Snapper reproductive biology over a large spatial and temporal range. Specimens with reproductive data were collected from 1979 to 2014 and the majority (82% of 3,221) came from fishery-independent sampling, primarily chevron trap catches (Tables 2.21 – 2.28). Many of the commercial fishermen involved in the collection of specimens since 1999 were permitted to land undersized specimens. Data from a published study by FWRI (Lowerre-Barbieri et al. 2015 - SEDAR41-RD57) assessing Red Snapper reproduction off the east coast of Florida, the stock's center of abundance, were also used for SEDAR41. The FWRI data were based on a fishery-independent hooked gear survey (n=1,305), with 696 females that had gonadal development assessed histologically. Although the Lowerre-Barbieri et al. (2015) study collected data from only the 2012 spawning season, it assesses a range of factors affecting reproductive resilience, including the distribution of spawning activity over space and time and if larger, older females exhibit differences in: spawning habitat, reproductive timing, batch fecundity, or egg quality. In SEDAR41, the data from MARMAP/SERFS and FWRI were combined, for a total of 3,917 specimens with reproductive data. All age-related results presented in this section were based on calendar age and maximum (pinched tail) total length. Information below on sexual maturity, sex ratio, spawning seasonality, spawning fraction, and spawning frequency are based on histology, the most accurate technique utilized to assess reproductive condition in fishes.

2.8.2 Spawning Seasonality

Based on the presence of females with spawning indicators (i.e., the occurrence of hydrated oocytes and/or postovulatory follicles) spawning along the Atlantic coast of the southeastern U.S. generally occurs from April through October and peaks during June through August (Figure 2.9). Off the east coast of Florida, spawning indicators occurred from 4 April to 20 September 2012 and the proportion of females with spawning indicators peaked in June (Lowerre-Barbieri et al. 2015). These results are generally similar to those reported in previous assessments (SEDAR24-RD01, Brown-Peterson et al. 2009). During the period April – October, the dataset analyzed for the assessment revealed the occurrence of spawning as early as April 4th (northern Florida) and as late as October (27th) off South Carolina. In addition, specimens with spawning indicators were noted in 2000 (Ft. Pierce, FL: Nov. 13 & 16, n=2; Dec. 15, n=1. Carolinas: Jan. 3, n=1). Spawning females were captured at inner-shelf to shelf-break depths (15-74 m) from St. Lucie Inlet (FL) to the north side of Cape Lookout (NC; Figures 2.10 & 2.11). In the previous assessment, spawning depth was described as mid-shelf to shelf-break (23-72 m) and the latitudinal range was narrower, from Cape Fear, NC, to Melbourne, FL (SEDAR24-RD01).

Recommendation

The LHWG recommends using a spawning season for Red Snapper of April – September.

2.8.3 Sexual Maturity

The LHWG evaluated maturity data to determine if there has been a temporal shift in age at maturity. SERFS data were divided into two periods, the early period (1980-2000) representing SERFS data from a published study of Red Snapper life history (White and Palmer 2004) and the recent period representing data collected by SERFS during 2001-2013 (SEDAR41-DW35) and FWRI data. Note that fishery independent sampling efforts have changed over time with sampling in earlier years (MARMAP) being more concentrated off South Carolina and Georgia, while in more recent years a large number of sampling stations was added off North Carolina, Florida, and Georgia. Probit analysis using the logistic model (proportion mature = 1 - 1/(1 + exp(a+b*age)) showed that female age at 50% maturity (A50) declined from 2.0 yr (95% CI = 1.6-2.2) in the early period to 1.3 yr (95% CI = 1.1-1.5) in the recent period (Table 2.11). However, a plot of the capture location of Ages 1-3 females revealed that specimens were captured primarily off South Carolina and Georgia in the early period versus being caught primarily off Florida in the recent period (Figure 2.12). Given the lack of comparable historic and current samples to confirm changes over time one maturity curve was estimated based on all specimens, including those collected in 2014. The estimate of female A50 was 1.3 yr (95% CI = 1.0-1.4). Mature gonads were present in 38% of females at Age 1, 81% at Age 2, 93% at Age 3, 96% at Age 4, and 100% at Ages > 4 (Table 2.12). The length at 50% maturity (L50) for female Red Snapper from 1979-2000 and 2001-2013 was 381 mm TL (Gompertz, [prop. mature = 1 - exp(-exp(a+b*age))], 95% CI = 366-392) and 328 mm TL (Logistic, 95% CI = 273-356; Table 2.13), respectively. The overall estimate of L50 for females, based on data from 1979-2014, was 325 mm TL (Logistic, 95% CI = 317-331 mm). However, Lowerre-Barbieri et al. (2015) showed Red Snapper are maturing earlier than expected based on Beverton-Holt life history invariants and also earlier than the mean age at maturity for lutjanids (3.5 yr), even though the red snapper potential reproductive lifespan is considerably longer (45 to 49 yr) than the mean for lutjanids (11.7 yr; Martinez-Andrade 2003).

Age at maturity in male Red Snapper was assessed with SERFS data alone. Mature gonads were present in 94% of males at Age 1, 98% at Age 2, 99% at Age 3, and 100% at Ages > 3 (Table 2.14). The logistic model could not be fit to the data to produce a reliable estimate of A50 (i.e., value was negative). Data from 1979-2014 were used to estimate that the L50 for males was 166 mm TL (Logistic, 95% CI = 95-205 mm; Table 2.15).

Recommendation

Given the differing spatial distribution of the specimens between periods, the LHWG recommend use of one maturity curve, based on all specimens, for the assessment. The estimate of female A50 was 1.3 yr (95%CI = 1.0-1.4).

2.8.4 Sex Ratio

Only the SERFS data were used for this and the analyses indicated that there are differences from a 1:1 sex ratio for Red Snapper among certain age and size classes (Table 2.16). In general, males were more common at sizes less than 400 mm TL and Ages < 3 and females were more common at sizes greater than 600 mm TL and Ages >10. The overall sex ratio for all Red Snapper assigned an age, including data from 2014, was not significantly different from the expected 1:1 (n=2,845, Chi-Square=0.84, DF=1, P=36); restricting the analysis to Chevron trap data from 1990-2013 yielded the same result (n=1276, Chi-Square=0.614, DF=1, P=0.43). A length-based (mm TL) analysis of data from 1979-2013 yielded the same 1:1 ratio (n=2196, Chi-Square=0.117, DF=1, P=0.73).

Recommendation

Use a population sex ratio of 1:1 (female : male), since there was no statistical difference in the sex ratio. However, it was noted that the sex ratio varies with calendar age.

2.8.5 Fecundity and Spawning Frequency

Batch Fecundity (BF)

In SEDAR24, a proxy relating gonad weight to whole fish weight was chosen to estimate fecundity because the one estimate of batch fecundity available for Atlantic coast Red Snapper (Brown-Peterson et al. 2009) was based on 12 specimens of a limited size range (560-937 mm TL) captured from a limited geographic area (St. Augustine to Melbourne). An estimate of fecundity at age from the GoM was also considered, but this equation was not as predictive as an estimate of fecundity at length (see Woods 2003; SEDAR7-DW-35) because batch fecundity reached an asymptote at an age of approximately 10-12 yr. In a recent study along the Atlantic coast of Florida by Lowerre-Barbieri et al. (2015), batch fecundity was estimated in 44 specimens ranging in size from 391-846 mm TL. These data were combined with an additional 25 batch fecundities from SERFS, and the combined data set showed larger females produced significantly more eggs per batch than smaller females (Figure 2.13). Batch fecundities ranged from 14 - 4,200 (x 10^3) eggs per female, and significantly increased with TL ($BF=3.012 \times 10^{-8} TL^{4.775}$, 375-862 mm TL, n=69; see SEDAR41-DW49).

Spawning fraction, spawning interval, and spawning frequency

Because the terminology associated with spawning frequency can be confusing, we define them here. Spawning fraction measures the proportion of mature females spawning daily (Hunter and Macewicz 1985; Murua et al. 2003). Spawning interval refers to the time period between spawning events and at the population level is estimated as the reciprocal of the spawning fraction. Spawning frequency refers to the number of spawning events within a spawning season and is traditionally calculated by dividing the number of days within this spawning season by the spawning interval. These definitions follow Lowerre-Barbieri et al. 2011.

To evaluate the level of reproductive activity in the population over the spawning season, an analysis was run using SERFS data to calculate the proportion of spawners among all adult females (active + inactive) in preparation for the SEDAR41 Data Workshop in August 2014. The results showed that the proportion of female Red Snapper with at least one indicator of imminent spawning (migratory nucleus or hydrated oocytes(HO)) or recent spawning (postovulatory complexes, POCs) is consistently around 0.5, as the proportion ranged from 0.41 to 0.54 during June through September, which includes the peak of spawning. These spawning indicators as a group have an estimated duration of 34 hr (SEDAR31-DW07), thus proportionally reducing the range of values to a 24-hr period resulted in a spawning fraction of 0.29 to 0.38. Using traditional methods to assess spawning interval, these proportions correspond to one spawn approximately every 3 days or 70 spawning events in a 210 day (April-October) spawning season. An age-based analysis revealed that there is minimal variation in spawning frequency from Age 2 through Age 38, with no evidence of a clear increasing or decreasing trend (Table 2.10).

Lowerre-Barbieri et al. (2015) using hook-and-line sampling showed slightly higher spawning activity, with an overall spawning fraction of 0.33 for the HO method and 0.18 based on day 1 post-ovulatory follicles (POFs). Using traditional methods to assess spawning interval, these proportions correspond to one spawn approximately every 3 days (HO) or once every 5.7 d (POFs). Based on the proportion of spawning capable females with spawning indicators (i.e., undergoing hydration or with signs of recent spawning), spawning activity was not evenly distributed throughout the spawning season, exhibiting a clear maximum in June. Although the temporal pattern of spawning activity with size was not statistically significant, large fish (≥ 700 mm TL) demonstrated a more even distribution of spawning activity over the months of May (0.64), June (0.75), and July (0.63) than smaller fish .

Spawning frequency by size

Since Red Snapper exhibit indeterminate fecundity, the number of eggs produced per female per year (i.e. annual fecundity) is calculated as the product of batch fecundity (described above) and spawning frequency (the number of batches produced per female per year). Spawning frequency is typically estimated by multiplying the estimated spawning duration by the spawning rate, known as spawning fraction (Murua et al. 2003). This method is analogous to calculating a definite integral (i.e. calculus); essentially, determining the area under a function over an interval. In this case, the function is a horizontal line with a y-intercept equal to the overall spawning fraction, and the interval is the estimated duration of the spawning season, which often increases in batch spawners with size and age (Fitzhugh et al. 2012; Cooper et al. 2013), and was shown to do so in Red Snapper (Lowerre-Barbieri et al. 2015). Since the function is linear, the calculation is simple and it is not usually thought of as a definite integral, though it is. In SEDAR41-DW49, Klibansky fit a more complex, four-parameter plateau-shaped function to the 1979-2014 SERFS (=SCDNR) data. Since the curve is symmetrical and asymptotically approaches the x-axis early and late in the year, the area under this curve can be calculated over the entire year, to estimate spawning frequency. Since spawning fraction has been shown to increase with size or age in multiple species the plateau function was extended by replacing the mean spawning period duration parameter d with a linear function of total length, such that $d = d_0$ -+ d_1TL. Both the basic plateau model and the size-dependent plateau model were separately fit to the data, and the fits of the models compared with Akaike's Information Criterion (AIC). The size-dependent model produced a much stronger fit than the basic model, improving AIC by 42.5 (note that improvements >10 are considered strong; Bolker 2008) and was therefore accepted as the preferred model. The estimate of the slope parameter d_1 was positive (0.42) suggesting an increase in spawning period duration of 4.2 days for every 10 mm of TL. Taking the integral of this model at a particular TL provides an approximation of spawning frequency, which are provided in (SEDAR41-DW49).

Recommendation

The LHWG recommended using the equation, generated from the combined FWRI and SCDNR data, relating total length to batch fecundity, and the relationship between spawning frequency and TL presented in SEDAR41-DW49. Utilizing the total egg production (TEP) method of estimating stock reproductive potential, the equation is:
TEP = proportion female x proportion mature x batch fecundity x spawning frequency. The age-specific estimates of spawning frequency are given in SEDAR41-DW49.

2.9 Movements and Migrations

Since the 2014 DW review of the available literature, no new information became available and the 2014 LHWG recommendations did not change. Red snapper show great site fidelity as adults, which may result in slower replenishment of areas subject to local depletion (Johnson 2013). However, there is increased movement during tropical storms, which may explain reappearance of Red Snapper in formerly depleted areas, in spite of their sedentary nature (Cowan 2011).

Red Snapper undertake short-term movements associated with daily feeding excursions and spawning activities during summer. Adults prefer deeper waters and more complex habitats, so there are apparently ontogenetic movements as well. Red Snapper juveniles are attracted to structure and the dimension and complexity of their habitat increases with fish size (Patterson 2007; Diamond *et al.* 2010). In the South Atlantic, more complex (higher relief; mixture of bottom types) habitats are found in deeper mid-shelf and shelf-edge reefs. This may result in larger fish moving further offshore into more complex reefs as they grow. It should be noted, however, that there was no discernible difference in the distribution of fish by size or age over different depths in the South Atlantic (SEDAR 24).

There have been several tagging studies of Red Snapper, particularly on artificial structures in the GoM, and some recent large efforts in the Atlantic off of Florida. The results confirm long-term site fidelity (months to years), punctuated by very short feeding and spawning excursions.

Addis *et al.* (2013) found that, in spite of previous reports of relative immobility of Red Snapper, they showed the greatest movement among 12 reef fish species tagged on artificial reef sites in the GoM. Mean distance moved among recaptures (173 of 2114 tagged) was 37.1 km (20 nautical miles). During the study, a hurricane passed over the study area, thus adding an unplanned factor to movement analyses. Fish size, reef depth, days at large, and hurricane exposure significantly affected the likelihood of Red Snapper movement, but only fish size significantly affected distance moved (Addis *et al.* 2013).

In another study on artificial reefs in the Gulf, Red Snapper stayed near the artificial reefs (<100 m movement, with 75% of movements within 30 m of the structure), but were significantly farther from the reefs at night (mean = 27.5 m, SD = 7.1) than day (mean = 19.1 m, SD = 8.2). Home range and mean distance from the reef increased with fish size. These fish also showed long-term residence of 332–958 d based on passive acoustic monitoring (Topping and Szedlmayer 2011a).

Tagging data from a number of artificial-reef studies in the GoM demonstrate that, while a substantial percentage of tagged fish were recaptured near their release sites, movement on the scale of hundreds of km also occurs. Because of occasional longer movements, there is sufficient mixing to promote genetic exchange within regions, but overall movement is likely insufficient to affect population demographic differences observed among regions (Patterson 2007).

On natural reefs in the Gulf, Beaumariage (1969) found that 90% of recaptured Red Snapper (of 1,126 tagged) were caught within 5 km of their release site. With very rare exception, there is no reported movement of Red Snapper between the Gulf and South Atlantic (Burns *et al.* 2004). In the Red Snapper largest tagging study, Burns *et al.* (2004) tagged and released 5,272 Red Snapper in the GoM (from Naples, FL, to the eastern border of Texas) and Atlantic (from Cape Canaveral, FL, to Georgia) over a 13-yr period. Approximately 40% of these fish were tagged in the Atlantic. Forty-four percent of the specimens were recaptured within 1.9 km of the tagging site. Less than 10 of the 410 recapture events showed movement >100 miles and movement between the GoM and the Atlantic coast is not mentioned in the report. In a later study, Burns *et al.* (2008) reported 529 Gulf and Atlantic Red Snapper recaptures. Approximately 28.7% were recaptured within 3 km, 15.1% were recaptured within 10 km, and only 3.8% were recaptured more than 50 km of the original tag site. In general, recaptures indicated north/south movement on the Atlantic coast and east and southeast movement (from the Panhandle) in the GoM. A single Red Snapper tagged in the Florida panhandle (during a previous study) was recaptured on the Atlantic coast of Florida.

The results of two smaller studies also indicate minimal movement in Atlantic Red Snapper. The SC Marine Gamefish Tagging Program reported 1,597 Red Snapper tagged with 171 recaptures. Ninety-three percent were recaptured within 2 km of the tagging site. SCDNR (MARMAP) data included 45 tagged Red Snapper with two recaptures, one of which was recaptured in the same vicinity as tagged. The other recapture had no location data.

In a large recent study in the South Atlantic, Brodie *et al.* (2013) tagged 3,441 Red Snapper and reported 211 recaptures (6.1%). Days at large ranged from 0 to 887, and distance traveled ranged from 0 to 237 km (128 nautical miles). Eight fish were recaptured twice and one fish was recaptured three times. The majority of recaptured fish with confirmed location information were caught <1 km from where they were initially tagged, indicating high site fidelity.

Two Red Snapper successfully tagged with acoustic tags at Gray's Reef National Marine Sanctuary (~20 m depth off Sapelo Island GA) were very active on a small spatial scale, appearing on multiple receivers within the 12.6 ha (31 acre) area of the receiver array (Carroll 2010). They exhibited high short-term (several months) site fidelity. One Red Snapper was present 112 d (out of 340 d at large) at the site where it was released and the other was present 580 d (out of 730 d at large) at a site near where it was released. Both individuals were detected on multiple receivers around the array, but returned to a single receiver site on a daily basis. Detections of both Red Snapper were low to absent during the spawning season (May to October), indicating that Red Snapper may move to aggregation sites or into deeper water to spawn, but return to a home territory.

In a larger acoustic tagging study on artificial reefs in the GoM, Topping and Szedlmayer (2011b) found a median residence time of 542 d, ranging from 1 to 1099 d, with 72% of fish staying at least 1 yr at the site. Some fish (n = 12) showed seasonal and directed movements to other sites (up to 8 km away) and returned to original sites up to 7 months later. Diel movements away from the structure tended to occur at night, similar to the pattern seen at Gray's Reef off Georgia. Site fidelity and residence times of Red Snapper found by Topping and Szedlmayer (2011b) were greater than in any previous study, but similar to those found by Carroll (2010).

Recommendation

Available data and the results of studies in the GoM indicate high site fidelity, but that tropical storms may cause greater than normal movement that might help dispersal to depleted areas. This needs to be confirmed in the South Atlantic. More research on Red Snapper movements and migrations in Atlantic waters is needed. Additional acoustic and traditional tagging is needed on known spawning locations to document spawning migrations or aggregations, and return of fish to non-spawning areas.

2.10 Meristic Conversion Factors

Due the large data set, the addition of the 2014 was unlikely to change the conversion factors and the SEDAR41 panel recommended to use the conversions presented at the 2014 DW (Tables 2.17 and 2.18). Data for the length-length, whole weight – gutted weight, and whole weight (g) – length (mm) regressions were pulled from the Southeast Region Headboat Survey (Atlantic portion only), Southeast fishery-independent survey (SCDNR MARMAP and SEFIS), MRIP and Florida FWRI. Maximum total length was agreed upon to be the length type used in the assessment. Linear regressions were run to convert natural total length (TL_{nat}), fork length (FL) and standard length (SL) to maximum total length (TL_{max}, Table 2.17). A no intercept regression was run to convert gutted weight to whole weight. Natural log (Ln) transformed whole weight and length regressions were run for all four length types (Table 2.18). The regression equations were then converted to power equations which included ½ mean squared error (MSE) to account for the transformation bias. Regression parameters are included in Tables 2.17 and 2.18, and Figures 2.14 and 2.15 to illustrate the scatter plot of data points with obvious outliers excluded. Each data source was reviewed before final inclusion in the regression analyses. Outliers were identified and removed from the data set used for meristic conversions. For the whole weight – gutted weight regression, only data from the fishery-independent source were used. Data provided by Florida FWRI was found to not be reliable and removed at the recommendation of the data provider.

2.11 Sample Sizes Available for Analyses

An overview of the available sample sizes and trips by year and state for the various analyses used by the LHWG is provided in Tables 2.19 - 2.26.

2.12 Recommendations for Alternative Parameters Estimates and Comparison of Recommended Parameter Choices between South Atlantic and Gulf of Mexico

Note that alternative parameters estimates and approached recommended by the LHWG are listed under the various chapters discussing the analyses and parameter choices.

An overview of a comparison of parameter choices recommended by the SEDAR 41 LH WG and those used in previous GoM assessments for Red Snapper are given in Table 2.27. As the parameter choice is not always straight forward, the LH WG recommends reviewing the appropriate section of the stock assessment reports for details on the parameter choices.

2.13 Itemized List of Tasks for Completion Following Workshop

- Updating the Life History Working Group report section.
- Completing comparison of parameters and approaches between the South Atlantic and Gulf of Mexico.

2.15 Tables

Table 2.1

Age-varying mortality estimates for Red Snapper. The recommended estimate, Charnov et al. (2013) scaled from the age at full recruitment (4+) to the point estimator obtained using the Then et al. (2015) method, is highlighted. Lower and upper represent 95% confidence intervals of natural mortality calculated from inter-reader variation for age estimates of the oldest observed fish.

Age	Charnov	Scaled Charnov	Lower	Upper

Table 2.2

Discard mortality rates used in SEDARs for Red Snapper.

	GoM			South Atlantic			
	SEDAR 7	SEDAR31		SEDAR 15	SEDAR 24	SEDAR 41	
Sector		Pre-Regulation	Post-Regulation			Pre-Regulation	Post-Regulation
Recreational	15-40%	21-22%	10-11%	40%	39-41%	37%	28.5%
Commercial	71-88%	74-87%	55-74%	90%	48%	48%	38%

Table 2.3

Estimate of discard mortality for South Atlantic Red Snapper using a depth model (Burn et al. 2002) and a tag/return model (Sauls et al. 2014). The estimated regulation reduction was applied to the depth model to compare pre- and post-regulation estimates of discard mortality. The reduction was derived from the SEDAR 31 model and estimated using the function in Figure 2.4.

Fleet	Burns et al. 2002	Estimated Regulation Reduction	Sauls et al. 2014 DW 33
Charter	36%	28%	26.7%
Headboat	31%	23%	28.5%
Recreational	35%	27%	N/A
Commercial	48%	38%	N/A

Table 2.4

Number of commercial trips intercepted and number of individual age samples between brackets of Red Snapper landed in the commercial fishery from North Carolina through the east coast of Florida, including the Keys.

Table 2.6

Red Snapper age samples collected by NCDMF during the 2012 - 2014 mini-seasons. All samples were from donated carcasses and considered non-random.

Mode	2012	2013	2014
Charter Boat	5	2	35
Headboat	43		79
Private	2	2	15
Unknown Fishery	2		62

Table 2.7

Red Snapper age samples collected by SCDNR during the 2012 - 2014 mini-seasons. All samples were considered non-randomly collected.

Mode	2012	2013	2014
Charter Boat		2	
Headboat	6	11	40
Private	37	31	33
Unknown Fishery			34

Table 2.8

Red Snapper age samples collected by GADNR and FWRI during the 2012 and 2013 mini-seasons. (Note: data were combined due to confidentiality of data.) Samples were collected by a combination of intercepted trips and carcass donations. “No” indicates donated fish/carcasses that were considered non-randomly collected and not used to characterize age structure of the landings. “Yes” indicates samples collected by state agency personnel who intercepted trips and followed random sample design, but may have collected samples outside of regular MRIP, Headboat, or commercial TIP surveys.

	2012		2013		2014	
Mode	No	Yes	No	Yes	No	Yes
Carcass Program	23		34		94

Table 2.9

Summary of von Bertalanffy growth model parameters for the population and fishery-dependent data.

Source	N	Linf	StDev	K	StDev	t_0	StDev
Population	27,696	911.36	2.1189	0.24	0.00187	-0.33	0.0155
Fishery-Dependent	23,472	901.72	2.1531	0.24	0.00205	-0.65	0.0191

Table 2.10

The proportion of Red Snapper spawners (# female spawners/# adult females) by increment group in SERFS histological data from April through September of 1978-2014, including all projects, and gears. A spawner had one or more indicators of spawning, which have a combined duration of approximately 34 h (See SEDAR31-DW07). Spawning season duration represents the # of days between the first and last occurrence of spawners by age class. Cal. Age = calendar age, HO = hydrated oocytes, OM = oocyte maturation, POC = postovulatory complex.

Cal. Age (yr)	N	Prop. Spawners (OM, HO, POC; ~34 h)	Est. Spawning Season Duration (d)	# Batches/ind.fish by Age
1	34	0.12	1	0.1
2	230	0.55	138	53.6
3	295	0.42	152	45.1
4	166	0.34	167	40.1
5	158	0.43	158	48.0
6	99	0.41	164	47.5
7	81	0.46	118	38.3
8	51	0.41	133	38.5
9-11	30	0.37	83	21.7
12-14	19	0.47	72	23.9
15-38	17	0.47	121	39.9
2+	1146	0.42	131	38.7
Total	1180			

batches = (24 hr*Proportion Spawners/34 hr) x Spawning Season Duration

Table 2.11

Results of various regression model analyses for age and length at maturity for male & female Red Snapper, by period. Data from all sources (SERFS and FWRI) and gears were combined, with the exception of male length at maturity (SERFS data used only). Age is expressed in calendar age (Cal.Age) and length is maximum (pinched tail) total length in mm. n=number of fish used in analyses, A_{50}= age at which 50% of population has reached sexual maturity, L_{50}=length at which 50% of the population has reached sexual maturity.

						Parameter Estimate	
Analysis	Period	Model	n	A_{50}/L_{50}	95% CI	**Intercept (Std Err)**	**Cal.Age or MaxTL (Std Err)**

Table 2.17

Red Snapper length – length conversion equations and whole weight – gutted weight no intercept equation. TL_{max}: maximum Total Length (with "pinched" caudal fin), TL_{nat}: Natural Total Length (with caudal fin spread) FL: Fork length, SL: Standard length, WW: whole wet weight, GW: gutted wet weight. Range is length or weight range. **Linear regression: y=a*x+b.** Note that the assessment units will be Maximum Total Length (TL_{max}) in mm for length and pound for weight. See also Figures 2.17.

Variables	Units	a (SE)	b (SE)	n	R^2	Range of X
TL_{max} = TL_{nat}	mm	4.62 (1.16)	1.02 (0.00)	1,872	0.99	321 - 943
TL_{max} = FL	mm	2.22 (0.45)	1.07 (0.00)	4,691	0.997	64 - 955
TL_{max} = SL	mm	22.09 (0.83)	1.22 (0.00)	4,622	0.99	54 - 825
TL_{nat} = FL	mm	14.45 (1.32)	1.03 (0.00)	4,108	0.98	240 - 910
TL_{nat} = SL	mm	38.83 (2.06)	1.15 (0.00)	1,832	0.98	242 - 770
TL_{nat} = TL_{max}	mm	-0.54 (1.14)	0.97 (0.00)	1,872	0.99	324 - 970
FL = TL_{nat}	mm	-1.89 (1.29)	0.95 (0.00)	4,108	0.98	262 - 970
FL = SL	mm	19.36 (0.73)	1.14 (0.00)	4,559	0.99	54 - 825
FL = TL_{max}	mm	-0.58 (0.42)	0.93 (0.00)	4,691	0.997	70 - 997
SL = FL	mm	-12.98 (0.66)	0.87 (0.00)	4,559	0.99	64 - 955
SL = TL_{nat}	mm	-21.24 (1.86)	0.85 (0.00)	1,832	0.98	321 - 946
SL = Tl_{max}	mm	-13.44 (0.70)	0.81 (0.00)	4,622	0.99	70 - 997
WW = GW	g	no intercept	1.10 (0.00)	937	0.999	148 - 14,710

Table 2.18

Red Snapper Ln – Ln transformed whole weight (g)– length (mm) and the inverse of that regression converted to the power equation . TL_{max}: maximum Total Length (with "pinched" caudal fin), TL_{nat}: Natural Total Length (with caudal fin spread) FL: Fork length, SL: Standard length, W: whole wet weight. Range is length or weight range. Note that the assessment units will be Maximum Total Length (TL_{max}) in mm for length and pound for weight. See also Figure 2.18.

Variables	Units	a (SE)	b (SE)	MSE	n	R^2	Range of X	Converted Power Equation
W = TL_{max}	g, mm	-11.06 (0.04)	2.99 (0.01)	0.01	2,930	0.99	90 - 997	$W = 1.65*10^{-5} L^{2.99}$
W = TL_{nat}	g, mm	-11.17 (0.03)	3.01 (0.00)	0.02	13,565	0.97	197 - 1024	$W = 1.42*10^{-5} L^{3.01}$
W = FL	g, mm	-11.07 (0.04)	3.03 (0.01)	0.03	7,106	0.97	47 - 955	$W = 1.58*10^{-5} L^{3.03}$
W = SL	g, mm	-9.69 (0.05)	2.88 (0.01)	0.02	2,893	0.98	71 - 813	$W = 6.25*10^{-5} L^{2.88}$
TL_{max} = W	mm, g	3.73 (0.01)	0.33 (0.00)	0	2,936	0.98	12 - 15,850	$L = 41.89 W^{0.33}$
TL_{nat} = W	mm, g	3.78 (0.00)	0.32 (0.00)	0	13,565	0.97	80 - 18,000	$L = 43.82 W^{0.32}$
FL = W	mm, g	3.74 (0.01)	0.32 (0.00)	0	7,106	0.97	12 - 15,850	$L = 42.10 W^{0.32}$

Table 2.19

Number of trips (gear deployments) that collected Red Snapper, by gear type, and year, from Fishery Independent Surveys (MARMAP/SEAMAP-SA, and SEFIS) used by LHWG. Gear codes on the top row are SCDNR Marine Resources Research Institute (MRRI) gear codes: 000=unknown. 014= hook and line; 022=Yankee trawl; 041=mini Antillean s-trap- baited; 043=snapper/bandit reel, electric or manual; 053=blackfish trap; 065=spear gun; 071=flatline otter trawl; 073=experimental trap; 074=Florida Antillean trap; 233=75' Falcon Trawl without TED; 324=chevron trap.

2.16 Figures

Figure 2.1

Computer Generated Native Distribution Map for Red Snapper (*Lutjanus campechanus*) in red and modeled future range map based on IPCC A2 emissions scenario in yellow. www.aquamaps.org, version of Aug. 2013. Web. Accessed 5 Aug. 2014.

Figure 2.2

Discard mortality function by depth (m) for Red Snapper derived from Burns et al. (2002) and used in SEDAR 24. This is the preferred function to estimate the pre-regulation discard mortality for the commercial sector in SEDAR 41.

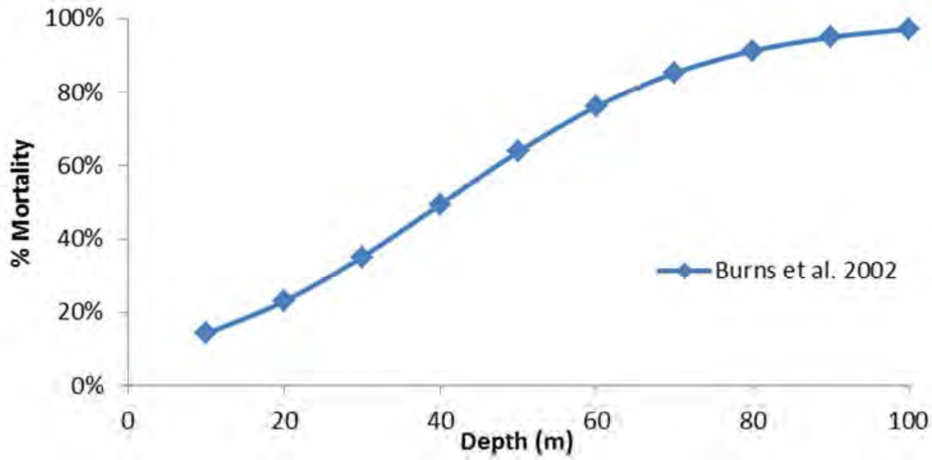

Figure 2.3

Proportion of total discards by depth of observed discards for Red Snapper in the charter boat and headboat fishery off Florida, observed discards for Red Snapper in commercial fishery in the South Atlantic, and reported depths fished during the Red Snapper mini-season off Florida.

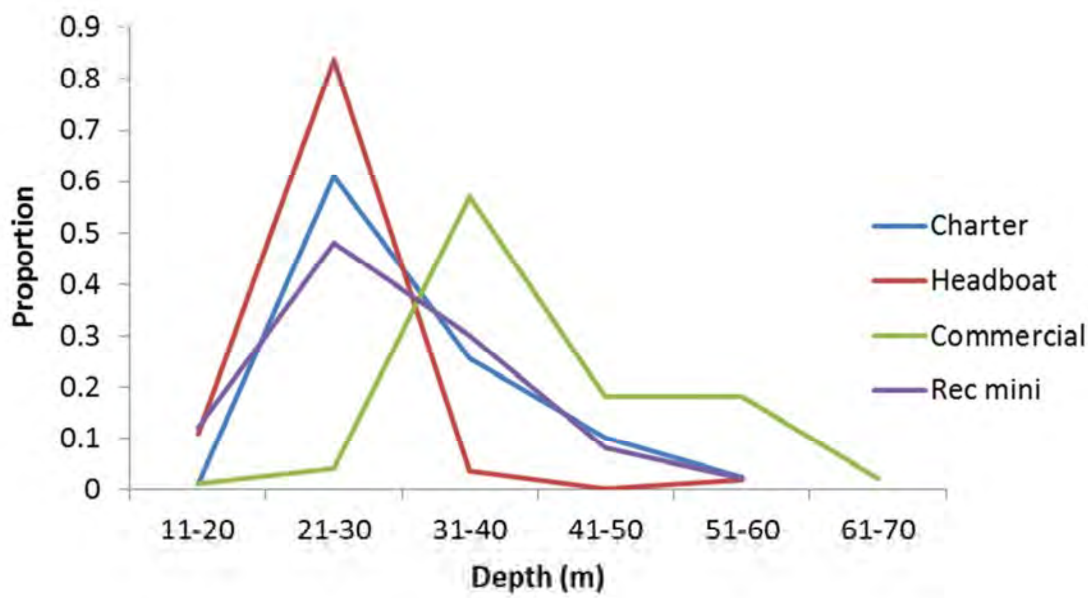

Figure 2.4

The percent of discard mortality associated with regulations plotted with total discard mortality based on data from SEDAR 31 for Red Snapper in the GoM. Linear regression analysis results are given in the legend.

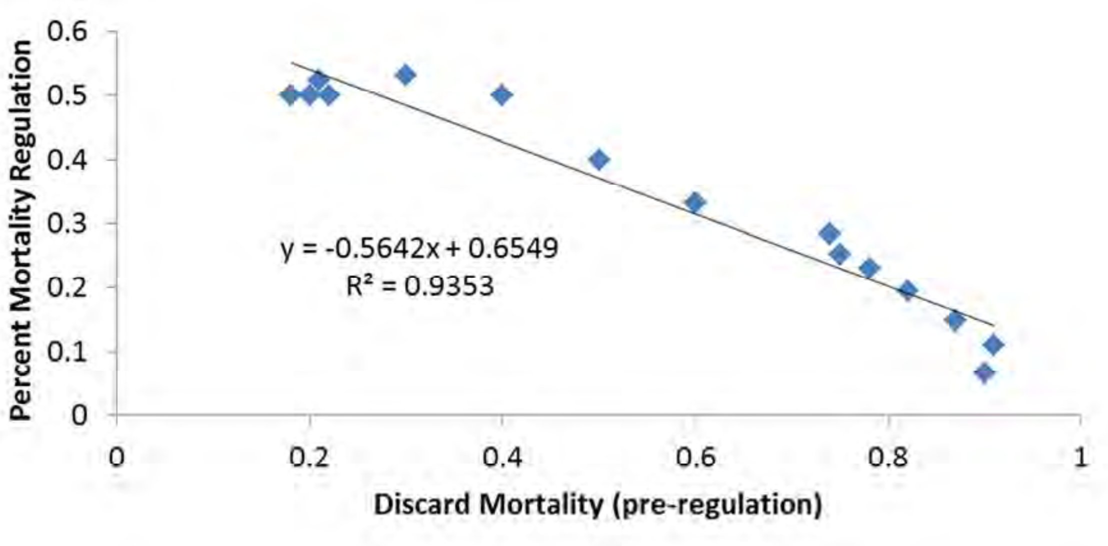

Figure 2.5

Between lab age reading bias plots of Red Snapper calibration set. Error bars represent 95% confidence intervals.

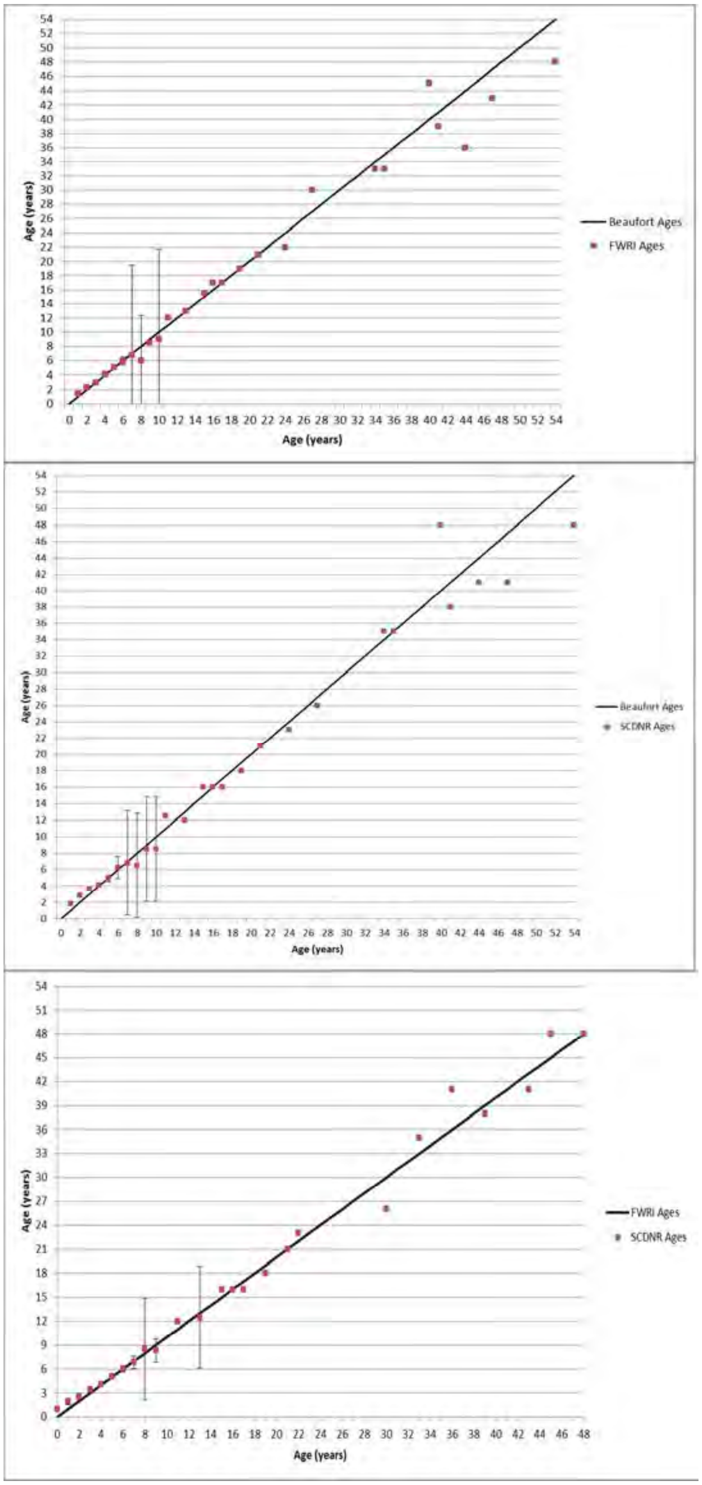

Figure 2.6

Population growth model of U.S. South Atlantic Red Snapper,

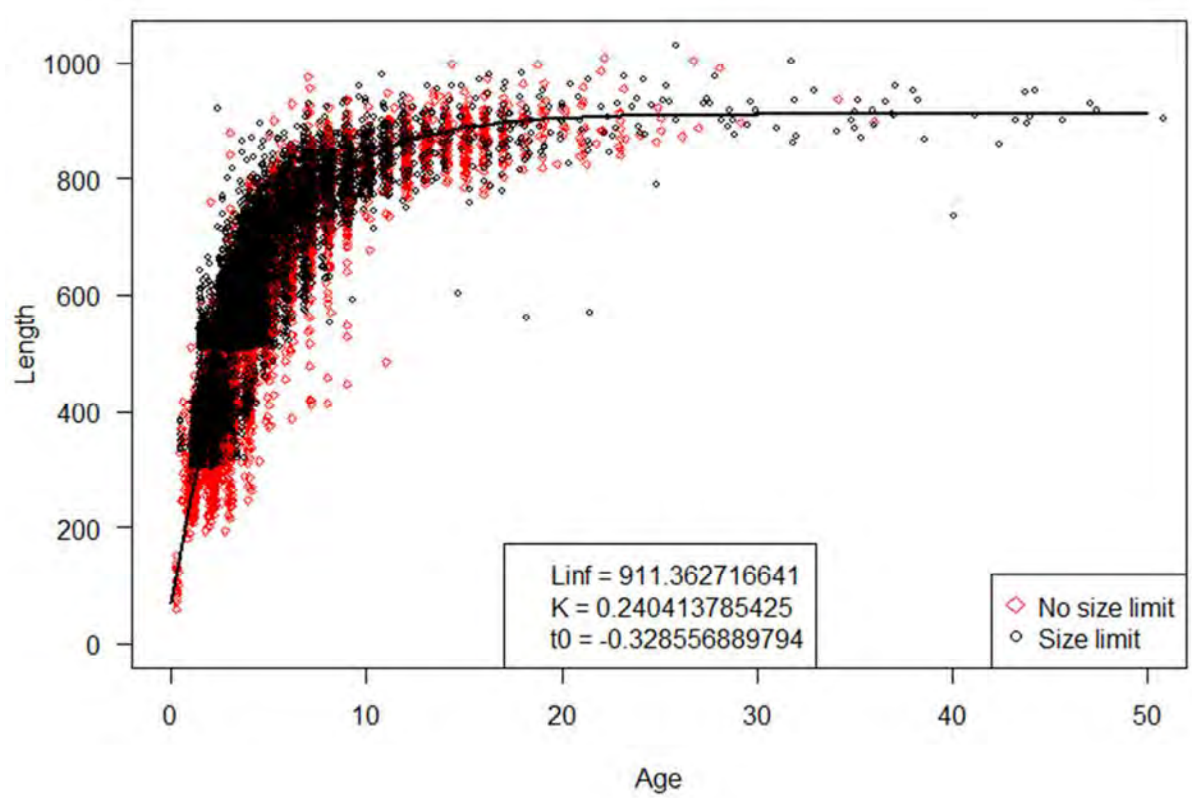

Figure 2.7

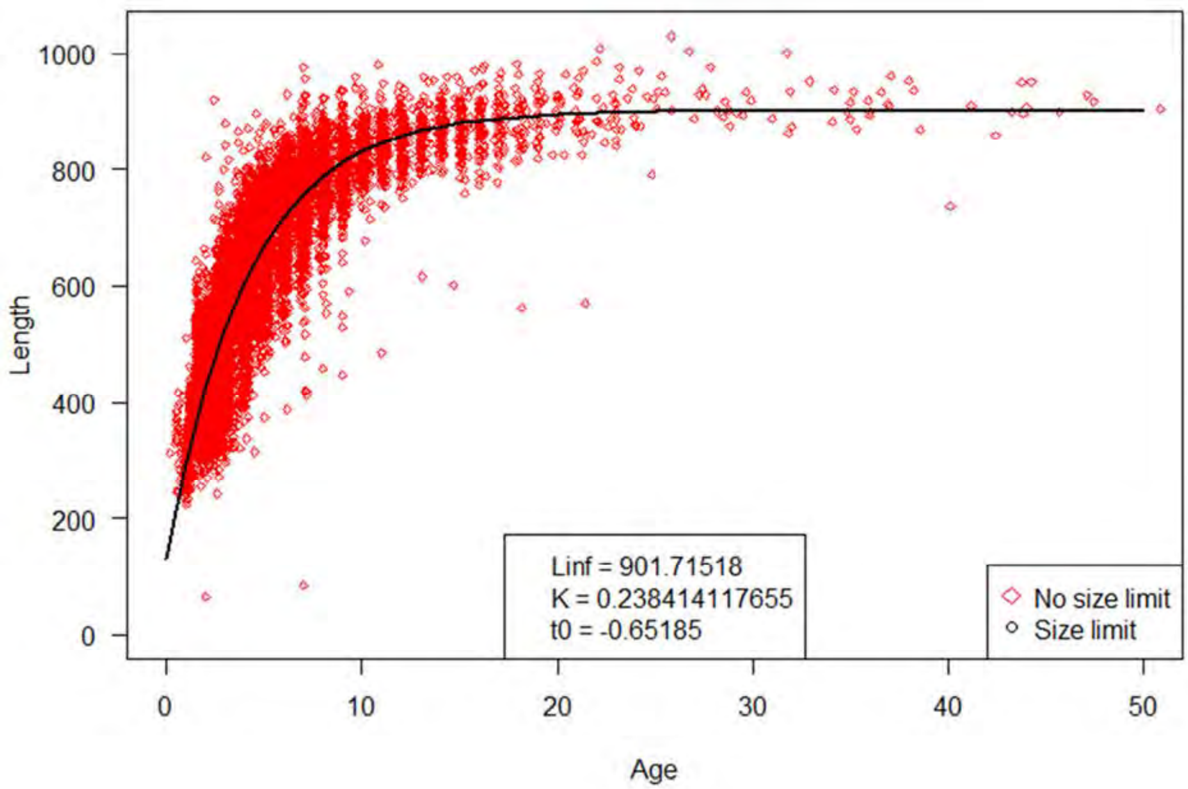
Fishery-dependent growth model of U.S. South Atlantic Red Snapper,



.

Figure 2.8

U.S. South Atlantic Red Snapper male and female maximum total length at age. Error bars represent 95% confidence intervals.

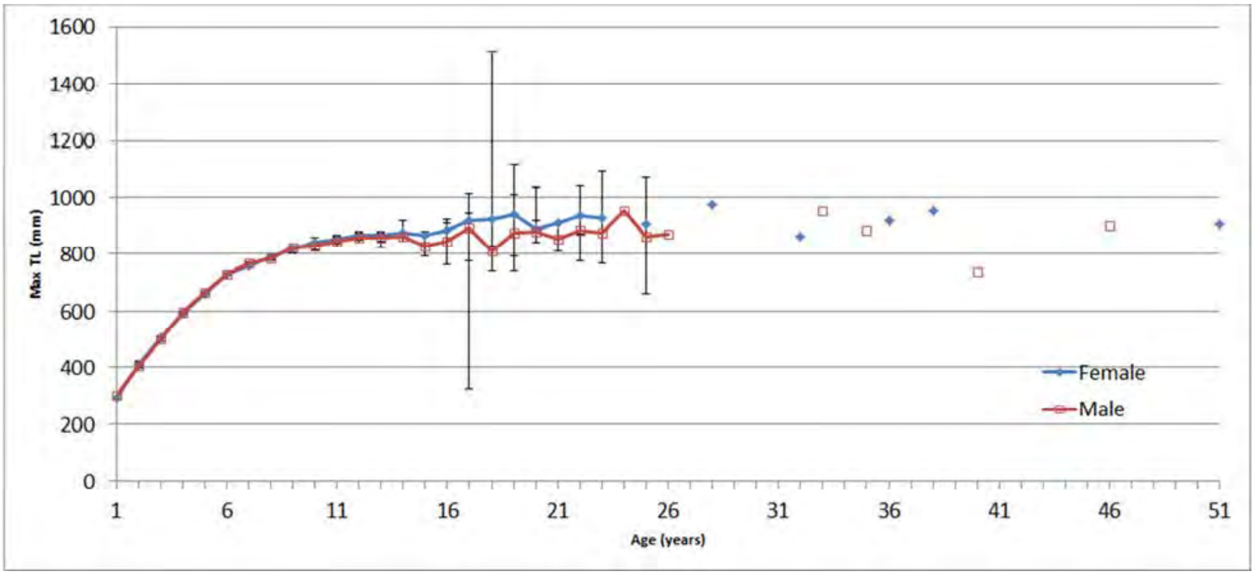


Figure 2.9

Female Red Snapper spawning seasonality, 1979-2013. Developing= Primary growth oocytes and cortical alveoli stage through partially yolked oocytes, Regenerating= Primary growth oocytes only, may have traces of late-stage atresia, Vitellogenic= mid- to late-vitellogenic oocytes present, Immature=Primary growth oocytes only, Regressing=More than 50% of vitellogenic oocytes undergoing alpha or beta atresia, Spawning= Completion of yolk coalescence & hydration and/or presence of POCs.

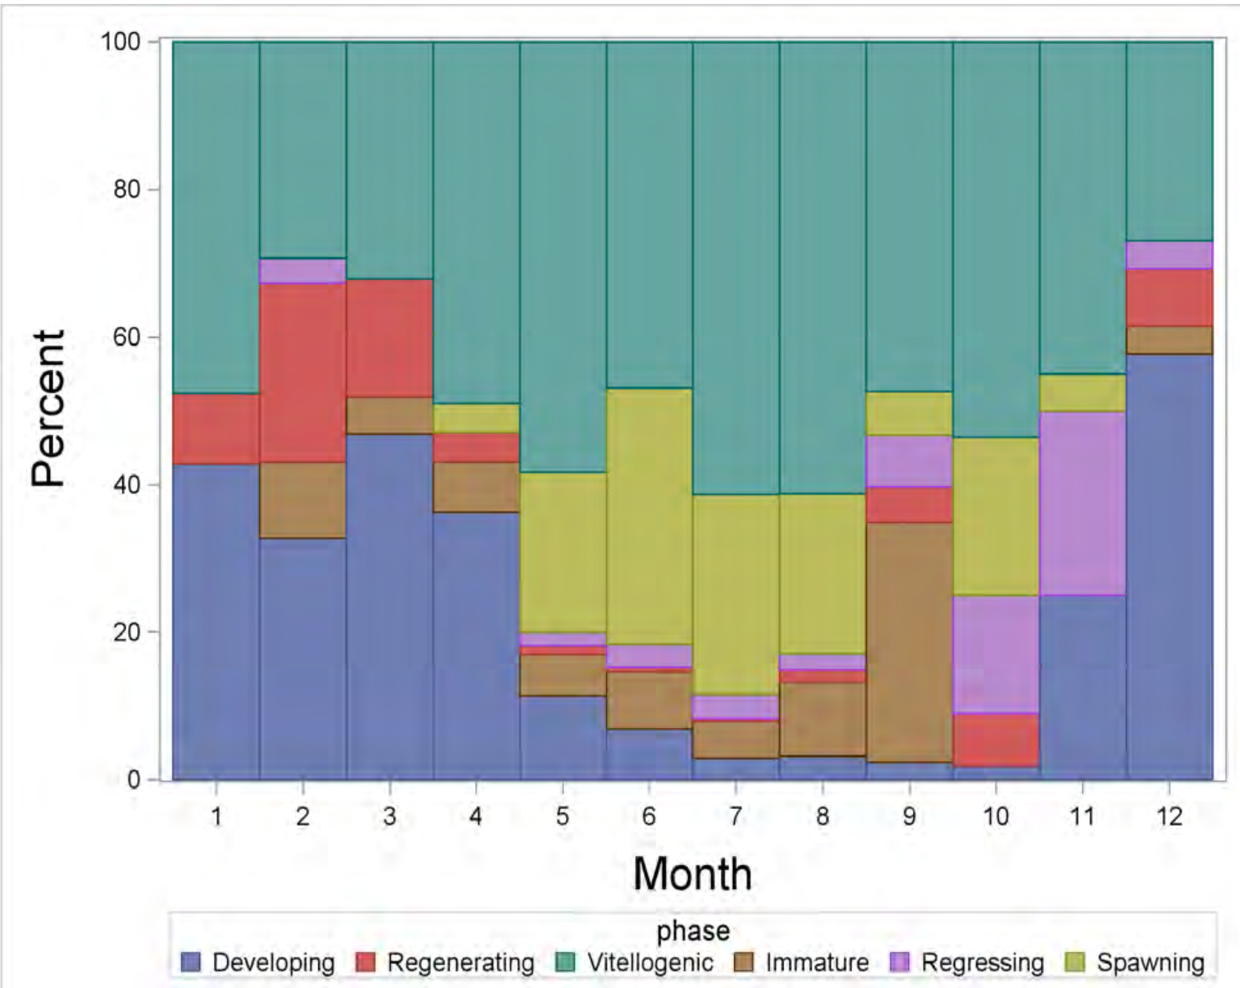

Figure 2.10

Locations where spawning female Red Snapper were collected by fishery-independent sources, 1977-2013.

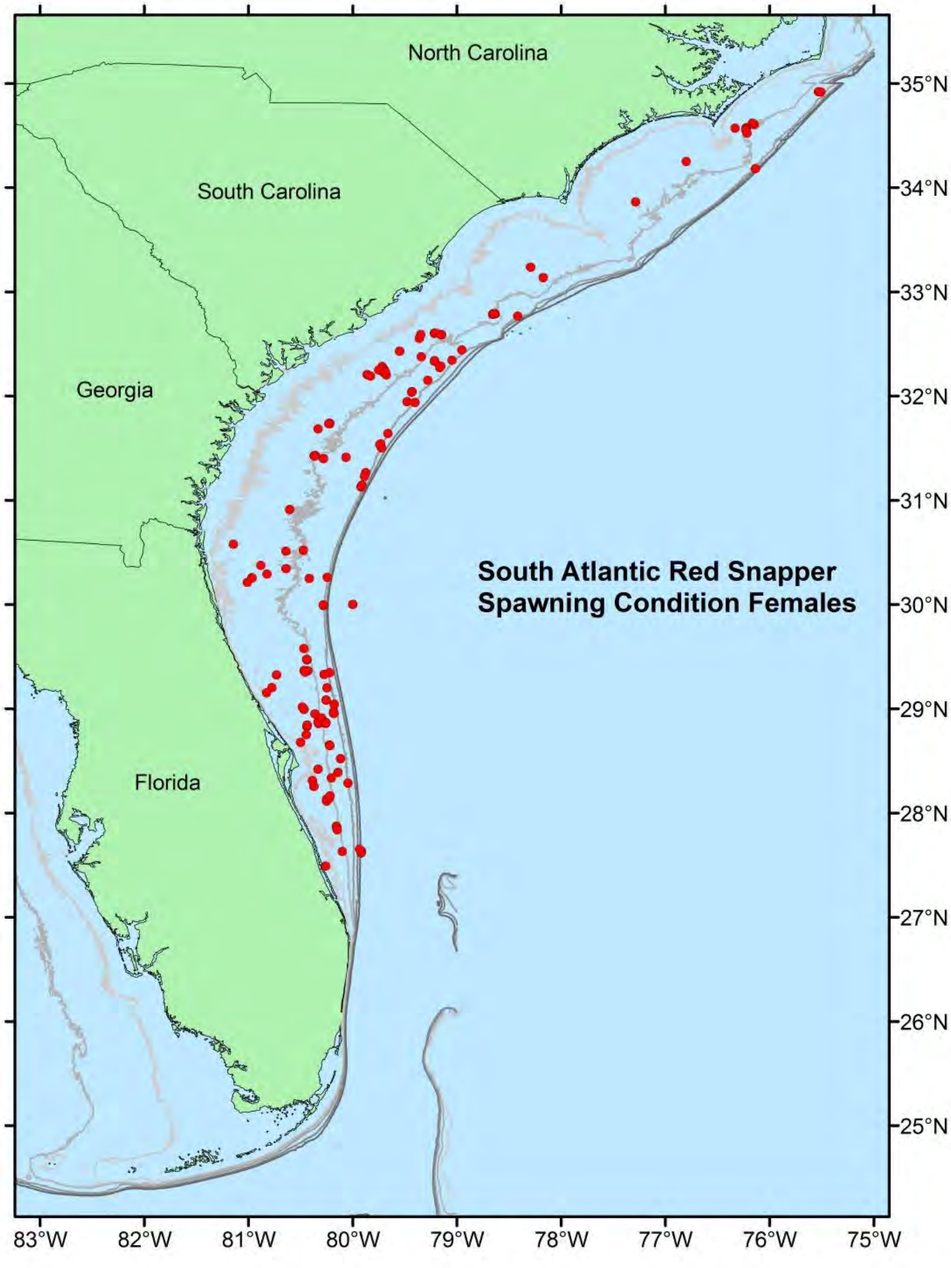

Figure 2.11

Locations where specimens of age 1 female Red Snapper were collected by fishery-independent sources, 1977-2013. Immature females collected 21-42 meters depth. Mature females collected 22-42 meters depth.

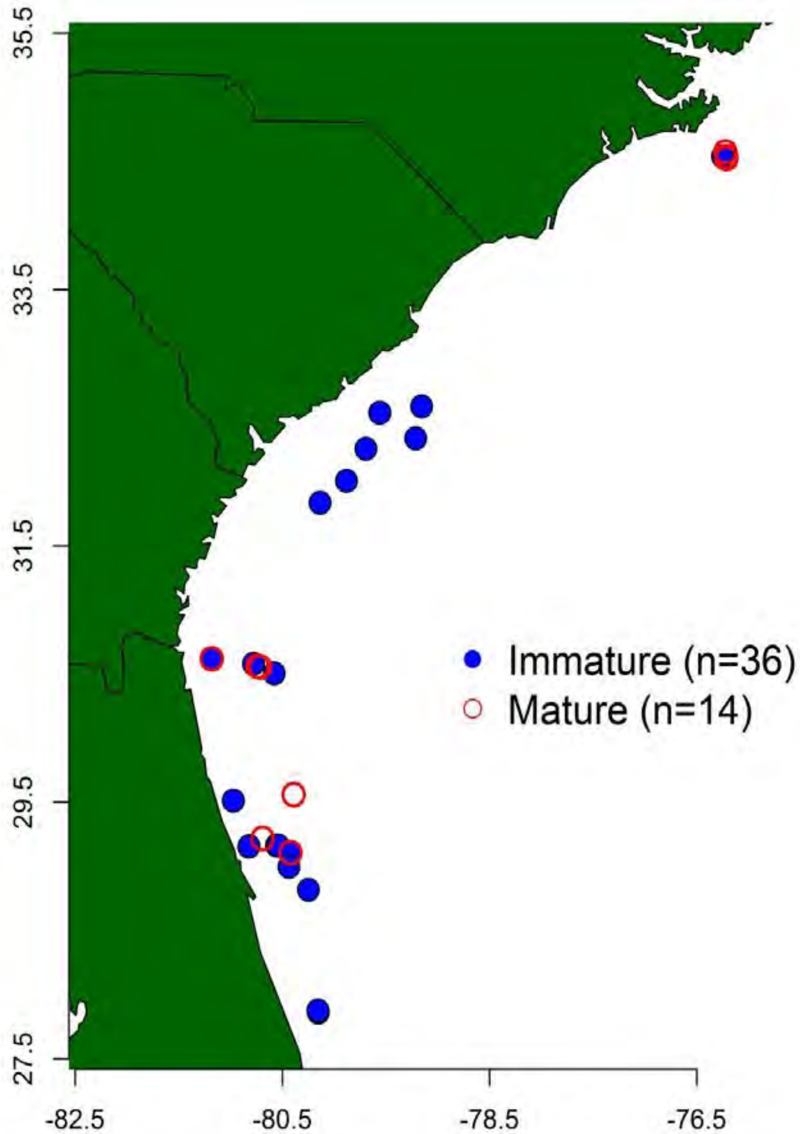

Figure 2.12

Locations where mature female Red Snapper, age 1-3, were collected by fishery-independent sources, by period.

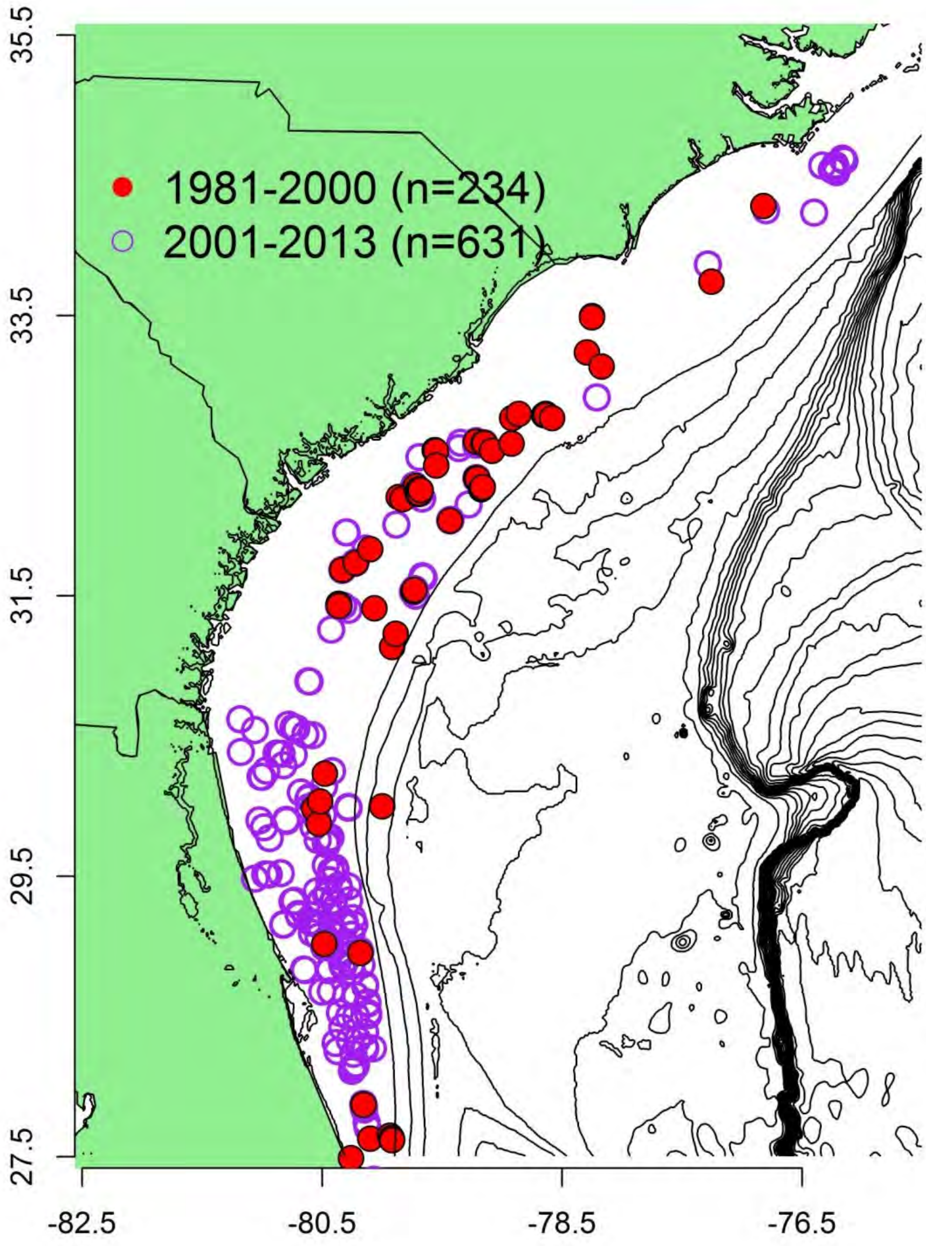

Figure 2.13

Scatterplot of Red Snapper batch fecundity estimates by max total length (TL; mm). Black points represent observed values, while lines indicated models fit by several methods. The solid blue line is a power model fit with negative binomial error (i.e. the recommended method) and the shaded area represents the 95% CI around that line. The dashed line represents a linear fit to log transformed TL and batch fecundity, while the dotted represents this same fit, incorporating a bias correction (Figure from SEDAR41-DW49).

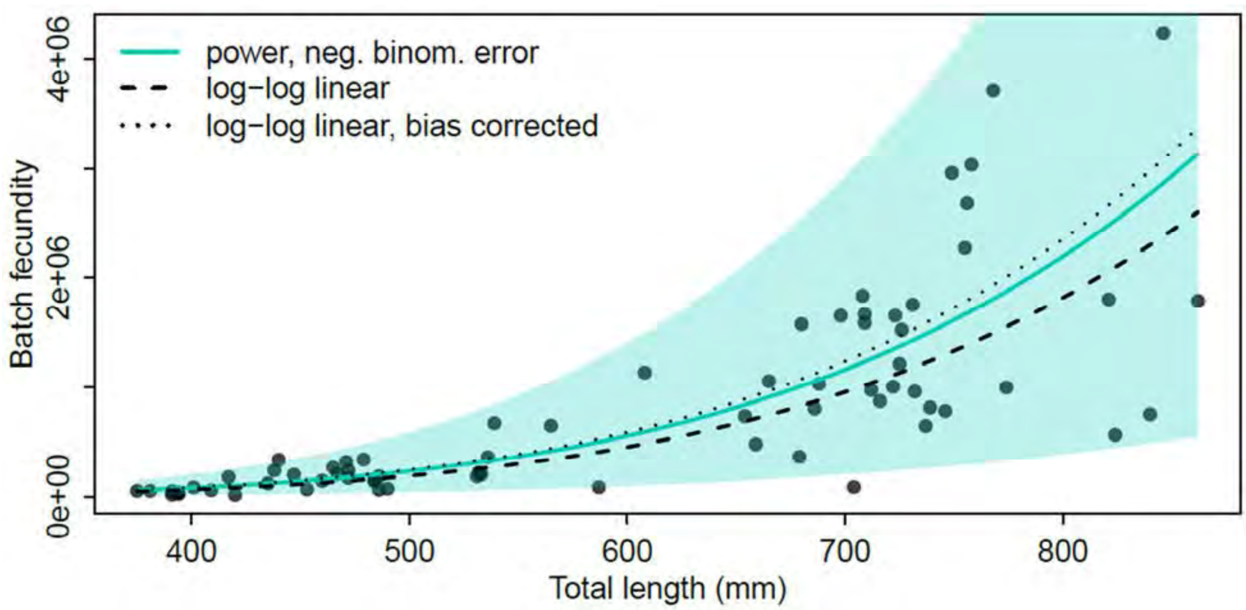

Figure 2.14

Red Snapper scatter plot of raw data used in conversion equations. The various plots represent the various length – length relationships. Data from a variety of fishery dependent and fishery independent sources were used. See Table 2.20 for equations and statistics.

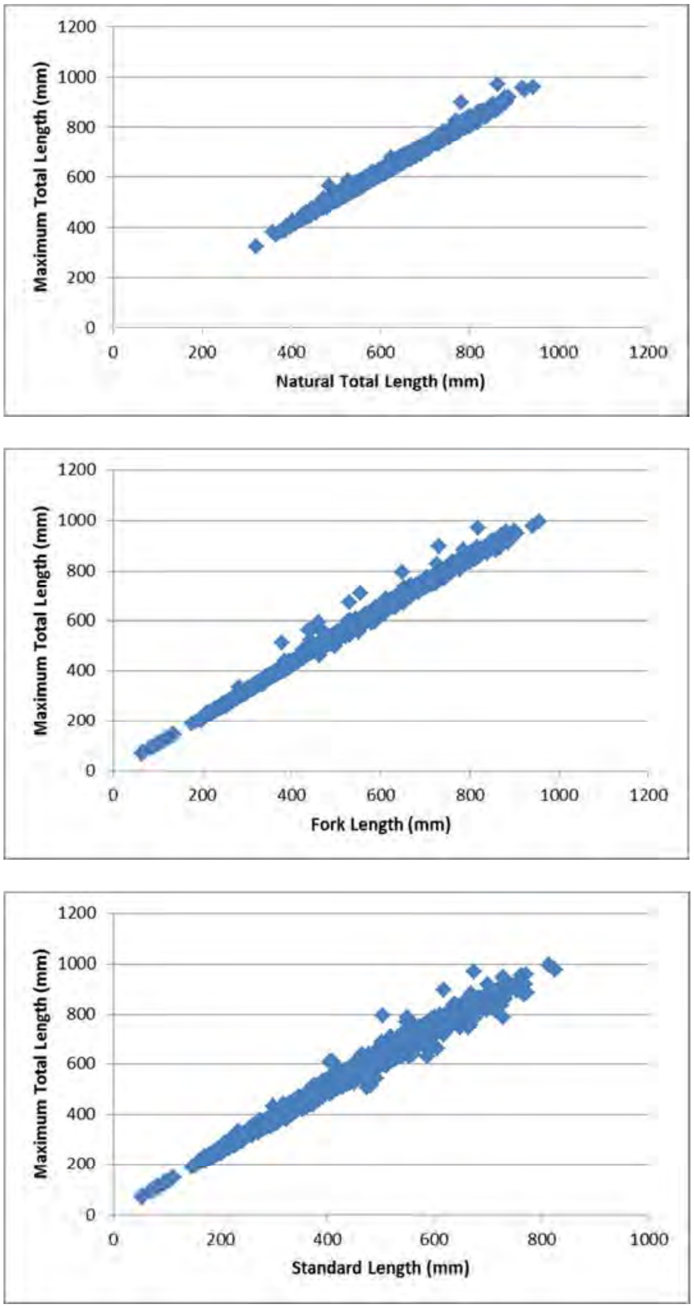

Figure 2.15

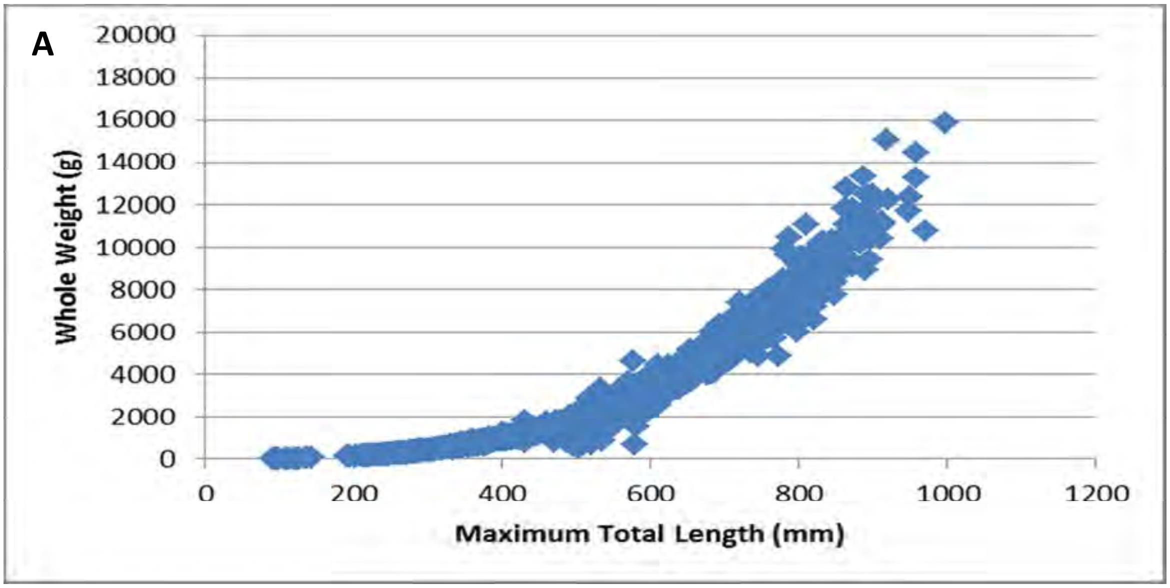
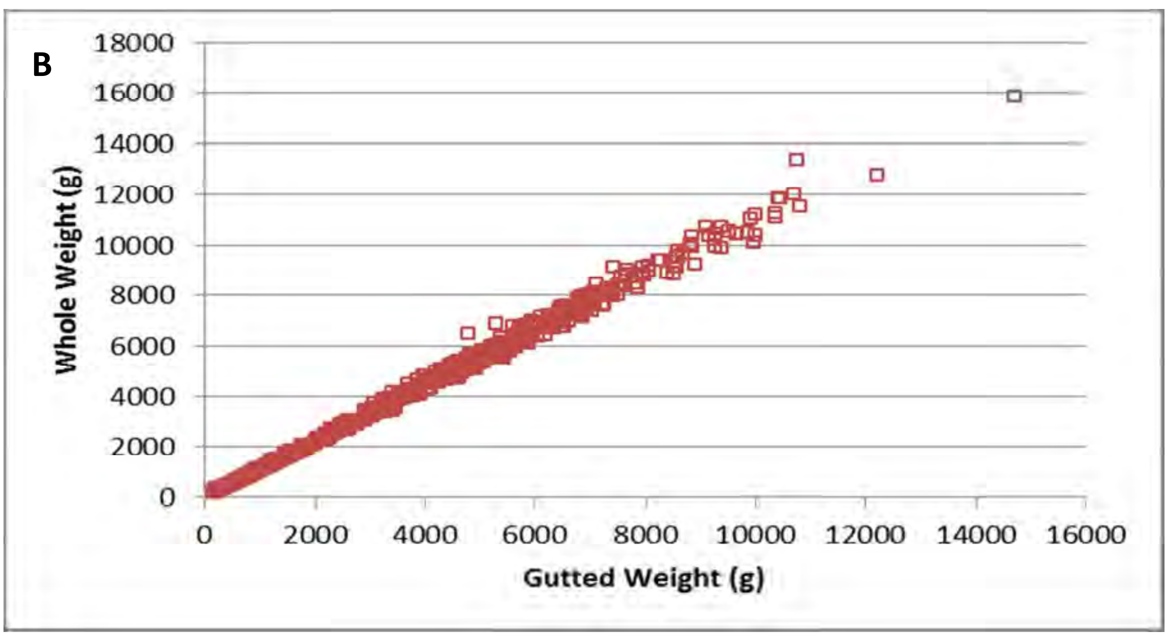
Red Snapper scatter plot of raw data used in conversion equations. Whole Weight – Maximum Total Length (A) and Whole Weight – Gutted Weight (B). Data from a variety of fishery dependent and fishery independent sources were used for analysis. See Table 2.21 for equations and statistics.





3. Commercial Fishery Statistics

3.1 Overview

Stock boundaries for red snapper in SEDAR 24 were between the GMFMC/SAFMC jurisdiction line in the Florida Keys to the NC/VA border. For SEDAR 41, the Life History Workgroup recommended using all data north of North Carolina.

Topics discussed by the Commercial Workgroup began with a discussion of stock boundaries, both the southern boundary with the Gulf of Mexico and the northern boundary (north of North Carolina).

To develop annual landings by gear and state, no adjustments were deemed necessary for misidentification of red snapper with other snapper species or inclusion of unclassified snappers that would have been analogous to SEDAR assessments for other snapper-grouper species. Commercial landings for the U.S. South Atlantic red snapper stock were developed by gear (handline, diving/spears, other) in whole weight for the period 1950 through 2014 based on federal and state databases. Intermittent landings estimates from historical reports were also consulted for 1902-1949. Data were more consistent after 1926 so historic data from 1927-1949 will be provided. Interpolated data for years when no red snapper were reported between 1927 and 1949 were calculated based on ratios of reported landings by state during years when at least one state reported. Corresponding landings in numbers were estimated from mean weights estimated from TIP by gear, state, and year for 1950-2014.

Discards, developed from the snapper-grouper logbook, were estimated for recent years (1993-2014) subsequent to the last change in minimum size limit for red snapper along the U.S. South Atlantic coast. Sampling intensity for lengths and age by gear, state and year were considered, and length and age compositions will be developed by gear and year for which sample size was deemed adequate.

Several research recommendations were updated and amended from SEDAR 24.

3.1.1 Commercial Workgroup Participants

Julie DeFilippi	Workgroup co-leader/ Data Provider	ACCSP
Kevin McCarthy	Workgroup co-leader/ Data Provider	SEFSC Miami
Joe Myers	Rapporteur/Data Provider	ACCSP
Steve Brown*	Data provider	FL FWC
Julie Califf	Data provider	GA DNR

Amy Dukes	Data provider	SC DNR
Kenny Fex	Commercial	NC/Snapper-Grouper AP
Stephanie McInerny*	Data provider	NC DMF
David Nelson	Commercial	FL
Larry Beerkircher*	Data provider	SEFSC Miami
2014 Only Workshop		
Neil Baertlein	Workgroup leader	SEFSC Miami
Zach Bowen	Commercial	GA/SAFMC
Chris Conklin	Commercial	SC/SAFMC
Jack Cox	Commercial	NC/SAFMC
Refik Orhun*	Data provider	SEFSC Miami

3.1.2 Issues Discussed at the Data Workshop

Landings issues discussed at the data workshop historic included landings, apportionment of Florida landings, and quantifying uncertainty. Historic reported landings, pre-1950, are largely incomplete and likely inaccurate. Whether or not to interpolate landings was discussed. Landings collected by the Florida Trip Ticket program are often felt to have mis-reported gear and area. NOAA's Coastal Fisheries Logbook data were used to correct for this, however 2010-2014 data could not be used for mean proportions for landings prior to 1993. Since landings data are simply summed, no value of uncertainty could be calculated. It was therefore discussed to use the methodologies used in SEDAR24 to estimate CVs based on method of data collection.

Discard issues discussed primarily involved the inclusion and exclusion of open and closed season discard rates from 2010-2014. Ultimately these years were treated separately.

Methods of extracting and filtering TIP length data were also discussed by the workgroup.

3.2 Review of Working Papers

SEDAR41-DW09: This report discussed fishery-independent and fishery-dependent sampling of red snapper during 2012 and 2013 when there were limited commercial seasons. It was determined that TIP samplers in Florida were actively targeting red snapper while sampling, therefore, estimated trip compositions during these years may have higher red snapper counts compared to years when red snapper sampling was random.

SEDAR41-DW22: This report suggested a re-evaluation of the gear selectivities used in the red snapper stock assessment for South Atlantic hook and line fleets.

SEDAR41-DW23: This report documented the development of the red snapper fishery in the US South Atlantic over time and discusses decadal advances in equipment and gear since the late 1800s.

SEDAR41-RD10: This report presented estimates of red snapper landings and discards from the commercial and recreational fisheries in 2012. Landings and discards were not provided by gear grouping. In the South Atlantic, commercial landings data from recent years are typically provided by the state for stock assessments to ensure edits performed after the data are sent to ACCSP are captured. These estimates were not used by the Commercial Workgroup.

SEDAR41-RD13: This report presented estimates of red snapper landings and discards from the commercial and recreational fisheries in 2013. Landings and discards were not provided by gear grouping. In the South Atlantic, commercial landings data from recent years are typically provided by the state for stock assessments to ensure edits performed after the data are sent to ACCSP are captured. These estimates were not used by the Commercial Workgroup.

SEDAR41-RD39: This report discussed data from 2007-2010 collected by an observer program tasked to characterize the shrimp fisheries in the US Gulf of Mexico and South Atlantic. Data for the South Atlantic penaeid and rock shrimp fisheries are available back to 2008. Red snapper bycatch between 2008 and 2010 was very minimal. The total impact of shrimp trawls on the red snapper fishery was determined by the Commercial Workgroup to be negligible.

Review and final decisions determined during 2014 workshop.

3.3 Commercial Landings

***DW ToR #6**: Provide commercial catch statistics, including both landings and discards in both pounds and number. Evaluate and discuss the adequacy of available data for accurately characterizing harvest and discard by species and fishery sector or gear. Evaluate, discuss, and characterize the sources of uncertainty, and data limitations (such as temporal and spatial coverage) for each data source. Provide ranges and/or distributions of uncertainty for data sources used in the stock assessment models. Provide length and age distributions for both landings and discards if feasible. Provide maps of fishery effort and harvest by species and fishery sector or gear.*

Commercial landings of red snapper were compiled from 1950 through 2014 for the entire US Atlantic Coast. Sources for landings in the US South Atlantic (Florida through North Carolina) included the Florida Trip Ticket program (FTT), South Carolina Department of Natural Resources (SCDNR), North Carolina Division of Marine Fisheries (NCDMF), and the Atlantic Coastal Cooperative Statistics Program (ACCSP). Landings from the Mid- and North Atlantic (north of the NC-VA border) were solely from ACCSP. Further discussion of how landings were compiled from the above sources can be found in section 3.3.5.

3.3.1 Commercial Gears Considered

In preparation for the SEDAR 41 Data Workshop, the commercial working group settled on the following numerical gear codes (ACCSP) for dividing red snapper commercial landings into three categories for consideration by the Workgroup. These gears are detailed in Table 3.1 and included:

Handline (300-303, 320, 700, 701),
Diving (660, 661, 750), and
Other (remaining gear codes including unknown).

Separating handline and diving gears was done because there are differences in the discard mortality and there may be differences in the selectivity and, therefore, length data between the two gears. Diving gear may catch larger red snapper on average.

These were the same gear groupings chosen in SEDAR 24; however, for SEDAR 24, landings with "other" gear type were pooled with handlines, the dominant gear. After further consideration by the Commercial Workgroup, the "other" gear type will be provided separately for SEDAR 41.

Decision 1: The Commercial Workgroup suggested grouping red snapper landings into three gear categories: Handline, Diving/Spears, and Others. The "other" gear category can be lumped into Handline if necessary.

This decision was approved by the plenary.

3.3.2 Stock Boundaries

DW ToR #1*: Review stock structure and unit stock definitions and consider whether changes are required.*

Landings will be provided from the GMFMC/SAFMC boundary in the Florida Keys and extend to north to the most northern extent of reported red snapper landings. The extent of the range can be seen in Figure 3.1 and the GMFMC/SAFMC boundary in Figure 3.2. Landings were obtained from the states north of North Carolina (ACCSP). Prior to 1987, reported red snapper landings were infrequent, occurring only in 1950 (300 lbs whole weight), 1970 (300 lbs), and 1983 (100 lbs). Landings became more frequent beginning in 1987, with positive landings for 1987-1988, 1992-1999, and 2001-2014. If we assume landings were truly 0 in those years none were reported for 1950-2014, then the average annual reported landings of red snapper from north of North Carolina was 98pounds (whole weight). While assuming years with no landings were zero, average landings beginning in 1987 was 234 pounds.

Decision 2: The Life History Workgroup recommended using all available data from the GMFMC/SAFMC jurisdiction line in the Florida Keys to as far north as landings were reported on the Atlantic coast. Because very few red snapper landings were reported north of North Carolina, the addition of these landings should not have an effect on overall landings trends.

This decision was approved by the plenary.

3.3.3 Misidentification and Unclassified Snappers

The next topics of discussion included whether misidentification of red snapper with other snapper species was a concern and whether red snapper landings may be incorporated in significant quantities in the unclassified snapper category. Neither of these issues was considered significant by the SEDAR 15 and SEDAR 24 Commercial Workgroups. The SEDAR 41 Commercial WG discussed and agreed with this decision. There are similar species to red snapper being landed but markets and regulations are different so there should be no misidentifications. Also red snapper have always been kept separate from the unclassified snappers because of their value. If any unclassified snappers were actually red snapper then it was insignificant. Data supporting this is anecdotal.

Decision 3: The Workgroup concurs with prior SEDAR decisions that concerns about mis-identification and unclassified snappers are not significant, and no adjustments are needed.

This decision was approved by the plenary.

3.3.4 Historical Commercial Landings

Historic landings were obtained from NOAA Fisheries' Office of Science and Technology which has available landings from 1880-1949. While reported landings are available back to 1880, consistent landings aren't seen until the 1920s. For this reason, we are providing landings from 1927 through 1949. This is also consistent with what was provided in SEDAR 24. After 1927 there are some gaps in reported landings, including 1933, 1935 and most of the 1940s. For these years when no landings were reported, linear interpolations were made using the first year before and first year after the gap in reporting. Interpolated values were for the years' total landings. Apportionments to state were based on a state's average proportion for years known. For years when at least 1 state reported, null landings were treated as zero. Treating these nulls as missing and inserting a given states' proportion based on 'complete' years, resulted in unrealistically high landings. Landings for the years 1942-1944 were made zero due to the port closures during

World War II. Reported and interpolated landings will be provided with the interpolated landings marked as such for possible exclusion in the assessment (Table 3.2, Figure 3.3).

Decision 4: Provide historic landings for 1927-1949. Interpolated values will be provided and noted.

This decision was approved by the plenary.

3.3.5 Commercial Landings by Gear and State

Statistics on commercial landings (1950 to present) for all species on the Atlantic coast are maintained in the Atlantic Coastal Cooperative Statistics Program (ACCSP) Data Warehouse. The Data Warehouse is an online database of fisheries dependent data provided by the ACCSP state and federal partners. Data sources and collection methods are illustrated by state in Figure 3.4. The Data Warehouse was queried in August 2015 for all red snapper landings (annual summaries by state and gear category) from 1950–2014 from Florida (Atlantic coast plus Monroe County) through Maine (ACCSP 2015). Data are presented using the gear categories as determined at the workshop. The specific ACCSP gears in each category are listed in Table 3.1. Commercial landings in pounds (whole weight) were developed based on classified red snapper by the Workgroup from each state as available by gear for 1950-2014.

<u>Florida</u>

Comparisons were made between Florida's commercial trip ticket data (1986-2014) and the NMFS logbook data (1992-2014). Both datasets were very similar in landings trends and level of landings reported for matching years by gear. The workgroup decided to use the total red snapper landings from the Florida trip ticket data over the logbook data primarily because the logbook data were of a shorter time series and trip ticket data are more complete from year to year. Red snapper have always been reported to species in Florida trip ticket. Final landings are reported as whole weight pounds.

One issue that arose with regard to red snapper landings from Florida South Atlantic waters in the trip ticket data was how to separate South Atlantic from Gulf of Mexico landings in Monroe county (Florida Keys). Red snapper landings in Monroe county have historically been a small portion of the Florida SA landings averaging about 4% annually. However, regulations limiting East coast harvest in recent years caused an increase in the proportion of Monroe South Atlantic red snapper to total Florida South Atlantic red snapper to as much as 10% in 2010 per NMFS logbook. It was decided to use the NMFS logbook data to proportion out South Atlantic red snapper in the trip ticket data since it is believed that fisher reported area fished data were generally more accurate than area fished data reported by dealers. Additionally, it was decided to use NMFS logbook data to apportion landings by gear in the trip ticket data. While both

programs collected gear by trip over the same time series (since 1992), the workgroup decided that gear reported by fisher would generally be more accurate than dealer reported gears.
The total amount of South Atlantic red snapper by year in the Florida was determined by first calculating the proportion of Monroe county South Atlantic red snapper in the logbook data for years 1993-2014. This was done by dividing the amount of SA red snapper into total red snapper landings for Monroe county only, then applying those proportions to the corresponding years for Monroe county total red snapper landings from the trip ticket data. An average proportion for SA Monroe county was calculated from the combined 1993-2014 logbook data and applied to corresponding total Monroe red snapper landings in the trip ticket data from 1986-1992. South Atlantic Monroe county and non-Monroe South Atlantic landings from trip ticket data were then combined into total South Atlantic red snapper landings for Florida. NMFS logbook data were then used to calculate proportions of Florida South Atlantic red snapper harvest by gear. This was done by dividing landings for each gear into total Florida South Atlantic landings, then applying those proportions to the total South Atlantic red snapper landings for Florida by year from 1993-2014. The average proportion of logbook landings over all years by gear was then applied to trip ticket landings from 1986-1992.

Landings from the ACCSP database were selected for 1950-1985.

Decision 5: The Workgroup recommends using 1993-2014 logbook data to apportion Florida landings prior to 1993.

This decision was approved by the plenary.

<u>Georgia</u>

GA DNR staff examined ACCSP landings and compared them to state held versions. It was determined that ACCSP landings were a match and would be used in place of state provided data for the entire time series.

<u>South Carolina</u>

Landings data for red snapper in South Carolina came from two different data sources. The old NMFS Canvass system data, supplied by ACCSP, provided landings data for the state from 1956 to 1971. Data from 1972 to 2014 was provided by SCDNR. This incorporated two different data reporting styles, the first from 1972 to 2003, allowed wholesale seafood dealers to report total monthly landings by species. The second data reporting style, 2004 to 2014, required wholesale seafood dealers to complete individual trip-level. All landings data are provided by year and approved gear type.

Red snapper were landed in gutted pounds. The South Carolina conversion factor used (1.075) to calculate whole pounds was different then the recommended and approved SEDAR 41 conversion factor (1.10). From 1972 to 2003, landings were only available in whole pounds, and since 2004, both gutted and whole pounds were available. To be consistent, all whole pounds were back calculated using the state applied conversion to determine gutted pounds and then the SEDAR 41 conversion factor was applied to determine whole pounds for all years of data. Gear combinations recommended by the Commercial Workgroup for Red Snapper were Handline, Diving/Spears, and Other.

North Carolina

Prior to 1978, the National Marine Fisheries Service collected commercial landings data for North Carolina. Port agents would conduct monthly surveys of the state's major commercial seafood dealers to determine the commercial landings for the state. Starting in 1978, the North Carolina Division of Marine Fisheries entered into a cooperative program with the National Marine Fisheries Service to maintain the monthly surveys of North Carolina's major commercial seafood dealers and to obtain data from more dealers.

The North Carolina Division of Marine Fisheries Trip Ticket Program (NCTTP) began on 1 January 1994. The NCTTP was initiated due to a decrease in cooperation in reporting under the voluntary NMFS/North Carolina Cooperative Statistics Program in place prior to 1994, as well as an increase in demand for complete and accurate trip-level commercial harvest statistics by fisheries managers. The detailed data obtained through the NCTTP allows for the calculation of effort (i.e. trips, licenses, participants, vessels) in a given fishery that was not available prior to 1994 and provides a much more detailed record of North Carolina's seafood harvest.

North Carolina commercial landings of red snapper were provided for 1972-2014 by year and gear type. Landings for North Carolina before 1972 were provided by ACCSP. Gears were grouped into the following categories: Handlines, Diving/Spears, and Others[1]. Most red snapper in North Carolina are reported in gutted condition. From 1972-1993, whole pounds were converted back to gutted using the state conversion code of 1.08 and reconverted to whole pounds using the conversion factor provided by the Life History Workgroup (1.10). From 1994-2014, landings reported as gutted were converted to whole pounds using 1.10. Landings reported as whole were not reconverted.

---

[1] SAS code used to group trip ticket gears into these categories:

```
If Gear1=480 and Gear2=610 and Gear3=. Then Gear1=610;
If Gear1=676 and Gear2=660 and Gear3=. Then Gear1=610;
If Gear1=677 and Gear2=610 and Gear3=. Then Gear1=610;
```

```
Length Geartype $ 15;
If (600 LE Gear LE 616) or Gear in (660,665) Then Geartype='Handlines';
Else if Gear in (760,943) Then Geartype='Spears';
Else Geartype='Others';
```

Combined State Results

Landings are presented in Tables 3.3 and 3.5 and Figures 3.5-3.6. Since 1950, Florida produced over 81% of the commercial harvest, Georgia 4.7%, South Carolina 7.6% and North Carolina 6.1%. Since 1950 handlines have represented about 97% of the catch compared with 2% for diving, and just under 1% other gears.

Decision 6: The Workgroup made the following decisions for reporting commercial landings:

- Landings should be reported as whole weight in pounds and number of fish
- Final landings data would come from the following sources:
    - VA-North: 1950-2014 (ACCSP)
    - NC: 1950-1993 (ACCSP)
      1994-2014 (NCDMF)
    - SC: 1950-1979 (ACCSP)
      1980-2014 (SCDNR)
    - GA: 1950-2014 (ACCSP)
    - FL: 1950-1985 (ACCSP)
      1986-2014 (FL FWC)

This decision was approved by the plenary.

Whole vs. Gutted Weight

Historically, conversions between whole and gutted weight have been based on state specific values. The standard conversion of snappers for Georgia and Florida from gutted weight to whole weight is by multiplying gutted weight by 1.11. South Carolina uses a conversion of about 1.075, obtained by dividing gutted weight by 0.93. North Carolina uses a conversion multiplier of 1.08. For all states North of North Carolina because the conversion factors typically used by each state was not known at the Data Workshop, the federal conversion of 1.08 was assumed. During SEDAR 41, data by state were converted back from whole pounds to gutted weight using the above mentioned conversions and then from gutted weight to whole weight based on data from the Life History Workgroup. The no-intercept regression estimate for slope is 1.10 (the ratio of means for gutted weight to whole weight).

Decision 7: The Commercial Workgroup will provide red snapper landings in pounds whole weight.

This decision was approved by the plenary.

Confidentiality Issues

Landings of red snapper were pooled across states by gear to meet the rule of 3 and ensure confidential landings were not presented in this report. Landings by state and gear will be provided to the data compiler for use in the assessment.

Uncertainty (2015 data workshop)

The commercial workgroup estimated uncertainty in commercial fishery landings, after consultation with assessment biologists, by modifying the methodology used in SEDAR 24. These estimates of uncertainty are not coefficients of variation, but are estimates of possible reporting error; i.e., represent the range in actual commercial landings relative to the reported landings.

In making these uncertainty estimates, two assumptions were made:

1. *Landings may be underreported during all years; however, underreporting was likely highest during early years of the time series and were more accurate in recent years.* This assumption was based upon the following information and data workshop expert testimony: during the period 1950 (beginning of landings time series) to 1961 landings were summarized annually by state and likely did not include landings from small scale dealers. In the years 1962-1977 landings data were collected annually, but under a more all-inclusive program (General Canvass). Monthly landings summaries were collected during the period 1978 to the beginning of trip ticket data collection (starting dates vary among states). The most recent landings data, collected through state trip ticket programs, were assumed to be most reliable and inclusive of all red snapper commercial landings.
2. *Landings may be overestimated during the years 1950-1977 because vermilion snapper may have been reported as red snapper landings.* Market values of similarly sized vermilion snapper and small red snapper were identical and no effort was made to differentiate species specific landings. This practice was phased out during the mid to late 1970's. The workgroup chose 1977 as the final year of misreporting based

upon expert testimony and observed increases in reported vermilion snapper landings. The workgroup recognizes that misreporting of vermilion snapper landings as red snapper landings diminished gradually over time, but lacks sufficient data to accurately characterize that trend.

During workgroup discussions it was recognized that using the levels of landings uncertainty recommended during SEDAR 24 (40-50% uncertainty) would poorly inform the assessment model of landings during the early years of the time series (1950-1977). The group agreed, based upon expert opinion, that an upper bound ½ that recommended during SEDAR 24 be used for the period from 1950-1977 (i.e., 25% landings during 1950-1961, 20% during 1962-1977, 10% during the period 1978 until implementation of state trip ticket programs (varies by state), and 5% during the period of trip ticket reporting (state specific starting years). See Table 3.5, Figure 3.4 for state specific bounds.

The workgroup recommended that a lower bound be set to account for vermilion snapper misreported as red snapper. The workgroup recognized the possibility that such misreporting may have resulted in an underestimate of the true red snapper landings. The lower bound for commercial landings uncertainty was set based upon expert opinion because the workgroup was aware of no available data by which a direct estimate of vermilion snapper misreporting could be estimated. The lower bound of landings uncertainty was set as symmetric with the upper bound for the period from 1950-1977, following the modified SEDAR 24 recommendation (Table 3.4, Figure 3.4).

Decision 8: The Workgroup recommends estimating landings uncertainty following modified (as per discussions with assessment biologists) SEDAR 24 recommendations for landings upper bound and lower bounds.

This decision was approved by the plenary.

3.3.6 Converting Landings in Weight to Landings in Numbers

Commercial landings in weight were converted to commercial landings in numbers based on average weight (in pounds whole weight) from the TIP data for each state, gear, and year. These data were generally available from 1983 to 2014 for handlines. Data for the remaining gear types were sparse, with much more limited data from diving and other gear types available (annual sample sizes by gear, state and year are summarized in Table 3.12). For 1983-2014 annual estimates of mean weight by state and year for handline were applied to the corresponding landings in weight when sample size greater than or equal to 50 (Table 3.6). For years when samples size was less than 50, a mean weight calculated from all years was applied by state. Since no lengths were available for northern states (Virginia through Maine), a mean across all states was applied. The mean weight as calculated from all years was also applied to those years from 1950-1982.

Samples for diving and other gear was limited and sporadic, which would have resulted in a collapsing strata to a single overall mean weight for a gear in order to yield adequate sample sizes. Additionally, large sample sizes in longline and trawl in the 'Other' gear skewed means. More detailed discussion can be found section 3.6.1. The workgroup determined that mean weights as calculated for the handline would be applied to all landings. Calculated numbers of fish can be found in Table 3.5 and Figure 3.6. Mean weights by state and year are provided in Table 3.6.

3.4 Commercial Discards

3.4.1 Directed Fishery Discards

2015 updated analyses
Calculations of the total number of red snapper discarded or kept as bait/eaten from the commercial fishery were updated to include data from 2014. For the 2015 Data Workshop, discards from the trolling fishery were also calculated because some red snapper discards were reported by those vessels. Methods were otherwise unaltered from those recommended during the initial SEDAR41 data workshop in August 2014. Updated calculated discards are provided in Tables 3.7-3.10. Calculated discards for all gears other than vertical line (handline and electric/hydraulic gear) were low. The number of calculated red snapper kept for bait or eaten never exceeded 54 fish in any year for all gears combined and were fewer than 12 fish in all other years. Tables of red snapper kept for bait or eaten have not been provided. Very minor differences in calculated discards between the 2014 data workshop calculations and the 2015 calculations were likely due to updates or edits to the discard logbook and/or coastal logbook data sets.

2014 analyses
Commercial discards were calculated for vertical line (handline and electric/hydraulic reel) vessels in the US South Atlantic using methods described in SEDAR41-DW36. Other gears reported 51 or fewer total trips (per gear) with red snapper discards during the period 2002-2013.

Two methods were used to calculate total discards. A continuity approach followed the methods of SEDAR24 and the 2010 update assessment. Those assessments used delta-lognormal model generated least squares means of year-specific discard rate to calculate total yearly discards for the period 2002-2013 (when discard data were reported). Discard rate for the period 1992-2001 (prior to discard reporting) was assumed to be the mean discard rate over the years 2002-2013, weighted by sample size. An alternative method used yearly nominal discard rates for the years

2002-2013. Separate discard rates were calculated for open and closed red snapper fishing seasons. Calculation of discards for the years 1992-2001 used the mean discard rate for the years 2002-2009 (years with no closed seasons). Both methods used discard rates multiplied by year specific total vertical line effort reported to the coastal logbook program to calculate total discards. Discards were reported in numbers of red snapper.

The working group recommendation and the final recommendation made in plenary session were to calculate total discards using nominal discard rates. To address likely underreporting of discards (reporting "no discards" allows the fisher to remain in compliance for renewing federal fishing permits), data included in that calculation were filtered to remove records from vessels that never reported discards of any species during a year. In addition, data from vertical line vessels that reported more than 17 trips without reporting discards of any species (17=the mean number of reported trips prior to the first trip with reported discard plus two standard deviations of that mean) were excluded. Those data filters were used following the recommendation of the SEDAR32 data workshop. Including data from those fishers that habitually reported no discards would have resulted in discard rates that were erroneously low. Trips targeting mackerel are unlikely to have discards of red snapper, therefore, trips that reported only landings of mackerel species were excluded from this analysis. Additional data filters included the removal of clearly erroneous data (values of gear-specific effort data beyond the 99.9 percentile of the data). Discard logbook data with multiple gears fished on a trip were also excluded because discards could not be unambiguously attributed to a particular gear. That data filtering step was not necessary when summing total effort from the logbook data because reported effort data was gear-specific.

Decision 9: The Workgroup accepts the discard estimates of red snapper for 1992-2014 as developed in working paper S41-DW36.

This decision was approved by the plenary.

The commercial working group accepted the methods described in SEDAR41-DW36 for calculating commercial vertical line vessel red snapper discards for the years 1992-2013. Red snapper discards were reported from 51 or fewer trips with gear other than vertical lines, suggesting that discards from other commercial gears was minimal. The specific method chosen by the working group was the use of year and fishing season (open/closed) specific nominal discard rates. Those discard rates were used with corresponding year and season specific total vertical line effort reported to the coastal logbook program to calculate total discards. The working group also endorsed using the mean discard rate over the years 2002-2009 (years with no red snapper seasonal closures), weighted by sample size, as the discard rate for the period 1992-2001 (prior to discard reporting). During 1992 only 20% of vessels in Florida were required to report to the logbook program; effort reported for Florida was expanded by a factor of five. No effort data were available for calculating discards prior to 1992.

The discard calculations rely on self-reported discard and effort data. Perhaps the most important source of error in the commercial discard calculations was misreporting and non- reporting of discards, both of red snapper and other species. An effort was made to minimize that potential error by removing data from vessels that never reported discards of any species during a year. In addition, data from vertical line vessels that reported more than 17 trips without reporting discards of any species (the mean number of reported trips prior to the first trip with reported discard plus two standard deviations of that mean) were excluded. Although such clear instances of discard non-reporting were identified and excluded, other cases of non-reporting and misreporting have not been quantified. The degree to which continued non or misreporting may have affected the discard calculations is unknown.

The total commercial discards provided in SEDAR41-DW36 may represent a minimum estimate of the number of red snapper discarded from the commercial fishery.

Decision 10: The conclusion of the commercial working group was that given the very limited observer data, fisher reported discard data represent the best available information on commercial red snapper discards.

This decision was approved in plenary.

3.4.2 Shrimp Bycatch

The possibility of constructing red snapper bycatch estimates from the south Atlantic shrimp fishery was investigated. Beginning in 2007, a mandatory observer program was put in place to sample trips in the penaeid and rock shrimp fisheries. During this time only 7 fish, from 872,192 pounds of samples (shrimp and fish), were encountered. These seven red snapper were caught only in rock shrimp trips. Additionally, several fishers present at the data workshop, who have fished in the shrimp fishery, corroborated this extremely low encounter rate. The workgroup felt that total bycatch is negligible in the shrimp fishery and therefore recommended not modelling shrimp bycatch.

Decision 11: Red snapper bycatch from the shrimp fishery will not be constructed as bycatch is negligible.

This decision was approved by the plenary.

Review and final decisions determined during 2014 workshop.

3.5 Commercial Effort

The distribution of directed commercial effort in trips by year was compiled from the Coastal Fisheries Logbook Program (CFLP) for 1993-2013 and supplied here for informational purposes. These data are presented in Figure 3.7. The distribution of harvest by statistical grid, as reported to the CFLP, is a displayed in Figure 3.8. Figure 3.9 shows a distribution of harvest by depth and latitude.

Review and final decisions determined during 2014 workshop. Not updated at 2015 workshop.

3.6 Biological Sampling

Length Samples

Commercial length data were available from the SEFSC Trip Interview Program for all years, 1983 to 2014. TIP data were pulled from the SEFSC TIPONLINE.TIP_MV table, which is a master view table that collapses the one-to many relational tables in the main TIP database tables. The TIP_MV table is audited weekly to insure that the contents agree with the master data tables.

REGIONS other than South Atlantic are filtered out. Data were assigned as South Atlantic samples via a hierarchal procedure. If area fished was in the interview's effort information (e.g. usually derived from captain), this information was used. If the Captain's information was not available, but area fished was provided in the interview's landings information (e.g. derived from the dealer's records/trip tickets), then the landings information was used. If area fished was in neither the effort nor the landings information, then the state and county of landing were used to make a region assignment (e.g., all records not previously resolved that landed in NC, SC, or GA were assumed to be south Atlantic samples, and all records not previously resolved that landed in FL's east coast counties (Dade county northward) were also assumed to be south Atlantic samples).

IS_DISABLED='Y' TRIPS are filtered out. TIP allows errant data to exist in the database until such time as the issue can be resolved. TIP also allows testing trips in the production database. These only make up 0.2 % of all south Atlantic TIP interviews. It is unlikely that BSD would import these records and that agents would send age structures from errant trips. Agents cannot disable trips, only system and database administrators can.

FISHING_MODE<>'COMMERCIAL' are filtered out. TIP is meant to be a commercial representative sampling program, however the TIP database has been used to house recreational, scientific, experimental, etc. data collections. Non-commercial trips make up 14% of south Atlantic TIP interviews.

BIAS_TYPE<>'NO BIAS KNOWN' are filtered out. In the past, samplers where asked to record if they felt the trip was representative, or biased for some particular reason. Trips with a bias indicated make up 1.9% of south Atlantic TIP interviews.

INTERVIEW_TYPE='TRIP_SURVEY' are filtered out. An interview type coded Trip Survey means that the sampling was taken from the aggregated landings of more than one trip (this could involve a single vessel but multiple trips, or multiple vessels). In these cases, if the sampler knew that the gear type and/or area fished varied among the trips included in the trip survey, historical practice was to assign area fished and gear type to what the sampler believed characterized the "majority" of the catch (and therefore in theory the majority of the sampled specimens). Since area fished and gear type cannot be conclusively identified for a trip survey, then if these variables are necessary for the assessment, they should be filtered out. It should be noted that this filter disproportionately affects the lengths available from South Carolina samples in the 1980's and early 1990's. For example, in the south Atlantic data overall trip survey lengths are about 2% of the data, but for South Carolina trip survey lengths account for 41% of the length data. Filtering out these records results in zero lengths for South Carolina in the years 1985, 1986, 1987, 1989, 1990, 1992, and 1995.

GEAR TYPE: Will be determined by the first gear type listed in the trip record. The assumption is that if a trip uses multiple gear types, a single gear type is the primary type used, and is listed by the sampler first. Where a gear type was not obtained via an interview, then the gear information from the dealer was used.

OBSERVATION-SPECIFIC FILTERING:

SAMPLE_RANDOM=NO are filtered out. Samples coded as 'NO" for this variable are assume to have some type of sampling issue; the sample was selected by a non-random or targeted method. These observations may not be representative of the trip's catch and should not be used. For red snapper, samples identified as non-random are 3% of the observations (after above trip filtering is applied as well).

CONDITION_TYPE='GUTTED-HEAD OFF' were removed as length collection should be impossible if the fish was in such condition. Null values for condition type were left in, as it was historically standard practice by many samplers to only record a condition when a weight was taken, also many samplers seemed to operate under the impression that leaving this value as null meant the fish was in standard industry condition (for red snapper, this means the head is left on). Only 4 records were affected by this filter.

LENGTH1_MM= NULL or 0 will be filtered out. A very small number of observations in TIP do not have length data. Some unreasonable lengths were filtered out: for red snapper two lengths of 59 and 70 mm were deleted as unreasonably small, and two lengths of 14541.5 and 5500 mm were deleted as unreasonably large, leaving the length range as 185 mm to 1120 mm.

Age Samples

Most of the age structures were obtained from TIP port agents and ageing analyst coordinated with TIP data collection experts to obtain consistency in filtering data. Ageing analysts contacted state sampling representatives to determine if increased sampling outside the TIP program in recent years were biased in any way. The increased sampling for red snapper since 2009 outside the TIP program accounts for the years with more ages than lengths. Given the complexities of the length and age databases, determining individual lengths not included in the length data may increase the probability of duplicating records and other errors.

3.6.1 Sampling Intensity

Length samples

Gear-specific summaries of the quantity and quality of the length data show that the majority of the length data available for red snapper are from the handline fishery (Table 3.11). All other gears are characterized by relatively poor annual sample sizes, coverage, and variability in the mean length and weight across gears. Annual sample sizes of lengths and number of trips sampled are summarized in Tables 3.12 and 3.13, respectively, by gear and state for red snapper in the U.S. South Atlantic from the TIP database for 1983-2014. The state-specific sample sizes are inadequate to weight samples for any of the gears. Even the most abundant gear, handline, has no length samples for many year/state combinations. A value of zero cannot be weighted and small sample sizes cause spikes in a composition for areas with average or greater landings. A comparison of the relative number of fish sampled across states to the relative landings across states is shown in Figure 3.11. Overall, North Carolina is relatively over-sampled for most of the time period, South Carolina is sporadic with many zero years prior to 1996 where it is then relatively oversampled, Georgia is sporadic through about 1994 with adequate sampling through 2006 and then undersampled, Florida, the state that dominates the landings, is relatively undersampled until about 1992 and then adequately sampled with the exception of a few low years. The workgroup recommends combining North Carolina and South Carolina length samples and weighting by the combined landings for handline gear. The workgroup recommends combining Georgia and Florida length samples and weighting by the combined landings for handline gear. The regional relationship between handline length samples and landings is shown in Figure 3.12. Diving sample sizes are inadequate to develop annual length comps with the exception of a few years. However, a qualitative comparison of the 6 years with 30 or more diving samples shows a general agreement with the handline gear with a shift towards slightly larger fish (Figure 3.10). The “other” gear includes sporadic sampling by states and very different gear types (e.g. longline and trawl).

Age samples
Annual sample sizes for commercial handline and other gears by state are given in Tables 3.14 and 3.15. The age samples are dominated by South Carolina through 1995, then Florida provides the majority if not all of the length samples by trip from 1998-2003. From 2004 to 2008 sampling is greater in the Carolinas.

3.6.2 Length/Age Distribution

Length distributions - Landings
All red snapper lengths were converted to maximum TL in mm using the formula provided by the SEDAR 41 Life History Workgroup and binned into one centimeter groups with a floor of 0.6 cm and a ceiling of 0.5 cm. The length data and landings data were divided into handline, diving/spears, and other gears. Unweighted red snapper handline annual length compositions are provided in the SEDAR 41 data workbook and shown in Figure 3.13.

Age distributions – Landings
Calendar ages were determined by ageing experts and provided to commercial composition analysts for summary. . Unweighted red snapper handline annual age compositions are provided in the SEDAR 41 data workbook and shown in Figure 3.14 (to a maximum of 47 years) and Figure 3.15 (pooled at 15 years).

Length distribution - Discards
Observer reported length frequency data of discarded red snapper were available for use in the SEDAR41 stock assessment. Sampling protocols and collection procedures of those data are reported in GSAFF (2008). Those data were collected from vessels fishing vertical line gear (handline and electric/hydraulic reels) between latitudes 30N and 33N during 2007-2011. A length composition was developed combined across years to represent discard sizes for years with a 20 inch size limit and after the 2010 closure. Data from 2007-2009 with 144 fish and 13 trips was used to develop the 20 inch size limit discard size distribution (provided in the SEDAR 41 data workbook and shown in Figure 3.16).

3.6.3 Adequacy for Characterizing Catch

Length samples
The TIP sample sizes for the development length distributions appear to be adequate for the commercial handline fishery with the exception of 1983 were only 35 fish were collected from 12 trips in North Carolina and 2010 where all fish come from 4 trips. Overall there is more uncertainty in the handline length data prior to 1996 and after 2009. Lack of coverage is the

primary reason for the increased uncertainty in the early and late years with the combined effect of the closure and mini-seasons for 2010-2014.

Lengths samples from the diving and other gear activities were limited. Ultimately the workgroup felt the length distributions for diving could be informed by the handline length distributions (Figure 3.10). Development of any length distributions from other gears would be uninformative due to the lack of spatial and temporal coverage and the disparity in mean length for the different gears. The total landings for all gears other than handline represents only about 6% of the overall landings and assuming they are represented by the handline length compositions would very minimally increase the uncertainty of an assessment.

Age samples

Age samples prior to 1996 when Florida samples are modestly represented may not adequately characterize catch as most if not all samples come from South Carolina. Weighting age compostions by length compostions can correct for bias in sampling age structures from the overall sample as well as region-specific differences.

Decision 12: The Workgroup recommends only development of a handline length distribution which should be weighted regionally (Car and GFL). Years with limited trips or very limited spatial coverage should not be used to characterize catch (including but not limited to 1983 and 2010). The workgroup recommends development of annual handline age compositons weighted by the annual handline length compositions. Years with limited trips or very limited spatial coverage should not be used to characterize catch.

3.7 Comments on Adequacy of Data for Assessment Analyses

Landings

The working group considered the majority of landings data from the U.S. south Atlantic to be adequate for assessment analyses. Data appeared to be most accurate and reliable from the various state data bases in the most recent years. This is likely due to the implementation of state trip ticket programs, beginning with Florida in 1986. Reliable monthly landings data can be found back to 1978. Historic landings prior to 1950 were found to be the least reliable, as there appears to be missing data for various years and states. It was also felt that proper species identification for reporting were made as red snapper is a highly sought fish and therefore handled separately from other snappers.

Discards

Discards estimates may be less adequate for assessment analyses. The only discard data available is from a self-reported data collection program. It is likely that recollections of fish thrown back are not always accurate and will vary from fisher to fisher. There is also an issue of 'no discard' trips reported. The frequency of 'no discard' trips has risen over the past 10 years, from 30% to over 60% of all discard reports submitted. It is unknown which of these are real and which reports were submitted simply to comply with reporting requirements. Observer data were investigated, but data were deemed insufficient for discard estimation.

Length and age samples

Length and age samples from the handline fishery are adequate for assessment analyses. The increased uncertainty for years with limited coverage could be modeled by reducing the weighting factor (typically trip sample size) by the proportion landings represented by missing states. However, length and age samples from diving and other gears are insufficient for analyses.

3.8 Relative Selectivity for Commercial Gears

To potentially address gear selectivity, SEDAR41 assessment scientists requested additional information concerning hook types and sizes used in the red snapper fishery through time. Most fishery dependent data collection programs do not collect this information including the various state trip ticket programs and the Coastal Fisheries Logbook Program. There is however, data available from a south Atlantic observer program that ran from mid-2006 through 2011. There were limited observer data that included hook size recorded from reels with red snapper catch. A total of 38 trips by 17 vessels with red snapper catch were observed from 2006 (1 vessel/1 trip) to 2011 (6 vessels/10 trips). All were vertical line (handline/bandit rig) trips. There were 785 red snapper observed: 456 discards, 320 landed, 6 kept as bait, and 3 with unknown disposition. Manufacturer hook sizes were recorded for 161 caught fish and there were 104 unique trip/set/reel/hook size combinations. Observers directly measured hook size more frequently than they recorded the manufacturer's hook size: 446 discarded red snapper and 317 landed red snapper have measured hooks size. These data along with further analyses will be provided at the SEDAR 41 Assessment workshop.

In addition to observer data, anecdotal data were provided by commercial fishermen. Captain Kenny Fex state that in the mid-1980s, off North Carolina, 5/0 J-hooks were used for small fish, while 10/0 J-hooks and 13/0 circle hooks were used for large grouper and snapper. By the mid-1990s J-hooks were no longer used as circle hooks were found to be more effective. In more recent years 4/0 and 12/0 circle hooks have been used for small and big fish. Two hooks per line has been the gear configurations consistently through this time period. Captain Chris Conklin also added that 10/0 and 12/0 circle hooks have been consistently used.

Lastly, it is worth noting that circle hooks sizes may vary between manufacturers (Serafy 2012). For example, a 10/0 circle hook manufactured by Mustad may be a different size than Eagle Claw's 10/0 circle hook.

Not updated at 2015 workshop.

3.10 Research Recommendations

The Workgroup reviewed recommendations from SEDAR 24 and offers additional recommendations:

Landings

- Improve gear and effort data for each trip.
- Standardize methodology for developing average proportions to parse out unclassified landings.

Discards

- Investigate the validity and magnitude of "no discard" trips. This may include fisher interviews throughout the region.
- Examine potential impacts of "no discard" trips on estimated discards.
- Improve discard logbook data collections via program expansion or more detailed reporting (i.e. electronic logbooks, etc.)
- Establish an observer program that is representative of the fisheries in the South Atlantic.

Biosampling

- Establish an observer program that is representative of the fisheries in the South Atlantic.
- Angler education with regards to recording depths on paper logbooks (i.e. standardized units); validation of additions to the logbook form still needed.
- Standardize TIP sampling protocol to get representative samples at the species level.
- Standardize TIP data extraction.

These recommendations were approved by the plenary.

Table 3.7 Calculated yearly total discards of red snapper (in numbers of fish) by vertical line vessels including 2014 discards. Vertical line vessels accounted for approximately 97% of calculated discards. Yearly nominal discard rates calculated separately for open and closed red snapper seasons. Effort is in hook hours fished. Discard rate used for the years 1992-2001 was the weighted mean rate for the years 2002-2009. Trips (discards) = trips reporting to the discard logbook program. Trips (total effort) = number of trips reporting to the coastal logbook program.

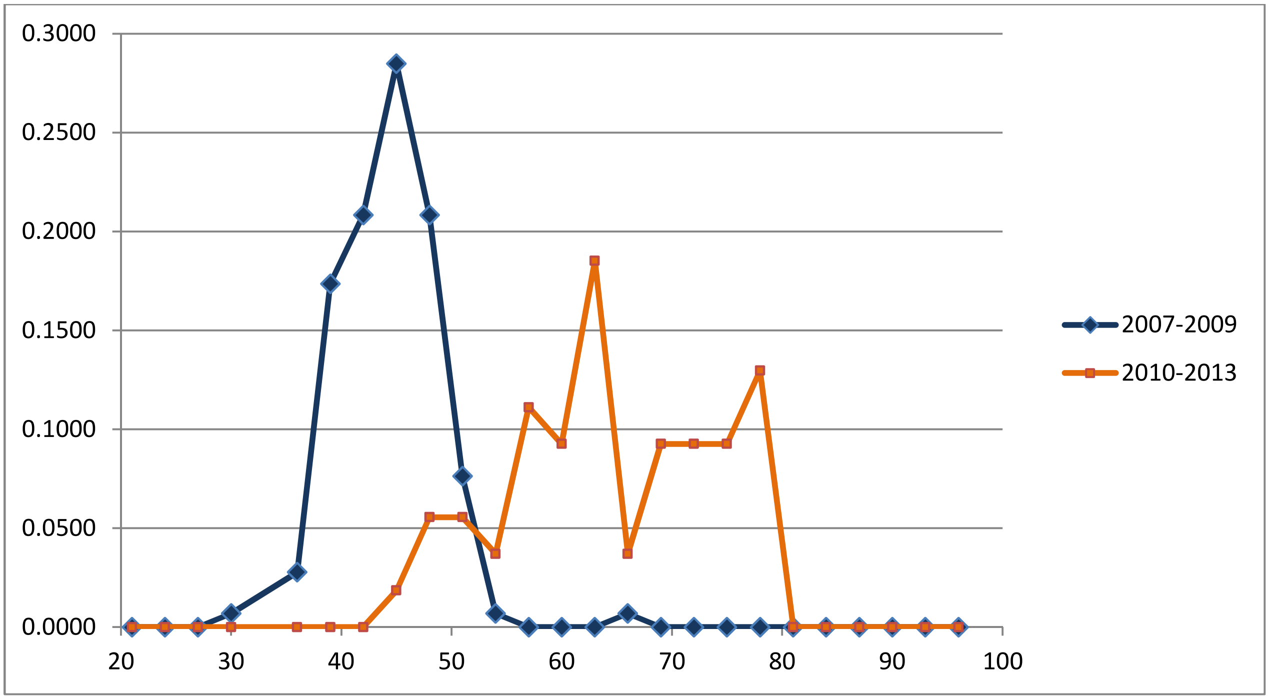

Figure 3.16 Commercial discard length distribution for the period with a 20 inch size limit (2007-2009) and during the closure (2010-2013). These were estimated from limited commercial observer data from 2007-2013.

Appendix A

NMFS SECPR Accumulated Landings System (ALS)
Information on the quantity and value of seafood products caught by fishermen in the U.S. has been collected starting in the late 1800s (inaugural year is species dependent). Fairly serious collection activity began in the 1920s. The data set maintained by the Southeast Fisheries Science Center (SEFSC) in the SECPR database management system is a continuous dataset that begins in 1962.

In addition to the quantity and value, information on the gear used to catch the fish, the area where the fishing occurred and the distance from shore are also recorded. Because the quantity and value data are collected from seafood dealers, the information on gear and fishing location are estimated and added to the data by data collection specialists. In some states, this ancillary data are not available.

Commercial landings statistics have been collected and processed by various organizations during the 1962-to-present period that the SECPR data set covers. During the 16 years from 1962 through 1978, these data were collected by port agents employed by the Federal government and stationed at major fishing ports in the southeast. The program was run from the Headquarters Office of the Bureau of Commercial Fisheries in Washington DC until 1970. After 1970 it was run by the newly created National Marine Fisheries Service, which had replaced the Bureau of Commercial Fisheries. Data collection procedures were established by Headquarters and the data were submitted to Washington for processing and computer storage. In 1978, the responsibility for collection and processing were transferred to the SEFSC.

In the early 1980s, the NMFS and the state fishery agencies within the Southeast began to develop a cooperative program for the collection and processing of commercial fisheries statistics. With the exception of two counties, one in Mississippi and one in Alabama, all of the general canvass statistics are collected by the fishery agency in the respective state and provided to the SEFSC under a comprehensive Cooperative Statistics Program (CSP).

The purpose of this documentation is to describe the current collection and processing procedures that are employed for the commercial fisheries statistics maintained in the SECPR database.

1960 - Late 1980s
=================
Although the data processing and database management responsibility were transferred from the Headquarters in Washington DC to the SEFSC during this period, the data collection procedures remained essentially the same. Trained data collection personnel, referred to as fishery reporting

specialists or port agents, were stationed at major fishing ports throughout the Southeast Region. The data collection procedures for commercial landings included two parts.

The primary task for the port agents was to visit all seafood dealers or fish houses within their assigned areas at least once a month to record the pounds and value for each species or product type that were purchased or handled by the dealer or fish house. The agents summed the landings and value data and submitted these data in monthly reports to their area supervisors. All of the monthly data were submitted in essentially the same form.

The second task was to estimate the quantity of fish that were caught by specific types of gear and the location of the fishing activity. Port agents provided this gear/area information for all of the landings data that they collected. The objective was to have gear and area information assigned to all monthly commercial landings data.

There are two problems with the commercial fishery statistics that were collected from seafood dealers. First, dealers do not always record the specific species that are caught and second, fish or shellfish are not always purchased at the same location where they are unloaded, i.e., landed. Dealers have always recorded fishery products in ways that meet their needs, which sometimes make it ambiguous for scientific uses. Although the port agents can readily identify individual species, they usually were not at the fish house when fish were being unloaded and thus, could not observe and identify the fish.

The second problem is to identify where the fish were landed from the information recorded by the dealers on their sales receipts. The NMFS standard for fisheries statistics is to associate commercial statistics with the location where the product was first unloaded, i.e., landed, at a shore-based facility. Because some products are unloaded at a dock or fish house and purchased and transported to another dealer, the actual 'landing' location may not be apparent from the dealers' sales receipts. Historically, communications between individual port agents and the area supervisors were the primary source of information that was available to identify the actual unloading location.

Cooperative Statistics Program
==============================
In the early 1980s, it became apparent that the collection of commercial fisheries statistics was an activity that was conducted by both the Federal government and individual state fishery agencies. Plans and negotiations were initiated to develop a program that would provide the fisheries statistics that are needed for management by both Federal and state agencies. By the mid-1980s, formal cooperative agreements had been signed between the NMFS/SEFSC and each of the eight coastal states in the southeast, Puerto Rico and the US Virgin Islands.

Initially, the data collection procedures that were used by the states under the cooperative agreements were essentially the same as the historical NMFS procedures. As the states developed their data collection programs, many of them promulgated legislation that authorized their fishery agencies to collect fishery statistics. Many of the state statutes include mandatory data submission by seafood dealers.

Because the data collection procedures (regulations) are different for each state, the type and detail of data varies throughout the Region. The commercial landings database maintained in SECPR contains a standard set of data that is consistent for all states in the Region.

A description of the data collection procedures and associated data submission requirements for each state follows.

Florida
=======

Prior to 1986, commercial landings statistics were collected by a combination of monthly mail submissions and port agent visits. These procedures provided quantity and value, but did not provide information on gear, area or distance from shore. Because of the large number of dealers, port agents were not able to provide the gear, area and distance information for monthly data. This information, however, is provided for annual summaries of the quantity and value and known as the Florida Annual Canvas data (see below).

Beginning in 1986, mandatory reporting by all seafood dealers was implemented by the State of Florida. The State requires that a report (ticket) be completed and submitted to the State for every trip. Dealers have to report the type of gear as well as the quantity (pounds) purchased for each species. Information on the area of catch can also be provided on the tickets for individual trips. As of 1986 the ALS system relies solely on the Florida trip ticket data to create the ALS landings data for all species other than shrimp.

Georgia
=======

Prior to 1977, the National Marine Fisheries Service collected commercial landings data Georgia. From 1977 to 2001 state port agents visited dealers and docks to collect the information on a regular basis. Compliance was mandatory for the fishing industry. To collect more timely and accurate data, Georgia initiated a trip ticket program in 1999, but the program was not fully implemented to allow complete coverage until 2001. All sales of seafood products landed in Georgia must be recorded on a trip ticket at the time of the sale. Both the seafood dealer and the seafood harvester are responsible for insuring the ticket is completed in full.

South Carolina
===========
Prior to 1972, commercial landings data were collected by various federal fisheries agents based in South Carolina, either U.S. Fish or Wildlife or National Marine Fisheries Service personnel. In 1972, South Carolina began collecting landings data from coastal dealers in cooperation with federal agents. Mandatory monthly landings reports on forms supplied by the Department are required from all licensed wholesale dealers in South Carolina. Until fall of 2003, those monthly reports were summaries collecting species, pounds landed, disposition (gutted or whole) and market category, gear type, and area fished; since September 2003, landings have been reported by a mandatory trip ticket system collecting landings by species, disposition and market category, pounds landed, ex-vessel prices with associated effort data to include gear type and amount, time fished, area fished, along with vessel and fisherman information.

South Carolina began collecting TIP length frequencies in 1983 as part of the Cooperative Statistics Program. Target species and length quotas were supplied by NMFS and sampling targets were established for monthly commercial trips by gear sampling was set to collect those species with associated length frequencies. In 2005, SCDNR began collecting age structures (otoliths and spines) in addition to length frequencies, using ACCSP funding to supplement CSP funding. Typically for every four fish measured a single age structure was collected. This sampling periodicity was changed in 2010 to collect both a length and age structure from every fish intercepted as a recommendation from the SEFSC.

North Carolina
===========
The National Marine Fisheries Service prior to 1978 collected commercial landings data for North Carolina. Port agents would conduct monthly surveys of the state's major commercial seafood dealers to determine the commercial landings for the state. Starting in 1978, the North Carolina Division of Marine Fisheries entered into a cooperative program with the National Marine Fisheries Service to maintain the monthly surveys of North Carolina's major commercial seafood dealers and to obtain data from more dealers.

The North Carolina Division of Marine Fisheries Trip Ticket Program (NCTTP) began on 1 January 1994. The NCTTP was initiated due to a decrease in cooperation in reporting under the voluntary NMFS/North Carolina Cooperative Statistics Program in place prior to 1994, as well as an increase in demand for complete and accurate trip-level commercial harvest statistics by fisheries managers. The detailed data obtained through the NCTTP allows for the calculation of effort (i.e. trips, licenses, participants, vessels) in a given fishery that was not available prior to 1994 and provides a much more detailed record of North Carolina's seafood harvest.

NMFS SECPR Annual Canvas Data for Florida

The Florida Annual Data files from 1976–1996 represent annual landings by county (from dealer reports) which are broken out on a percentage estimate by species, gear, area of capture, and distance from shore. These estimates are submitted by Port agents, which were assigned responsibility for the particular county, from interviews and discussions from dealers and fishermen collected throughout the year. The estimates are processed against the annual landings totals by county on a percentage basis to create the estimated proportions of catch by the gear, area and distance from shore. The sum of percentages for a given Year, State, County, Species combination will equal 100.

Area of capture considerations: ALS is considered to be a commercial landings database which reports where the marine resource was landed. With the advent of some State trip ticket programs as the data source the definition is more loosely applied. As such one cannot assume reports from the ALS by State or county will accurately inform you of Gulf vs. South Atlantic vs. Foreign catch. To make that determination you must consider the area of capture.

4. Recreational Fishery Statistics

4.1 Overview

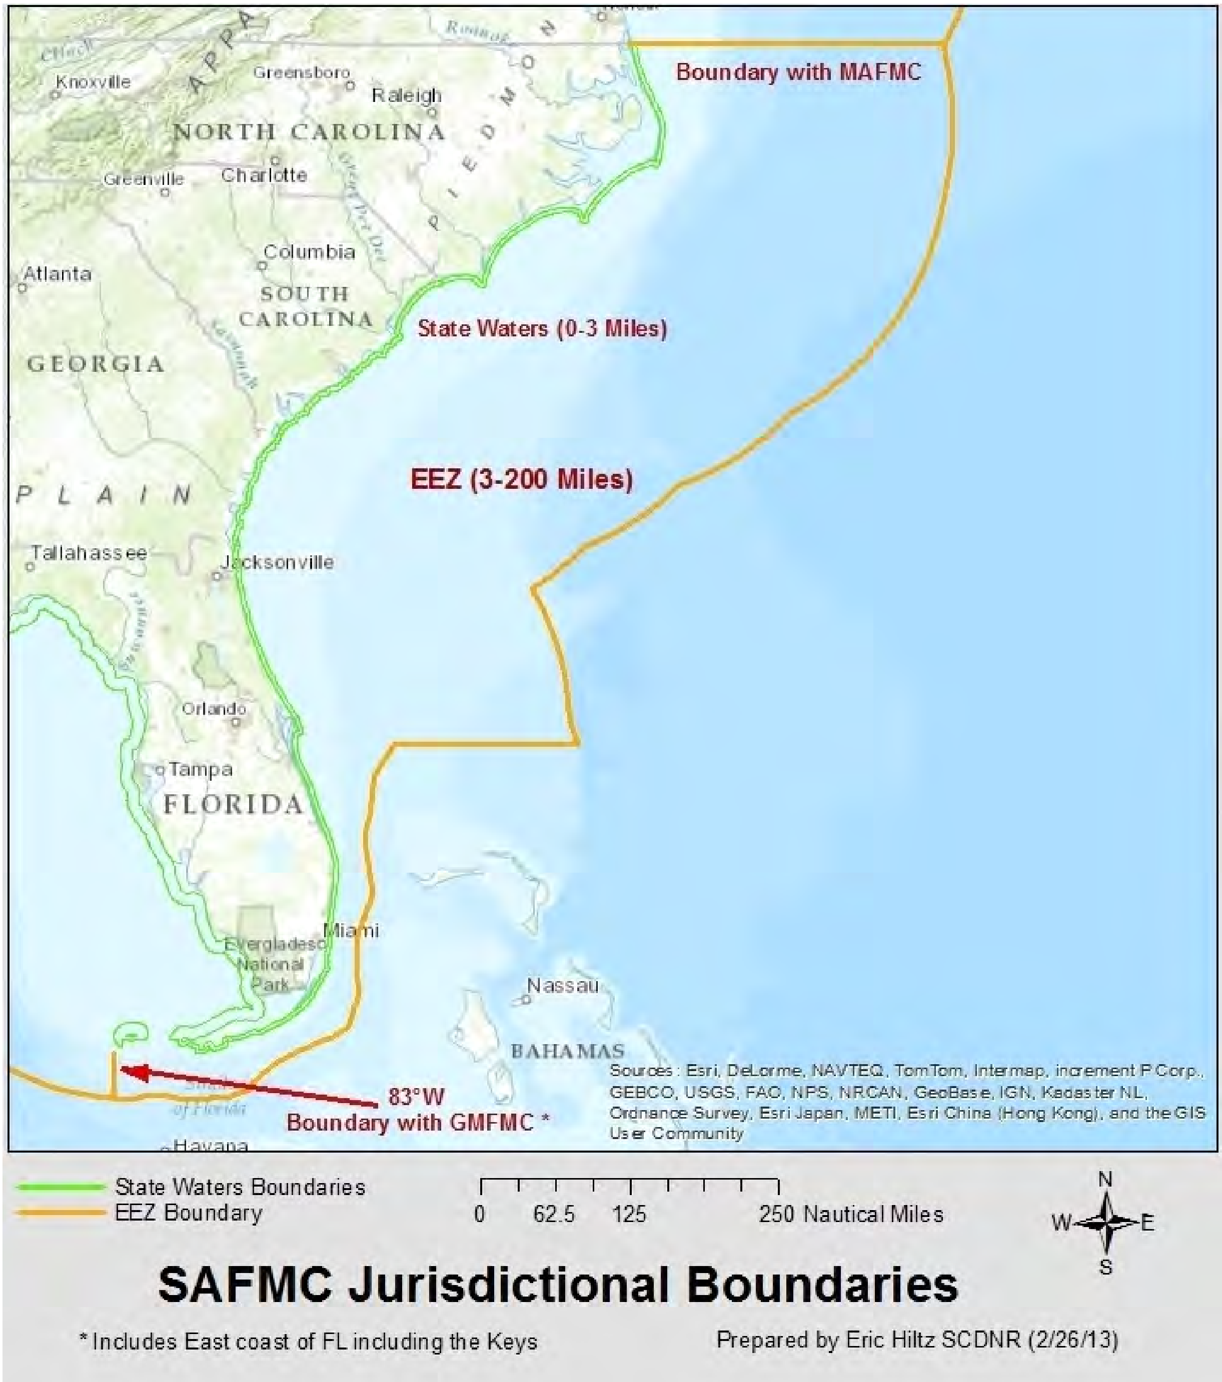
4.1.1 Recreational Working Group (RWG) Membership

Members- Ken Brennan (Leader, NMFS Beaufort, NC), Mark Brown (SAFMC Appointee/Industry rep SC), Sonny Davis (SAFMC Appointee\ Industry rep NC), Kelly Fitzpatrick (NMFS Beaufort, NC), Dawn Franco (GADNR), Eric Hiltz (SCDNR), Rusty Hudson (SAFMC Appointee\ Industry rep FL) Robert Johnson (SAFMC Appointee\ Industry rep FL), Mike Larkin (SERO), Vivian Matter (NMFS SEFSC), Beverly Sauls (FWC, FL), Bill Shearin (SAFMC Appointee\ Industry rep GA), Erik Williams (NMFS Beaufort, NC) and Chris Wilson (NCDNR)

4.1.2 Issues

1) Allocation of Monroe county catches to the Atlantic or the Gulf of Mexico: may vary by data source depending on differing spatial resolutions of the datasets.
2) Headboat estimated landings start in 1972 for NC and SC, 1977 in GA\NEFL and 1981 in SEFL. Estimating red snapper headboat landings from 1972 to1980 (date dependent on region) for periods of partial geographic coverage in the SRHS.
3) Headboat discards. Data are available from the SRHS since 2004. Review whether they are reliable for use, and determine if there are other sources of data prior to 2004 that could be used as a proxy to estimate headboat discards.
4) Calibration of Marine Recreational Fisheries Statistics Survey (MRFSS) to Marine Recreational Information Program (MRIP) 1981-2003.
5) Charter boat landings: MRFSS charter survey methods changed in 2003 in East Florida and in 2004 for Georgia and north.
6) Combined charter boat/headboat landings, 1981-1985: Official headboat landings are available from the SRHS. Therefore, the headboat component of the MRFSS combined charter boat/headboat mode must be parsed out.
7) Usefulness of historical data sources to generate estimates of landings prior to 1981. Review previous methods (SEDAR 24) and other data sources.
8) Review data sources provided for landings and discards in 2012, 2013, and 2014 and decide which will be used for final numbers/estimates.
9) MRIP APAIS adjustment: change in survey protocols starting in 2013.

4.1.3 South Atlantic Fishery Management Council Jurisdictional Boundaries



4.2 Review of Working Papers

SEDAR41-DW-01, *Georgia Headboat Red Snapper Catch & Effort Data, 1983-2014. Capt. Steve Amick and Kathy Knowlton 2015.*
This working paper presents detailed red snapper catch records from a GA headboat. The captain, Steve Amick, recorded his catch records in personal logbooks at the end of every fishing day, including number of released fish (a data element not available for headboats from the NMFS survey until 2004). He offered to provide these data through a cooperative effort with personnel at the Georgia Department of Natural Resources for consideration at SEDAR41. A portion of these data (percent released fish) was used to estimate headboat discards prior to 2007 in SEDAR24. Data elements included vessel, trip type, number red snapper released alive, number red snapper harvested, number of anglers, number of vessel trips and, since 2010, lengths of released fish. Throughout the entire time period (1983 through 2014), Captain Amick typically fished depths of 90-120 feet in the NMFS headboat survey grid 31-80 southeast of Savannah, GA. However, once the moratorium on red snapper harvest began in 2010, Captain Amick's fishing methods changed in an effort to capture and release fewer red snapper. These changes include number of hooks per angler, rigging, bait type, maximum depth fished and angler experience. These changes were significant, and caution should be used when comparing data in the time series from 2010-2014 to those data prior to 2010. Combined, these data represent ~4,400 snapper-grouper fishing trips in which ~45,000 anglers caught ~48,000 and harvested ~22,000 red snapper. They also represent lengths of ~2,000 red snapper released during 2010-2014. The RFWG accepted this working paper and data within for further detailed review.

SEDAR41-DW02, *Georgia Red Snapper Catch and Effort Data Collection during Mini-seasons, 2012-2014. Kathy Knowlton 2015.*
The Georgia red snapper catch and effort data collection during mini-seasons 2012 thru 2014 included phone surveys and biological data collection from for-hire captains, a coast wide carcass collection program, and an electronic survey open to private anglers. Commercial biological sampling was conducted in 2013 and 2014. Biological data collected included centerline length, whole weight (if applicable), sex, and otoliths. General fishing location or depth were also requested for each angler trip. Dockside sampling was mostly from two for-hire captains, at one location, that had previously participated extensively in voluntary red snapper research. A second dockside sampling location was added in 2014. For-hire catch and effort data were collected via telephone interviews with the Georgia for-hire captains who actively fished with and possessed the federal snapper-grouper CH/HB permit. Calls were placed on the Mondays following the fishing weekend, or following the season, and repeated attempts were made throughout the week until the captains were reached. Data elements included whether the trip did or did not target red snapper, number of anglers, and number of fish released and harvested. A voluntary electronic catch survey was available to the public to submit any fishing

trips that targeted red snapper (including trips that targeted but did not catch red snapper). Data elements included trip date and duration, trip departure location, depth fished, number of anglers, number and size of harvested and released fish, and whether the harvested fish were donated to a GADNR carcass freezer. Biological data collected in 2012 included 64 fish via dockside and carcass program sampling (40 whole for-hire fish and 24 carcasses). Effort data collected in 2012 included 16 for-hire trips (2 HB and 14 CH) equaling 100 angler trips (24 HB and 76 CH) and 8 private boat mode vessel trips equaling 31 angler trips. Biological data collected in 2013 included 91 fish via dockside and carcass program sampling (28 whole for-hire fish, 21 gutted commercial fish, and 42 carcasses). Effort data collected in 2013 included 11 for-hire trips (2 HB and 9 CH) equaling 70 angler trips (23 HB and 47 CH) and 13 private boat mode vessel trips equaling 53 angler trips. Biological data collected in 2014 included 283 fish via dockside and carcass program sampling (146 whole for-hire fish, 13 gutted commercial fish, and 124 carcasses). Effort data collected in 2014 included 45 for-hire trips (10 HB and 35 CH) equaling 312 angler trips (132 HB and 180 CH) and 21 private boat mode vessel trips equaling 120 angler trips.

SEDAR41-DW17, *Estimates of Historic Recreational Landings of Red Snapper in the South Atlantic Using the FHWAR Census Method. Brennan, K 2014.*
The National Survey of Fishing, Hunting, and Wildlife-Associated Recreation Survey (FHWAR) has been conducted every 5 years since 1955 and is one of the oldest and most comprehensive recreational surveys. The FHWAR census method utilizes information from these surveys including U.S. angler population estimates and angling effort estimates from 1955–1985 for the South Atlantic region. To obtain historical red snapper landings prior to 1981, estimated saltwater angler trips (1955-1980) are multiplied by average catch rates that are calculated from early years (1981-1985) of the MRFSS/MRIP data. Interpolation is used to complete time series.

SEDAR41-DW18, *South Carolina Red Snapper Catch & Biological Sampling Data Collection during Mini-Seasons, 2012-2013. Duke, A and E. Hiltz 2014.*
Red snapper carcasses were donated to the South Carolina Department of Natural Resources (SCDNR) by private anglers via a freezer collection program and dockside sampling. The mandatory charter logbook information that the SCDNR collects was also used to help access the mini-seasons. Additionally, an online survey was created for anglers to use to tell us about their red snapper catch.

SEDAR41-DW21, *North Carolina Division of Marine Fisheries Red Snapper Carcass Collections, 2012-2013. Duvall, M 2013.*
A pilot carcass collection program was initiated in September 2012 and continued during the 2013 red snapper season to collect biological information for the SEDAR 41 stock assessment. Eight carcass drop-off locations equipped with freezers, informational pamphlets and supplies were strategically chosen at facilities along the coast. Catch cards were used to record trip data

(date, depth, mode of fishing, effort in terms of party size and hours fished, catch information, and contact information) for each donated carcass. Incentives were offered for participation and included fish citation certificates, fish towels, and drink koozies. A total of 82 red snapper carcasses were collected (40 charter boat, 39 headboat, and 3 private boats) during 2012. In 2013, a total of 34 red snapper carcasses were collected (2 charter boat, 29 headboat, and 3 private boats).

SEDAR41-DW23, *Atlantic Red Snapper (Lutjanus campechanus) Fishing History Timeline Hudson, R 2014.*
Southeastern Fisheries Association- East Coast Fisheries Section provides the SEDAR 41 data workshop (DW) working paper to establish a historical timeline of the development of the US Atlantic Red snapper fishery, and follows various events that affected the prosecution of that fishery across time.

SEDAR41-DW24, *Atlantic Red Snapper (Lutjanus campechanus) and Gray triggerfish (Balistes capriscus) Historical Fishing Pictures Summary Hudson, R 2014.*
Southeastern Fisheries Association- East Coast Fisheries Section provides the SEDAR 41 data workshop (DW) a cache of historical deep sea for-hire fishing pictures accurately dated during the 1950's to the 1970's. This collection is from the Ponce de Leon Inlet, Greater Daytona Beach, Volusia County, Florida region. The historically professional photographs are significant as they demonstrate, visually, the for-hire recreational landings of Atlantic Red snapper and Red snapper by day, month and year for this region.

SEDAR41-DW25, *Atlantic Red Snapper (Lutjanus campechanus) and Gray triggerfish (Balistes capriscus) Index of For-Hire Vessels from the SAFMC region Hudson, R 2014.*
Southeastern Fisheries Association- East Coast Fisheries Section provides the SEDAR 41 data workshop (DW) an index of for-hire vessels from the South Atlantic Fishery Management Council (SAFMC) region that mostly participated in the fisheries for Atlantic Red snapper and Red snapper.

SEDAR41-DW26, *Atlantic Red Snapper (Lutjanus campechanus) and Gray triggerfish (Balistes capriscus) Photographic and Other Evidence of For-Hire Vessels in the SAFMC region Hudson, R 2014.*
Southeastern Fisheries Association- East Coast Fisheries Section provides the SEDAR 41 data workshop (DW) photographic and other evidence of for-hire vessels from the South Atlantic Fishery Management Council (SAFMC) region that mostly participated in the fisheries for Atlantic Red snapper and Red snapper.

SEDAR41-DW-27, *Red snapper mini-season ad-hoc working group report. Siegfried, K 2014.*

The main objective of the red snapper mini season ad hoc working group is to inform the decision that the recreational workgroup will make on which landings and discards to report for red snapper during the mini seasons in 2012 and 2013. In 2009, an interim rule was enacted to prohibit harvest of red snapper from January 4, 2010 to June 2, 2010. This rule was extended until December and an emergency rule was used to prohibit harvest through 2011. In 2012 and 2013, emergency rules were used to re-open the fishery for a very short duration. The 2012 mini-season was six days long: 9/14-9/16 & 9/21-9/23. The 2013 mini-season was three days long: 8/23-8/25. The key issue is that MRIP was not designed to capture short pulses of fishing, but rather to capture 2-month intervals (waves) of landings, discards, and effort. When a short opening occurs in a fishery, it is unlikely that MRIP will capture the event during its random sampling. If MRIP does happen to capture the event in terms of catch rate, the event will be scaled up by effort in that wave. State partners from North Carolina, South Carolina, Georgia, and Florida supplied data from studies conducted in each state during the 2012 and 2013 mini-season as an attempt to supplement the MRIP data. A detailed explanation of how MRIP estimates are calculated was included in this document. Full descriptions of methods and data collected are available in the working papers SEDAR41-DW-21 (North Carolina), SEDAR41-DW18 (South Carolina), SEDAR41-DW02 (Georgia), and SEDAR41-RD14 and SEDAR41-RD15 (Florida). Merits and deficiencies of each study were briefly outlined, as well as any potential bias.

SEDAR41-DW32, *SCDNR Charterboat Logbook Program Data, 1993 – 2013. Hiltz, E 2014.*
The South Carolina Department of Natural Resources (SCDNR) charterboat logbook program was used to develop indices of abundance for red snapper from 1993 – 2012. The indices of abundance are standardized catch per unit effort (CPUE; catch per angler hour). For red snapper, a delta GLM was used to produce annual abundance estimates. The indices are meant to describe the population trends of fish caught by V1 (6-pack) charter vessels operating in or off of South Carolina.

SEDAR41-DW33, *Size Distribution, Release Condition, and Estimated Discard Mortality of Red Snapper Observed in For-Hire Recreational Fisheries in the South Atlantic, Sauls, B., C. Wilson and K. Fitzpatrick.*
Since 2004, trained fishery observers have been employed on randomly selected headboat fishing trips to observe angler fishing activity and collect detailed information on discarded fish. In addition, observers were employed on charter vessels on the Atlantic coast of Florida in 2013. This paper summarizes the number of sampled trips by state, generates sample weights, and plots weighted length frequencies for all observed red snapper (both harvested and discarded) from headboats. Additional data collected in Florida on hook type, fishing depth, and release condition of observed discards is also synthesized.

SEDAR41-DW38, *Historic catch rates of Red Snapper by headboats through historic photograph analysis. Gray et al. 2014.*
Photographs that span 1951 through 1974 represent historic evidence of catch rates of common recreational species in the Daytona Beach area during that time, including catch rates for Red Snapper. These photographs precede fisheries dependent monitoring estimates, providing historic catch per unit effort (CPUE) rates for stock assessments. Results presented here are a preliminary analysis for Red Snapper CPUE.

SEDAR41-DW42, *South Atlantic Red Snapper (Lutjanus campechanus) monitoring in Florida: Revised recreational private boat mode estimates for 2012 and 2013 mini-seasons, and new private boat mode estimates for the 2014 mini-season. Sauls, B.*
This report provides revised estimates of Red Snapper recreational harvest during mini-season openings in 2012 and 2013 for the private boat segment off the Atlantic Coast of Florida. Methods and results were previously described in reference documents for the first Data Workshop for SEDAR41 (SEDAR41-RD14, SEDAR41-RD15). New results for the 2014 fishing season are also presented in this paper.

4.3 Recreational Landings

Total recreational landings are summarized below by survey. A map and figures summarizing the total recreational red snapper landings are included in Figure 4.11.1.

4.3.1 Marine Recreational Fisheries Statistics Survey (MRFSS) and Marine Recreational Information Program (MRIP)

Introduction
The Marine Recreational Fisheries Statistics Survey (MRFSS) and the Marine Recreational Information Program (MRIP) provide a long time series of estimated catch per unit effort, total effort, landings, and discards for six two-month periods (waves) each year. MRFSS/MRIP provides estimates for three recreational fishing modes: shore-based fishing (SH), private and rental boat fishing (PR), and for-hire charter and guide fishing (CH). When the survey first began in Wave 2 (Mar/Apr), 1981, headboats were included in the for-hire mode, but were excluded after 1985 in the South Atlantic and Gulf of Mexico to avoid overlap with the Southeast Region Headboat Survey (SRHS) conducted by the NMFS Beaufort, NC lab.

The MRFSS/MRIP survey covers coastal Atlantic coast states from Maine to Florida. The state of Florida is sampled as two sub-regions. The east Florida sub-region includes counties adjacent to the Atlantic coast from Nassau County south through Miami-Dade County, and the west Florida sub-region includes Monroe County (Florida Keys) and counties adjacent to the Gulf of Mexico. Separate estimates are generated for each Florida sub-region, and those estimates may be post-stratified into smaller regions based on proportional sampling. Sampling is not conducted in Wave 1 (Jan/Feb) north of Florida because fishing effort is very low or non-existent, with the exception of NC, where wave 1 has been sampled since 2006.

The MRFSS/MRIP design incorporates three complementary survey methods for estimating catch and effort. Catch data are collected through angler interviews during dockside intercept surveys of recreational fishing trips after they have been completed. Effort data are collected using two telephone surveys. The Coastal Household Telephone Survey (CHTS) uses random digit dialing of coastal households to obtain detailed information about the previous two months of recreational fishing trips from the anglers. The weekly For-Hire Survey was implemented in the South Atlantic in the 2000's and interviews charterboat operators (captains or owners) to obtain the trip information with only one-week recall period. Effort estimates from the two telephone surveys are aggregated to produce total effort estimates by wave. Catch rates from dockside intercept surveys are combined with estimates of effort from telephone interviews to estimate total landings and discards by wave, mode, and area fished (inland, state, and federal waters).

Catch estimates from early years of the survey are highly variable with high proportional standard errors (PSE's), and sample size in the dockside intercept portion have been increased over time to improve precision of catch estimates. Several quality assurance and quality control improvements were implemented for the intercept surveys in 1990. Prior to 1990 the contractor did not have regional representatives hired to supervise the samplers in any given area. All samplers were hired as independent sub-contractors and communicated directly with the contractor's home office staff. It is much more likely that the samplers who worked in the 80's would have varied more in their interpretation of sampling protocols and their ability to identify at least some of the more difficult-to-recognize species. There were a number of other changes made to enhance consistency in sampling protocols and improve error-checking in the Statement of Work for the 1990-1992 contracts. Improvements have continued over the years, but the biggest changes happened at that time (personal communication, NMFS). Full survey documentation and ongoing efforts to review and improve survey methods are available at: http://www.st.nmfs.noaa.gov/recreational-fisheries/MRIP/program-evolutionSurvey methods for the for-hire fishing mode have seen the most improvement over time. Catch rate data have improved through increased sample quotas and additional sampling (requested and funded by the states) to the intercept portion of the survey. It was also recognized that the random household telephone survey was intercepting relatively few anglers in the for-hire fishing mode and the For-Hire Telephone Survey (FHS) was developed to estimate effort in the for-hire mode. The new method draws a random sample of known for-hire charter and guide vessels each week and vessel operators are called and asked directly to report their fishing activity. The FHS was officially adopted in the Gulf coast states (including Monroe County in West Florida) in 2000, in East Florida in 2003, and in Georgia through Maine in 2005. The FHS was pilot tested in the

Gulf of Mexico in 1998 and 1999 and in Georgia through Maine in 2004. The FHS does not consider the estimates during pilot years as official estimates; however, FHS data for these years have been used since 2005(e.g. SEDAR 7 red snapper, SEDAR 16 king mackerel, SEDAR 25 black sea bass, etc.).

A further improvement in the FHS method was the pre-stratification of Florida into smaller sub-regions for estimating effort. Pre-stratification defines the sample unit on a sub-state level to produce separate effort estimates by these finer geographical regions. The FHS sub-regions include three distinct regions bordering the Atlantic coast: Monroe County (sub-region 3), SE Florida from Dade through Indian River counties (sub-region 4), and NE Florida from Martin through Nassau counties (sub-region 5). The coastal household telephone survey method for the for-hire fishing mode continues to run concurrently with the newer FHS method.

Calibration of traditional MRFSS charter boat estimates

Conversion factors have been estimated to calibrate the traditional MRFSS charterboat estimates with the FHS for 1986-2003 in the South Atlantic (SEDAR16-DW-15, Sminkey, 2008) and for 1981-2003 in the mid-Atlantic (SEDAR17-Data Workshop Report, 2008). 1986-2003 South Atlantic calibration factors were updated in 2011 (SEDAR25-Data Workshop Report, 2011). The relationship between the old charterboat method estimates of angler trips and the FHS estimates of angler trips was used to estimate the conversion factors. Since these factors are based on effort, they can be applied to all species' landings. In the Gulf of Mexico and the South Atlantic, the period of 1981-1985 could not be calibrated with the same ratios developed for 1986+ because in the earlier 1981-1985 time period, MRFSS considered charterboat and headboat as a single combined mode. Thus, in order to properly calibrate the estimates from 1981-1985, headboat data from the Southeast Region Head-boat Survey (SRHS) were included in the analysis. To calibrate the MRFSS combined charterboat and headboat mode effort estimates in 1981-1985, conversion factors were estimated using 1986-1990 effort estimates from both modes, in equivalent effort units, an angler trip (SEDAR28-DW-12). These calibration factors were applied to the charterboat estimates and are tabulated in Table 4.10.1. The calibration factors have been updated or developed since SEDAR 24.

Separation of SA combined charter/headboat mode

In the South Atlantic, 1981-1985 charter and headboat modes were combined into one single mode for estimation purposes. Since the NMFS Southeast Region Headboat Survey (SRHS) began in this region in 1981, the MRFSS combined charter/headboat mode must be split in order to not double estimate the headboat mode for these years. MRFSS charter/headboat mode was split in these years by using a ratio of SRHS headboat angler trip estimates to MRFSS charter boat angler trip estimates for 1986-1990. This method has been used in the past (SEDAR 28-Spanish mackerel and cobia). The mean ratio was calculated by state (or state equivalent to match SRHS areas to MRFSS states) and then applied to the 1981-1985 estimates to strip out the headboat component. These headboat estimates were then eliminated from the MRFSS estimates.

MRIP weighted estimates, APAIS changes, and the calibration of MRFSS estimates
The Marine Recreational Information Program (MRIP) was developed to generate more accurate recreational catch rates by re-designing the MRFSS sampling protocol to address potential biases including port activity and time of day. Revised catch and effort estimates from 2004 to 2012, based on MRIP's improved estimation methodology, were released on January 25, 2012. For estimates prior to 2004, an MRIP Calibration Workshop was held in 2012, and the Consultant's Report recommended that MRFSS estimates prior to 2004 be calibrated to the new MRIP estimation method (Boreman, 2012) using a method developed by an MRFSS/MRIP Calibration Ad-hoc Working Group following the Calibration Workshop (Salz et al. 2012).

Starting in 2013, wave 2, the MRIP Access Point Angler Intercept Survey (APAIS) implemented a "revised sampling design that includes an updated sampling frame; eliminates interviewer latitude in selecting interviewing sites; establishes discrete sampling periods of fixed duration, including nighttime sampling; and requires interviewers to collect detailed information about the number of completed boat and angler fishing trips during the sampling period" (MRIP Implementation Plan 2011). To address this new survey design change, a second Calibration Workshop was held in 2014 and the final report from that workshop recommended an additional calibration for catch estimates (Carmichael and Van Vorhees 2015). The recommended interim calibration approach, found in Appendix 2 of the report, uses the ratio of the catch estimated in 2013 using the entire sampling period for the new MRIP APAIS design, versus catch estimated in 2013 using only during peak sampling periods in the old MRFSS survey design. Red snapper catch for all years prior to 2013 was re-estimated using this ratio, based on a single year of data from the new APAIS design (2013), for each sub-region, state, and mode combination with all waves and areas combined. Tables 4.10.2 and 4.10.3 show the differences between the South Atlantic red snapper MRIP APAIS landing and discard estimates and the MRIP estimates for the time period 2004-2012.

As new MRIP APAIS estimates are available for a portion of the recreational time series that the MRFSS covers, conversion factors between the MRFSS estimates and the MRIP APAIS estimates were developed in order to maintain one consistent time series for the recreational catch estimates. Ratio estimators, based on the ratios of the means, were developed for South Atlantic red snapper to hind-cast catch and variance estimates by fishing mode. In order to apply the charter boat ratio estimator back in time to 1981, charter boat landings were isolated from the combined charter boat /headboat mode for 1981-1985. The MRFSS to MRIP APAIS calibration process is the same as the original MRFSS to MRIP adjustment that has been used since 2012, which is detailed in SEDAR31-DW25 and SEDAR32-DW02. Table 4.10.4 shows the ratio estimators used in the calibration. Figure 4.11.2 shows the MRIP versus MRIP APAIS adjusted estimates for South Atlantic red snapper along with the 95% confidence intervals. The RWG expressed concern with basing the MRIP APAIS adjustment on 2013 red snapper MRIP data. The mini season in this year consisted of three fishing days which resulted in low sample sizes in the MRIP database. The group had reservations about using an adjustment based on so little data. The RWG suggested using an additional year of data from 2014 to increase the amount of information used in the adjustment. This was not feasible for this assessment due to limited MRIP staff time. In accordance with the recommendations set forth by the MRIP Calibration Workshop II, MRIP personnel will continue to investigate the remaining two methods described in the report. It is possible that one of them will be determined to be a better method at some future date. In the interim, the simple ratio method is recommended by the MRIP Calibration Workshop II and the RWG.

Monroe County

Monroe County MRFSS landings from 1981 to 2003 can be post-stratified to separate them from the MRFSS West Florida estimates. Post-stratification proportionally distributes the state-wide (FLE and FLW) effort into finer scale sub-regions and then produces effort estimates at this finer geographical scale. This is needed for the private and shore modes (all years) and charter boat mode (prior to FHS). FHS charter boat mode estimates are already pre-stratified, as discussed above. Monroe County MRIP landings starting in 2004 can be estimated separately from the remaining West Florida estimates using domain estimation. The Monroe County domain includes only intercepted trips returning to that county as identified in the intercept survey data. Estimates are then calculated within this domain using standard design-based estimation which incorporates the MRIP design stratification, clustering, and sample weights.

Although Monroe county estimates can be separated using these processes, they cannot be partitioned into those from the Atlantic Ocean and those from the Gulf of Mexico. Red snapper are less common on the extreme south Atlantic coast of Florida. In accordance with SEDAR 24 (SA red snapper) and SEDAR 31 (Gulf red snapper), the recreational workgroup recommends allocating Monroe County estimates from MRIP to the Gulf of Mexico.

Shore Estimates

Red snapper is an offshore species with a strong association with reefs and hard bottom. Several species of nearshore fish are often referred to as “red snapper” by anglers, which may explain the infrequent red snapper shore landings in the MRIP time series. In accordance with SEDAR 24, the recreational workgroup recommends omitting the MRIP shore mode estimates.

Calculating landings estimates in weight

The MRFSS and the MRIP surveys use different methodologies to estimate landings in weight. To apply a consistent methodology over the entire recreational time series, the Southeast Fisheries Science Center (SEFSC) implemented a method for calculating average weights for the

MRIP (and MRIP adjusted) landings. This method is detailed in SEDAR32-DW-02. The length-weight equation developed by the Life History Working Group (W=1.58E-5*(L^3.03)) was used to convert red snapper sample lengths into weights, when no weight was recorded. W is whole weight in grams and L is fork length in millimeters.

1981, wave 1

MRFSS began in 1981, wave 2. In the east coast of Florida, catch for 1981 wave 1 was estimated by determining the proportion of catch in wave 1 to catch in all other waves for 1982-1984 by fishing mode and area. These proportions were then used to estimate wave 1 in 1981 from the estimated catches in other waves of that year. This methodology is consistent with past SEDARs (e.g. SEDAR 28 Spanish mackerel and cobia).

Variances

Variances are provided by MRFSS/MRIP for their recreational catch estimates. Variances are adjusted to take into account the variance of the conversion factor when an adjustment to the estimate has been made (FHS and MRIP conversions). However, the variance estimates of the charter and headboat modes in 1981-1985 are missing. This is due to the MRIP calibration procedure, which requires the combined charter/headboat mode to be split in order to apply the MRIP adjustment to the charter mode back to 1981. In addition, variance estimates are not available for weight estimates generated through the SEFSC method described above.

Results

MRIP landings in numbers of fish and in whole weight in pounds are presented in Table 4.10.5. CVs associated with estimated landings in numbers are also shown. South Atlantic red snapper estimates include North Carolina through East Florida, not including Monroe County, FL. There are no red snapper estimates in MRIP north of North Carolina. MRIP estimates shown are through 2011. Mini season estimates from 2012 to 2014 will be discussed separately.

The RWG examined the high MRIP estimate in 1985 (288,971 fish). The 1984 estimate (212,547 fish) was also quite high, showing an increase in landings these two years. As stated above, the estimates in these early years of the survey are highly variable. The 1985 estimate is made up of a number of cells: FLE, PR, ocean>3mi, wave 1 (81,635 fish); FLE, PR, ocean>3mi, wave 5 (51,675 fish); FLE, CH, ocean>3mi, wave 4 (42,631 fish); NC, CH, ocean>3mi, wave 4 (50,776 fish) among others. Table 4.10.6 shows the estimates for 1984 and 1985 by state, wave, and mode. The RWG investigated two estimates which occurred in waves 1 and 2 that were particularly concerning due to the time of year they occurred. These are highlighted in the table in yellow. The 1984 wave 2 private mode estimate from Florida was based on 3 trips, all with an area greater than 3 miles

1a) Volusia County, March, 2 anglers, 1 fish, size: 330mm; 0.6kg
2a) St. John County, April, 4 anglers, 35 fish, no size information

3a) Duval County, April, 2 anglers, 35 fish, sizes: 232-329mm; 0.2- 0.5kg

The 1985 wave 1 private mode estimate from Florida was based on 4 trips, all occurring in February.

1b) Indian River County, >3 miles, 1 angler, 6 fish, no size information

2b) Indian River County, >3 miles, 4 anglers, 16 fish, sizes: 430-530mm; 1.4- 2.3kg

3b) Dade County, <3 miles, 2 anglers, 1 fish, size: 430mm; 0.9kg

4b) Dade County, <3 miles, 4 anglers, 1 fish, size: 410mm, 1.3kg

The RWG speculated that the red snapper intercepted in trips 1a, 3a, 3b, and 4b were probably vermilion snapper due to their small sizes and in the cases of 3b and 4b, the location of where they were caught. In the case of the 1985 wave 1 private mode estimate from Florida, suspected trips only account for less than 10% of that particular estimate. This was determined using the breakdown of the final estimate by area fished. Less than 10% of that estimate came from area fished less than 3 miles (trips 3b and 4b). It is difficult to make changes to the intercept data many years after the data is collected and the RWG recommends using the resulting estimates "as is" and taking into consideration an appropriate measure of the precision (personal communication, NMFS). Further changes preferred by the assessment panel could include modeling, substitutions, or sensitivity runs. These should be fully documented and approved at the Assessment Workshop.

4.3.2 Southeast Region Headboat Survey

Introduction

The Southeast Region Headboat Survey (SRHS) estimates landings and effort for headboats in the South Atlantic and Gulf of Mexico. The Headboat Survey began in 1972 in North Carolina and South Carolina. In 1976 the survey was expanded to northeast Florida (Nassau-Indian River counties) and Georgia, followed by southeast Florida (St. Lucie-Monroe counties) in 1978. Due to headboat area definitions and confidentiality issues, Georgia and East Florida data must be combined. The SRHS began in the Gulf of Mexico in 1986 and extends from Naples, FL to South Padre Island, TX. The South Atlantic and Gulf of Mexico headboat surveys generally include 70-80 vessels participating in each region annually.

The SRHS incorporates two components for estimating catch and effort. 1) Biological information: size of the fish landed are collected by port samplers during dockside sampling, where fish are measured to the nearest mm and weighed to the nearest 0.01 kg. These data are used to generate mean weights for all species by area and month. Port samplers also collect otoliths and spines for ageing studies during dockside sampling events. 2) Information about total catch and effort are collected via a logbook form that is filled out by vessel personnel for individual trips. These logbooks are summarized by vessel to generate estimated landings by species, area, and time strata. Most recently, the SRHS implemented electronic logbook reporting in the South Atlantic and Gulf of Mexico as of Jan 1, 2013. Headboat personnel now have the ability to report trip information via a website or mobile application.

In the early years of the SRHS, there was only partial geographic coverage in the South Atlantic. Red snapper landings are available in NC and SC beginning in 1972. Landings are not available for GA/NEFL from 1974-1975 or SEFL from 1972-1980. For SEDAR 24, estimates for these areas/time periods were calculated using the ratio of NC and SC landings from 1972-1980 for periods of partial coverage. A three year ratio was used to estimate landings for the areas and time periods without coverage. For GA/NEFL a three year ratio is calculated by dividing the total landings for NEFL (1976-1978) by NC and SC combined total landings (1976-1978). This ratio is then multiplied to the 1974 and1975 combined total landings for NC and SC, resulting in the total landings for NEFL for 1974 and 1975. The same approach was used to calculate landings for SEFL 1972-1980 by using the total landings from 1981- 1983. This same method and landings were accepted for use in SEDAR 41.

Catch Estimates
Final SRHS landings estimates are shown in Table 4.10.7, by year and state in Figure 4.11.3. SRHS areas 1-17 are included in the red snapper stock.

Characterizing sources of uncertainty
Variances estimates are not currently available for the SRHS catch estimates. Further research is required to develop a suitable method to calculate variance. The RWG included this as a research recommendation.

4.3.3 Red Snapper Mini-Season Landings

Introduction
The main objective of the red snapper mini season ad hoc working group was to provide information to the recreational workgroup to aid in decisions that were needed on which landings and discards to report for red snapper during the mini seasons in 2012, 2013 and 2014. In 2009, an interim rule was enacted to prohibit harvest of red snapper from January 4, 2010 to June 2, 2010. This rule was extended until December and an emergency rule was used to prohibit harvest through 2011. In 2012, 2013 and 2014, emergency rules were used to re-open the fishery for a very short duration. The 2012 mini-season was six days long: 9/14-9/16 & 9/21-9/23. The 2013 mini-season was three days long: 8/23-8/25. The 2014 mini-season was 8 days long: 7/11-7/13, 7/18-7/20, and 7/25-7/26. The key issue is that MRIP was not designed to capture short pulses of fishing, but rather to capture 2-month intervals (waves) of landings, discards, and effort. When a short opening occurs in a fishery, it is unlikely that MRIP will capture the event during its random sampling. If MRIP does happen to capture the event in terms of catch rate, that event will be scaled up by effort in that wave.

The sources of mini-season data that were reviewed for potential use are as follows:

- Marine Recreational Information Program (MRIP)
- North Carolina Department of Marine Fishers (NCDMF) state survey
- South Carolina Department of Natural Resources (SCDNR) state survey
- Georgia Department of Natural Resources (GADNR) state survey
- Florida Fish and Wildlife Conservation (FWC) Commission state survey

State partners in the South Atlantic supplied data from studies conducted in each state during the 2012, 2013 and 2014 mini-seasons as an attempt to supplement the MRIP data. Brief synopses of the type of data provided are illustrated in Table 4.10.8. Full descriptions of methods and data collected are available in the working papers SEDAR41-DW27 (MRIP), SEDAR41-DW-21 (NC), SEDAR41-DW18 (SC), SEDAR41-DW02 (GA), SEDAR41-DW-42 (FL).

The recreational workgroup developed a set of rules in order to determine which data set was more appropriate for landings by state (NC, SC, GA, and FLE), mode (charter and private), and wave (1-6):
Either MRIP or state available
• Use state number if no MRIP number exists, making note of any potential bias
• Use MRIP number if no state number exists

Both MRIP and state numbers available
• Landings - Recommend using the estimate/number (MRIP or State) that is more reliable (e.g. larger sample size). In 2014, this option was clarified to include accounting for CV's, and/or biases associated with each survey.

The majority of the waves had either MRIP or State survey data available. When only the state survey data was available, potential sources of bias were considered, and noted in the decisions below. However, using the only available data for the wave was favored over using no data at all. There were several cases of overlap for landings data in 2012 (Table 4.10.9) and 2014 (Table 4.10.11). Florida was the only state that had an overlap of landings data in 2013 (Table 4.10.10).

Issue: *How to characterize the recreational landings during mini-seasons in 2012 for each state, mode, and wave.*

Option 1: Use State number if no MRIP number is available, making note of any potential bias
Option 2: Use MRIP number if no State number is available
Option 3: Use the estimate/number (MRIP or State) that is more reliable (e.g. larger sample size) when both MRIP and State numbers were available.

Decision(s):

Option 1.

- State Charter (CH) - SC (waves 3, 4, and 5) and FLE (wave 5).
- State Private (PR) - NC (wave 5) and SC (Wave 5)

The CH landings from SC and FLE were self-reported through either the logbook program (SC) or telephone survey (FLE) without methods to validate the reported landings. The PR landings from NC were primarily based on number of donated carcasses and are therefore not considered to be a random sample. Some of the PR landings from SC were from donated carcasses but also include intercepts from the SFS.

Option 2.

- MRIP FLE (wave 2).

Option 3.

- MRIP CH - NC (wave 5) - The NC charter MRIP estimate was selected over the state number because the state number was based on donated carcasses and is therefore not considered to be a random sample.
- MRIP PR - GA (wave 5) – The GA private MRIP estimate was selected over the state number because the state number was based on a voluntary self-reported online survey with a very small sample size and was not a random sample.
- State CH – GA (wave5) - The GA state CH numbers were selected over MRIP because the state survey was a census of all active captains that held federally permitted snapper grouper licenses and also had a larger sample size.
- State PR – FLE (wave 5)- The PR landings from FLE did not capture what might have occurred outside of the mini-season, however, the FLE state PR estimate were selected over MRIP due to larger sample sizes along with randomly selected intercept sites, and weighted estimates and was considered a more reliable estimate.

Issue 2: *How to characterize the recreational landings during mini-season in 2013 for each state, mode, and wave.*

Option 1: Use state number if no MRIP number is available, making note of any potential bias
Option 2: Use MRIP number if no state number is available
Option 3: Use the estimate/number (MRIP or State) that is more reliable (e.g. larger sample size) when both MRIP and state numbers were available.

Decision(s):

Option 1.

- State CH and PR – all of 2013 for NC, SC, and GA

The CH landings from NC were based on donated carcasses. The CH landings from SC and GA were self-reported through either the logbook program (SC) or telephone survey (GA) without methods to validate the reported landings but are considered to be a census of all charter captains that would have been fishing during the mini-season. The PR landings from NC and SC were primarily based on number of donated carcasses and are therefore not considered to be a random sample. The PR landings from GA were collected through a voluntary self-reported online survey with a very small sample size.

Option 2.

- MRIP CH - FLE (wave 5)

Option 3.

- State CH and PR - FLE (wave 4).

The state surveys were selected over MRIP due to larger sample sizes for the state survey and that MRIP estimated catch could have potentially been scaled up by effort in the whole 2 month time period.

Issue 3: *How to characterize the recreational landings during mini-season in 2014 for each state, mode, and wave.*

Option 1: Use State number if no MRIP number is available, making note of any potential bias
Option 2: Use MRIP number if no State number is available
Option 3: Use the estimate/number (MRIP or State) that is more reliable (taking into account sample sizes, CV's, and/or biases associated with the survey) when both MRIP and State numbers were available.

Decision(s):
Option1.

- State Charter (CH) – SC (Wave 3 and 4) - The CH landings from SC were self-reported through the logbook program without methods to validate the reported landings.
- State Private (PR) – NC (wave 4) - The PR landings from NC were based on number of donated carcasses and are therefore not considered a random sample.

Option 2.

- MRIP (PR) – FLE (Wave 1,3, and 6)

Estimates for MRIP based on 1 angler trip for each wave with high CV (>1.0) and therefore could be an overestimate of actual landings. These intercepts were verified by looking at the field data sheets.

Option 3.

- MRIP (CH) – NC (Wave 4) - The MRIP estimates were selected for CH in NC (wave 4) due to fact that the state survey number was based on carcass donations and likely to be an underestimate of statewide landings and had a larger associated bias compared with the MRIP survey methodology. The number of angler trips for NC was low (3) but the group felt that there was less potential for bias in the MRIP survey than the NC state survey.
- State (PR) – SC (Wave 4) - The SC state survey also relied solely on carcass donations but the state survey number was determined to be a more accurate representation, in this case, due to the fact that the MRIP estimate was derived from only one angler trip. The number of angler trips was not reported from the SC state survey, only conclusion was the value was greater than 1.
- State (CH) – GA (Wave 4) - The GA state CH number was selected over MRIP because the state survey was a census of all active captains that held federal snapper/grouper permits and also had a larger sample size (180) than MRIP (1).
- MRIP (PR) – GA (Wave 4) - The MRIP PR estimate was chosen over the GA state survey because the state survey information was voluntary angler reported data with no way of validating information or accounting for non-reporting.
- State (CH) – FLE (Wave 4)
- State (PR) – FLE (Wave 4)

The FLE state CH and PR estimates (wave 4) were selected over MRIP due to larger sample sizes and robust survey methodology that included randomly selected intercept sites and weighted estimates. However, it was noted that the FLE state survey could likely be an underestimate of recreational landings since there was no accounting for any fishing that may have occurred outside of the season. There were reported landings in FLE through MRIP on the day following the end of the season, Sunday July 27.

Uncertainty concerning data sources

There was extensive discussion about which data source to choose when both MRIP and state survey data were available for an individual mode and wave. The merits and deficiencies of each data source were discussed at length for the red snapper mini-seasons in 2012, 2013 and 2014. Several RWG members expressed concerns that MRIP is likely to overestimate landings of red snapper because of expansion by effort from the entire wave. Each state survey was unique and there was little similarity in methods used. The SC logbook was a census of all charter captains that would have been targeting Snapper/Grouper species during the mini-season, but it was also noted that these data are self-reported without validation and that there may be some recall bias when logs are handed in one month after the fishing occurred. The GA CH telephone survey was a census of all active CH captains that held federal permits for Snapper/Grouper species, with minimal recall bias because phone calls were made the Monday following each weekend within the mini-season in 2012 and 2013, and the Monday following the end of the mini-season in 2014, but like SC, these are all self-reported data without validation. The FLE CH telephone survey attempted to reach all captains that would have targeted red snapper during the mini-season, data were expanded to account for all captains that were not reached, recall bias was minimal because phone calls were made the week following each weekend opening, but was not a representation of any fishing that might have occurred outside of the mini-season. The SC State Finfish Survey (SFS) was only conducted in 2012 and were solely a record of number of specimens sampled without any effort information. The GA online survey was self-reported information that included number of fish harvested and/or released and number of anglers but could not be used to expand data into an estimate. A consistent comment concerning voluntary angler reported data was that it was likely to produce an underestimate since not all anglers who caught fish will participate. The FLE private boat intercept survey directly targeted the mini-season and should be an accurate estimate of total catch and effort during the mini-season, but as stated above is not a representation of any harvest that might have occurred outside the mini-season. The RWG took all of these points under consideration when deciding which data to use and felt confident in the choices that were made.

4.3.4 Historic Recreational Landings

Introduction
The historic recreational landings time period is defined as pre-1981 for the charter boat, headboat, private boat, and shore fishing modes, which represents the start of the Marine Recreational Fisheries Statistics Survey (MRFSS) and availability of landings estimates for red snapper. The Recreational Working Group was tasked with reviewing all available historical sources of red snapper landings to evaluate potential methods to compile landings prior to the available time series of MRFSS and headboat estimated landings.

The sources of historical landings that were reviewed for potential use are as follows:

- Review and Analysis of Methods to Estimate Historic Recreational Red Snapper Landings in the South Atlantic, SEDAR24-DW11.
- Anderson, 1965.
- The National Survey of Fishing, Hunting, and Wildlife-Associated Recreation Survey (FHWAR) census method, SEDAR41-DW17.
- Review of red snapper historical photos; SEDAR41-DW 24 and SEDAR41-DW 26.
- Preliminary analysis of historical photos: SEDAR41-DW 38.

SEDAR24-DW11
The SEDAR 24 Historic Fisheries Working Group (HFWG) considered several historic data sets for comparison with available recreational data sets as a possible means for regressing recreational statistics back in time. The HFWG recommended the methods that use (1) the ratios

with the commercial red snapper landings and (2) the post-adjusted U.S. Fish and Wildlife Saltwater Angling Survey estimates, be considered by the data workshop for inclusion in the stock assessment. The final decision for SEDAR 24 was to use the ratios with the commercial red snapper landings

Anderson, 1965

The RWG discussed the Anderson study as a possible source of information for historical red snapper landings. The study area designated as the Cape Canaveral area included Brevard and Volusia counties in Florida. The recreational data was obtained from field surveys from February to October, 1963 and was further limited to the southern portion of the study area. The RWG considered this spatially and temporally limiting for possibly expanding estimated landings prior to 1981. However, the RWG did conclude that the data could be used as a reference point for comparison to other methods (i.e. FWHAR method)

Preliminary analysis of historical photos

After reviewing numerous black and white photos from the east coast of Florida charter boat and headboat fishery (courtesy of R. Hudson, see below) back to the early 1950's; it was apparent that red snapper was a common recreational species in the Daytona Beach area during that time. As part of a preliminary analysis of photographs that span 1951 through 1974, 377 photographs with red snapper present were examined for historic catch rates. Red Snapper and anglers were counted and recorded from each picture in order to calculate catch per unit effort (CPUE). The results are reported in SEDAR41-DW38. Although the results were preliminary for this data workshop, the RWG agreed this analysis shows great potential for providing historic CPUE rates for future stock assessments. A proposal is being developed to provide a more complete analysis of the photographs.

FHWAR census method

The FHWAR method (SEDAR41-DW17) was first used in SEDAR 28 to reconstruct landings back to 1950. The two key components from these FHWAR surveys that they used in the census method to produce both estimates of U.S. saltwater anglers and the estimates of U.S. saltwater days. The first objective was to determine the total saltwater anglers and saltwater days for the South Atlantic (SA) by using the summary information of U.S. anglers and U.S. saltwater anglers from the FHWAR surveys. The ratio of U.S saltwater anglers to the total U.S anglers was applied to the total number of anglers for the SA to yield the total saltwater anglers for SA. The same method was used to calculate the total saltwater days for the SA from the FHWAR surveys 1955-1985.

In the FHWAR surveys the South Atlantic included the entire state of Florida, east and west coasts. In order to address the management boundaries for red snapper the saltwater angler days for Florida's west coast (FLW) were separated from the SA saltwater angler days using the ratio of the MRFSS total angler trips for FLW to the MRFSS total angler trips for the South Atlantic (Delaware to FLW). The average ratio from 1984-1986 was applied to the total saltwater days for the SA 1955-1985 to remove FLW effort.

Similar to the SWAS there was a 12 month recall period for respondents, which resulted in greater reporting bias. Research concluded this bias resulted in overestimates of both the catch and effort estimates in the FHWAR surveys from 1955 to 1985. Consequently, as was case in SEDAR 28, an adjustment for recall bias was necessary. The total saltwater days for the SA 1955-1985 were adjusted for recall bias in the FHWAR surveys. The MRFSS total angler trips (private and charter boat modes) for the SA 1984 to1986 was averaged and divided by the total saltwater days for 1985 from the FHWAR survey. This multiplier was then applied to the total SA saltwater days 1955-1985 to adjust for recall bias. In 1984 a 12 inch size limit was instituted in the SA. In order to reflect the discard history prior to 1984 a mean CPUE for red snapper in the SA from the combined estimates from MRFSS and SRHS for 1981 to 1983 was then applied to the adjusted saltwater angler days for the SA 1955-1985 to estimate the historical red snapper landings for those years (Table 4.10.12).

Issue: Available historical red snapper landings prior to 1981.

Option 1: Use the ratio of historic commercial landings as a proxy for recreational catch (SEDAR 24 method)

Option 2: Use FHWAR census method to estimate red snapper landing 1955-1980 in the South Atlantic. Use interpolation to complete time series.

Option 3: Use available recreational time series for the MRFSS\MRIP 1981to 2013and headboat estimates 1972 - 2014.

Decision: *Option 2*.
Option #2: Use FHWAR census method with modifications to estimate red snapper landing back in time.

Historical Catch Estimates
Final historical landings estimates are shown in Table 4.10.13. and Figure 4.11.4.

Uncertainty concerning the FHWAR census method
Standard deviations and variances are provided for the historical recreational catch estimates using the FHWAR census method Table 4.10.12.

4.3.5 Potential Sources for Additional Landings Data

SCDNR Charter boat Logbook Program Data, 1993 – 2014

The Recreational Fisheries Working Group discussed the possibility of replacing the MRIP charter mode estimates for South Carolina from 1993 to 2014 with the SCDNR Charter boat Logbook Program estimates. The SCDNR Charter boat Logbook Program is a mandatory logbook program and is a complete census. However, the data are self-reported and no field validation is done on catch or effort. SCDNR charter boat logbook data were compared with MRIP charter mode estimates (Figure 4.11.5). The Recreational Fisheries Working Group recommended not replacing the MRIP charter boat estimates with the SCDNR Charter boat Logbook Program estimates for 1993 – 2014. The MRIP estimates represent a longer time series and switching from the MRFSS dataset (1981 – 1992) to the SCDNR Charter boat logbook dataset (1993-2014) would artificially reduce the total catch potentially due to the change in methodology that would not necessarily be indicative of a change in the red snapper population which could affect the stock assessment model. Concern was also expressed about replacing the MRIP dataset with the SCDNR Charter boat logbook dataset because the data would only be replaced for one state (SC) and one mode (charter). Additionally since MRFSS/MRIP estimates are currently used to monitor annual catch limits (ACL's), the group thought it would be appropriate to use these estimates for the recreational landings data.

4.4 Recreational Discards

Total recreational discards are summarized below by survey. A map and figures summarizing the total recreational red snapper discards are included in Figure 4.11.6.

4.4.1 MRFSS/MRIP Discards

Discarded live fish are reported by the anglers interviewed by the MRIP/MRFSS. Consequently, neither the identity nor the quantities reported are verified. Lengths and weights of discarded fish are not sampled or estimated by the MRFSS/MRIP.

MRFSS/MRIP estimates of live released fish (B2 fish) were adjusted in the same manner as the landings (i.e. using charterboat calibration factors, MRIP adjustment, substitutions, etc. described above in section 4.3.1).

MRIP discards in numbers of fish and associated CVs are presented in Table 4.10.14. South Atlantic red snapper estimates include North Carolina through East Florida, not including Monroe County, FL. There are no red snapper estimates in MRIP north of North Carolina.

4.4.2 Headboat At-Sea Observer Survey Discards

An observer survey of the recreational headboat fishery was launched in NC and SC in 2004 and in GA and FL in 2005 to collect more detailed information on recreational headboat catch, particularly for discarded fish. Headboat vessels are randomly selected throughout the year in each state, and the east coast of Florida is further stratified into northern and southern sample regions. Biologist's board selected vessels with permission from the captain and observe anglers as they fish on the recreational trip. Data collected include number and species of fish landed and discarded, size of landed and discarded fish, and the release condition of discarded fish (FL only) Data are also collected on the length of the trip, area fished (inland, state, and federal waters) and, in Florida, the minimum and maximum depth fished. In the Florida Keys (sub-region 3) some vessels that run trips that span more than 24 hours are also sampled to collect information on trips that fish farther offshore and for longer durations, primarily in the vicinity of the Dry Tortugas. The red snapper discard data from the MRFSS At-Sea Observer Headboat program and the Southeast Region Headboat Survey (SRHS) logbook were compared (SEDAR 41-DW_29, 2014). Based on the results of these comparisons, it was determined that the SRHS discard rates was validated by the MRFSS/MRIP At-Sea Observer data. Therefore, the SRHS discard estimates would be used and the MRFSS/MRIP At-Sea Observer data was not recommended for use in this assessment.

4.4.3 Headboat Logbook Discards

The Southeast Region Headboat Survey logbook form was modified in 2004 to include a category to collect self-reported discards for each reported trip. This category was described on the form as the number of fish by species released alive and number released dead. Port agents instructed each captain on criteria for determining the condition of discarded fish. A fish was considered "released alive" if it was able to swim away on its own. If the fish floated off or was obviously dead or unable to swim, it was considered "released dead". As of Jan 1, 2013 the SRHS began collecting logbook data electronically. Changes to the trip report were also made at this time, one of which removed the condition category for discards i.e., released alive vs. released dead. The new form now collects only the total number of fish released regardless of condition. These self-reported data are currently not validated within the Headboat Survey. It was determined that the logbook discard data would be used from 2004-2014. This analysis was updated to include the 2014 data, which supported the decision to use the logbook discard data (SEDAR 41-DW_29, 20142015). The RWG concluded that a proxy should be used to estimate the headboat red snapper discards for years prior to 2004. The RWG considered the following three possible data sources to be used as a proxy for estimated headboat discards for 1981-2003 (Figure 4.11.7a & 4.11.7b).

- MRIP CH discard ratio proxy method 1981-2003.
- Captain Steven Amick's discard ratio proxy method 1983-2003. (SEDAR 28-Data Workshop Report, 2010).
- MRIP CH:SRHS discard ratio proxy method 1981-2003 (SEDAR 28-Assessment Workshop Report, 2012).
- SRHS Dockside sample method

Issue: Discard information not available prior to 2004, need a proxy for estimated headboat discards from 1981-2003.

Option 1: MRIP CH: Apply the MRFSS charter boat discard:landings ratio to estimated headboat landings in order to estimate headboat discards from 1981-2003; then apply a 3 year (1981-1983) mean discard:landings ratio to estimated headboat landings in order to estimate headboat discards from 1972-1980.

Option 2: Captain Steve Amick's discard:landings ratio: Apply ratio to estimated headboat landings in order to estimate headboat discards from 1983-2003; then apply a 3 year mean discard:landings ratio to estimated headboat landings in order to estimate headboat discards from 1972-1983.

Option 3: MRIP CH:SRHS: Calculate a ratio of the mean ratio of SRHS discard:landings (2004-2013) and MRIP CH discard:landings (2004-2013). Apply this ratio to the yearly MRIP charter boat discard:landings ratio (1981-2003) in order to determine the yearly SRHS discard:landings ratio (1981-2003). This ratio is then applied to the SRHS landings (1981-2003) in order to estimate headboat discards (1981-2003). Then apply a 3 year (1981-1983) mean discard:landings ratio to estimated headboat landings in order to estimate headboat discards from 1972-1980.

Option 4: SRHS Dockside sample method: From the SRHS dockside samples calculate the mean ratio of fish less than 12in TL (1981-1983) and subtract from that the mean ratio of fish less than 12in TL (1992-2003); apply that to the SRHS landings (1984-2003) to get the number of fish <12in TL discarded (1984-2003). Calculate the mean ratio of fish 12in TL to less than 20in TL (1984-1991) and subtract from that the mean ratio of fish less 12in TL to less than 20in TL (1992-2003); apply that to the SRHS landings (1992-2003) to estimate the number of fish 12in TL to less than 20in TL discarded (1992-2003).

Decision: Option 4. The SRHS dockside sample method uses information collected directly from the SRHS to estimate discards based management measures (i.e. size limits). It was concluded this method would most accurately reflect changes in discards which were due in large part to changes in management. Both the MRIP CH:SRHS discard ratio method and the MRIP CH discard ratio method followed the same pattern, or agreed well with the SRHS discard ratio in 2004-2009. However, these methods produce highly variable discard estimates for this species. Captain Steve Amick's discard ratio was not recommended due to the reduced time series and limited geographical range. While the MRIP PR discard method did follow a similar pattern as the SRHS in 2004-2009, this method would have caused increased variability in the discard estimate and therefore this method was not recommended. Final discard estimates from the SRHS are shown in Table 4.10.15 by year and state and in Figure 4.11.8.

4.4.4 Red Snapper Mini-season Discards

Introduction
The main objective of the red snapper mini season ad hoc working group was to provide information to the recreational workgroup to aid in decisions that were needed on which discards to report for red snapper during the mini seasons in 2012, 2013 and 2014. The 2012 mini-season was six days long: 9/14-9/16 & 9/21-9/23. The 2013 mini-season was three days long: 8/23-8/25. The 2014 mini-season was 8 days long: 7/11-7/13, 7/18-7/20, and 7/25-7/26. The key issue was that MRIP would be more likely to encompass the entire two month time period while some state surveys only captured the short time interval during the mini-season.
The sources of mini-season data that were reviewed for potential use are as follows:

- Marine Recreational Information Program (MRIP)
- North Carolina Department of Marine Fishers (NCDMF) state survey
- South Carolina Department of Natural Resources (SCDNR) state survey
- Georgia Department of Natural Resources (GADNR) state survey
- Florida Fish and Wildlife Conservation (FWC) Commission state survey

State partners in the South Atlantic supplied data from studies conducted in each state during the 2012, 2013 and 2014 mini-season as an attempt to supplement the MRIP data. Brief synopses of the type of data provided are illustrated in Table 4.10.16. Full descriptions of methods and data collected are available in the working papers SEDAR41-DW27(MRIP), SEDAR41-DW-21 (NC), SEDAR41-DW18 (SC), SEDAR41-DW02 (GA), SEDAR41-RD14 and SEDAR41-RD15 (FL).

The recreational workgroup developed a set of rules in order to determine which data set was more appropriate for discards by state (NC, SC, GA, and FLE), mode (charter and private), and wave (1-6):

Either MRIP or state available
• Use state number if no MRIP number exists, making note of any potential bias
• Use MRIP number if no state number exists

Both MRIP and state numbers available
• Discards - Recommend using the estimate/number (MRIP or State)
that is more reliable or encompasses the whole 2 month time period. In 2014, this option was clarified to include accounting for CV's, and/or biases associated with each survey.

The majority of the waves had either MRIP or State survey data available. When only the state survey data was available, potential sources of bias were considered, and noted in the decisions below. However, using the only available data for the wave was favored over using no data at all.

Florida, Georgia and South Carolina had cases of overlap for discard data in 2012 (Table 4.10.16). Florida and Georgia had cases of overlap for discard data in 2013 and 2014 (Table 4.10.17 and 4.10.18).

Issue 1: How to characterize the recreational discards during mini-seasons in 2012 for each state, mode, and wave.

Option 1: Use State number if no MRIP number is available, making note of any potential bias
Option 2: Use MRIP number if no state number is available
Option 3: Use the estimate/number (MRIP or state) that is more reliable (e.g. larger sample size or that encompasses the whole 2 month time period) when both MRIP and State numbers were available.

Decision(s):
Option 1.

- State CH - SC (waves 2, 3, & 6)
- State PR - SC (wave 5)

The CH discards from SC were self-reported data through the logbook without methods for validation but were considered to be a census of all charter captains fishing during the mini-season. The PR discards from SC were reported through the SFS survey were raw numbers (i.e. not an estimate).

Option 2.

- MRIP CH - NC and FLE for all of 2012 and GA (wave 3).
- MRIP PR - NC (wave 5), SC (wave 3), and FLE (waves 2, 3, 4, & 6)

Option 3.

- State CH - SC (waves 4 & 5) - The SC state survey was selected over MRIP due to larger sample size and because it also encompassed the entire 2 month period.
- MRIP CH - GA (wave 5)
- MRIP PR - GA (wave 5) and FLE (wave 5)

MRIP was selected over the state surveys, even though the state surveys had a larger sample size, because MRIP encompassed the entire two month period and not just the mini season.

Issue 2: How to characterize the recreational discards during mini-season in 2013 for each state, mode, and wave.

Option 1: Use State number if no MRIP number is available, making note of any potential bias
Option 2: Use MRIP number if no state number is available

Option 3: Use the estimate/number (MRIP or state) that is more reliable (e.g. larger sample size or that encompasses the whole 2 month time period) when both MRIP and state numbers were available.

Decision:
Option 1.

- State CH - SC (all waves 2013)
- State PR - GA (wave 4)

The CH discards from SC were self-reported data through the logbook without methods for validation. The PR discards from GA were collected through a voluntary self-reported online survey with a very small sample size.

Option 2.

- MRIP CH - NC (all waves 2013), GA (wave 5) and FLE (waves 1, 5 & 6).
- MRIP PR - NC and SC (all waves 2013), GA (wave 5), and FLE (waves 2, 3 & 5)

Option 3.

- MRIP CH - GA and FL (wave 4)
- MRIP PR - FLE (wave 4)

MRIP was selected over the state surveys, even though the state surveys had a larger sample size, because MRIP encompassed the entire two month period and not just the mini season.

Issue 3: *How to characterize the recreational discards during mini-seasons in 2014 for each state, mode, and wave.*

Option 1: Use State number if no MRIP number is available, making note of any potential bias
Option 2: Use MRIP number if no State number is available
Option 3: Use the estimate/number (MRIP or State) that is more reliable (taking into account sample sizes, CV's, and/or biases associated with the survey) when both MRIP and State numbers were available.

Decision(s): Option1.

- State Charter (CH) – SC (Wave 2 through 6) - The CH discards from SC were self-reported data through the logbook and, as stated for previous years, lack validation methods and had a high potential for recall bias.
- State Charter (CH) – GA (Wave 4) - The CH discards for GA were also self-reported through telephone census of charter captains that held a federal snapper/grouper permit with no method of validation but a lower potential recall bias since numbers were submitted immediately after the mini-season. These discards are raw numbers (i.e. not an estimate).

Option 2.

- MRIP (CH) – NC (Wave 3 and 4)
- MRIP (CH) – GA (Wave 2 and 3)
- MRIP (CH) – FLE (Wave 1, 2, 3, 5 and 6)
- MRIP (PR) – NC (Wave 4)
- MRIP (PR) – SC (Wave 3, 4 and 6)
- MRIP (PR) – GA (Wave 2 and 3)
- MRIP (PR) – FLE (Wave 1, 2, 3, 5 and 6)

Some of the estimated discards are based on a fairly low number of angler trips (e.g. 1 or 2 trips) and have high CV's (>1.0).

Option 3.

- MRIP (PR) – GA (Wave 4)
- MRIP (CH) – FLE (Wave 4)
- MRIP (PR) – FLE (Wave 4)

MRIP estimated discards was preferred over state surveys because MRIP encompassed the entire two month period (i.e. complete wave).

Uncertainty concerning data sources

In most cases, only MRIP or state survey information, but not both, were available for each individual wave. The main concern of potential bias with state survey information was that data were self-reported without means of validation. There was also concern that the state surveys were unlikely to represent discards outside of the mini-season while MRIP would represent discards for each wave. The SC logbook was the only exception since the discards were reported for an entire month, not just the mini-season. However, as stated in 4.3.3, the logbook data are self-reported and there is potential for recall bias. The merits and deficiencies of each data source discussed in 4.3.3 were considered when making decisions. The RWG took all of these points under consideration when deciding which data to use and felt confident in the choices that were made.

Total recreational catch from all surveys and all years are presented in Table 4.10.19.

4.5 Biological Sampling

4.5.1 Sampling Intensity Length/Age/Weight

Length samples from recreational landings were obtained from the Marine Recreational Fisheries Statistics Survey and the Southeast Region Headboat Survey.

Any existing natural total length measurements were converted to maximum total length using the following equation derived for the combined South Atlantic stock by the Life History Working Group at the SEDAR 32 data workshop:

$TL_{max} = 4.62 + 1.02TL_{nat}$ ($R^2 = 0.99$)

MRFSS/MRIP Biological Sampling

The MRFSS/MRIP angler intercept survey includes the sampling of fish lengths from the harvested (landed, whole condition) catch. Up to 15 of each species landed per angler interviewed are measured to the nearest mm along a center line (defined as tip of snout to center of tail along a straight line, not curved over body). In those fish with a forked tail, this measure would typically be referred to as a fork length, and in those fish that do not have a forked tail it would typically be referred to as a total length with the exception of some fishes that have a single, or few, caudal fin rays that extend further. Weights are typically collected for the same fish measured although weights are not preferred when time is constrained. Aging structures and other biological samples are not collected during MRFSS/MRIP assignments because of concerns over the introduction of bias to survey data collection.

The number of red snapper measured in the South Atlantic (NC to FLE) from MRFSS/MRIP by year, mode, and state are summarized in Table 4.10.20. The number of angler trips with measured red snapper measured in the South Atlantic (NC to FLE) in the MRFSS/MRIP by year, mode, and state are summarized in Table.4.10.21 There were concerns about low sample sizes for lengths from 1987 to 1998. Caution should be used for these years since the lengths collected may not necessarily be representative of the fishery. Information on the weights collected (number, mean, minimum, and maximum weights) by year and state from the MRFSS/MRIP is tabulated in Table 4.10.22

In 1986 suspect intercepts were found with 155 red snapper weighing 0.1 kg and measuring 197-210mm. Samples came from Volusia County, charter mode, ocean>3mi, wave 1 from multiple days with the same interviewer. In 1988 suspect intercepts were found with 25 red snapper weighing 0.1 kg and measuring 93-212mm. Samples came from Miami-Dade County, private mode, mostly inshore from multiple waves with a different sampler than the 1986 suspect intercepts. Other years, states, FL counties, and samplers show similar low weight red snappers. The RWG speculated that these red snapper were probably vermilion snapper, however, as these intercepts are many and varied it is difficult to make any adjustments as this would introduce additional bias. In general, it is difficult to make changes many years after the data is collected and the RWG recommends using the resulting estimates "as is" and taking into consideration an appropriate measure of the precision, which is most likely nearly twice as high in these early years than the survey data suggests (personal communication, NMFS).

Headboat Survey Biological Sampling

Lengths were collected from 1972 to 2014 by headboat dockside samplers. From 1972 to 1975, only North Carolina and South Carolina were sampled whereas Georgia and northeast Florida were sampled beginning in 1976. The Southeast Region Headboat Survey conducted dockside sampling for the entire range of Atlantic waters along the southeast portion of the US from the NC-VA border through the Florida Keys beginning in 1978. Weights are typically collected for the same fish measured during dockside sampling. Also, biological samples (scales, otoliths, spines, stomachs and gonads) are collected routinely and processed for aging, diet studies, and maturity studies.

Annual numbers of red snapper measured for length in the headboat fleet and the number of trips from which red snapper were measured are summarized in Table 4.10.23. Dockside mean weights for the headboat fishery are tabulated for 1972-2014 in Table 4.10.24

State of Florida Mini-Season Surveys

Red Snapper lengths were collected during random intercept surveys of private recreational boats in Florida during the recreational harvest season openings in 2012, 2013, and 2014. Site selection methods and intercept survey procedures are detailed in SEDAR41-DW42. Length frequency distributions for harvested Red Snapper by year and sample size (numbers of trips) were provided to the SEDAR41 data compiler. Mean weight of harvested Red Snapper during each season is also provided in Table 4.10.25.

SCDNR State Finfish Survey (SFS)

Red Snapper lengths were collected through the SCDNR State Finfish Survey (SFS) from 1988 to 2012. Starting in 2013 SCDNR took over MRIP sampling responsibilities in SC. Because of this the SFS survey was terminated except for January and February sampling. No Red Snapper were sampled during those months in 2013 and 2014. The SFS collects finfish intercept data in South Carolina through a non-random intercept survey at public boat landings along the SC coast. The survey focuses on known productive sample sites, targets primarily private boat mode, and is conducted year-round (January- December) using a questionnaire and interview procedure similar to the intercept portion of the MRIP. From 1988 through March 2009 mid-line lengths were measured and from April 2009 to 2011 total lengths were measured. From 1988 to 2012 85 red snapper lengths were collected by SFS personnel. The Recreational Fisheries Working Group recommended the SCDNR SFS length data for all modes be used to supplement the MRFSS/MRIP length data for length compositions. Mid-line (fork) measurements from 1988-2009 were converted to total length measurements using the following equation from the Life History Working Group at the SEDAR 41 data workshop:

$TL_{MAX} = 2.22 + 1.07*FL$

Summarized length data from 1988 – 2012 can be found in Table 4.10.26.

Headboat At-Sea Sampling (NC-east FL)
Length frequencies and sample sizes for Red Snapper discards observed by state biologists during Headboat At-Sea sampling from North Carolina through the east coast of Florida, and methods used to weight samples by state, are summarized in SEDAR41-DW33. Overall weighted length frequency distributions for observed Red Snapper discards by year were provided to the SEDAR41data compiler. Raw sample sizes for numbers of discarded fish measured and numbers of trips sampled are provided in Table 4.10.27.

Aging data
The number of red snapper aged from the recreational fishery and the number of trips with aged red snapper by year, state, and mode is summarized in Table 4.11.28. The number of trips provided is a combination of angler and vessel trips. It should be noted that for all modes, the number of age samples were low for certain years.

4.6 Recreational Effort

Total recreational effort is summarized below by survey. Effort is summarized for all marine fishing by mode, regardless of what was caught. A map and figures summarizing MRFSS/MRIP effort in angler trips are included in Figure 4.11.9. A map and figures summarizing SRHS effort in angler days are included in Figure 4.11.10.

4.6.1 MRFSS/MRIP Effort

Effort estimates for the recreational fishery survey are produced via telephone surveys of both anglers (private/rental boats and shore fishers) and for-hire boat operators (charterboat anglers, and in early years, party or charter anglers). The methods have changed during the full time series (see section 4.3 for descriptions of survey method changes and adjustments to survey estimates for uniform time-series of catch estimates). An angler-trip is defined as a single day of fishing by a single angler in the specified mode, not to exceed 24 hours. MRFSS effort estimates are presented from 1981 to 2003. MRIP effort estimates are presented starting in 2004. Angler trip estimates are tabulated in Table 4.10. 29 by year and mode and include all South Atlantic states from North Carolina through East Florida.

4.6.2 Headboat Effort

Catch and effort data are reported on logbooks provided to all headboats in the survey. These forms are completed by the captain or designated crew member after each trip and represent the total number and weight of all the species kept, along with the total number of fish discarded for each species. Data on effort are provided as number of anglers on a given trip. Numbers of anglers are standardized, depending on the type of trip (length in hours), by converting number of anglers to “angler days” (e.g., 40 anglers on a half-day trip would yield 40 * 0.5 = 20 angler days). Angler days are summed by month for individual vessels. Each month, port agents collect these logbook trip reports and check for accuracy and completeness. Although reporting via the logbooks is mandatory, compliance is not 100% and is variable by location. To account for non-reporting, a correction factor is developed based on sampler observations, angler numbers from office books and all available information. This information is used to provide estimates of total catch (expanded or corrected for non-reporting) by month and area, along with estimates of effort.

Estimated headboat angler days have decreased in the South Atlantic in recent years (Table 4.10.30). The most obvious factor which impacted the headboat fishery in the Atlantic was the high price of fuel. This coupled with the economic down turn starting in 2008 resulted in a marked decline in angler days in the South Atlantic headboat fishery. Reports from industry staff, captains\owners, and port agents indicated fuel prices, the economy and fishing regulations are the factors that most affected the amount of trips, number of passengers, and overall fishing effort. However, estimated angler days have risen in recent years (2012-2014).

4.8 Itemized List of Tasks for Completion Following Workshop

The length and age distributions will be prepared and discussed in a working paper for the Assessment Workshop.

Table 4.10.15. Estimated South Atlantic red snapper discards for SRHS by year and state. Due to headboat area definitions and confidentiality issues, Georgia and East Florida discards must be combined. 2004-2014 uses the SRHS logbook discards. 1981-2003 HB mode uses SRHS dockside sample discard ratio proxy method. Zero discards are assumed prior to 1983.

5. Measures of Population Abundance

5.1 Overview

Seven fishery independent data sets were considered for use as an index of abundance (Table 5.1). During the data webinar prior to the DW, five of these datasets were discarded because of small sample sizes or limited geographic extent. Two fishery independent data sets were retained for further consideration at the DW: SERFS chevron traps and SERFS video survey.

Six fishery dependent data sets were considered for use as an index of abundance (Table 5.1). During the data webinars, five were recommended for further consideration at the DW. Ultimately, the DW recommended indices from three of these fishery dependent data sets for potential use in the assessment model: recreational headboat, headboat at-sea-observer data, and commercial handline.

In total, the DW recommended two fishery independent indices (SERFS chevron traps and video survey) and three fishery dependent indices (recreational headboat index, headboat at-sea observer index, and a commercial handline index) for potential use in the red snapper stock assessment. These indices are listed in Table 5.1, with pros and cons of each in Table 5.2.

Group Membership

Membership of this DW Index Working Group (IWG) included Nate Bacheler, Joey Ballenger, Nicholas Ballew, Peter Barile, Russ Brodie, Rob Cheshire, Kevin Craig, Eric Fitzpatrick, Kevin Purcell, Christina Schobernd, Kyle Shertzer (chair), Katie Siegfried, Tracy Smart, Ted Switzer, and Erik Williams. Several other DW panelists and observers contributed to the IWG discussions throughout the DW1 and DW2 workshops.

5.2 Review of Working Papers

The relevant working papers describing index construction were presented to the IWG. In most cases, the IWG recommended modifications to the initial modeling attempts, such that data treatments and/or model specifications were updated during the DW. Final working papers reflect decisions made during the DW, using addenda if necessary. In addition to working papers on index construction, the IWG also discussed any working papers available at the DW that were relevant to indices of abundance, namely SEDAR41-DW08, SEDAR41-DW11, and SEDAR41-DW46. SEDAR41-DW08 describes a pilot program for data collection using hook gear, SEDAR41-DW11 describes habitat models for gray triggerfish, and SEDAR41-DW46 describes evaluation of the headboat data set.

The index working papers provide information on sample sizes, diagnostics of model fits, and in some cases, maps of catch and effort. A summary of each index is provided below.

5.3 Fishery Independent Indices

Until 2009, virtually all fishery independent sampling of reef fishes in southeast U.S. Atlantic waters was conducted by the Marine Resources Monitoring, Assessment, and Prediction (MARMAP) program. In 2009, the Southeast Area Monitoring and Assessment Program – South Atlantic (SEAMAP-SA) program joined the chevron trap survey through their Reef Fish Complement. In 2010, the Southeast Fisheries Independent Survey (SEFIS) was created and joined the chevron trap survey. The partner-led survey is now referred to as the Southeast Reef Fish Survey (SERFS). With the advent of the partner programs, sampling coverage in the region has expanded, primarily in Florida. SERFS now samples between Cape Hatteras, North Carolina and St. Lucie Inlet, Florida, and it targets a sampling universe of approximately 3,000 sites of hard-bottom habitats between approximately 15 and 100 meters deep.

5.3.1 Chevron Trap

5.3.1.1 Methods, Gears, and Coverage

Chevron traps were baited with whole and cut Clupeids and deployed at stations randomly selected by computer from a database of live bottom stations on the continental shelf and shelf edge and soaked for approximately 90 minutes.

An index of abundance was developed by standardizing catch (number of Red Snapper caught) using a zero-inflated negative binomial model (SEDAR41-DW54; Zuur et al. 2009). Effort (trap soak minutes) was included as an offset in the regression. Analyses were computed using the *pscl* library in R (Jackman 2008; Zeileis et al 2008; R Development Core Team 2014). Model covariates included sampling characteristics and environmental data.

5.3.1.2 Sampling Intensity and Time Series

Chevron traps were deployed from 1990 through 2014, ranging from 219 to 1465 traps per year meeting the depth criteria for this analysis. Prior to 2010, red snapper were caught in chevron traps infrequently (SEDAR41-DW51). In 2010 with the advent of SERFS, sampling coverage in the region has expanded, primarily in Florida. Consequently, the spatial coverage of the survey after 2010 adequately covered the center of the distribution of red snapper and percent positives increased to levels high enough to develop an index. The time series was truncated for index development to 2010-2014 based on recommendations of the IWG. The annual number of traps (collections) used to compute the index is shown in Table 5.3.

5.3.1.3 Size/Age Data

The ages of red snapper collected by chevron traps (1990-2014) ranged from 0 to 26 (median = 2, mean = 3.3, n= 2085), and sizes ranged from 19 to 99 cm maximum (pinched tail) total length.

For the truncated time series (2010-2014), ages ranged from 0 to 26 (median = 2, mean = 3.4, n= 1686). Age composition data are available for estimating the selectivity of this gear.

5.3.1.4 Catch Rates

Standardized catch rates are shown in Table 5.3 and in Figure 5.1 (top panel). The units on catch rates are in numbers of fish. Effort was modeled as an offset, rather than as the denominator in the response variable.

5.3.1.5 Uncertainty and Measures of Precision

Measures of precision were computed using a bootstrap procedure (Efron and Tibshirani 1994), in which sampling events were drawn at random (by year) with replacement. The CVs are shown in Table 5.3.

5.3.1.6 Comments on Adequacy for Assessment

This index was considered to be adequate for the assessment. Recent years of the survey show that traps can and do catch red snapper, and sample sizes in the truncated time series were sufficiently large to create a meaningful index. Because the chevron trap index is fishery independent and has accompanying selectivity information (lengths and ages), it was considered by the IWG to be the highest ranking source of information on trends in population abundance.

Several issues were addressed or discussed. During DW1, models included covariates as categorical variables. For DW2, models applied the zero-inflated negative binomial but included covariates as continuous variables using polynomials and backward selection by Bayesian Information Criterion. The polynomial approach was ultimately adopted. In addition, the group discussed a modeling approach to project the index back in time when data were sparse (SEDAR41-DW51; SEDAR41-DW53). That longer time series (Figure 5.1, bottom panel) was not recommended as a primary index, but might reasonably be considered for a sensitivity analysis of the assessment model. One topic discussed by the group, but not explicitly addressed, was the non-independence between chevron traps and the video survey; this topic was identified for future research.

5.3.2 Video Survey

5.3.2.1 Methods, Gears, and Coverage

In 2010 the SERFS program began attaching video cameras to a limited number of chevron traps (Georgia and Florida only), with cameras being attached to all traps beginning in 2011 as a standard component of the sampling program. An index of abundance for red snapper was developed based on these videos using a zero-inflated negative binomial modeling approach

(SEDAR41-DW45, Zuur *et al*. 2009). All data manipulation and analyses were conducted using R (R Development Core Team 2014). Modeling was executed using the ***zeroinfl*** function in the ***pscl*** package (Jackman 2008; Zeileis et al. 2008).

5.3.2.2 Sampling Intensity and Time Series

The video index time series consists of only 5 years (2010-2014). Additionally, the first year of sampling was regionally limited to the coastal shelf of Georgia and Florida, representing approximately 20-33% of the sampling intensity in later years (SEDAR41-DW45). The IWG recognized differences in sampling in 2010 (more limited spatial coverage, different camera), but ultimately thought that 2010 should be included in the red snapper index for two reasons. First, the initial year of sampling was located in the core of red snapper's spatial distribution, and second, SERFS data provide the only information on relative abundance with fishery closures starting in 2010. Furthermore, a camera calibration study made it possible to adjust 2010 values for consistency with those from subsequent years. This decision was supported by the recommendations of the Video Index Development Panel, a special working group convened in the spring of 2014 to guide and recommend a set of best practices for the development of a video indices based on SERFS data in the south Atlantic (SEDAR41-RD23).

A total of 4923 videos were considered for development of the red snapper index. Of those, 514 were removed based on modeling considerations (SEDAR41-DW45), leaving a total of 4409 videos for index construction. These data span a wide latitudinal and depth range, covering a substantial region of the south Atlantic coastal shelf (SEDAR41-DW45, Figure 2). Detailed information on the depth, latitudinal, and seasonal distribution of sampling can be found in the index working paper (SEDAR41-DW45, Table 2).

5.3.2.3 Size/Age Data

As currently implemented, the size and age composition of populations sampled with the SERFS video survey gear are unknown, and therefore selectivity of the gear cannot be estimated from data. However, in a different system, Langlois et al. (2015) compared length compositions of snappers and groupers caught in traps to those observed on video cameras, and found those length compositions to be quite similar. Based on that, the IWG recommended applying selectivity of chevron traps to the video gear, in one of two ways: 1) if chevron trap selectivity is flat-topped, the video gear selectivity should mirror that of the chevron traps, or 2) if chevron trap selectivity is dome-shaped, the video gear selectivity should mirror only the ascending portion and then assume flat-topped selectivity. This recommendation was based on the expectation that the video gear should be flat-topped, because older, larger fish are present throughout the depths sampled and because there is no known reason why larger (older) individuals would be less observable on video than smaller (younger) individuals. The IWG recognized the need for age/size compositions of the video survey, and recommended future research to remedy this limitation.

5.3.2.4 Catch Rates

Annual standardized index values for red snapper, including CVs, are presented in Table 5.4 and in Figure 5.2.

5.3.2.5 Uncertainty and Measures of Precision

Using a bootstrap procedure with 1000 replicates, confidence intervals of 2.5% and 97.5% were calculated for each year of the survey (Figure 5.2), as were CVs (Table 5.4). Due to the changes in sampling distribution and equipment (SEDAR41-RD23), the nominal value for 2010 (2.61) was considerably higher than the standardized index value for 2010 (1.21), which was expected because of a camera calibration to the standardized index (SEDAR41-RD23, SEDAR41-DW45).

5.3.2.6 Comments on Adequacy for Assessment

The red snapper video index (2010-2014) was recommended for use in the assessment. The resulting index was ranked second of the two fishery independent sources based on the absence of information concerning the age composition of the video sampling gear. Non-independence between the video survey and chevron traps was discussed and identified as a topic for future research.

5.4 Fishery Dependent Indices

In general, indices from fishery independent data are believed to represent abundance more accurately than those from fishery dependent data. This is because fishery dependent indices can be strongly affected by factors other than abundance, such as management regulations on the focal or other species, shifts in targeting, changes in fishing efficiency (technology creep), and density dependent catchabililty (hyperdepletion or hyperstability). The standardization procedures attempt to account for some of these issues to the extent possible.

5.4.1 Recreational Headboat Index

The headboat fishery in the south Atlantic includes for-hire vessels that typically accommodate 11-70 passengers and charge a fee per angler. The fishery uses hook and line gear, generally targets hard bottom reefs as the fishing grounds, and generally targets species in the snapper-grouper complex. This fishery is sampled separately from other fisheries, and the available data were used to generate a fishery dependent index.

Headboats in the south Atlantic are sampled from North Carolina to the Florida Keys (Figure 5.3). Data have been collected since 1972, but logbook reporting did not start until 1973. In addition, only North Carolina and South Carolina were included in the earlier years of the data set. In 1976, data were collected from North Carolina, South Carolina, Georgia, and northern Florida, and starting in 1978, data were collected from southern Florida.

Variables reported in the data set include year, month, day, area, location, trip type, number of anglers, species, catch, and vessel identification. Biological data and discard data were recorded for some trips in some years.
The IWG, along with headboat captains, discussed several key issues related to this index:

- Beginning in 1992, a 20" TL minimum size regulation was implemented. In some cases, the size limit may have influenced the fishing behavior of headboats that relied heavily on red snapper catch. Thus, the IWG recommended modeling the change in selectivity that likely resulted from the size limit, and further acknowledged that the assessment model could be configured to allow for time-varying catchability.
- The red snapper closure starting in 2010 led to a shift in fishing behavior (avoidance). Because of that, and because this index is based on landings only (i.e., no discards included), the IWG decided to end the index in 2009.

5.4.1.1 Methods of Estimation

Data Filtering

The headboat data and programmatic evaluation (SEDAR41-46) found a small percentage of logbook reports to be extreme outliers. Those values were likely erroneous and were removed from the data set prior to deriving the index.

Trips to be included in the computation of the index need to be determined based on effective effort for red snapper. This may not be straightforward, because some trips caught red snapper only incidentally, and some trips likely directed effort at red snapper unsuccessfully. Given that direct information on species targeted is not available, effective effort must be inferred.

To determine which trips should be used to compute the index, the method of Stephens and MacCall (2004) was applied. The Stephens and MacCall method uses multiple logistic regression to estimate a probability for each trip that the focal species was caught, given other species caught on that trip. Species compositions differ across the south Atlantic; thus, the method was applied separately for two different regions: north (areas 2-10) and south (areas 11, 12, and 17) (Shertzer *et al.* 2009). To avoid rare species, the number of species in each analysis was limited to those species that occurred in 1% or more of trips. The most general model therefore included all species in the snapper-grouper complex which occurred in 1% or more of trips as main effects, excluding red porgy. Red porgy was removed because of regulations (closure followed by strict bag limits), which could erroneously remove trips likely to have caught red snapper in recent years. A backward stepwise AIC procedure (Venables and Ripley 1997) was then used to perform further selection among possible species as predictor variables. In this procedure, a generalized linear model with Bernoulli response was used to relate presence/absence of red snapper in headboat trips to presence/absence of other species.

Model Description

Response and explanatory variables

The response variable, catch per unit effort (CPUE), has units of fish/angler and was calculated as the number of red snapper caught divided by the number of anglers. All explanatory (predictor) variables were modeled as categorical, rather than as continuous.

Years – 1976-2009

Area – Areas were pooled into regions of North Carolina (NC=2,3,9,10), South Carolina (SC=4,5), Georgia and North Florida (GNFL=6,7,8), and south Florida (sFL=11,12,17).

Season – The seasons were defined as winter (January, February, March), spring (April, May, June), summer (July, August, September) and fall (October, November, December).

Party – Five categories for the number of anglers on a boat were considered in the standardization process. The categories included: ≤20 anglers, 21-40 anglers, 41-60 anglers, 61-80 anglers, and >80 anglers. The minimum number of anglers per vessel was set at 6, which excluded the lower 0.5% of trips. These trips were excluded because they were possibly misreported and likely don't reflect the behavior of headboats in general.

Trip Type – Trip types of half and full day trips were included in the analysis. Three-quarter day trips were pooled with half-day trips (<10%). Multi-day trips were removed because most were in Florida and likely targeting deepwater species for some portion of the trip.

Standardization

CPUE was modeled using the delta-glm approach (Lo *et al.* 1992; Dick 2004; Maunder and Punt 2004). In particular, fits of lognormal and gamma models were compared for positive CPUE. Also, the combination of predictor variables was examined to best explain CPUE patterns (both for positive CPUE and the Bernoulli submodels). All analyses were performed in the R programming language (R Development Core Team 2014), with much of the code adapted from Dick (2004).

Bernoulli submodel. One component of the delta-GLM is a logistic regression model that attempts to explain the probability of either catching or not catching red snapper on a particular trip. First, a model was fit with all main effects to determine which effects should remain in the binomial component of the delta-GLM. Stepwise AIC (Venables and Ripley1997) with a backward selection algorithm was then used to eliminate those that did not improve model fit. In this case, the stepwise AIC procedure did not remove any predictor variables. No concerning patterns were apparent in the quantile residuals (Dunn and Smyth 1996).

Positive CPUE submodel. To determine predictor variables important for describing positive CPUE, the positive portion of the model was fitted with all main effects using both the lognormal and gamma distributions. Stepwise AIC (Venables and Ripley1997) with a backward selection algorithm was then used to eliminate those that did not improve model fit. In this case, no predictor variables were removed for either error term.

Both submodels (Bernoulli and either lognormal or gamma) were then combined, and the models were compared using AIC. In this case, the delta-lognormal distribution performed best and used in the final analysis. No concerning patterns were apparent in standard diagnostic plots of residuals.

5.4.1.2 Sampling Intensity

The resulting data set contained more than 51,000 trips across years with approximately 30–80% positive for red snapper. Annual numbers of trips used to compute the index are shown in Table 5.5.

5.4.1.3 Size/Age Data

The sizes/ages represented in this index should be the same as those of landings from the corresponding fleet (See section 4 of the DW report).

5.4.1.4 Catch Rates

Standardized catch rates and associated error bars are shown in Figure 5.4, and tabulated in Table 5.5. The units on catch rates were number of fish landed per angler.

5.4.1.5 Uncertainty and Measures of Precision

Measures of precision were computed using the bootstrap procedure. Annual CVs of catch rates are tabulated in Table 5.5.

5.4.1.6 Comments on Adequacy for Assessment

The index of abundance created from the headboat data was considered by the IWG to be adequate for use in the assessment. The data cover a wide geographic range relative to most of the stock, and logbooks are intended to represent a census of the headboats. The data set has an adequately large sample size and has a long enough time series to provide potentially meaningful information for the assessment. For the duration of the index, sampling was consistent over time, and some of the data were verified by port samplers and observers.

After DW1, industry representatives questioned the headboat data set, in particular the "veracity of data reported by the fishery" prior to 1992 (SEDAR41-DW40). The DW panel recognized the importance of those concerns, and recommended that the assessment be paused until the headboat data set could be thoroughly evaluated. That evaluation (SEDAR41-DW46) was conducted and available to inform DW2. It found "no evidence of chronic misreporting by vessels, no evidence of apparent temporal trends in potentially misreported data, and minimal spatial trends in potentially misreported data." The evaluation did identify a small percentage of obviously erroneous data that were corrected or removed from the data base, and it recommended that standard data filtering techniques be applied when developing indices of abundance. Such techniques were applied for SEDAR41, and the DW2 index working group thought there was sufficient justification to recommend the headboat index for use in the assessment.

The primary caveat concerning this index was that it was derived from fishery dependent data. Headboat effort generally targets snapper-grouper species and not necessarily the focal species, which should minimize changes in catchability relative to fishery dependent indices that target more effectively. The closure of the red snapper was addressed by terminating the index in 2010, and changes in selectivity and possibly catchability (e.g, in 1992) could be addressed by the assessment model.

5.4.2 Headboat At-sea Observer Program

The data used for this index were all trips in the headboat at-sea observer database which discarded red snapper from 2005 to 2014. The at-sea-observer program occurred during 2004-2014 in North and South Carolina, but started in Florida and Georgia in 2005. In addition, coverage in the Florida Keys was not consistent across years and therefore not included. Observer coverage occurred on approximately 2% of headboat trips.

Trip-level information included state, county, Florida region, year, month, day, dock to dock hours (total trip hours), the number of hours fished (to the nearest half hour), the total number of anglers on the boat, the number of anglers observed on a trip, the number of red snapper discarded, minimum depth of the fishing trip, and maximum depth of the fishing trip. Depth information was not collected for South Carolina, North Carolina, and Georgia; therefore, it was not used in this analysis. Refer to working paper SEDAR41-DW33 for more details regarding this program.

5.4.2.1 Methods of Estimation

Data Treatment

Data from 2004 were dropped from the analysis because Georgia and Florida were not sampled. Trips that fished at night targeting sharks or trips that were designated drift fishing were removed from the analysis. All other trips were thought to be fishing for snapper-grouper species. Observer trips by year and area relative to all headboat trips, as well as total red snapper observed, are presented in SEDAR41-DW14.

A 20" TL minimum size regulation has been in place since 1992. In SEDAR 24, headboat at-sea observer data were used to index discards below 20" TL minimum. A 2010 closure has created a scenario where all fish observed are discarded (mini-seasons in 2012 and 2013 were removed). During this closure period, discards greater than 20" TL were removed.

Although the closure went into effect in 2010, the IWG recommended treating this index as a single time series, 2005-2014. This was because the index only included fish less than 20" TL, and it was believed that any attempts at avoiding these smaller fish began in 1992 with implementation of the minimum size limit and continued with the closure in 2010. That is, with respect to fish less than 20" TL, fishing behavior remained relatively consistent throughout the time series. This notion was corroborated by testimony of an industry representative who contributed to the group's discussions. Although the IWG recommended a single time series, the group acknowledged that the assessment model could account for time-varying catchability, if necessary.

Response and explanatory variables

The response variable, catch (≤20 inches) per unit effort (CPUE), is defined as units of fish/angler interviewed and was calculated as the number red snapper discarded divided by the number of anglers interviewed. All explanatory (predictor) variables were modeled as categorical, rather than as continuous.

Years – 2005-2014

Area –Area was defined as North Carolina, South Carolina and Georgia, north Florida (nFL), south Florida, (excluding the keys, flreg=3)

Season – The seasons were defined as winter (January, February, March), spring (April, May, June), summer (July, August, September) and fall (October, November, December).

Party – Four categories for the number of anglers on a vessel were considered in the standardization process.

Hrsf– Four categories for the number of hours fished were considered in the standardization process.

Standardization

CPUE was modeled using the delta-glm approach (Lo *et al.* 1992; Dick 2004; Maunder and Punt 2004). In particular, fits of lognormal and gamma models were compared for positive CPUE. Also, the combination of predictor variables was examined to best explain CPUE patterns (both for positive CPUE and the Bernoulli submodels). All analyses were performed in the R programming language (R Development Core Team 2014), with much of the code adapted from Dick (2004).

Bernoulli submodel. One component of the delta-GLM is a logistic regression model that attempts to explain the probability of either catching or not catching red snapper on a particular trip. First, a model was fit with all main effects to determine which effects should remain in the binomial component of the delta-GLM. Stepwise AIC (Venables and Ripley1997) with a backward selection algorithm was then used to eliminate those that did not improve model fit. In this case, the stepwise AIC procedure did not remove any predictor variables. No concerning patterns were apparent in the quantile residuals (Dunn and Smyth 1996).

Positive CPUE submodel. To determine predictor variables important for describing positive CPUE, the positive portion of the model was fitted with all main effects using both the lognormal and gamma distributions. Stepwise AIC (Venables and Ripley1997) with a backward selection algorithm was then used to eliminate those that did not improve model fit. In this case, no predictor variables were removed for either error distribution.

Both submodels (Bernoulli and either lognormal or gamma) were then combined, and the models were compared using AIC. Based on the selection criterion, the delta-lognormal model with all factors was used. No concerning patterns were apparent in standard diagnostic plots of residuals.

5.4.2.2 Sampling Intensity

The resulting data set contained 1700 trips across all years with approximately 15-30% of those trips having positive catches of red snapper. Annual numbers of trips used to compute the index are shown in Table 5.6.

5.4.2.3 Size/Age Data

The sizes/ages represented in this index should be the same as those of discards (≤20 inches) from the corresponding fleet (See section 4 of the DW report).

5.4.2.4 Catch Rates

Standardized catch rates and associated error bars are shown in Figure 5.5, and tabulated in Table 5.6. The units on catch rates were number of fish (≤20 inches) caught per angler.

5.4.2.5 Uncertainty and Measures of Precision

Measures of precision were computed using a jackknife procedure. Annual CVs of catch rates are tabulated in Table 5.6.

5.4.2.6 Comments on Adequacy for Assessment

The indices of abundance created from the headboat at-sea data were considered by the IWG to be adequate for use in the assessment. Because these data excluded fish greater than 20 inches, the index may provide information on recruitment prior to other indices. Lagged correlations with other indices suggested recruits would enter this index one year prior to indices from other fishery dependent data sources (Table 5.8).

5.4.3 Commercial Handline Index

Landings and fishing effort of commercial vessels operating in the southeast U.S. Atlantic have been monitored by the NMFS Southeast Fisheries Science Center through the Coastal Fisheries Logbook Program (CFLP). The program collects information about each fishing trip from all vessels holding federal permits to fish in waters managed by the Gulf of Mexico and South Atlantic Fishery Management Councils. Initiated in the Gulf in 1990, the CFLP began collecting logbooks from Atlantic commercial fishers in 1992, when 20% of Florida vessels were targeted. Beginning in 1993, sampling in Florida was increased to require reports from all vessels permitted in coastal fisheries, and since then has maintained the objective of a complete census of federally permitted vessels in the southeast U.S.

Catch per unit effort (CPUE) from the logbooks was used to develop an index of abundance for red snapper landed with vertical lines (manual handline and electric reel), the dominant gear for this red snapper stock. The time series used for construction of the index spanned 1993–2009, when all vessels with federal snapper-grouper permits were required to submit logbooks on each fishing trip. The January 2010 closure of the red snapper fishery prevented extending the series. The 2012-2014 red snapper mini-seasons had targeting issues as well as a 75 pound trip limit which confounds the catch rate from those trips.

5.4.3.1 Methods of Estimation

Data Treatment

For each fishing trip, the CFLP database included a unique trip identifier, the landing date, fishing gear deployed, areas fished, number of days at sea, number of crew, gear-specific fishing effort, species caught, and weight of the landings. Fishing effort data available for vertical line gear included number of lines fished, hours fished, and number of hooks per line. For this southeast U.S. Atlantic stock, areas used in analysis were those between 24 and 37 degrees latitude, inclusive of the boundaries (Figure 5.6).

Data were restricted to include only those trips with landings and effort data reported within 45 days of the completion of the trip. Reporting delays beyond 45 days likely resulted in less reliable effort data (landings data may be reliable even with lengthy reporting delays if trip ticket reports were referenced by the reporting fisher). Also excluded were records reporting multiple gears fished, which prevents designating catch and effort to specific gears. Therefore, only those trips that reported one gear fished were included in the analyses. Where trips reported multiple areas, the first area reported was used in the analysis. Only the latitude from the area designated was used in the analysis assuming most trips with multiple areas fished were moving across the shelf rather than north and south.

Clear outliers (>99.5 percentile) in the data were also excluded from the analyses. These outliers were identified for all snapper/grouper trip manual handlines as records reporting more than 6 lines fished, 8 hooks per line fished, 10 days at sea, 5 crew members or 105 hours fished; outliers were identified for electric reels as records reporting more than 6 lines fished, 10 hooks per line fished, 12 days at sea, 5 crew members or 143 hours fished. Trips reporting fewer than 4 hours fished for both gears were removed. Positive red snapper trips reporting greater than 24 pounds/hook-hr were excluded for both gears.

To determine which trips should be used to compute the index, the method of Stephens and MacCall (2004) was applied. The Stephens and MacCall method uses multiple logistic regression to estimate a probability for each trip that the focal species was caught, given other species caught on that trip. Species compositions differ across the south Atlantic; thus, the method was applied separately for areas north and south of Cape Canaveral, which has been identified as a zoogeographical boundary (Shertzer et al. 2009). Cape Canaveral falls in the middle of the one degree commercial sampling grid and was assigned to the south with the split at 29 degrees. To avoid rare species, the number of species in each analysis was limited to those species that occurred in 1% or more of trips. The most general model therefore included all species in the snapper-grouper complex which occurred in 1% or more of trips as main effects, excluding red porgy. Red porgy was removed because of regulations (closure followed by strict bag limits), which could erroneously remove trips likely to have caught red snapper in recent years. A backward stepwise AIC procedure (Venables and Ripley 1997) was then used to perform further selection among possible species as predictor variables. In this procedure, a generalized linear model with Bernoulli response was used to relate presence/absence of red snapper in commercial trips to presence/absence of other species. An alternative generalized linear model with Bernoulli response related the catch in pounds of other species to the presence/absence of red snapper. Although the alternative method theoretically may be more efficient at identifying species associations, the IWG rejected the method due to concerns that the increase in trip limits in recent years may bias the results.

Model Description

Response and explanatory variables

The response variable, CPUE, was calculated for each trip as,

CPUE = pounds of red snapper/hook-hour

where hook-hours is the product of number of lines fished, number of hooks per line, and total hours fished. Explanatory variables, all categorical, are described below.

The explanatory variables were year, season, latitude, crew size, and days at sea, each described below:

Years – Year was necessarily included, as standardized catch rates by year are the desired outcome. Years modeled were 1993–2009.

Season – The seasons were defined as winter (January, February, March), spring (April, May, June), summer (July, August, September) and fall (October, November, December).

Lat – Location is reported as latitude and longitude in one degree increments centered at the middle (e.g., CFLP lat=28 is centered at 28.5 degrees). The few trips with latitude reported north of 34 degrees and south of 24 degrees were pooled into the 34 and 24 degree bins, respectively (Figure 5.6).

Crew size – Crew size (crew) was pooled into three levels: one, two, and three or more.

Days at sea – Days at sea (sea days) was pooled into three levels: one or two days, three or four days, and five or more days.

Standardization

CPUE was modeled using the delta-glm approach (Lo et al. 1992; Dick 2004; Maunder and Punt 2004). In particular, fits of lognormal and gamma models were compared for positive CPUE. Also, the combination of predictor variables was examined to best explain CPUE patterns (both for positive CPUE and the Bernoulli submodels). All analyses were performed in the R programming language (R Development Core Team 2014), with much of the code adapted from Dick (2004).

Bernoulli submodel. One component of the delta-GLM is a logistic regression model that attempts to explain the probability of either catching or not catching red snapper on a particular trip. First, a model was fit with all main effects to determine which effects should remain in the binomial component of the delta-GLM. Stepwise AIC (Venables and Ripley1997) with a backward selection algorithm was then used to eliminate those that did not improve model fit. In this case, the stepwise AIC procedure did not remove any predictor variables. No concerning patterns were apparent in the quantile residuals (Dunn and Smyth 1996).

Positive CPUE submodel. To determine predictor variables important for describing positive CPUE, the positive portion of the model was fitted with all main effects using both the lognormal and gamma distributions. Stepwise AIC (Venables and Ripley1997) with a backward selection algorithm was then used to eliminate those that did not improve model fit. In this application, the lognormal distribution outperformed the gamma distribution, and was therefore used to compute the index.

Both submodels (Bernoulli and lognormal) were then combined into a single delta-lognormal model (1993-2009), with all predictor variables used for both submodels. No concerning patterns were apparent in standard diagnostic plots of residuals.

5.4.3.2 Sampling Intensity
Annual numbers of trips used to compute the index is typically greater than 1000, as shown in Table 5.7.

5.4.3.3 Size/Age Data
The sizes/ages represented in this index should be the same as those of landings from the corresponding fleet (See section 3 of the DW report).

5.4.3.4 Catch Rates
Standardized catch rates and associated error bars are shown in Figure 5.7 and are tabulated in Table 5.7. The units on catch rates were pounds of fish landed per hook-hour.

5.4.3.5 Uncertainty and Measures of Precision
Estimates of variance were based on 1000 bootstrap runs where trips were chosen randomly with replacement (Efron and Tibshirani 1994). Annual CVs of catch rates are tabulated in Table 5.7.

5.4.3.6 Comments on Adequacy for Assessment

The index of abundance created from the commercial logbook data was considered by the IWG to be adequate for use in the assessment. The data cover a wide geographic range relative to that of the stock, and logbooks represent a census of the fleet. The data set has an adequately large sample size and has a long enough time series to provide potentially meaningful information for the assessment.

Several concerns were discussed by the IWG, all related to this index coming from fishery dependent data. First, commercial fishermen may target different species through time. If changes in targeting have occurred, effective effort can be difficult to estimate. However, the DW recognized that the method of Stephens and MacCall (2004), used here to identify trips for the analysis, can accommodate changes in targeting, as long as species assemblages are consistent. Second, the data are self-reported and largely unverified. Some attempts at verification have found the data to be reliable. Third and probably foremost, the data are obtained from a directed fishery and therefore the index could contain problems associated with any fishery dependent index. Fishing efficiency of the fleet has likely improved over time due to improved electronics. In addition, overall efficiency may have changed throughout the time series if fishermen of marginal skill have left the fishery at a greater rate than more successful fishermen. Also of concern is whether catch rates in a directed fishery are density-dependent. As fish abundance decreases, fishermen may maintain relatively high catch rates, and as fish abundance increases, catch rates may saturate.

5.4.4 Other Fishery Dependent Data Sources Considered During the DW

Several data sources were discussed during the pre-DW webinar for the potential to support indices of abundance, and some of these were discarded based on initial summaries of data. Two data sources were recommended during the webinar for further consideration, but were subsequently not recommended by the DW for use in the assessment: SCDNR charterboat logbooks and the MRFSS/MRIP data (Table 5.1). Reasons for their exclusion are provided in Table 5.2.

5.5 Consensus Recommendations and Survey Evaluations

The DW recommended two fishery independent (chevron traps and videos) and three fishery dependent indices (headboat logbooks, headboat at-sea observer data, commercial handline logbooks) for potential use in the red snapper stock assessment. Pearson correlations and significance values (p-values) between indices are presented in Table 5.8. All recommended indices and their CVs are in Table 5.9, and the indices are compared graphically in Figure 5.8.

The IWG discussed relative ranking of the ability of each index to represent true population abundance. Based on these discussions, the indices recommended for the assessment were ranked as follows, with pros and cons of each listed in Table 5.2.

1. Chevron traps
2. Video
3. Headboat index
4. Headboat at-sea observer index
5. Commercial handline index

Note that these rankings were made during the DW and are based solely on *a priori* information about each index. Therefore, the rankings should be considered preliminary, as they do not benefit from viewing indices for consistency with other data sets (e.g., age comp data). The assessment panel, with all data in hand, will be in a better position to judge the indices for use in the assessment.

5.7 Tables

Table 5.1. Table of the data sources considered for indices of abundance.

Fishery Type	Data Source	Area	Yrs	Units	Standardization Method	Issues	Use?
Recreational	Headboat	NC-FL	1976-2009	N kept/ angler	Delta-GLM	Fishery dependent, self reported	Yes
Recreational	MRFSS/ MRIP	NC-FL	1995-2013	N caught/ angler-hr	Nominal	Fishery dependent. Potential bias in intercepts. Not standardized	No
Recreational	Headboat-at-sea-observer	NC-FL	2005-2014	N caught ≤20"/ angler	Delta-GLM	Fishery dependent.	Yes
Recreational	SCDNR charterboat logbook	SC	1993-2013	N caught/ angler-hr	Delta-GLM	Limited geographic coverage; outside core red snapper habitat	No
Commercial	Commercial logbook handline	NC-FL	1993-2009	lb kept/ hook-hour	Delta-GLM	Fishery dependent, self reported	Yes
Commercial	Commercial logbook diving	NC-FL	1993-2009	lb kept/ hook-hour		Fishery dependent, self reported; small sample sizes, almost all from FL	No
Independent	SERFS: chevron trap	NC-FL	1990-2014	N caught	Zero inflated negative binomial	Expanded spatial coverage through time	Yes
Independent	SERFS: video survey	NC-FL	2010-2014	N observed	Zero inflated negative binomial	Ages/sizes unknown	Yes
Independent	SEAMAP trawl survey	SC				Few samples (~1 fish/yr)	No

Independent	MARMAP: blackfish trap	Mostly SC	1981-1987			Few samples	No
Independent	MARMAP: Florida trap	Mostly SC	1981-1987			Few samples	No
Independent	MARMAP: Short-bottom longline					Few samples	No
Independent	MARMAP: Kali pole					Few samples	No

Table 5.2. Table of the pros and cons for each data set considered at the data workshop. Note that several data sources were considered (Table 5.1), but discarded, prior to the DW.

Fishery independent indices

SERFS Chevron Trap Index (*Recommended for use*)
Pros:
- Fishery independent random hard bottom survey
- Adequate regional coverage
- Standardized sampling techniques
- All fish caught are aged and measured

Cons:
- Short time series

SERFS Video Index (*Recommended for use*)
Pros:
- Fishery independent random hard bottom survey
- Adequate regional coverage
- Standardized sampling techniques
- Relatively high detection probabilities
- Likely to be less selective than capture gears

Cons:
- Short time series, with sampling differences in the first year
- Ages/sizes observed are unknown

Fishery dependent indices

Recreational Headboat (*Recommended for use*)
Pros:
- Complete census
- Covers the entire management area
- Some data are verified by port samplers and observers
- Large sample size
- Strongly correlated with headboat at-sea-observer index
- Generally non-targeted for focal species, which should minimize changes in catchability relative to fishery dependent indices that target specific species

Cons:
- Fishery dependent (i.e., potentially affected by regulations, targeting, hyperdepletion, hyperstability)
- Little information on discard rates, particularly before mid-2000s
- Catchability may vary over time or with abundance

- Effective effort is difficult to identify

General recreational (MRFSS) (*Not recommended for use*)
Pros:
- Intercept data by port samplers
- Spans the management area
- Includes estimates of discards

Cons:
- Nominal index only, not standardized
- Fishery dependent (i.e., potentially affected by regulations, targeting, hyperdepletion, hyperstability)
- Catchability may vary over time or with abundance
- Potential bias in trips intercepted
- High variability
- Effective effort is difficult to identify

Commercial Logbook – Handline (*Recommended for use*)
Pros:
- Complete census
- Covers the entire management area
- Large sample size

Cons:
- Fishery dependent (i.e., potentially affected by regulations, targeting, hyperdepletion, hyperstability)
- Data are self-reported and largely unverified
- Catchability may vary over time or with abundance
- Landings could be cross-referenced with other data sources, but effective effort difficult to identify
- No information on discard rates
- Potential shifts in species targeted; commercial fishermen more skillful than general recreational fishermen at targeting focal species

Headboat at-sea observer index (*Recommended for use*)
Pros:
- Observer program
- Good discard data (provides amount of discards and length frequency)
- Random sampling design
- Broad spatial coverage

Cons:

- Fishery dependent (i.e., potentially affected by regulations, targeting, hyperdepletion, hyperstability)
- Relatively short time series
- Information overlaps with headboat index, but this was mitigated by using fish <20inches
- Coverage of fleet is ~2%, but varies across states

SCDNR Charterboat ***(Not recommended for use)***

Pros:

- Census

Cons:

- Fishery dependent (i.e., potentially affected by regulations, targeting, hyperdepletion, hyperstability)
- South Carolina only, limited geographic coverage relative to south Atlantic
- Outside core habitat of red snapper
- No field validation

Table 5.3 The number of trapping events (N), standardized index, and CV for the red snapper index computed from SERFS chevron traps.

2005	1067	0.61	0.786	1.188	0.058
2006	893	0.49	0.440	0.597	0.071
2007	1108	0.48	0.599	0.665	0.064
2008	955	0.56	1.933	1.223	0.066
2009	911	0.63	4.918	1.942	0.073

Table 5.8. Pearson correlation values for indices recommended for use. P-values (in parentheses) represent the probability of obtaining the Pearson value under the null hypothesis of correlation=0. The HB at-sea index was lagged by one year when compared with other fishery dependent indices, because it only included fish ≤20 inches and would therefore track recruits prior to the other indices. CVT=chevron traps, HB=headboats, and Comm=commercial handline.

	Headboat	HB at-sea	CVT	Video	Comm
Headboat	1.000				
HB at-sea	0.971 (0.006)	1.000			
CVT	-	0.569 (0.316)	1.000		
Video	-	0.166 (0.790)	0.613 (0.272)	1.000	
Comm	0.788 (0.000)	0.780 (0.120)	-	-	1.000

Table 5.9. Red snapper standardized indices of abundance and annual CVs recommended for potential use in the stock assessment. CVT=chevron traps, HB=headboats, and Comm=commercial handline. Each index is scaled to its mean.

	Standardized indices					**CVs**

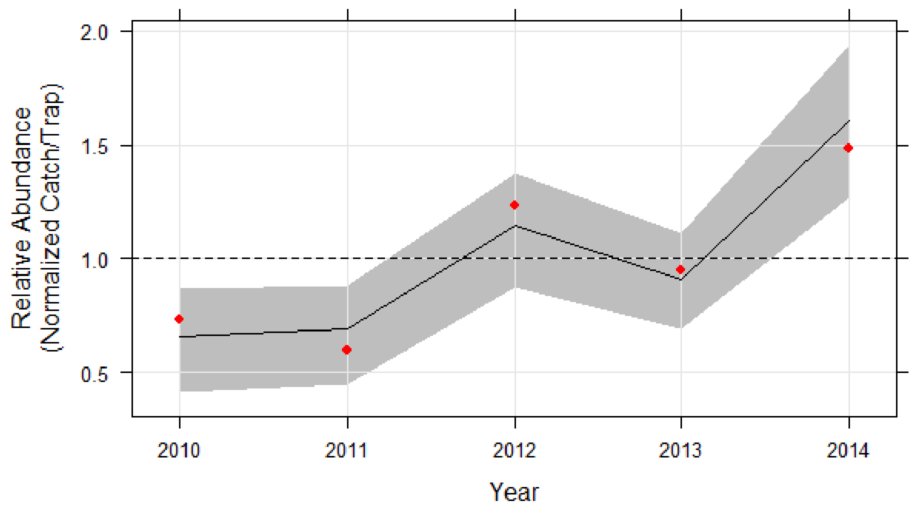
5.8 Figures

Figure 5.1. The nominal (red dots) and standardized index (solid black line) for red snapper computed from SERFS chevron traps. Gray shaded area represents 95% confidence interval as estimated from 10,000 bootstraps. (Top panel): the index recommended for use in the assessment. (Bottom panel): longer index developed for consideration as a sensitivity run.



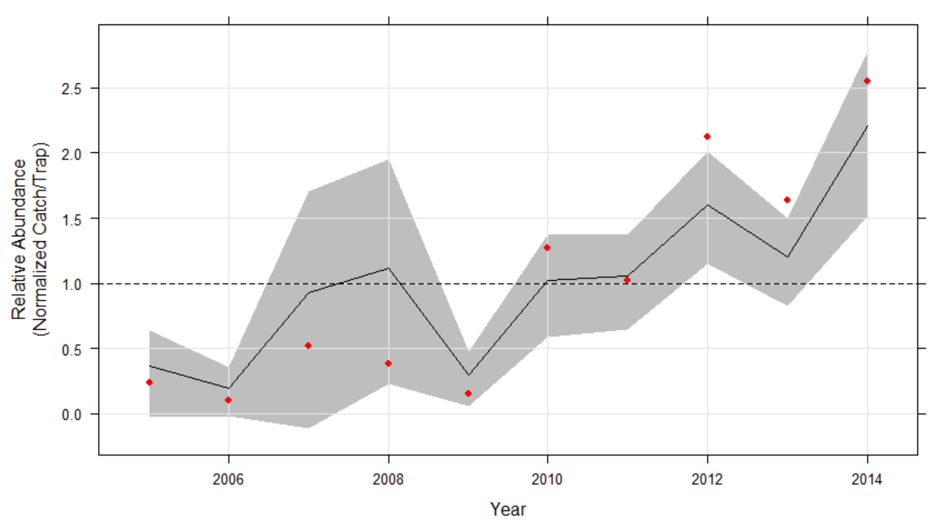


Figure 5.2. The nominal and standardized index for red snapper computed from the SERFS video survey.

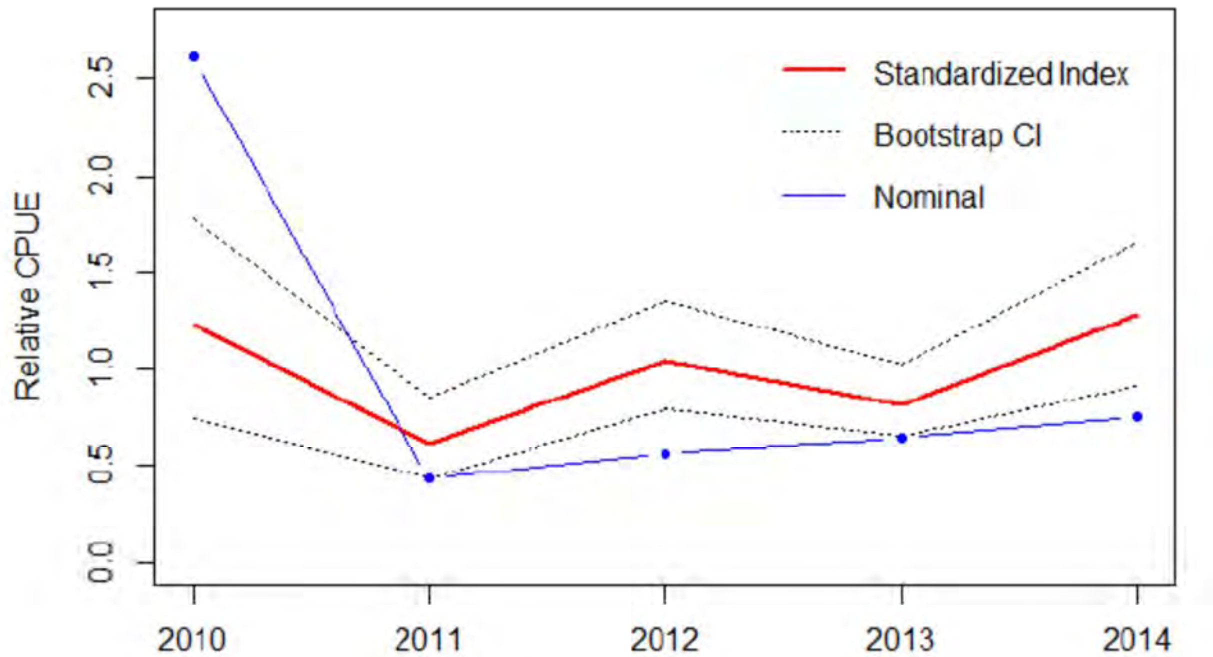

Figure 5.3. Map of headboat sampling area definitions. For analysis, areas were pooled as described in the text.

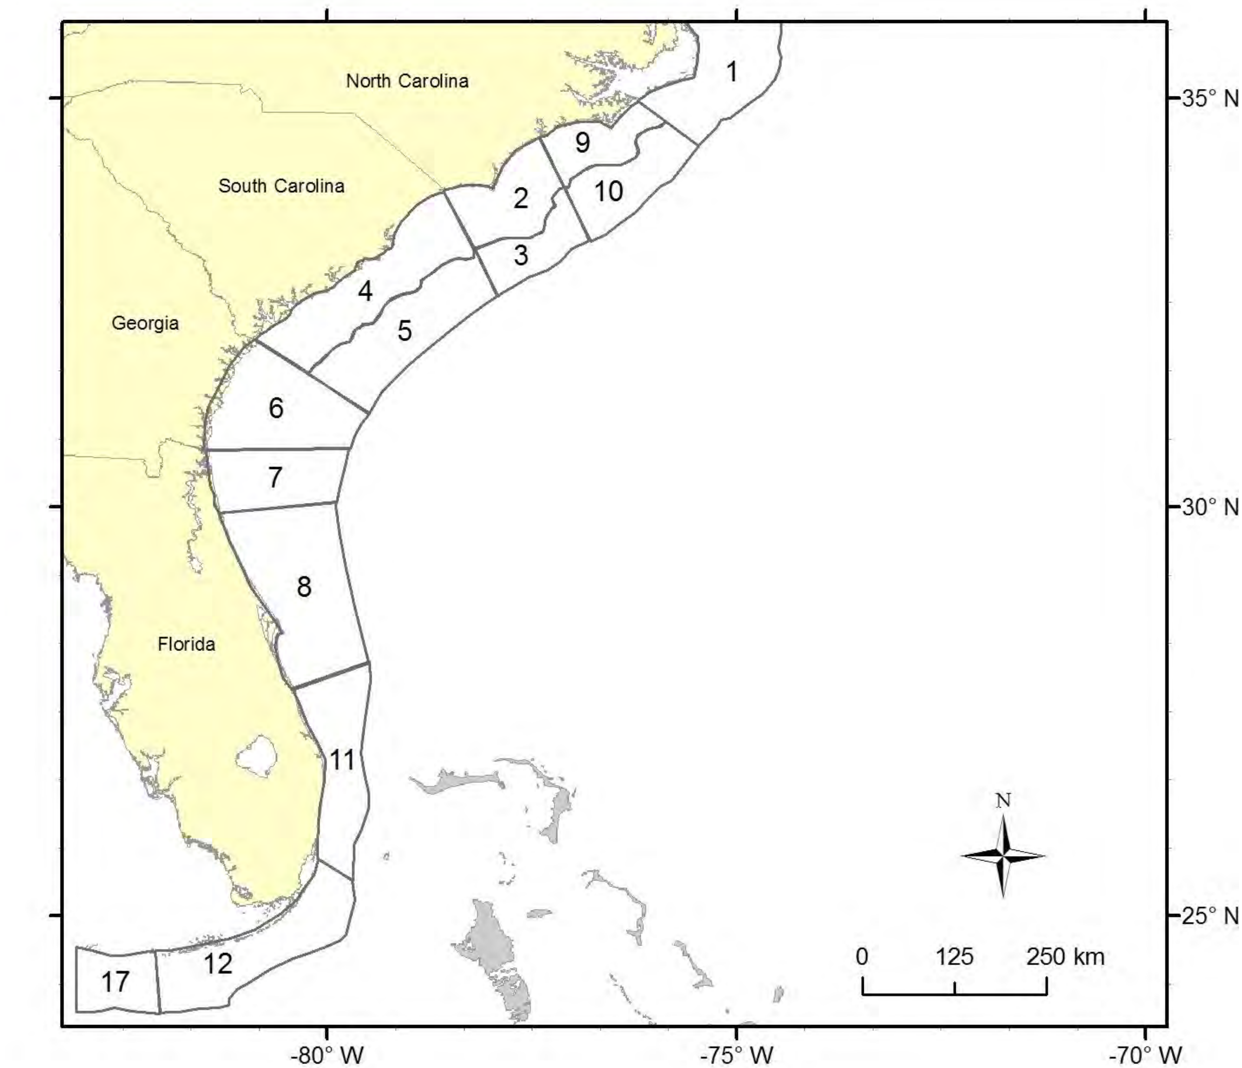

Figure 5.4. The nominal and standardized index for red snapper computed from headboat data, 1976-2009. Error bars represent approximate 95% confidence intervals.

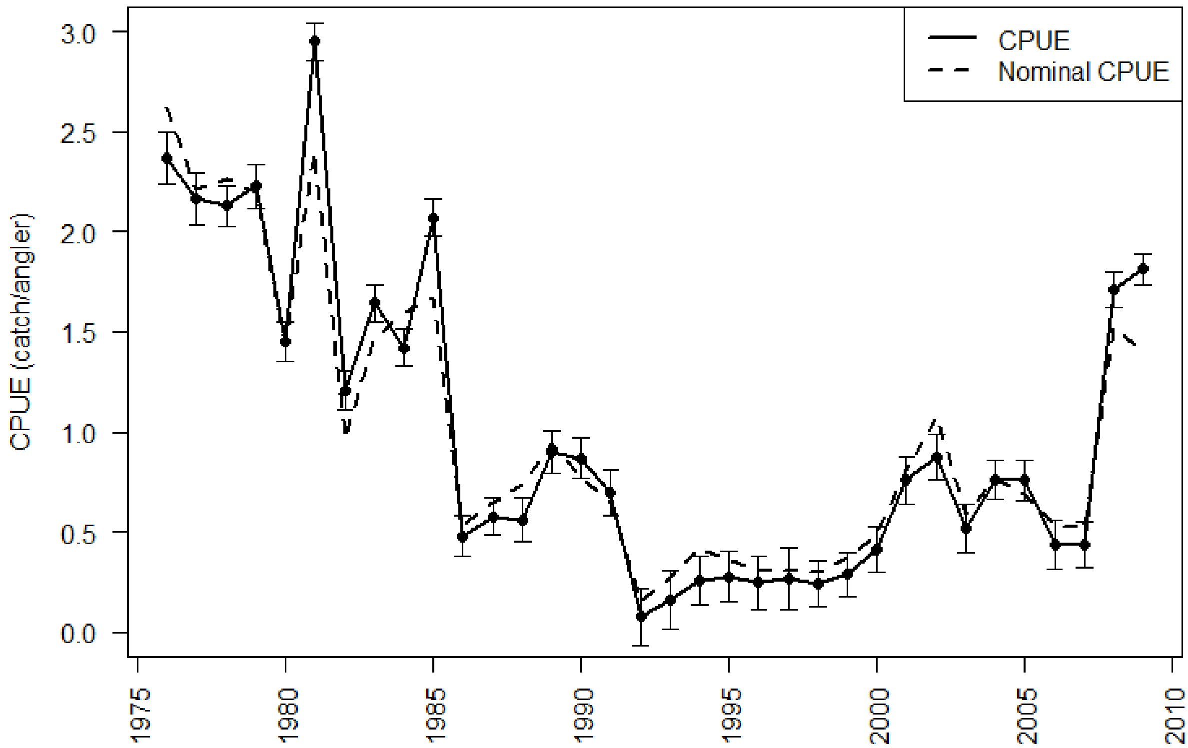

Figure 5.5. The standardized and nominal index with error bars at (+/-) 2 standard deviations computed for red snapper (≤20" TL) using the headboat at-sea observer data, 2005-2014.

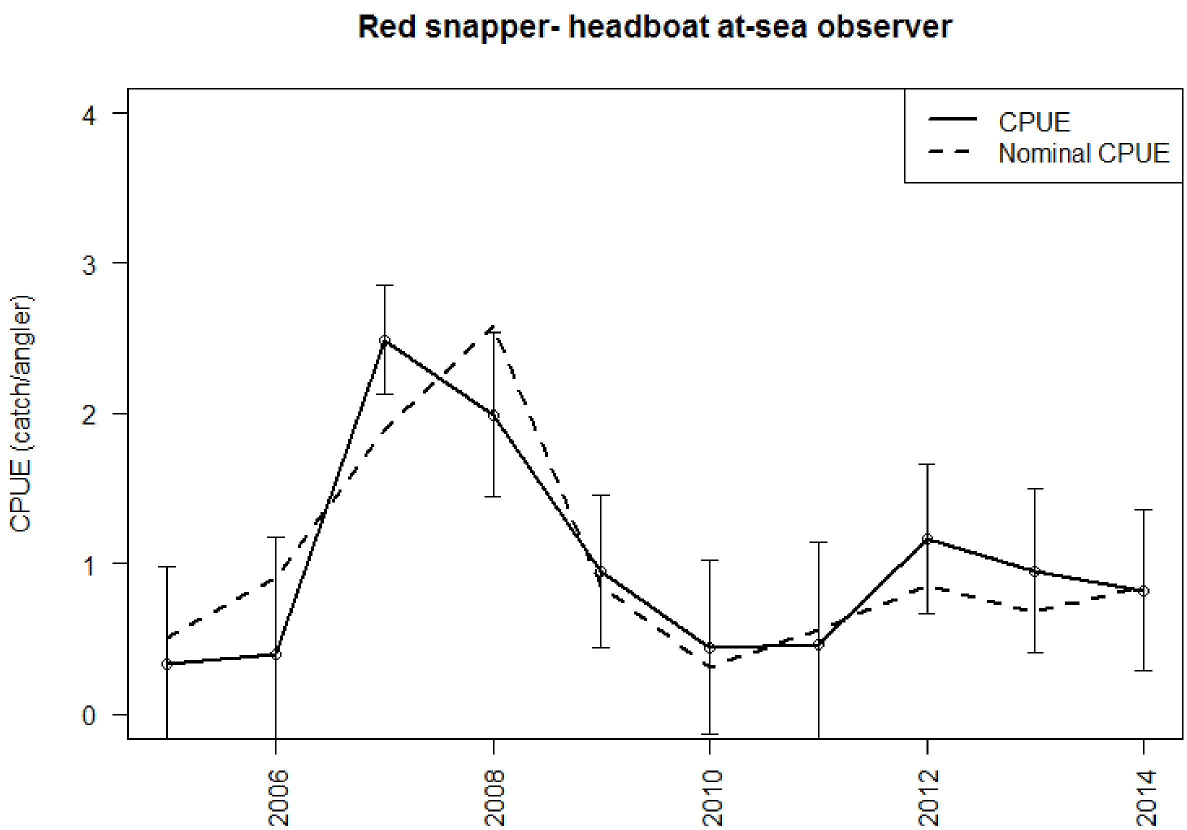

Figure 5.6. Latitude reported in the Coastal Fisheries Logbook Program (CFLP, commercial logbooks). Area is recorded in degrees where the first two digits signify degrees latitude, second two degrees longitude.   Only latitude was used in this analysis.

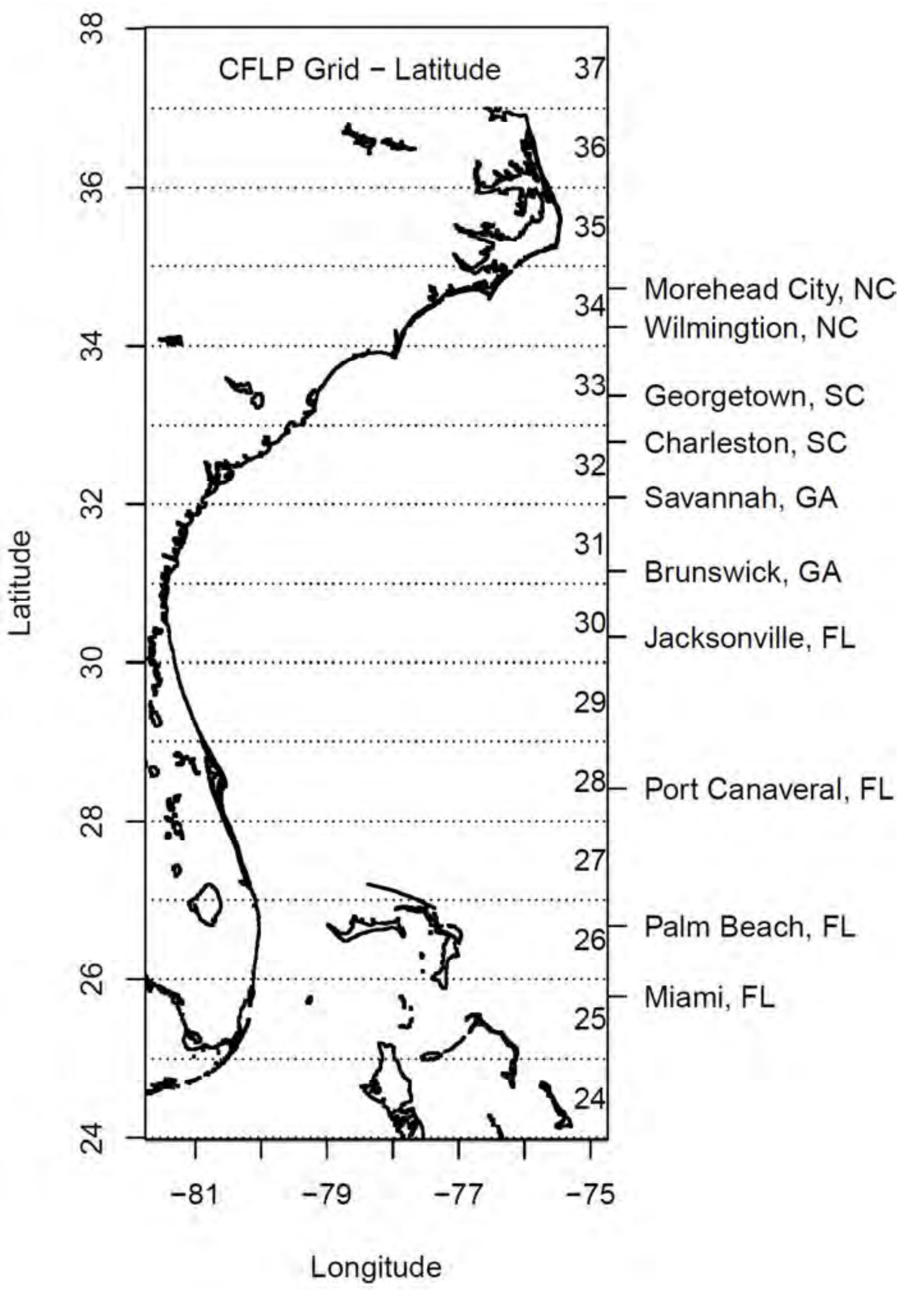

Figure 5.7. The nominal and standardized index for red snapper computed from commercial logbook handline data, 1993–2009. Error bars represent approximate 95% confidence intervals. The nominal (Nominal CPUE), Standardized Stephens and MacCall approach approved for use in SEDAR 41 (SandM.CPUE), and positive-only (SEDAR 41 Pos CPUE) runs are shown.

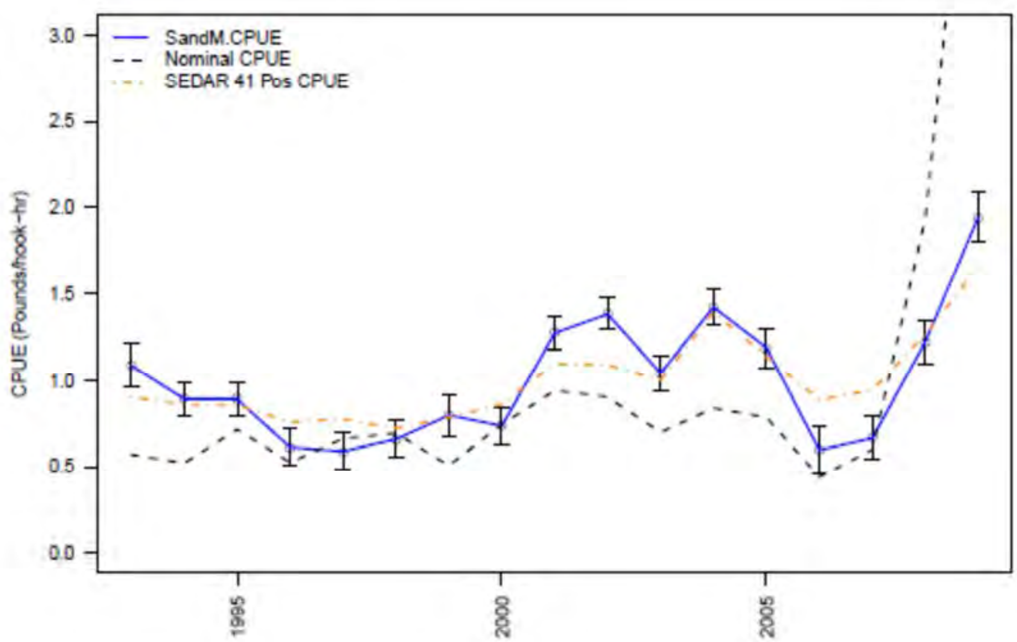

Figure 5.8. All indices (scaled to their respective means) recommended for potential use in the red snapper stock assessment. CVT=Chevron traps, and HB=Headboat.

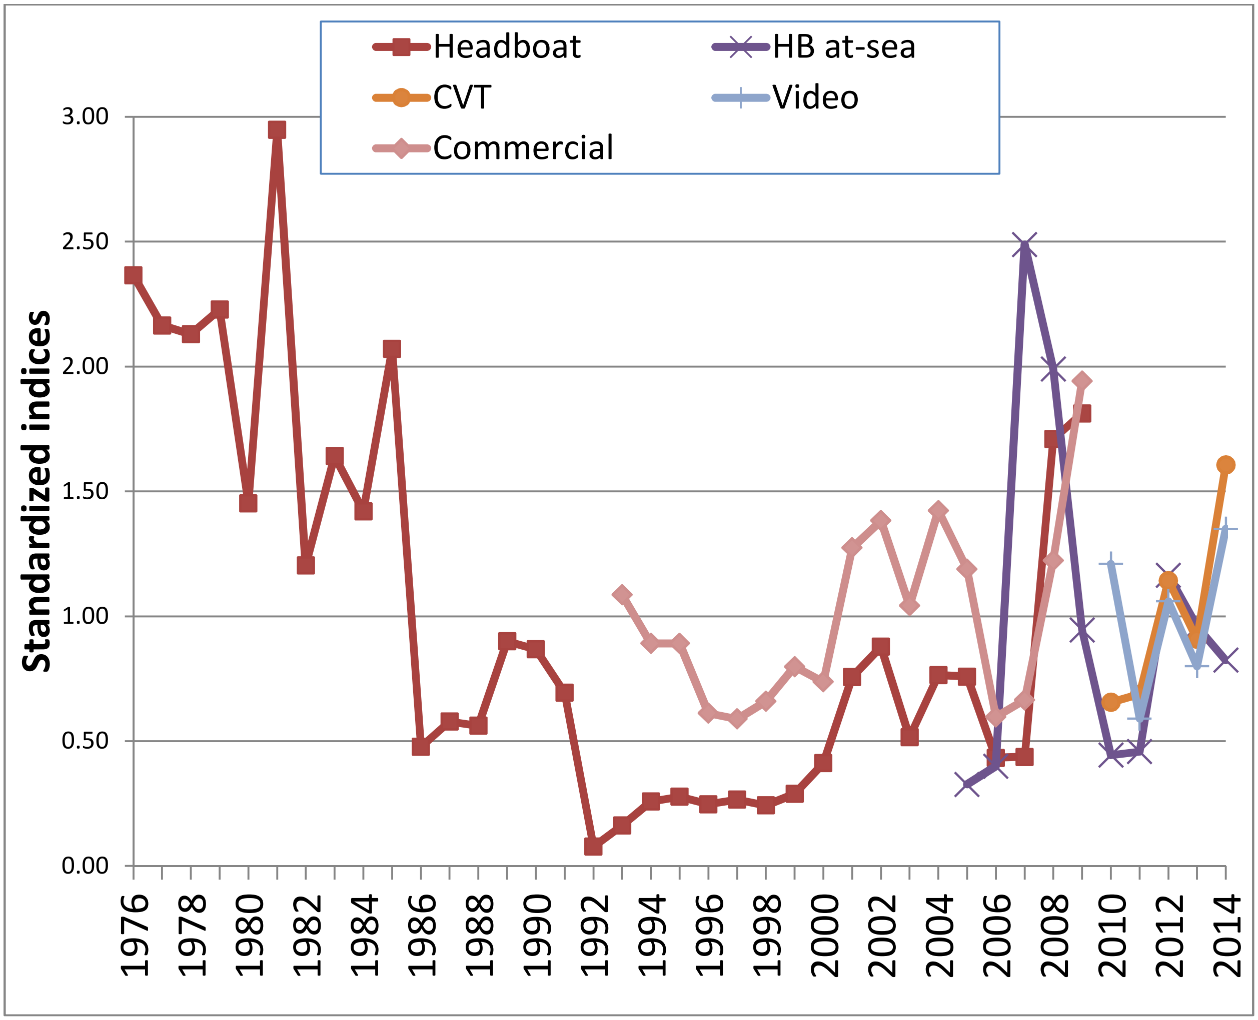

6. Analytical Approach

Based on the reports received from the data workshops and the webinars held to date (8/20/2015), the data are sufficient to attempt to fit the BAM model with the ASPIC as a simpler complementary model. The data provided will include catches, discards, indices, length and age compositions, and life history information. This is consistent with the modeling approach and data available for SEDAR 24.

7. Research Recommendations

7.1 Life History

Red Snapper Mini Season

If this program, along with continued closure of the fishery, is to extend into future seasons, an exploration of methods to further incentivize angler participation would be useful. After brief interviews with participants from the recreational fishers group at SEDAR 41, the following suggestions were provided to increase angler participation:

- Free fish cleaning at donation site.
- As people may be tired after being out on the water all day and with busy boat ramps, short questionnaire from a biologist on-site could be used instead of the anglers filling the forms out or requiring fishermen to fill out a survey online after they return home.
- Advertise data collection at local bait & tackle shops.
- Use NOAA's announcement system on weather radio channel where they also announce season closures, etc. Since fishermen are frequently monitoring this channel for weather updates, it could be an effective communication route to announce the collection information (drop locations, reward information, etc.).
- Dry storage areas are a good place to sample; many people store boats there instead of trailering home.

Life History Research

- More research on red snapper movements and migrations in Atlantic waters is needed. Available data and the results of studies in the Gulf of Mexico indicate high site fidelity, but that tropical storms may cause greater than normal movement that might help dispersal to depleted areas. This needs to be confirmed in the South Atlantic. Additional acoustic and traditional tagging is needed on known spawning locations to document spawning migrations or aggregations, and return of fish to non-spawning areas.
- Evaluate more thoroughly the data/sample collection during the mini-season to improve utility for assessments. This should include what samples should be collected (e.g. reproductive information).

- Possible changes in life history parameters, in particular relative to reproduction, need to be further investigated.
- Much is unknown about the early life history of Red Snapper, in particular relative to spawning areas, larval and juvenile stages, including habitat and dispersal.
- Alternative methods of reproductive output. The methods described in Klibansky's SEDAR41-DW49 may provide a more accurate estimate of reproductive output than previously used. Further investigation into this modeling effort and use for future assessments should be investigated.
- Duration of spawning indicators. The definition of spawning indicators has received significant discussion recently. As this has significant implications for the estimates of reproductive output, further research is needed to define consistent criteria for spawning indicators in finfish.
- Continuing the age reading comparisons and calibrations between labs on a reference collection of known age fish would be beneficial for determining a more accurate aging error matrix and would provide accuracy to the age composition data.

7.2 Commercial

Landings

- Improve gear and effort data for each trip.
- Standardize methodology for developing average proportions to parse out unclassified landings.

Discards

- Investigate the validity and magnitude of "no discard" trips. This may include fisher interviews throughout the region.
- Examine potential impacts of "no discard" trips on estimated discards.
- Improve discard logbook data collections via program expansion or more detailed reporting (i.e. electronic logbooks, etc.)
- Establish an observer program that is representative of the fisheries in the South Atlantic

Biosampling

- Establish an observer program that is representative of the fisheries in the South Atlantic.
- Angler education with regards to recording depths on paper logbooks (i.e. standardized units); validation of additions to the logbook form still needed.
- Standardize TIP sampling protocol to get representative samples at the species level.
- Standardize TIP data extraction.

7.3 Recreational

- Complete analysis of available historic photos for trends in CPUE and mean size of landed Red Snapper and Gray Triggerfish for pre-1981 time period. (Ultimately all species).
- Formally archive data and photos for all other SEDAR target species.
- For Hire Survey (FHS) should collect additional variables (e.g. depth fished).
- Increasing sample sizes for at-sea headboat observers (i.e. number of trips sampled).
- Compute variance estimate for headboat landings.
- Mandatory logbooks for all federally permitted for-hire vessels.

7.4 Indices

- Compare existing methods and/or develop new methods to define effective effort in fishery dependent data.
- Estimate selectivity of video gear in the SERFS.
    - Tagging, stereo cameras
- For video reading, evaluate methods to score water clarity and habitat.
- Evaluate effect of (non) independence between chevron traps and videos, including methods to combine the indices.
- Continue exploring the use of continuous predictor variables (e.g., splines or polynomials) for ZIP and ZINB standardization models.
- Headboat at-sea observer program needs depth data from all states (not just FL) and increased coverage overall.
- SCDNR charterboat logbook program should be replicated by other states.
- Develop fishery independent hook-gear index (S41-DW08).

Southeast Data, Assessment, and Review

SEDAR 41

South Atlantic Red Snapper

SECTION III: Assessment Workshop Report

February 2016

SEDAR
4055 Faber Place Drive, Suite 201
North Charleston, SC 29405

NOTE: Modifications to the model results reported in this report were made during the Review Workshop held March 15-18, 2016. For complete results reflecting those changes, please see Addenda 1 of the Stock Assessment Report (Section VI). In April 2017, the SEFSC discovered an error in the assessment and provided an updated Assessment Workshop Report. The corrected report can be found in Addenda 2 of the Stock Assessment Report (Section VII).

List of Figures

1. Introduction

1.1 Workshop Time and Place

The SEDAR 41 Assessment Process was conducted through a combination of an in-person workshop and series of webinars held from October 2015 to February 2016. The in-person workshop was held December 14-17, 2015 in Morehead City, NC. The workshop was originally scheduled for November 2015, but was delayed approximately one month to ensure a preliminary base run would be available at the beginning of the workshop. Six assessment webinars were held, three pre-workshop and three post-workshop, on the following dates: November 2, November 17 and December 1, 2015 and January 11, January 27, and February 17, 2016.

1.2 Terms of Reference

1. Review any changes in data following the Data Workshop and any analyses suggested by the Data Workshop. Summarize data as used in each assessment model. Provide justification for any deviations from Data Workshop recommendations.

2. Develop population assessment models that are compatible and appropriate with available data. Document input data, model assumptions and configuration, and equations for each model considered.

3. Provide estimates of stock population parameters, including:
   - Fishing mortality, abundance, biomass, selectivity, stock-recruitment relationship, and other parameters as necessary to describe the population.
   - Appropriate measures of precision for parameter estimates.

4. Characterize uncertainty in the assessment and estimated values.
   - Consider uncertainty in input data, modeling approach, and model configuration.
   - Provide a continuity model consistent with the prior assessment configuration, if one exists, updated to include the most recent observations. Alternative approaches to a strict continuity run that distinguish between model, population, and input data influences on findings, may be considered.
   - Consider and include other sources of uncertainty as appropriate for this assessment.
   - Provide appropriate statistical measures of model performance, reliability, and ‘goodness of fit’.
   - Provide measures of uncertainty for estimated parameters.

5. Provide estimates of yield and productivity.
   - Include yield-per-recruit, spawner-per-recruit, and stock-recruitment models.

6. Provide estimates of population benchmarks or management criteria consistent with the available data, applicable FMPs, proposed FMPs and Amendments, other ongoing or proposed management programs, and National Standards.
   - Evaluate existing or proposed management criteria as specified in the management summary.
   - Recommend proxy values when necessary.

7. Provide declarations of stock status relative to management benchmarks, or alternative data poor approaches if necessary.

8. Provide uncertainty distributions of proposed reference points and stock status metrics that provides the values indicated in the management specifications. Include probability density functions for biological reference point estimates and population metrics (e.g. biomass and exploitation) used to evaluate stock status.

9. Project future stock conditions (biomass, abundance, and exploitation; including probability density functions) and develop rebuilding schedules if warranted; include estimated generation time. Develop stock projections for the following circumstances, in accordance with the guidance on management needs provided in the management history:
   A) If stock is overfished:
      F=0, F=current, F=Fmsy, Ftarget
      F=Frebuild (max exploitation that rebuilds in the greatest allowed time)
      Fixed landings equal to the ABC
   B) If stock is overfishing
      F=Fcurrent, F=Fmsy, F=Ftarget, Fixed landings equal to the ABC
   C) If stock is neither overfished nor overfishing
      F=Fcurrent, F=Fmsy, F=Ftarget, Fixed landings equal to the ABC
   D) If data-limitations preclude classic projections (i.e. A, B, C above), explore alternate models to provide management advice.
   E) Gray triggerfish projections should account for changes in selectivity that may result from actions in Snapper Grouper Amendment 29.

10. Compare and contrast productivity measures and assessment assumptions between the Gulf of Mexico and South Atlantic stocks.

11. Provide recommendations for future research, data collection, and assessments.
    - Be as specific as practicable in describing sampling design and sampling intensity.
    - Emphasize items which will improve future assessment capabilities and reliability, and reduce uncertainty.
    - Consider data, monitoring, and assessment needs.

12. Complete the Assessment Workshop Report in accordance with project schedule deadlines (Section III of the SEDAR Stock Assessment Report).

1.3 List of Participants

ASSESSMENT PANELISTS
Kevin Craig - Lead Analyst Gray Triggerfish, SEFSC Beaufort
Kate Siegfried – Lead Analyst Red Snapper, SEFSC Beaufort
Rob Cheshire, SEFSC Beaufort
Eric Fitzpatrick, SEFSC Beaufort
Nikolai Klibansky, SEFSC Beaufort
Kyle Shertzer, SEFSC Beaufort
Erik Williams, SEFSC Beaufort
Joey Ballenger, SCDNR
Luiz Barbieri, FL FWCC / SSC
Peter Barile, SFA
Jeff Buckel, NC State / SSC
Marcel Reichert, SCDNR / SSC
Alexei Sharov, MD DNR / SSC

APPOINTED OBSERVERS
Kenny Fex, NC
Rusty Hudson, FL
Robert Johnson, FL
David Nelson, FL

APPOINTED COUNCIL REPRESENTATIVES
Zack Bowen, SAFMC
Mark Brown, SAFMC
Chris Conklin, SAFMC

COUNCIL AND AGENCY STAFF
Julia Byrd, SEDAR Coordinator
Julie O’Dell, SEDAR / SAFMC
John Carmichael, SEDAR / SAFMC
Chip Collier, SAFMC
Mike Errigo, SAFMC
Nick Farmer, SERO
Mike Larkin, SERO

WORKSHOP ATTENDEES
Nate Bacheler, SEFSC Beaufort
Ken Brennan, SEFSC Beaufort
David Bush, NCFA
Michelle Duval, NCDMF / SAFMC
Kelly Fitzpatrick, SEFSC Beaufort
Jared Flowers, NCDMF
Laura Lee, NCDMF
Genny Nesslage, UMCES
Amy Schueller, SEFSC Beaufort / SSC
David Tucker, NC fisherman
Mike Wilberg, UMCES / CBC

WEBINAR ATTENDEES
Nate Bacheler, SEFSC Beaufort
Ken Brennan, SEFSC Beaufort
Lora Clarke, PEW
Roy Crabtree, SERO
Michelle Duval, NCDMF / SAFMC
Kelly Fitzpatrick, SEFSC Beaufort
Dawn Franco, GADNR
Jimmy Hull, SFA
Deidra Jeffcoat, GA fisherman
Kathy Knowlton, GADNR
Laura, Lee, NCDMF / SSC
Jean-Jacques Maguire, Science Center for Marine Fisheries – Quebec
Anne Markwith, NCDMF
Mike Nelson, FL fisherman
Paul Nelson, FL fisherman
George Sedberry, NOAA / SSC
Tom Sminkey, NOAA
Karolyn Stillman, SEFSC Beaufort
Yuying Zhang, FL International University

1.4 Document List

SEDAR 41 assessment working paper and reference document list.

Document #	Title	Authors
	Documents Prepared for the Assessment Workshop

1.5 Statements Addressing Each Term of Reference

The following are the terms of reference with a statement explaining how each was addressed in the assessment report:

Assessment Workshop Terms of Reference

1. Review any changes in data following the data workshop and any analyses suggested by the data workshop. Summarize data as used in each assessment model. Provide justification for any deviations from Data Workshop recommendations.

- ***The data review and data updates are provided in Sections 2.1 and 2.2. Tables, figures and written justification are provided for each data change.***

2. Develop population assessment models that are compatible and appropriate with available data. Document input data, model assumptions and configuration, and equations for each model considered.

- ***The stock assessment model configuration is described in Sections 3.1 through 3.16. The equations are provided in a technical memorandum referenced in Section 3.1.***

3. Provide estimates of stock population parameters, including: fishing mortality, abundance, biomass, selectivity, stock-recruitment relationship, and other parameters as necessary to describe the population. Provide appropriate measures of precision for parameter estimates.

- ***Estimated parameters are listed in Section 4.2. Specific estimate sections are as follows: fishing mortality – Section 4.6, abundance – Section 4.3, biomass – Section 4.4, selectivities – Section 4.5, and stock-recruitment relationship – Section 4.7. Measures of precision are provided by the Monte Carlo Bootstrap uncertainty analysis and are described and displayed alongside the point estimates.***

4. Characterize uncertainty in the assessment and estimated values. Consider uncertainty in input data, modeling approach, and model configuration. Provide a continuity model consistent with the prior assessment configuration, if one exists, updated to include the most recent observations. Alternative approaches to a strict continuity run that distinguish between model, population, and input data influences on findings, may be considered. Consider and include other sources of uncertainty as appropriate for this assessment. Provide appropriate statistical measures of model performance, reliability, and 'goodness of fit'. Provide measures of uncertainty for estimated parameters.

- ***Uncertainty in the assessment is captured by the analyses described in Section 3.24. The MCB analysis considered uncertainty in the data through the bootstrap step (described in Section 3.24.1), and used a probabilistic framework to capture uncertainty in key parameter estimates (Sections 3.25-3.28). A continuity run was done through sensitivity analysis where the key assumptions made for the previous benchmark assessment were adopted, but current data were used (Sections 3.20 and 4.11, sensitivity 24). Measures of goodness of fit are described in Section 3.18, and multiple supplementary plots are provided in SEDAR41-RW04. Measures of uncertainty for estimated parameters are provided by the MCB analysis.***

5. Provide estimates of yield and productivity. Include yield-per-recruit, spawner-per-recruit, and stock-recruitment models.

- ***Per recruit and equilibrium analyses are provided in Section 4.8.***

6. Provide estimates of population benchmarks or management criteria consistent with the available data, applicable FMPs, proposed FMPs and Amendments, other ongoing or proposed management programs, and National Standards. Evaluate existing or proposed management criteria as specified in the management summary. Recommend proxy values when necessary.

- ***The current proxy used in the rebuilding plan for Red Snapper is $F_{30\%}$, and that was used as a reference point for stock status determination. Those estimates are provided in Section 4.9.***

7. Provide declarations of stock status relative to management benchmarks, or alternative data poor approaches if necessary.

- ***The measures of stock status are in Section 4.10 along with measures of their uncertainty.***

8. Provide uncertainty distributions of proposed reference points and stock status metrics that provides the values indicated in the management specifications. Include probability density functions for biological reference point estimates and population metrics (e.g., biomass and exploitation) used to evaluate stock status.

- ***The distributions of the stock status are described in Section 4.10, and the corresponding plots are Figures 36, 38 and 39.***

9. Project future stock conditions (biomass, abundance, and exploitation; including probability density functions) and develop rebuilding schedules if warranted; include estimated generation time. Develop stock projections for the following circumstances, in accordance with the guidance on management needs provided in the management history:
A) If stock is overfished: F=0, F=current, F=Fmsy, Ftarget, F=Frebuild (max exploitation that rebuilds in greatest allowed time), Fixed landings equal to the ABC
B) If stock is overfishing: F=Fcurrent, F=Fmsy, F= Ftarget, Fixed landings equal to the ABC

- ***The stock is estimated to be overfished with overfishing occurring, therefore five standard projections were performed: $F=0$, $F=F_{current}$, $F=_{Fmsy\ proxy}$, F_{target}, $F=F_{rebuild}$ (max exploitation that rebuilds in greatest allowed time). Section 3.29 contains the descriptions of the runs, and Section 4.12 contains the results. The fixed landings projection will be performed when the SSC provides suggested ABCs.***

10. Compare and contrast productivity measures and assessment assumptions between the Gulf of Mexico and South Atlantic stocks.

- ***The table addressing this ToR is found in Section 9.***

11. Provide recommendations for future research, data collection and assessments. Be as specific as practicable in describing sampling design and sampling intensity. Emphasize items which will improve future assessment capabilities and reliability, and reduce uncertainty. Consider data, monitoring, and assessment needs.

- ***Research recommendations are in Section 5.3.***

12. Complete the Assessment Workshop Report in accordance with project schedule deadlines (Section III of the SEDAR Stock Assessment Report) – ***Report submitted on time.***

2 Data Review and Update

The input data for this assessment are described below, with focus on modifications from the SEDAR41 DW.

2.1 Data Review

In this benchmark assessment, the Beaufort assessment model (BAM) was fitted to data sources developed during the SEDAR 41 DW with some modifications and additions.

Model input compiled during the DW

- Life history: Life history meristics, population growth, female maturity, proportion female, number of batches at age, size-dependent batch fecundity, and discard mortality
- Landings and discards: Commercial handline landings and discards, Headboat landings and discards, Recreational landings and discards
- Indices of abundance: Commercial handline, Headboat, Headboat discards, SERFS chevron trap, SERFS video

Model input modified or developed after the DW

- Life history: Fishery-dependent growth estimates, Growth estimates during the 20 inch size regulation, Age–specific natural mortality
- Landings and discards: changes to the recreational discards
- Indices of abundance: Fishery–independent indices combined (Chevron trap and Video)
- Length compositions: Commercial handline, Headboat, Recreational
- Age compositions: Commercial handline, Headboat, Recreational, Chevron trap

2.2 Data Update

2.2.1 Life History

Estimates of the von Bertalanffy growth parameters were provided by the DW for the population as a whole: (911mm, 0yr^{-1}, and 0yr). Two alternative von Bertalanffy curves were generated: one for all fisheries when no size limit was in place, and another to represent the fish captured by all fisheries under a 20 inch size limit regulation. Age-specific mortality was updated due to an error in the original calculation which forced the t_0 value to 0. Life-history information is summarized in Tables 1 and 2.

2.2.2 Landings and Discards

The fleet structure to be modeled was decided after the DW. The general recreational fleet comprises the charterboat and private boat fleets, while the headboat fleet stands alone. The decision was made to separate headboat from all other recreational fishing modes because length compositions diverge later in the time series. The general recreational fleet discards contained some zeros (years 1982, 1986, and 1990) that the panel considered unlikely to be accurate due to the magnitude of the surrounding years' values. The decision was made by the panel to fill in the zeros with the lowest observed discards in the regulatory time block of the zero value. Total removals as used in the assessment are in Table 3.

2.2.3 Indices of Abundance

The DW provided a SERFS chevron trap and video index separately. However, because the data are collected from the same sampling platforms (i.e. cameras mounted on the chevron traps), the two indices are not independent measures of abundance. Therefore, the panel decided to combine the two using the Conn (2010) method for combining indices. All indices and their corresponding CVs are shown in Table 4, and Figure 1 shows the indices as recommended by the data workshop plotted with the new CVID index for comparison. Fishery dependent indices of abundance were assumed to have CVs of 0.2, which is consistent with Francis (2003).

2.2.4 Length Compositions

Length compositions for all data sources were developed in 3-cm bins over the range 21–99 cm (labeled at bin center). All lengths below and above the minimum and maximum bins were pooled. The commercial handline, general recreational and headboat lengths were weighted by the region and landings (SEDAR41-AW05 2015). For inclusion, length compositions in any given year had to meet the sample size criteria of $nfish > 30$ and $ntrips \geq 10$ (Table 5). Furthermore, the AW panel decided to eliminate length comps where age comps were available. There were conflicts between the length compositions and age compositions, and the panel thought, given the relative ease of ageing this species and the fact the model is age-structured, the age compositions would provide more informative signals of year-class strength and better represent the catch in each fleet or survey.

2.2.5 Age Compositions

For age composition data, the upper range was pooled at 13 years old because a very small proportion of the data exist past age 13. The age compositions were weighted by the length compositions in attempt to address bias in selection of fish to be aged. For inclusion, age compositions in any given year had to meet the sample size criteria of $nfish > 10$ and $ntrips \geq 10$ (Table 5). Age composition was preferred over length composition when both were available from a given fleet in a given year.

2.2.6 Additional Data Considerations

Size limits were in place beginning in 1983 (12 inch minimum size limit TL), and changed in 1992 (20 inch minimum size limit TL). A moratorium was put in place for Red Snapper in 2010, and three subsequent mini-seasons were allowed (2011-2014) with no size limit. The panel examined size composition data and determined that three time blocks should be used to account for size limits, or the lack thereof: 1950-1991, 1992-2009, and 2010-2014. Data available for this assessment are summarized in Tables 1–5.

3 Stock Assessment Methods

3.1 Overview

The primary model discussed during the Assessment Workshop (AW) was a statistical catch-age model implemented using the Beaufort Assessment Model (BAM) software (Williams and Shertzer 2015). BAM applies a statistical catch-age formulation, coded using AD Model Builder (Fournier et al. 2012). BAM is referred to as an integrated analysis because it uses all population dynamics-relevant data (e.g. removals, length and age compositions, and indices of abundance) in a single modeling framework. In contrast, production models (e.g. ASPIC or ASPM) or catch curve analyses only use subsets of the available data and often require simplifying assumptions. In essence, the catch-age model simulates a population forward in time while including fishing processes (Quinn and Deriso 1999; Shertzer et al. 2008). Quantities to be estimated are systematically varied until characteristics of the simulated population matches available data on the real population. The model is similar in structure to Stock Synthesis (Methot 1989; 2009). Versions of BAM have been used in previous SEDAR assessments of reef fishes in the U.S. South Atlantic, such as Red Porgy, Black Sea Bass, Tilefish, Blueline Tilefish, Gag, Greater Amberjack, Red Grouper, Snowy Grouper, and Vermilion Snapper, as well as in the previous SEDAR assessments of Red Snapper (SEDAR24 2010). In addition, a surplus production model implemented using ASPIC and a catch curve analysis (SEDAR41-AW08 2015) were used to provide supplementary information.

3.2 Data Sources

The catch-age model included data from three fleets that caught Red Snapper in southeastern U.S. waters: general recreational (charter and private boat), commercial handlines (hook-and-line), and recreational headboats. The model was fitted to data on annual landings (in numbers for the recreational fleets, in whole weight for commercial fleet); annual discards (in numbers for all fleets), annual length compositions of removals; annual age compositions of landings and surveys; three fishery dependent indices of abundance (commercial handlines, headboat, and headboat discards); and one fishery independent index of abundance (combined SERFS chevron trap and SERFS video index). Removals included landings and dead discards, assuming the mortality rates provided by the Data Workshop. Data used in the model are tabulated in §2 of this report.

3.3 Model Configuration

The assessment time period was 1950–2014. A general description of the assessment model follows.

3.4 Stock dynamics

In the assessment model, new biomass was acquired through growth and recruitment, while abundance of existing cohorts experienced exponential decay from fishing and natural mortality. The population was assumed closed to immigration and emigration. The model included age classes $1 - 20^+$, where the oldest age class 20^+ allowed for the accumulation of fish (i.e., plus group).

3.5 Initialization

Initial (1950) numbers at age assumed the stable age structure computed from expected recruitment and the initial, age-specific total mortality rate. That initial mortality was the sum of natural mortality and fishing mortality, where fishing mortality was the product of an initial fishing rate (F_{init}) and F-weighted average selectivity. The initial fishing rate was estimated using a prior centered around $F_{\text{init}} = 0.03$. The assumption matches what was used for SEDAR24 with the justification that the value should be small given the relatively low volume of landings prior to the assessment period. The initial recruitment in 1950 was assumed to be the expected value from the spawner-recruit curve. For the remainder of the initialization period (1950–1977), recruitment was assumed equal to expected values. Without sufficient age/length composition data prior to 1978, there is little information to estimate those historic recruitment deviations with accuracy.

3.6 Natural mortality rate

The natural mortality rate (M) was assumed constant over time, but decreasing with age. The form of M as a function of age was based on Charnov et al. (2013), a change from SEDAR24 which based natural mortality on the findings of Lorenzen (1996). The Charnov et al. (2013) approach inversely relates the natural mortality at age to somatic growth. As in previous SEDAR assessments, the age-dependent estimates of M_a were rescaled to provide the same fraction of fish surviving from age 4 through the oldest observed age (51 yr) as would occur with constant $M = 0.134$. This approach using cumulative mortality allows that fraction at the oldest age to be consistent with the findings of Then et al. (2014).

3.7 Growth

Mean size at age of the population, fishery removals under no size limit, and fishery removals under a 20 inch size limit (total length, TL) were modeled with the von Bertalanffy equation, and weight at age (whole weight, WW) was modeled as a function of total length (Figure 2, Table 2). Parameters of growth and conversions (TL-WW) were treated as input to the assessment model. For fitting length composition data, the distribution of size at age was assumed normal with a CV estimated by the assessment model for each growth curve.

3.8 Female maturity and sex ratio

Female maturity was modeled with a logistic function; parameters for this model and a vector of maturity at age were provided by the DW and treated as input to the assessment model (Table 2). The sex ratio was assumed to be 50:50, as recommended by the DW.

3.9 Spawning stock

Spawning biomass was modeled as population fecundity (number of eggs). For Red Snapper, peak spawning was considered to occur at the end of June. This included information on batch size as a function of age, as well as information on the number of annual batches as a function of age (SEDAR41-DW49 (2015) and Fitzhugh et al. (2012)).

3.10 Recruitment

Expected recruitment of age-1 fish was predicted from spawning biomass using the Beverton–Holt spawner-recruit model. Steepness, h, is a key parameter of this model, and unfortunately it is often difficult to estimate reliably (Conn et al. 2010). In this assessment, many initial attempts to estimate steepness resulted in a value near its upper bound of 1.0, indicating that the data were insufficient for estimation. Likelihood profiling showed that the value was likely above 0.92, and was unreliably estimated between 0.92 and 0.98. The AW Panel decided to assume an average annual recruitment while estimating lognormal deviations around that average. This was achieved by fixing steepness at $h = 0.99$.

3.11 Landings

Time series of landings from three fleets were modeled: commercial handline (1950–2014), general recreational (1955–2014), and headboat (1955–2014). Landings were modeled with the Baranov catch equation (Baranov 1918) and were fitted in either weight or numbers, depending on how the data were collected (1000 lb whole weight for commercial fleets, and 1000 fish for recreational). The DW provided observed landings back to the first assessment year (1950) for the commercial fleet and back to 1955 for the recreational fleets. However, sampling of headboats began in 1972 and other recreational sectors in 1981. Thus, historic landings of the recreational fleets were estimated indirectly by the DW using the FHWAR ratio method (SEDAR41 41dw17). Historic landings were considered (and treated) in this assessment as a primary source of uncertainty.

3.12 Discards

As with landings, discard mortalities (in units of 1000 fish) were modeled with the Baranov catch equation (Baranov 1918), which required estimates of discard selectivities and release mortality probabilities. Discards were assumed to have fleet-specific, year-specific mortality probabilities, as suggested by the DW. Until 2007, the rate for commercial handlines was 0.48, and 0.38 thereafter. Until 2011, the general recreational and headboat rate was 0.37, with 0.285 thereafter. Annual discard mortalities, as fit by the model, were computed by multiplying total discards (tabulated in the DW report) by the fleet-specific and year-specific discard mortality rate. For general recreational and headboat fleets, discard time series were assumed to begin in 1981; for the commercial handlines fleet, discards were modeled starting in 1992 corresponding to the implementation of the 20-inch size limit.

3.13 Fishing

For each time series of removals (landings and discards), the assessment model estimated a separate full fishing mortality rate (F). Age-specific rates were then computed as the product of full F and selectivity at age. The across-fleet annual F was represented by apical F, computed as the maximum of F at age summed across fleets.

3.14 Selectivities

Selectivity curves applied to landings were estimated using a parametric approach. This approach applies plausible structure on the shape of the curves, and achieves greater parsimony than occurs with unique parameters for each age. Flat-topped selectivities were modeled as a two-parameter logistic function. Dome-shaped selectivities were modeled by combining two logistic functions: a two-parameter logistic function to describe the ascending limb of the curve, and a two-parameter logistic function to describe the descending limb. To model landings, the AW Panel recommended flat-topped selectivity for commercial handlines and dome-shaped selectivity for headboat and the general recreational fleets.

The assessment panel devoted substantial discussion and exploration to the pattern (flat-topped or dome-shaped) of selectivity at age. Several working papers and scientific literature (SEDAR24-AW05, SEDAR24-AW09, SEDAR24-AW12, SEDAR31-AW04, SEDAR31-AW12, SEDAR41-DW50, SEDAR41-DW08, Patterson et al. (2012), Wells et al. (2008), and Mitchell et al. (2014)) helped guide the panel's decisions by providing insight into selectivity based on length and age compositions, depth distributions of fishing effort, skill levels of fishermen, and how circumstances contrasted between the Atlantic and Gulf of Mexico. The choice of flat-topped selectivity for commercial handlines landings and dome-shaped for all others was based on several criteria. Two related considerations were the fleet-specific depths of fishing effort and the distribution of age at depth. In general, the commercial handlines fleet fish

in deeper water than other fleets, and although there was only weak correlation between depth and age of older fish (5^+), younger fish (1–5) were more readily caught in shallower depths (SEDAR24-AW05, and Mitchell et al. (2014)). It was also suggested that commercial gear and fishermen can better handle larger fish (SEDAR24-AW12). Catch curve data were consistent with the hypothesis that older fish are more vulnerable to the commercial handlines fleet than to recreational fleets (SEDAR41-AW08 2015).

Selectivity of each fleet was fixed within each block of size-limit regulations, but was permitted to vary among blocks where possible or reasonable. Fisheries experienced four blocks of size-limit regulations (no limit prior to 1983, 12-inch limit during 1983–1991, 20-inch limit during 1992–2009, and no size limit during the moratorium/miniseasons 2010–2014). However, the panel combined blocks one and two after seeing that the 12-inch size limit had a negligible effect on the selectivity pattern. Age and length composition data are critical for estimating selectivity parameters, and ideally, a model would have sufficient composition data from each fleet over time to estimate distinct selectivities in each period of regulations. That was not the case here, and thus additional assumptions were applied to define selectivities, as follows. Because the general recreational fleet had little age or length composition data prior to 1998, this fleet mirrored the headboat fleet until the final time block. All domed-shaped selectivities meant to characterize landings were configured so as not to allow a selectivity of 0 at older ages, which was considered implausible. Size and age composition data show larger, older fish are caught by all fleets. However, the selectivity functions would reach zero before the plus group age of 20. Therefore, the panel examined the age composition data and used the information they contained to create a plus group for the selectivities. Headboat selectivities were fixed as constant after age 10 at the value estimated for age 10. For the general recreational fleet, the constant age at which we fixed selectivity was 13. These plus groups were consistent with how the age composition data were fitted.

Selectivities of discards were estimated in a similar fashion to the landings in that the general recreational fleet discards mirrored the headboat fleet discards. Both the commercial handline discards and the headboat discards had sufficient length composition to estimate selectivities.

Selectivities of fishery dependent indices were the same as those of the relevant fleet. The fishery independent CVID index selectivity was assumed logistic and informed by the SERFS chevron trap age compositions.

3.15 Indices of abundance

The model was fit to three fishery dependent indices of relative abundance (headboat 1976–2009; headboat discards 2005–2014; and commercial handlines 1993–2009), and one fishery independent index of abundance (SERFS combined video and trap, CVID). Predicted indices were conditional on selectivity of the corresponding fleet or survey, and were computed from abundance at the midpoint of the year or, in the case of commercial handlines, biomass. The headboat discard index tracks small fish (less than 20 inches) and was included as a measure of recruitment strength.

3.16 Catchability

In the BAM, catchability scales indices of relative abundance to the estimated population at large. For the base model, the AW Panel recommended a time-invariant catchability.

A sensitivity run adopted a time-varying catchability for the headboat index. In this formulation, catchability was estimated in two stanzas, pre- and post-1992. Choice of the year 1992 was based on the implementation of a fishery management plan that may have changed fishing behavior.

3.17 Biological reference points

Biological reference points (benchmarks) were calculated based on the fishing rate that would allow a stock to attain 30% of the maximum spawning potential which would have been obtained in the absence of fishing mortality. Computed benchmarks included the MSY proxy, fishing mortality rate at $F_{30\%}$, total biomass at $F_{30\%}$, and spawning stock at $F_{30\%}$ (Gabriel and Mace 1999). In this assessment, spawning stock measures total eggs of the mature stock. These benchmarks are conditional on the estimated selectivity functions and the relative contributions of each fleet's fishing mortality. The selectivity pattern used here was the effort-weighted selectivities at age, with effort from each fleet estimated as the full F averaged over the last three years of the assessment.

3.18 Fitting criterion

The fitting criterion was a penalized likelihood approach in which observed removals (landings and discards) were fit closely, and observed composition data and abundance indices were fit to the degree that they were compatible. Removals and index data were fit using lognormal likelihoods. Length and age composition data were fit using robust multinomial likelihoods (Francis 2011), and only from years that met minimum sample size criteria ($nfish > 30$ and $ntrips \geq 10$) for length compositions and ($nfish > 10$ and $ntrips \geq 10$) for age compositions. Commercial and headboat discard length composition minimum sample size threshold was set lower ($nfish > 10$) due to the fact that the discard composition data were the only information available to estimate selectivity.

The model includes the capability for each component of the likelihood to be weighted by user-supplied values. For data components, these weights were applied by either adjusting CVs (lognormal components) or adjusting effective sample sizes (multinomial components). In this application to Red Snapper, CVs of landings and discards (in arithmetic space) were assumed equal to 0.05, to achieve a close fit to these time series yet allowing some imprecision. In practice, the small CVs are a matter of computational convenience, as they help achieve the desired result of close fits to the landings, while avoiding having to solve the Baranov equation iteratively (which is complex when there are multiple fisheries). Weights on other data components (indices, age/length compositions) were adjusted iteratively, starting from initial weights as follows. The CVs of indices were set equal to the values estimated by the GLMs used for standardization or at the fixed value of 0.2 for the headboat and commercial handline indices. Effective sample sizes of the multinomial components were assumed equal to the number of trips sampled annually, rather than the number of fish measured, reflecting the belief that the basic sampling unit occurs at the level of trip. These initial weights were then adjusted until standard deviations of normalized residuals were near 1.0 (Francis 2011). In sensitivity runs, weights on the fishery dependent indices were adjusted upward to explore their effects (not because up-weighted runs were considered equally plausible).

For parameters defining selectivities, CV of size at age, and σ_R, normal priors were applied to maintain parameter estimates near reasonable values, and to prevent the optimization routine from drifting into parameter space with negligible gradient in the likelihood. For σ_R, the prior mean (0.6) and standard deviation (0.25) were based on Beddington and Cooke (1983) and Mertz and Myers (1996).

3.19 Configuration of a base run

The base run was configured as described above. This configuration does not necessarily represent reality better than all other possible configurations, and thus this assessment attempted to portray uncertainty in point estimates through sensitivity analyses and through a Monte-Carlo/bootstrap approach (described below).

3.20 Sensitivity analyses

Sensitivity runs were chosen to investigate issues that arose specifically with this benchmark assessment. They were intended to demonstrate directionality of results with changes in inputs or simply to explore model behavior, and not all were considered equally plausible. These model runs vary from the base run as follows:

- S1: Remove the 2008 and 2009 years from the handline and headboat indices
- S2: Upweight fishery independent index further than was explored in the Assessment Workshop (10X likelihood weight after the iterative reweighting)
- S3: Upweight handline and headboat indices (3X likelihood weight after iterative reweighting)
- S4: Fishery dependent indices only
- S5: High value of M
- S6: Low value of M
- S7: Low discard mortality probabilities (commercial handlines rate set to 0.38 or 0.28, all recreational set to 0.27 or 0.20)
- S8: High discard mortality probabilities (commercial handlines rate set to 0.58 or 0.48, all recreational set 0.45 or 0.36)
- S9: Longer combined chevron trap and video (CVID) index (2005-2014)
- S10: Reduced general recreational landings in 1984 and 1985 by taking the geometric mean of surrounding years
- S11: Steepness $h = 0.84$
- S12: Headboat discard index excluded after 2009
- S13: Ageing error matrix included
- S14: Low value for age-specific number of batches
- S15: High value for age-specific number of batches
- S16: Headboat discard index dropped
- S17: High landings
- S18: Low landings
- S19: High discards
- S20: Low discards
- S21: Dome-shaped selectivity for commercial handline fleet
- S22: Separate video and trap index rather than a single CVID index
- S23: Fishery independent index only
- S24: Continuity run: changes include SEDAR24 values such as M, steepness, maturity, and SSB
- S25: Two time blocks for Headboat logbook index catchability (pre- and post-1992)
- S26: Retrospective - 1 year of data
- S27: Retrospective - 2 years of data
- S28: Retrospective - 3 years of data
- S29: Retrospective - 4 years of data

- S30: Use 1978 as the starting year, applied a loose prior to the estimation of F_{init} that corresponds to the geometric mean of the fishing mortality for 1950-1977
- S31: Estimate selectivities without fixing a plus group (for the selectivity estimation)

Sensitivities 5, 6, 14, 15, and 17-20 used the 10th and 90th quantiles (as the low and the high respectively) from the bootstraps of the observed data described in the uncertainty analysis methods (Section 3.24).

3.21 Parameters Estimated

The model estimated annual fishing mortality rates of each fleet, selectivity parameters, catchability coefficients associated with indices, parameters of the spawner-recruit model (except steepness), annual recruitment deviations, and CV of size at age for each age and growth relationship.

3.22 Per Recruit and Equilibrium Analyses

Yield per recruit and spawning potential ratio were computed as functions of F, as were equilibrium landings and spawning biomass. Equilibrium landings and discards were also computed as functions of biomass B, which itself is a function of F. As in the computation of benchmarks (described in §3.23), per recruit and equilibrium analyses applied the most recent selectivity patterns averaged across fleets, weighted by each fleet's F from the last three years of the assessment (2012–2014).

3.23 Benchmark/Reference Point Methods

In this assessment of Red Snapper, the quantities $F_{30\%}$, $\text{SSB}_{\text{F}30\%}$, $B_{\text{F}30\%}$, and $L_{\text{F}30\%}$ were estimated as proxies for MSY-based reference points. Steepness was not reliably estimable, so the stock-recruit relationship was not used to identify a maximum yield. Instead, steepness was fixed at 0.99 in order to assume an average level of recruitment while estimating deviations around the mean. $F_{30\%}$ was used in the rebuilding plan for Red Snapper, therefore, it was used here to generate fishing benchmarks. However, because the stock-recruitment relationship was not estimated, assumptions about recruitment are required to generate biomass benchmarks. Here, equilibrium recruitment was assumed equal to expected recruitment (arithmetic average). On average, expected recruitment is higher than that estimated directly from the spawner-recruit curve, because of lognormal deviation in recruitment. Thus, in this assessment, the method of benchmark estimation accounted for lognormal deviation by including a bias correction in equilibrium recruitment. The bias correction (ς) was computed from the variance (σ_R^2) of recruitment deviation in log space: $\varsigma = \exp(\sigma_R^2/2)$. Then, equilibrium recruitment (R_{eq}) associated with any F is,

$$R_{eq} = \frac{R_0 \left[\varsigma 0.8 h \Phi_F - 0.2(1-h)\right]}{(h-0.2)\Phi_F} \tag{1}$$

where R_0 is virgin recruitment, h is steepness which is fixed in this assessment, and $\Phi_F = \phi_F/\phi_0$ is spawning potential ratio given growth, maturity, and total mortality at age (including natural and fishing mortality rates). Because steepness is fixed at 0.99, R_{eq} as a function of F is approximately a straight line. The R_{eq} and mortality schedule imply an equilibrium age structure and an average sustainable yield (ASY). The estimate of $F_{30\%}$ is the F giving 30% of the SPR, and the estimate of $L_{\text{F}30\%}$ is that ASY. The estimate of $\text{SSB}_{\text{F}30\%}$ follows from the corresponding equilibrium age structure, as does the estimate of discard mortalities $D_{F30\%\}}$, here separated from ASY (and consequently, $L_{\text{F}30\%}$).

Estimates of $L_{\mathrm{F30\%}}$ and related benchmarks are conditional on selectivity pattern. The selectivity pattern used here was an average of terminal-year selectivities from each fleet, where each fleet-specific selectivity was weighted in proportion to its corresponding estimate of F averaged over the last three years (2012–2014). If the selectivities or relative fishing mortalities among fleets were to change, so would the estimates of $L_{\mathrm{F30\%}}$ and related benchmarks.

The maximum fishing mortality threshold (MFMT) is defined by the SAFMC as $F_{30\%}$, and the minimum stock size threshold (MSST) as $75\%\mathrm{SSB}_{\mathrm{F30\%}}$. Overfishing is defined as $F >$ MFMT and overfished as SSB $<$ MSST. However, because this stock is currently under a rebuilding plan, increased emphasis is given to SSB relative to $\mathrm{SSB}_{\mathrm{F30\%}}$ (rather than MSST), as $\mathrm{SSB}_{\mathrm{F30\%}}$ is the rebuilding target. Current status of the stock is represented by SSB in the latest assessment year (2014), and current status of the fishery is represented by the geometric mean of F from the latest three years (2012–2014). Recent SEDAR assessments have considered the mean over the terminal three years to be a more robust metric.

3.24 Uncertainty and Measures of Precision

As in SEDAR24, this assessment used a mixed Monte Carlo and bootstrap (MCB) approach to characterize uncertainty in results of the base run. Monte Carlo and bootstrap methods (Efron and Tibshirani 1993; Manly 1997) are often used to characterize uncertainty in ecological studies, and the mixed approach has been applied successfully in stock assessment, including Restrepo et al. (1992), Legault et al. (2001), SEDAR4 (2004), and many South Atlantic SEDAR assessments since SEDAR19 (2009). The approach is among those recommended for use in SEDAR assessments (SEDAR Procedural Guidance 2010).

The approach translates uncertainty in model input into uncertainty in model output, by fitting the model many times with different values of "observed" data and key input parameters. A chief advantage of the approach is that the results describe a range of possible outcomes, so that uncertainty is characterized more thoroughly than it could be by any single fit or handful of sensitivity runs. A minor disadvantage of the approach is that computational demands are relatively high.

In this assessment, the BAM was successively re-fit in $n = 4000$ trials that differed from the original inputs by bootstrapping on data sources, and by Monte Carlo sampling of several key input parameters. The value of $n = 4000$ was chosen because a minimum of 3000 runs were desired, and it was anticipated that not all runs would converge or otherwise be valid. Of the 4000 trials, approximately 0.88% were discarded, because the model did not properly converge (in most cases, an estimated quantity was at its upper bound). This left $n = 3965$ MCB trials used to characterize uncertainty, which was sufficient for convergence of standard errors in management quantities.

The MCB analysis should be interpreted as providing an approximation to the uncertainty associated with each output. The results are approximate for two related reasons. First, not all combinations of Monte Carlo parameter inputs are equally likely, as biological parameters might be correlated. Second, all runs are given equal weight in the results, yet some might provide better fits to data than others.

3.24.1 Bootstrap of observed data

To include uncertainty in the indices of abundance, multiplicative lognormal errors were applied through a parametric bootstrap. To implement this approach in the MCB trials, random variables ($x_{s,y}$) were drawn for each year y of time series s from a normal distribution with mean 0 and variance $\sigma^2_{s,y}$ [that is, $x_{s,y} \sim N(0, \sigma^2_{s,y})$]. Annual observations were then perturbed from their original values ($\hat{O}_{s,y}$),

$$O_{s,y} = \hat{O}_{s,y}[\exp(x_{s,y} - \sigma^2_{s,y}/2)] \tag{2}$$

The term $\sigma^2_{s,y}/2$ is a bias correction that centers the multiplicative error on the value of 1.0. Standard deviations in log space were computed from CVs in arithmetic space, $\sigma_{s,y} = \sqrt{\log(1.0 + CV^2_{s,y})}$. As used for fitting the base run, CVs of indices of abundance were those provided by, or modified from, the data providers (tabulated in Table 4 of this assessment report).

Uncertainty was modeled for historical commercial landings similarly to the indices, and by the CVs provided by the commercial working group at the DW. No commercial discard CVs, headboat landings CVs, or headboat discard CVs by year were provided, therefore the panel had to make some assumptions. We assumed a value of $CV = 0.20$ for commercial discards and headboat discards. For headboat landings, we used information from the headboat program to assume a decreasing CV by time blocks (i.e. $CV = 0.15$ 1981-1995, $CV = 0.1$ for 1996-2007, and $CV = 0.05$ thereafter). General recreational landings and discards had complementary CVs, and those were used as provided except in a few instances. A CV greater than 1 was capped at 1, which was sufficiently large to represent high uncertainty but not so high that bootstrapped values caused implausible time series. The panel thought the resulting draws sufficiently represented uncertainty in spite of the dampening of a few years' CVs (Table 6).

Uncertainty in age and length compositions were included by drawing new distributions for each year of each data source, following a multinomial sampling process. Ages (or lengths) of individual fish were drawn at random with replacement using the cell probabilities of the original data. For each year of each data source, the number of fish sampled was the same as in the original data.

3.24.2 Monte Carlo sampling

In each successive fit of the model, several parameters were fixed (i.e., not estimated) at values drawn at random from distributions described below.

3.25 Natural mortality

A vector of age-specific natural mortality was provided by the Life History Working Group. They used the Charnov et al. (2013) estimator scaled to the Then et al. (2014) max age asymptotic M, and then used the uncertainty around the determination of maximum age to provide an upper and lower bound to the M vector. The Assessment Panel thought the upper ($M = 0.14$) and lower ($M = 0.12$) bound were too similar to the base vector to represent the true uncertainty around M. Instead, the AW Panel wanted to carry the uncertainty forward in both maximum age and the parameters of the Then et al. (2014) estimator of asymptotic M:

$$M = aT^b_{max} \tag{3}$$

To estimate uncertainty in a and b, we acquired the data of Then et al. (2014) and conducted a bootstrap of $n = 10,000$ iterations, drawing from the original data set with replacement. For each MCB iterations, one of the 10,000 fits was drawn at random, thus maintaining any correlation structure between a and b. We then drew T_{max} from a uniform distribution and calculated asymptotic M. For the age-dependent vector, we started with the Charnov age-dependent curve, and scaled it to the M estimate we calculated in the previous steps. A new M value was drawn and a new age-dependent vector was calculated for each MCB trial.

3.26 Discard mortality

The discard mortality working group provided an upper and lower bound for each time block (pre- and post-regulation) and fishery (commercial and recreational). Commercial rates before 2007 ranged from 38% to 58%, and 2007 to present ranged from 28% to 48%. Recreational rates before 2011 ranged from 27% to 45%, and 2011 on ranged from 20% to 36%. The rates decreased in response to the implementation of circle hooks, which are meant to cause fewer fatal bycatch events. We drew the rate for the earlier time period for each fleet from a truncated normal distribution with mean equal to the point estimate and a standard deviation devised to provide a 95% confidence interval similar to what the working group provided above. For the later time period for each fleet we also drew from a truncated normal distribution created similarly as in the previous step but with the upper bound fixed at the random draw from the earlier time period. The last step is meant to ensure that the second value is not larger than the first, so as to maintain the feature that discard mortality has decreased due to the circle hook regulation.

3.27 Batch Fecundity

Prior to the MCB analysis, a bootstrap procedure was run on the data set used to estimate batch fecundity at age for the base run. For each of 10000 bootstrap runs, the 69 paired observations of batch fecundity and fish length were sampled 69 times with replacement, the regression model refit, and the bootstrap parameters estimates saved to a data matrix. Once all bootstraps were run, the parameter matrix was trimmed by removing runs where either parameter value was outside of its 95% confidence interval. The parameters were found to be highly correlated, so during the MCB analysis, pairs of parameters were randomly drawn, with replacement, from the trimmed bootstrap parameter matrix. For each MCB run, predicted batch fecundity at age was calculated using a set of bootstrap parameters and a vector of length at age.

3.28 Batch number

Prior to the MCB analysis, a similar but separate bootstrap procedure was run on the data set used to estimate batch number at age for the base run. For each of 10000 bootstrap runs, the 1472 paired observations of spawning indicator presence, fish length, and day of the year were sampled 1472 times with replacement and the regression model refit. Predicted batch number at age was then calculated from the bootstrap parameter estimates and a vector of length at age, and the vectors saved to a data matrix. Once all bootstraps were run, the batch number at age matrix was trimmed by first summing batch number at age for each run, yielding lifetime batch number; runs where lifetime batch number was outside of the 95% confidence interval were trimmed. During the MCB analysis, a vector of batch number at age was randomly drawn, with replacement, from the trimmed bootstrap batch number at age matrix for each MCB run.

3.29 Projections

Projections were run to predict stock status in years after the assessment, 2015–2044. The year 2044 is the last year of the current rebuilding plan.

The structure of the projection model was the same as that of the assessment model, and parameter estimates were those from the assessment. Any time-varying quantities, such as recreational selectivity, were fixed to the most recent values of the assessment period. A single selectivity curve was applied to calculate removals, averaged across fleets using geometric mean Fs from the last three years of the assessment period, similar to computation of $L_{\mathrm{F30\%}}$ benchmarks (§3.23).

Expected values of SSB (time of peak spawning), F, recruits, and removals were represented by deterministic projections using parameter estimates from the base run. These projections were built on the spawner-recruit relationship with steepness fixed ($h = 0.99$) and with bias correction, and were thus consistent with estimated benchmarks in the sense that long-term fishing at $F_{30\%}$ would yield $L_{\mathrm{F30\%}}$ from a stock size at $\mathrm{SSB}_{\mathrm{F30\%}}$. Uncertainty in future time series was quantified through stochastic projections that extended the Monte Carlo/Bootstrap (MCB) fits of the stock assessment model.

3.29.1 Initialization of projections

Initial age structure at the start of 2015 was computed by the assessment model.

Fishing rates that define the projections were assumed to start in 2017. Because the assessment period ended in 2014, the projections required an initialization period (2015–2016). For 2015, a moratorium year, the landings selectivity was set to 0 and the discard selectivity was rescaled to peak at 1. Then, an optimization routine solved for the F that matched the current dead discards (mean of 2012-2014) in numbers. In 2016, a similar routine soved for the F that matched current landings (mean of 2012-2014), assuming a mini-season would occur.

3.29.2 Uncertainty of projections

To characterize uncertainty in future stock dynamics, stochasticity was included in replicate projections, each an extension of a single MCB assessment model fit. Thus, projections carried forward uncertainties in natural mortality, reproduction, landings, discards, and discard mortalities, as well as in estimated quantities such as selectivity curves, and in initial (start of 2015) abundance at age.

Initial and subsequent recruitment values were generated with stochasticity using a Monte Carlo procedure, in which the estimated Beverton–Holt model (i.e. R_0, σ_R estimated, and $h = 0.99$) of each MCB fit was used to compute mean annual recruitment values ($\bar{R}_y$). Variability was added to the mean values by choosing multiplicative deviations at random from a lognormal distribution,

$$R_y = \bar{R}_y \exp(\epsilon_y). \tag{4}$$

Here ϵ_y was drawn from a normal distribution with mean 0 and standard deviation σ_R, where σ_R is the standard deviation from the relevant MCB fit.

The procedure generated 20,000 replicate projections of MCB model fits drawn at random (with replacement) from the MCB runs. In cases where the same MCB run was drawn, projections would still differ as a result of stochasticity in projected recruitment streams. Central tendencies were represented by the deterministic projections of the base run, as well as by medians of the stochastic projections. Precision of projections was represented graphically by the 10^{th} and 90^{th} percentiles of the replicate projections.

3.30 Rebuilding time frame

Based on results from the previous SEDAR24 benchmark assessment, Red Snapper is currently under a rebuilding plan. In this plan, the terminal year is 2044, and rebuilding is defined by the criterion that projection replicates achieve stock recovery (i.e., $\mathrm{SSB}_{2044} \geq \mathrm{SSB}_{\mathrm{F30\%}}$) with probability of at least 50%. Here, the probability of stock recovery in each year of the rebuilding plan was computed as the proportion of stochastic projections where $\mathrm{SSB} \geq \mathrm{SSB}_{\mathrm{F30\%}}$, with $\mathrm{SSB}_{\mathrm{F30\%}}$ taken to be iteration-specific (i.e., from that particular MCB run).

Projection scenarios Five projection scenarios were considered.

- Scenario 1: $F = 0$
- Scenario 2: $F = F_{\text{current}}$
- Scenario 3: $F = F_{30\%}$
- Scenario 4: $F_{target} = 98\% F_{30\%}$
- Scenario 5: $F = F_{\text{rebuild}}$, with rebuilding probability of 0.5 in 2044
- Scenario 6: Discards only

The F_{current} is represented by the geometric mean of fishing mortalities from 2012-2014. The F_{rebuild} is defined as the maximum F that achieves rebuilding in the allowable time frame. The discards only scenario treated the initialization year 2016 the same as 2015 (discards only), and then applied the mean F (from 2015-2016) forward starting in 2017.

3.31 Surplus Production Model

3.31.1 Overview

A logistic surplus production model, implemented in ASPIC (Version 7.03; Prager 2005), was used to estimate stock status of Red Snapper off the southeastern U.S. While primary assessment of the stock was performed using the age-structured BAM, the surplus production approach was intended as a complement, for additional comparison with the age-structured model's results. More specifically, this model focuses on the dynamics of the removals as they relate to the indices of abundance, while ignoring any age data or age-structure in the population.

3.31.2 Data Sources

Data sources supplied to a production model include a time series of removals (i.e. landings plus dead discards) and one or more indices of abundance (i.e. catch per unit of effort). These inputs should be in units of biomass (i.e. weight), therefore some of the data developed at the SEDAR41 DW required additional formatting. These changes are detailed below.

Removals

The available removals time series comprised commercial landings (1950-2014), recreational landings (1955-2014), commercial dead discards (1992-2014), and recreational dead discards (1981-2014), in pounds, summed by year.

Commercial Landings

The SEDAR41 DW reported commercial landings in pounds, thus these data did not need to be modified for the production model.

Recreational landings

During the SEDAR41 DW, recreational landings for the historical period (1955-1980) were estimated in numbers of individuals using the The National Survey of Fishing, Hunting, and Wildlife-Associated Recreation Survey (FHWAR) census method (see SEDAR41-DW17). For the contemporary period (1981-2014), the SEDAR-41 DW reported Southeast Region Headboat Survey (SRHS) and Marine Recreational Information Program (MRIP) recreational landings in numbers and weights. Recreational landings from this period did not need to be modified, but were used to convert historical landings to weight.

Following a similar approach used in SEDAR24, recreational landings in weight and numbers for all fleets were combined by year for the first three years of the contemporary period; dividing annual landings in weight by landings in numbers produced annual mean weight estimates. The average of these three mean weights (3.4 lb) was then multiplied by the historical landings in numbers to convert them to weight. The historical and combined contemporary recreational landings series were then joined to produce a single time series of recreational landings, in pounds.

Dead Discards

Discard estimates were generated in numbers at the SEDAR-41 DW. Since many discarded fish survive after release, discard mortality rates were applied to discards in numbers to calculate dead discards. For commercial discards, a discard mortality rate of 0.48 was applied prior to regulations in 2007, and a rate of 0.38 was applied from 2007 onward. For recreational discards, a discard mortality rate of 0.37 was applied prior to regulations in 2011, and a rate of 0.285 was applied from 2011 onward.

Mean weight of commercial discards was estimated by converting lengths of commercial discards to weights using data and a conversion equation supplied by the SEDAR-41 DW, and then calculating the average weight of these individuals. The data on lengths of commercial discards were divided into two time periods before (2007-2009) and after (2010-2013) the fishery was closed. The average estimated weights of commercial discards from each time period (before = 2.93 lb; after = 8.84 lb) were multiplied by discards in numbers, for years before and after the closure, respectively.

Mean weight of recreational discards was estimated by converting lengths of recreational headboat-at-sea observer discards to weights using data and a conversion equation supplied by the SEDAR-41 DW, and then calculating the average weight of these individuals. Year-specific mean weight estimates were multiplied by recreational discards in numbers for corresponding years when available (2005-2014). For years prior to 2005 where year-specific mean weights were not available, discards in numbers were multiplied by the average mean weight across the available years before the 2010 closure (1.96 lb).

Indices of Abundance

Five indices of abundance were produced by the SEDAR-41 DW for Red Snapper: commercial logbook handline index (hereafter commercial handline; units = lb kept per hook-hour), headboat (number of fish kept per angler), headboat-at-sea-observer (number of fish caught $<20''$ per angler), Southeast Reef Fish Survey (SERFS) chevron trap (number of fish caught per trap), and the SERFS video (number of fish observed per video). The commercial handline index was already in weight and did not need to be converted. The headboat index was converted to pounds by multiplying by year-specific mean weights, generated by dividing headboat landings in pounds by landings in numbers for each year. The headboat-at-sea-observer index was converted to pounds by multiplying by the same mean weights used to convert recreational discards to weight. The SERFS chevron trap and video indices were converted to weights by multiplying by year-specific mean weights calculated from combined recreational (headboat and MRIP) landings in weight divided by landings in numbers.

3.31.3 Model Configuration and Equations

Production modeling used the model formulation and ASPIC software (version 7.03) of Prager (1994; 2005). This is an observation-error estimator of the continuous-time form of the Schaefer (logistic) production model (Schaefer 1954; 1957). Estimation was conditioned on catch. The logistic model for population growth is the simplest form of a differential equation which satisfies a number of ecologically realistic constraints, such as a carrying capacity (a consequence of limited resources). When written in terms of stock biomass, this model specifies that

$$\frac{dB_t}{dt} = rB_t - \frac{r}{K}B_t^2 \qquad (5)$$

where B_t is biomass in year t, r is the intrinsic rate of increase in absence of density dependence, and K is carrying capacity (Schaefer 1954; 1957). This equation may be rewritten to account for the effects of fishing by introducing an instantaneous fishing mortality term, F_t :

$$\frac{dB_t}{dt} = (r - F_t)B_t - \frac{r}{K}B_t^2 \qquad (6)$$

By writing the term F_t as a function of catchability coefficients and effort expended by fishermen in different fisheries, Prager (1994) showed how to estimate model parameters from time series of yield and effort.

For Red Snapper, the model proved difficult to fit. It was configured using various combinations of removals, indices, starting dates, prior distributions and starting values, resulting in approximately 324 configurations. Many of these runs were completed during early model development but many others incorporated small changes to data inputs or model specifications suggested by AW panel members during the Assessment Workshop. As the BAM developed, most of these runs became obsolete and are not presented here. The run configured according to recommendations by the SEDAR41 AW panel is presented here. This model configuration (run 320) contained removals from 1950 to 2014 and the four indices used in the BAM (Comm, HB, HB-at-sea, CVID) from 1976 to 2014. Following the recommendations of the AW panel, the CVID index was upweighted by a factor of three (i.e. CVs divided by three), and the headboat-at-sea index was shifted forward by one year, since it indexes younger fish than the other indices.

Three other runs (318, 319, and 323) are also presented to relate the main run (320) to ASPIC results from the previous Red Snapper assessment (SEDAR 24). All three runs contain only the commercial and headboat indices, starting in 1993 and 1976 respectively, and removals starting in 1950. But in run 318 (the continuity run), the final year of removals and indices is 2009, as in SEDAR 24, while in run 319 (the updated continuity run) the final year of removals and indices is 2014, as in the BAM for the current assessment. Since both the commercial and headboat indices ended in 2009 the only difference between the continuity run and updated continuity run is the removals estimates from 2010-2014. Finally a run was completed (run 323; best configuration $\frac{B_1}{K}$ fixed) that is identical to the best configuration run, but with $\frac{B_1}{K}$ fixed at the estimate for the continuity run, for reasons described below.

To evaluate the uncertainty in the model fit and parameter estimates of the best configuration run, 1000 bootstrap runs were conducted. Percentile confidence intervals were also calculated for parameters.

4 Stock Assessment Results

4.1 Measures of Overall Model Fit

In general, the Beaufort assessment model (BAM) fit well to the available data. Predicted length compositions from the commercial handline and discards from the commercial and headboat fleets were reasonably close to observed data in most years, as were predicted age compositions (Figure 3). The model was configured to fit observed commercial and recreational removals closely (Figures 4–9). Fits to indices of abundance generally captured the observed trends but not all annual fluctuations (Figures 10–13).

4.2 Parameter Estimates

Estimates of all parameters from the catch-age model are shown in Appendix B. Estimates of management quantities and some key parameters are reported in sections below.

4.3 Stock Abundance and Recruitment

In general, estimated abundance at age showed truncation of the older ages through most of the assessment period, but with some signs of increase during the last decade (Figure 14; Table 7). Total estimated abundance was at its lowest value in the early 1990s, but near its highest levels at the end of the time series, comparable to those in the early 1970s, but with a more truncated age structure. The MCB results reflect the same patterns with their associated uncertainties for total abundance and abundance of age 2+ (Figure 18). Annual number of recruits is shown in Table 7 (age-1 column) and in Figure 15. The highest recruitment values were predicted to have occurred in the mid-1980s, 2006, and the terminal year of the model (2014).

4.4 Total and Spawning Biomass

Estimated biomass at age followed a similar pattern as abundance at age (Figure 16; Table 9). Total biomass and spawning biomass showed similar trends—general decline through to the early-1990s, and relatively stable or slowly increasing patterns since the mid-1990s (Figure 17; Table 10). Terminal year estimates are at levels not seen since the 1970s.

4.5 Selectivity

Selectivity of the SERFS index is shown in Figure 19, and selectivities of landings from commercial and recreational fleets are shown in Figures 20, 21, and 22. Selectivities of discards from commercial and recreational fleets are shown in Figures 23, 24, and 25. In the most recent years, full selection occurred near ages 2–4, depending on the fleet and time block.

Average selectivities of landings, dead discards, and the total weighted average of all selectivities were computed from F-weighted selectivities in the most recent three assessment years (Figure 26). This average selectivity was used in computation of point estimates of benchmarks, as well as in projections. All selectivities from each time block, including average selectivities, are tabulated in Tables 11, 12, and 13.

4.6 Fishing Mortality and Removals

Estimates of total F at age are shown in Table 15. In any given year, the maximum F at age (i.e., apical F) may be less than that year's sum of fully selected Fs across fleets. This inequality is due to the combination of two features of estimated selectivities: full selection occurs at different ages among gears and several sources of mortality have dome-shaped selectivity.

Estimated time series of landings and discards are shown in Tables 18, 19, 20, 21. Table 16 shows total landings at age in numbers, and Table 17 in weight. Landings have been dominated by the general recreational and commercial handline fleet until recent years when the general recreational fleet became the dominant source of removals (Tables 18 and 19). Also since 2010, total landings remained below the level at $L_{\mathrm{F30\%}}$ (Figure 29).

Estimated discard mortalities occurred on a smaller scale than landings until the implementation of regulations and the use of mini-seasons, and have been above the $D_{F_{30\%}}$ level for most of the moratorium years (Tables 20 and 21, and Figure 30).

4.7 Spawner-Recruitment Parameters

The Beverton–Holt spawner-recruit curve is shown in Figure 31, along with the effect of density dependence on recruitment, depicted graphically by recruits per spawner as a function of spawning stock (1E8 Eggs). Values of recruitment-related parameters were as follows: steepness $h = 0.99$ (fixed), unfished age-1 recruitment $\widehat{R_0} = 330503$, and standard deviation of recruitment residuals in log space $\widehat{\sigma}_R = 0.79$ (which resulted in bias correction of $\varsigma = 1.37$). Uncertainty in these quantities was estimated through the MCB analysis (Figure 32).

4.8 Per Recruit and Equilibrium Analyses

Yield per recruit and spawning potential ratio were computed as functions of F. These computations applied the most recent selectivity patterns averaged across fleets, weighted by F from the last three years (2012–2014) (Figures 33 and 34).

As in per recruit analyses, equilibrium landings and spawning biomass were computed as functions of F (Figure 35). $F_{30\%}$ is used as a proxy for MSY, and the corresponding landings and spawning biomass are $L_{\mathrm{F30\%}}$ and $\mathrm{SSB}_{\mathrm{F30\%}}$.

4.9 Benchmarks / Reference Points

As described in §3.23, biological reference points (benchmarks) were derived analytically assuming equilibrium dynamics, corresponding to the spawner-recruit curve with fixed steepness $h = 0.99$ (Figure 31). Reference points estimated were $F_{30\%}$, $L_{\mathrm{F30\%}}$, $B_{\mathrm{F30\%}}$ and $\mathrm{SSB}_{\mathrm{F30\%}}$. Based on $F_{30\%}$, three possible values of F at optimum yield (OY) were considered—$F_{\mathrm{OY}} = 65\% F_{30\%}$, $F_{\mathrm{OY}} = 75\% F_{30\%}$, and $F_{\mathrm{OY}} = 85\% F_{30\%}$—and for each, the corresponding yield was computed. Standard errors of benchmarks were approximated as those from MCB analysis (§3.24).

Maximum likelihood estimates (base run) of benchmarks, as well as median values from MCB analysis, are summarized in Table 22. Point estimates of $L_{\mathrm{F30\%}}$-related quantities were $F_{30\%} = 0$ (y^{-1}), $L_{\mathrm{F30\%}} = 459$ (1000 lb), $B_{\mathrm{F30\%}} = 3693$ (mt), and $\mathrm{SSB}_{\mathrm{F30\%}} = 329948$ (1E8 Eggs). Median estimates were $F_{30\%} = 0$ (y^{-1}), $L_{\mathrm{F30\%}} = 450$ (1000 lb), $B_{\mathrm{F30\%}} = 3628$ (mt), and $\mathrm{SSB}_{\mathrm{F30\%}} = 299651$ (1E8 Eggs). Distributions of these benchmarks from the MCB analysis are shown in Figure 36.

4.10 Status of the Stock and Fishery

Estimated time series of stock status $\mathrm{SSB}/\mathrm{SSB}_{\mathrm{F30\%}}$ showed general decline throughout the beginning of the assessment period, a leveling off, and then a modest increase since 2010 (Figure 37, Table 10). Base-run estimates of spawning biomass have remained below the threshold (MSST) since the early-1970s. Current stock status was estimated in the base run to be $\mathrm{SSB}/\mathrm{SSB}_{\mathrm{F30\%}} = 0$ (Table 22), indicating that the stock has not yet recovered to $\mathrm{SSB}_{\mathrm{F30\%}}$. Median values from the MCB analysis indicated similar results $\mathrm{SSB}/\mathrm{SSB}_{\mathrm{F30\%}}$ =0. The uncertainty analysis suggested that the terminal estimate of stock status is robust (Figures 38, 39). Of the MCB runs, 100% indicated that the stock was below $\mathrm{SSB}_{\mathrm{F30\%}}$ in 2012. Age structure estimated by the base run generally showed fewer older fish than the (equilibrium) age structure expected at $L_{\mathrm{F30\%}}$, but it also showed increases since 2006.

The estimated time series of $F/F_{30\%}$ suggests that overfishing has occurred throughout most of the assessment period (Table 10, Figure 37). Current fishery status in the terminal year, with current F represented by the geometric mean from 2012–2014, was estimated by the base run to be $F/F_{30\%} = 3$ (Table 22). The fishery status was also robust (Figures 38, 39). Of the MCB runs, approximately 99.5% agreed with the base run that the stock is currently experiencing overfishing.

4.11 Sensitivity and Retrospective Analyses

Sensitivity runs, described in §3.3, were used for exploring data or model issues that arose during the assessment process, for evaluating implications of assumptions in the base assessment model, and for interpreting MCB results in terms of expected effects of input parameters. In some cases, sensitivity runs are simply a tool for better understanding model behavior, and therefore all runs are not considered equally plausible in the sense of alternative states of nature. Time series of $F/F_{30\%}$ and $\mathrm{SSB}/\mathrm{SSB}_{\mathrm{F30\%}}$ are plotted to demonstrate sensitivity to the changing conditions in each run. The sensitivity of the base run to changes in natural mortality, steepness, dome-shaped selectivity for the commercial handline fleet, various index adjusts for both the fishery dependent indices and fishery independent index, the use of an ageing error matrix and high and low levels of landings and discards was explored (Figures 40–52). Sensitivity 24 is a version of a continuity run in that various assumptions made about parameters for SEDAR 24 were adopted for this sensitivity (e.g. higher discard mortalities, lower M, using gonad weight as a proxy for SSB, different female maturity and fecundity information, higher max age, lower steepness, different time of year for peak spawning, and fixed recruitment standard deviation). Time series of stock and fishery status estimated by this assessment are similar to those from the previous, SEDAR24 assessment (Figure 53). Trends in $F/F_{30\%}$ from the two assessments generally track each other, though the magnitude of the variations differ. Trends in $\mathrm{SSB}/\mathrm{SSB}_{\mathrm{F30\%}}$ track each other, though there is divergence at the end of the time series where the current model estimates a more optimistic stock status.

None of the sensitivities show a recovered stock in 2014. A couple sensitivities suggest the stock is undergoing less overfishing than is estimated in the base. However, those runs eliminate the fishery independent index entirely, or upweight the fishery dependent indices to the point of swamping out any signal from the survey data. The vast majority of runs agree with the status indicated by the base run (Figure 54, Table 23). Results appeared to be most sensitive to natural mortality and steepness.

Retrospective analyses suggest a pattern of overestimating fishing mortality in the terminal year, however, the trend is less apparent for SSB (Figure 55).

4.12 Projections

Projections based on $F = 0$ allowed the spawning stock to grow such that the majority of replicate projections recovered to $\mathrm{SSB}_{\mathrm{F30\%}}$ by 2025 (Figure 56, Table 24), however the stock is already in a rebuilding plan so other projections were also requested in the TORs. This was not the case for projections based on $F = F_{\mathrm{current}}$ (Figure 57, Table 25), or if the fishing rate were reduced to $F_{30\%}$ (Figure 58, Table 26) or F_{target} (Figure 59, Table 27). By design, projections based on $F = F_{\mathrm{rebuild}}$ showed recovery with the desired probability in 2044 (Figure 60, Table 28). The projection with discard mortality only showed similar trajectories to the run assuming no other fishing mortality(Table 29 and Figure 61).

4.13 Surplus Production Model

4.13.1 Model Fit

For the best configuration run, model predictions underestimated observed values for the headboat index for the first ten years of the time series (1976-1985; Figure 62). They also underestimated the commercial index during the first five years of that series (1993-1997), while overestimating the headboat index for those same years. The model provided a very poor fit to the headboat-at-sea discard index (2006-2014) but produced a much better fit to the upweighted CVID index (2005-2014). The model did not fit high index values in 2008 and 2009 very closely, but predicted a slight decline from 2007-2009 followed by an increasing trend from 2010 to 2014.

4.13.2 Parameter Estimates and Uncertainty

The ASPIC model fits three main parameters ($\frac{B_1}{K}$, MSY, and F_{MSY}) as well as catchability coefficients (q_i) for each index i. Several other parameters can then be derived from these estimates: $r = 2F_{MSY}$, $K = \frac{2MSY}{F_{MSY}}$ and $B_{MSY} = \frac{K}{2}$. Recent status indicators $\frac{F}{F_{MSY}}$ and $\frac{B}{B_{MSY}}$ are calculated with the most recent estimates of F (2014) and B (2015). Estimates of the main parameters and recent status indicators for all four runs are presented in Table 30. Prior distributions and model estimates of the main parameters for the best configuration run are presented in Figure 63.

Across all runs, most of the main parameters varied very little (e.g. CV $MSY = 0.0027$; CV $F_{MSY} = 0.014$). By contrast $\frac{B_1}{K}$ varied widely (CV $\frac{B_1}{K} = 0.74$), due to variation in B_1 (CV $B_1 = 0.74$) rather than K (CV $K = 0.013$; Table 30). Among bootstrap runs based on the best configuration, distributions of $\frac{B_1}{K}$, MSY, and F_{MSY} were unimodal and relatively symmetrical (Figure 64).

4.13.3 Status of the Stock and Fishery

In the current best configuration run of the surplus production model, $\frac{B}{B_{MSY}}$ is greater than one, suggesting that the South Atlantic stock of Red Snapper is not overfished. The 95% bootstrap percentile confidence intervals for $\frac{B}{B_{MSY}}$ do not contain one (Figure 64). Since the surplus production model estimates that $\frac{F}{F_{MSY}}$ is less than one, the stock is considered to not be undergoing overfishing (Table 30; Figure 65). The 95% bootstrap percentile confidence intervals for $\frac{F}{F_{MSY}}$ do not contain one (Figure 64).

4.13.4 Interpretation

Status indicators in the continuity run (318), agree with the surplus production model from SEDAR 24 that South Atlantic Red Snapper were overfished and undergoing overfishing in 2009 (Table 30). However, in the updated continuity run (319), which is identical to the continuity run except for the 2010-2014 addition of landings data from 2010-2014, the surplus production model suggests that the stock is no longer overfished or undergoing overfishing. Despite several differences between the updated continuity run and the best configuration run (320), described above, most of the parameter estimates and status indicators are similar (Table 30). However the model estimate of $\frac{B_1}{K}$ is much lower in the best configuration run, driven by a lower estimate of B_1. After observing this difference, run 323 was configured by taking the best configuration run and fixing $\frac{B_1}{K}$ at the estimate from the continuity run to investigate potential influence. Fixing $\frac{B_1}{K}$ at this much lower value had little effect on status or most parameters, but caused the estimate of B_1 to go much lower.

As described above, the only data that go into a surplus production model are biomass of removals and abundance indices. Therefore such a model does not make use of many other sources of information such as sex, maturity, growth, fecundity, or population age and size structure. Because such data are available for Red Snapper, a model that uses them would be preferred for a detailed assessment on which to base management.

5 Discussion

5.1 Comments on the Assessment

Estimated benchmarks played a central role in this assessment. Values of $\text{SSB}_{\text{F30\%}}$ and $F_{30\%}$ were used to gauge the status of the stock and fishery to be consistent with established definitions of $MFMT$ and the existing rebuilding plan. The computation of the benchmarks was conditional on selectivity. If selectivity patterns change in the future, for example as a result of new size limits or different relative catch allocations among sectors, estimates of benchmarks would likely change as well.

The base run of the BAM indicated that the stock remains overfished $\mathrm{SSB}/\mathrm{SSB}_{\mathrm{F30\%}}$ =0, and that overfishing is occurring $F/F_{30\%}$ =3, though at a lower rate than in 2009 (F/F_{MSY} =4.12 for SEDAR 24). Median values from the MCB analyses were in qualitative agreement with those results. This assessment estimates that, since 2010, the stock has been increasing at a modest rate and is now at levels not seen since the 1970s.

In addition to including the more recent years of data, this benchmark assessment contained several modifications to the previous data of SEDAR24, such as the use of APAIS-adjusted MRIP estimates instead of MRFSS, a new method for the reconstruction of historic recreational catch, the inclusion of a new fishery-independent survey, and the corresponding age composition data. Furthermore, life-history information was updated, including female maturity, sex ratio, growth, natural mortality, fecundity, and meristics. The assessment model itself was also modernized to the current version of BAM. The sum of these improvements should result in a more robust assessment.

In general, fishery dependent indices of abundance may not track actual abundance well, because of factors such as hyperdepletion or hyperstability. Furthermore, this issue can be exacerbated by management measures. In this assessment, the commercial handline and headboat indices generated from logbook data, were not extended beyond 2009 because of the moratorium on Red Snapper. In general, management measures in the southeast U.S. have made the continued utility of fishery dependent indices will be questionable. This situation amplifies the importance of fishery independent sampling and sampling programs conducted by the states.

Many assessed stocks in the southeast U.S. have shown histories of heavy exploitation. High rates of fishing mortality can lead to adaptive responses in life-history characteristics, such as growth and maturity schedules. Such adaptations can affect expected yield and stock recovery, and thus resource managers might wish to consider possible evolutionary effects of fishing in their management plans (Dunlop et al. 2009; Enberg et al. 2009). Indeed, Red Snapper have a very young age at maturity relative to their maximum lifespan, and some have hypothesized that this may be an adaptive response to exploitation.

Because steepness could not be estimated reliably in this assessment, its value in the base run was fixed at 0.99. Fixing steepness at its upper bound was not meant to imply that the stock has perfect compensation at any exploitation or stock level. Rather, it was a computational convenience to use the stock recruitment curve with $h = 0.99$ in order to treat recruitment as an average through time while estimating deviations around that average. Thus MSY-based management quantities are not appropriate, and the AW Panel provided the proxy of $F_{30\%}$ as was used for management subsequent to the last assessment.

The assessment start year was 1950, so as to include the period of largest landings. To initialize the model in 1950, the initial age structure was assumed to be in equilibrium, based on natural mortality at age and F_{init}. Average recruitment was assumed until the recruitment deviations could be estimated at the onset of the composition data (1978). These assumptions are common in assessment models, and they were tested with sensitivity runs where the start was 1978 and with different values of F_{init}. The end results were qualitatively similar, which indicates that the base run is not sensitive to these assumptions.

A complementary analysis was conducted using a surplus production model (ASPIC). ASPIC treats the stock as a pooled biomass and ignores the age structure in the population and the landings. It is unable to take into account that different ages are differentially vulnerable to fishing and therefore was not able to incorporate the (time-varying) selectivities used in the BAM. ASPIC is also not able to take into account that the reproductive contribution of this species increases with age or that there is variability in recruitment through time. ASPIC is useful in examining the relationship between removals and the indices. However, for a long-lived species with age-based data available, the catch-age model (BAM) provides the best illustration of the stock and is a better indicator of stock status, because it can account for the age structure of the population and landings and for year-class strength.

5.2 Comments on the Projections

Projections should be interpreted in light of the model assumptions and key aspects of the data. Some major considerations are the following:

- In general, projections of fish stocks are highly uncertain, particularly in the long term (e.g., beyond 5–10 years).
- Although projections included many major sources of uncertainty, they did not include structural (model) uncertainty. That is, projection results are conditional on one set of functional forms used to describe population dynamics, selectivity, recruitment, etc.
- Fisheries were assumed to continue fishing at their estimated current proportions of total effort, using the estimated current selectivity patterns. New management regulations that alter those proportions or selectivities would likely affect projection results.
- The first five scenarios of projections assumed no change in the selectivity applied to discards. As stock increase generally begins with the smallest size classes, management action may be needed to meet that assumption.
- The projections assumed that the assumed spawner-recruit relationship applies in the future and that past deviations represent future uncertainty in recruitment. If future recruitment is characterized by runs of large or small year classes, possibly due to environmental or ecological conditions, stock projections may be affected.
- Projections apply the Baranov catch equation to relate F and landings using a one-year time step, as in the assessment. The catch equation implicitly assumes that mortality occurs throughout the year. This assumption is violated when seasonal closures or small intensive fishing seasons are in effect, introducing additional and unquantified uncertainty into the projection results.

5.3 Research Recommendations

- Increased fishery independent information, particularly maintaining reliable indices of abundance and composition data streams
- Red Snapper were modeled in this assessment as a unit stock off the southeastern U.S. For any stock, variation in exploitation and life-history characteristics might be expected at finer geographic scales. Modeling such sub-stock structure would require more data, such as information on the movements and migrations of adults and juveniles, as well as spatial patterns of larval dispersal and recruitment. In addition, it is unclear whether a spatial model would improve the assessment.
- More research to describe the juvenile life history of Red Snapper is needed, including more work to identify the location of juveniles before they recruit to the fishery.
- The effects of environmental variation on the changes in recruitment or survivorship.
- The Florida sampling program, during the miniseason in particular, provided invaluable data to this assessment. Programs such as these would be useful in all South Atlantic states, particularly if the management regulations continue to make established methods of index development or composition sampling from fleets less regular or possible.

Table 2. Size (TL) in inches and weight in pounds (lb) at age as applied to the population (Pop), fishery–dependent portion of the population (FD), and fishery–dependent portion of the population during the 20 mm size limit (FD20). The CV of length was estimated by the assessment model; other values were treated as input through the von Bertalanffy growth parameters.

Age	Pop.TL	CV.Pop.TL	Pop.lb	FD.TL	CV.FD.TL	FD.lb	FD20.TL	CV.FD20.TL	FD20.lb

Table 3. Observed time series of landings(L) and discards(D) for commercial lines (cH), headboat (HB), and general recreational (GR). Commercial landings are in units of 1000 lb whole weight. Recreational landings and discards and commercial discards are in units of 1000 fish. Confidential data have been redacted.

Table 10. Estimated time series of status indicators, fishing mortality, and biomass. Fishing mortality rate is apical F. Total biomass (B, mt) is at the start of the year, and spawning biomass (SSB, 1E8 Eggs) at the time of peak spawning (mid-year). The $MSST_{F30}$ is defined as $75\% SSB_{F30}$, with constant $M = 0.134$.

Year	F	F/F_{30}	B	$B/B_{unfished}$	SSB	$SSB/SSBB_{F30}$	$SSB/MSST_{F30}$

Table 14. Estimated time series of fully selected fishing mortality rates for commercial handlines (F.cH.L), headboat (F.HB.L), recreational (F.GR.L) landings (L) and discards (D). Also shown is Full F, the maximum F at age summed across fleets, which may not equal the sum of fully selected F's because of dome-shaped selectivities.

Year	F.cH.L	F.HB.L	F.GR.L	F.cH.D	F.HB.D	F.GR.D	Full F

Table 22. Estimated status indicators, benchmarks, and related quantities from the base run of the Beaufort catch-age model, conditional on estimated current selectivities averaged across fleets. Also presented are median values and measures of precision (standard errors, SE) from the Monte Carlo/Bootstrap analysis. Rate estimates (F) are in units of y^{-1}*; status indicators are dimensionless; and biomass estimates are in units of metric tons or pounds, as indicated. Spawning stock biomass (SSB) is measured as population fecundity (number of eggs). L refers to landings and R to recruitment*

Quantity	Units	Estimate	Median	SE
$F_{30\%}$	y^{-1}	0.15	0.15	0.01
$85\% F_{30\%}$	y^{-1}	0.12	0.13	0.01

Table 27. Projection results with fishing mortality rate fixed at $F = 98\%F_{30\%}$ starting in 2017. R = number of age-1 recruits (in 1000s), F = fishing mortality rate (per year), S = spawning stock (1E8 eggs), L = landings expressed in numbers (n, in 1000s) or whole weight (w, in 1000 lb*), and D = dead discards expressed in numbers (n, in 1000s) or whole weight (w, in 1000* lb*), pr.reb = proportion of stochastic projection replicates with* $\mathrm{SSB} \geq \mathrm{SSB}_{\mathrm{F30\%}}$. *The extension* b *indicates expected values (deterministic) from the base run; the extension* med *indicates median values from the stochastic projections.*

Table 30. Parameter estimates from selected ASPIC surplus production model runs 318 (continuity), 319 (updated continuity), 320 (best configuration), and 323 (best configuration with B_1/K fixed) All parameter values are rounded to 3 significant digits. MSY, B_1, and K are in units of 1000 pounds. Catchability parameters correspond to the commercial (q_1), headboat (q_2), headboat-at-sea (q_3), and CVID (q_4) indices.

Run	F/F_{MSY}	B/B_{MSY}	B_1/K	MSY	F_{MSY}	q_1	q_2	q_3	q_4	B_1	K
318	2.15	0.53	0.467	805	0.313	9.35e-07	7.14e-07			2400	5140
319	0.614	1.3	1.94	802	0.314	9.42e-07	7.14e-07			9930	5110

8 Figures

Figure 1. Indices of abundance used in fitting the assessment model. HB indicates the headboat logbook index; Handline indicated the the commercial handline logbook index; HB Disc indicated the headboat discard observer index, CVT indicates the SERFS chevron trap index; VID indicates the SERFS video index, and CVID indicates the combined chevron trap and video index. The CVT and VID indices were only used during sensitivity runs.

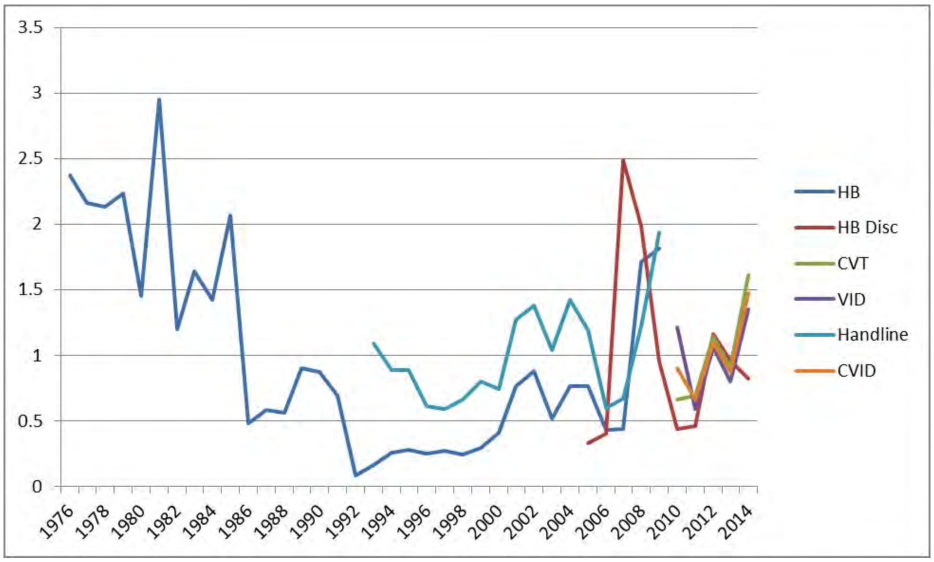

Figure 2. Mean total length at age (mm) and estimated upper and lower 95% confidence intervals of the population.

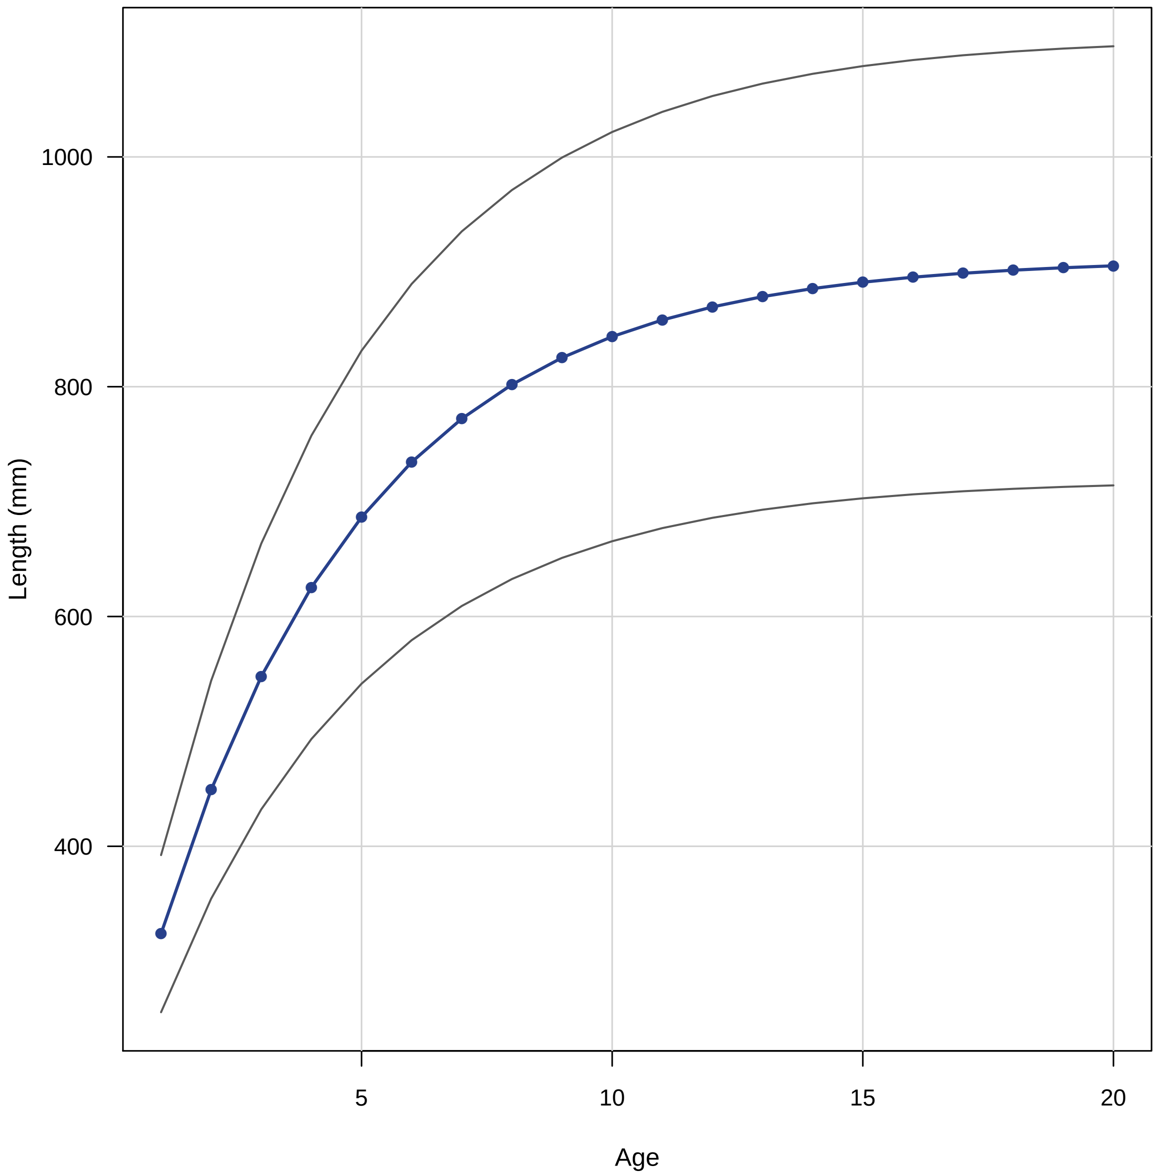

Figure 3. Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey. In panels indicating the data set, lcomp refers to length compositions, acomp to age compositions, CVT to MARMAP chevron trap, cH to commercial handline, HB to headboat and GR to general recreational.

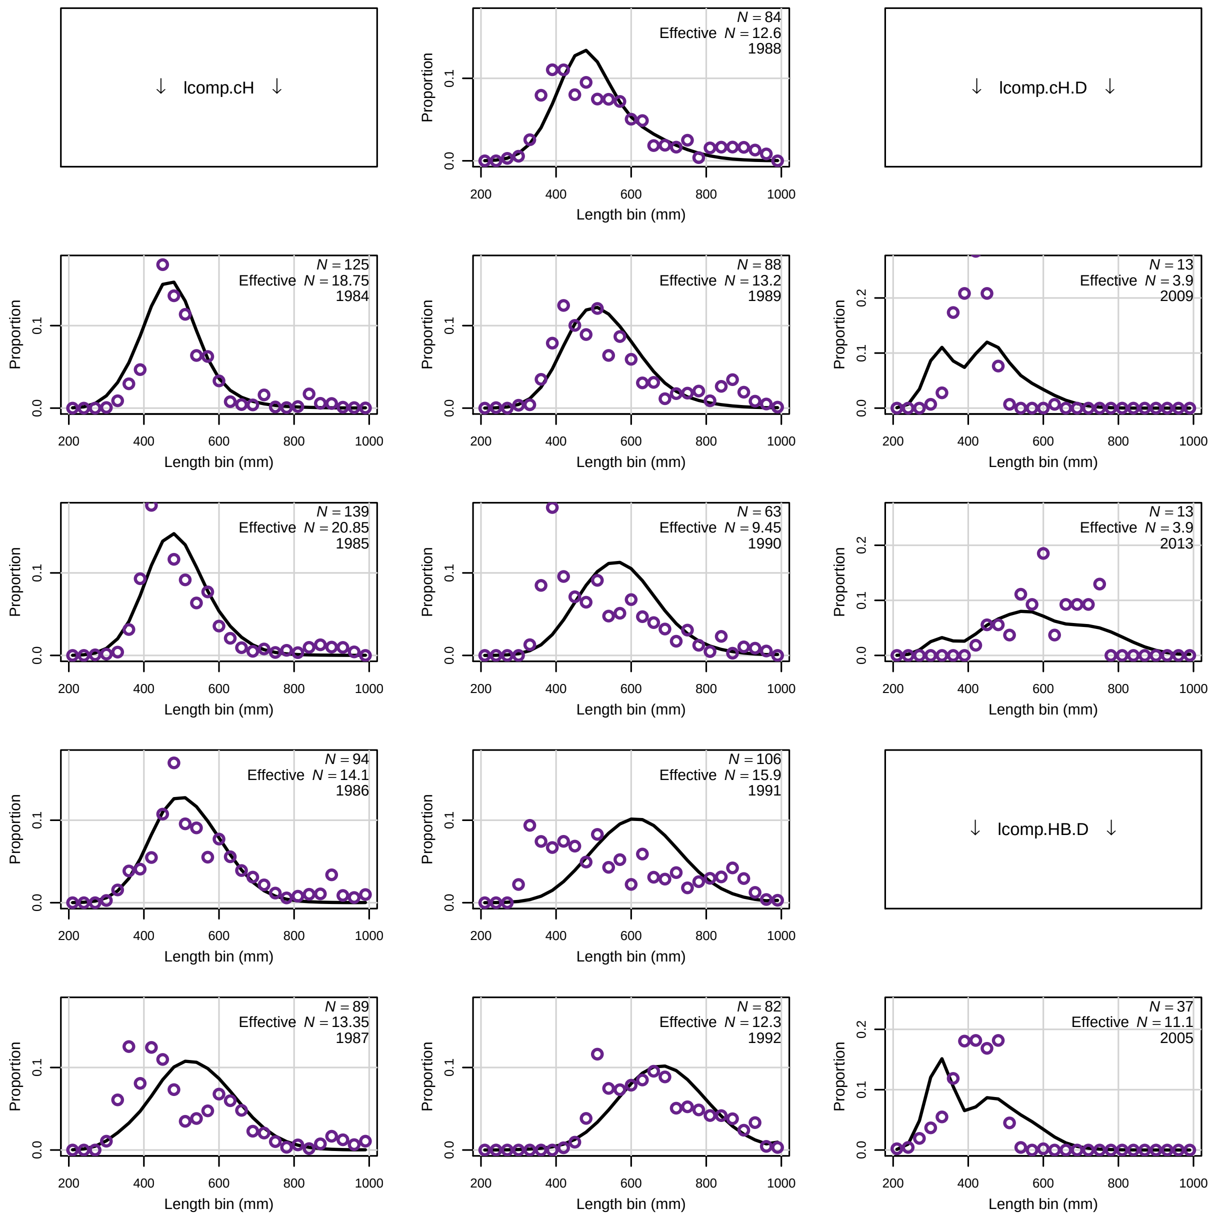

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey.

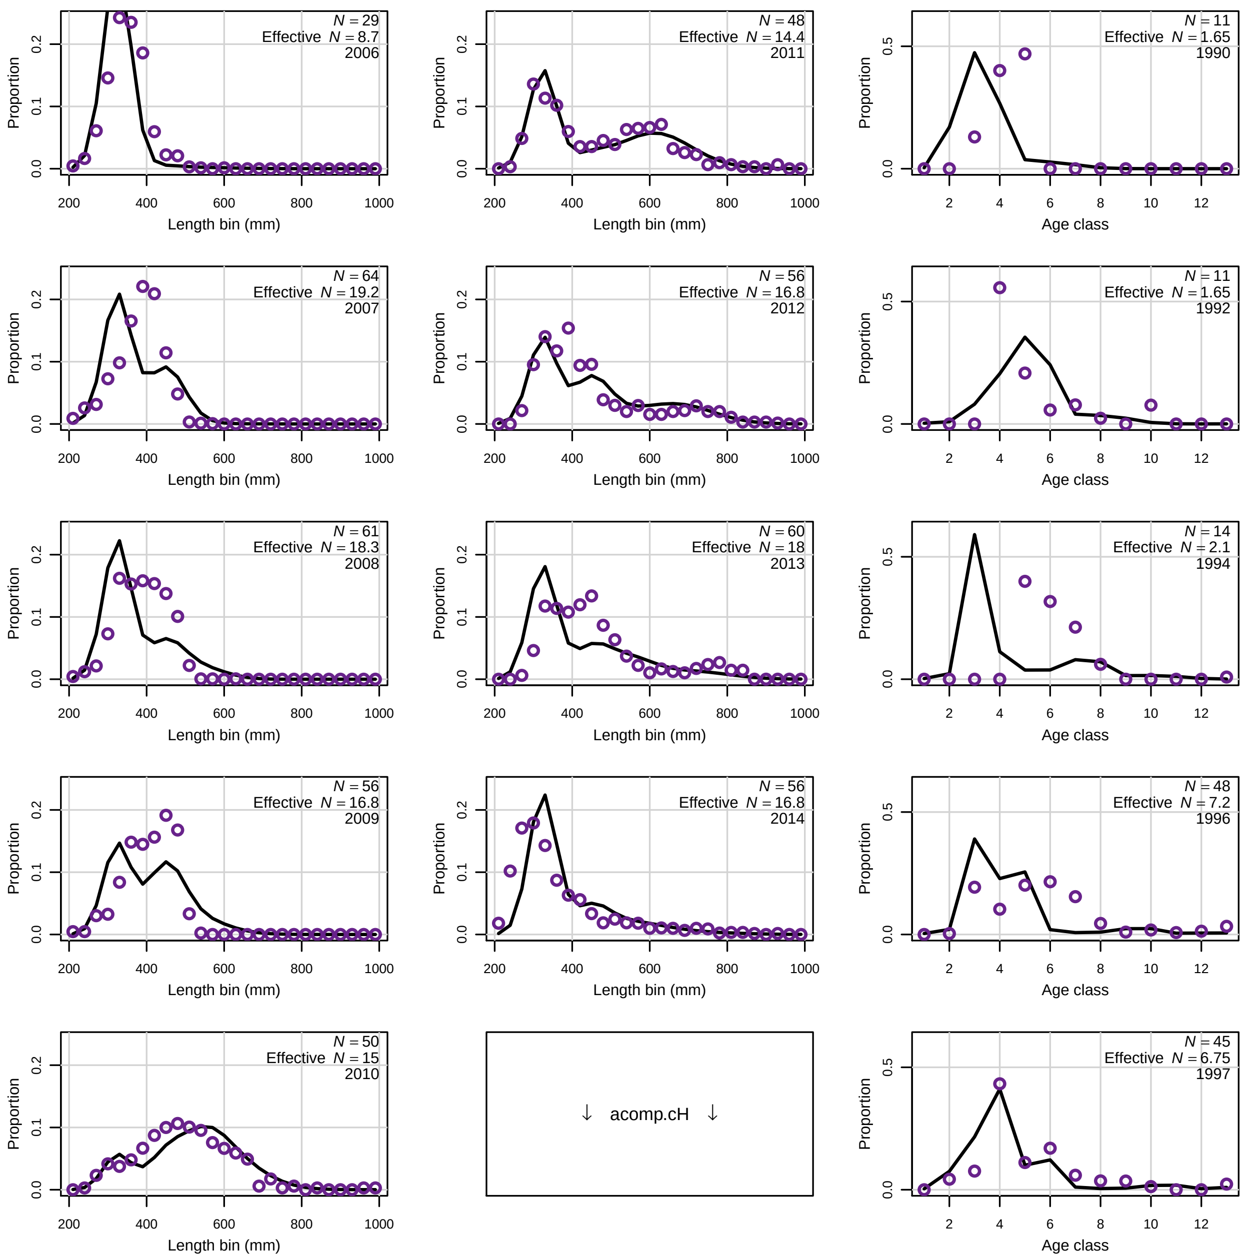

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey.

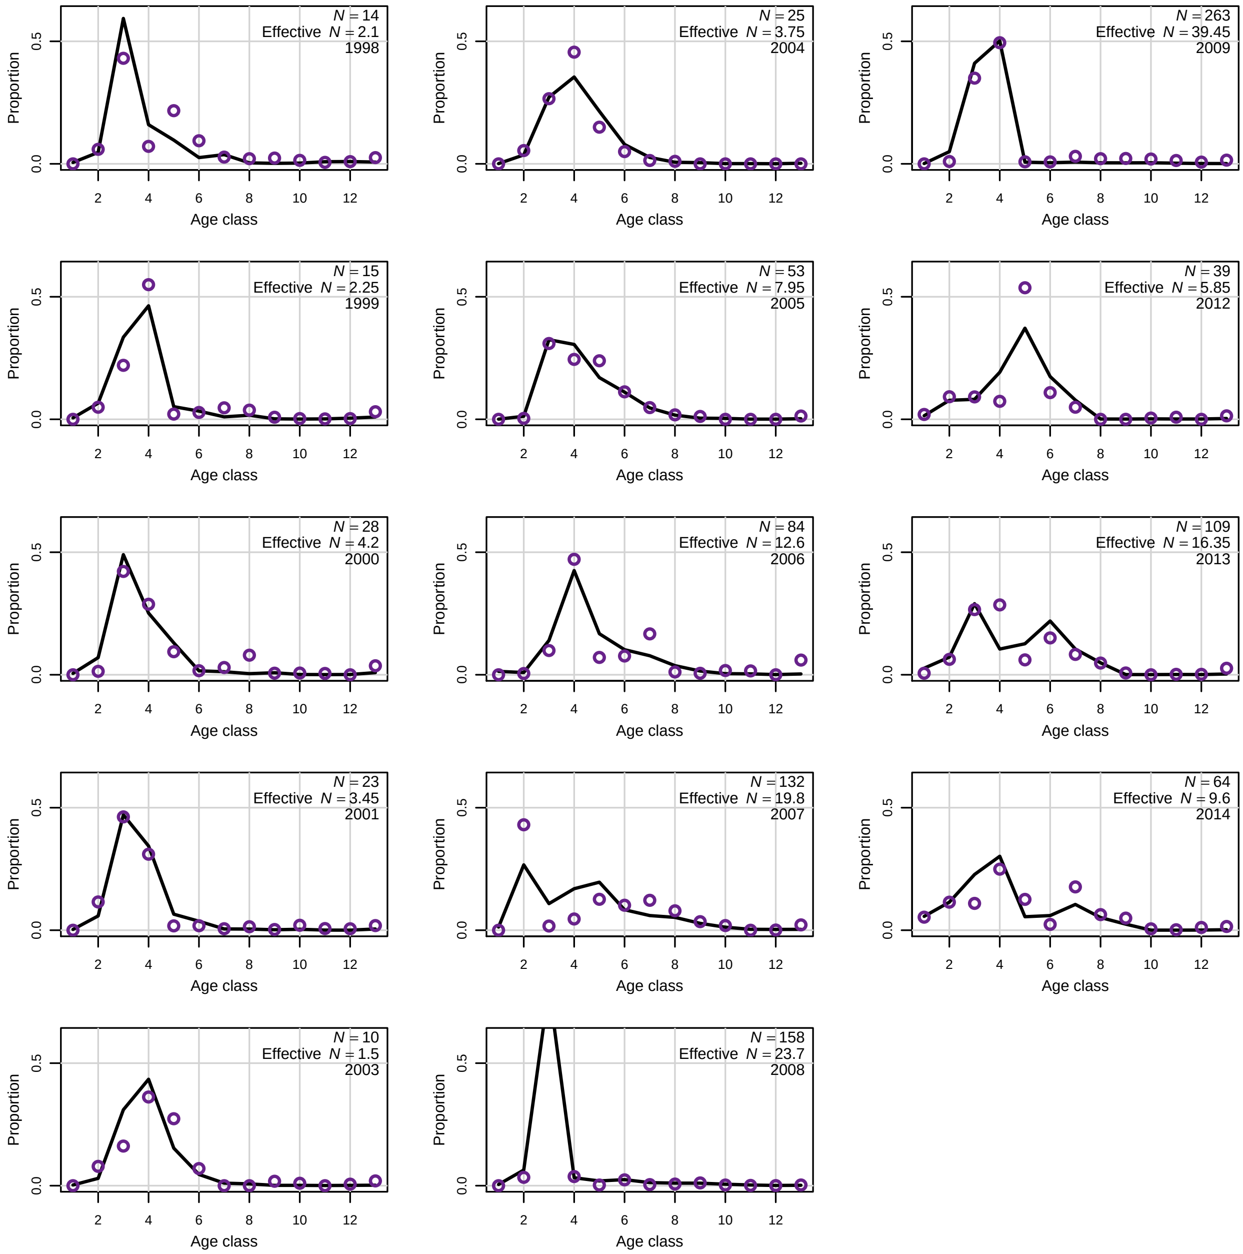

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey.

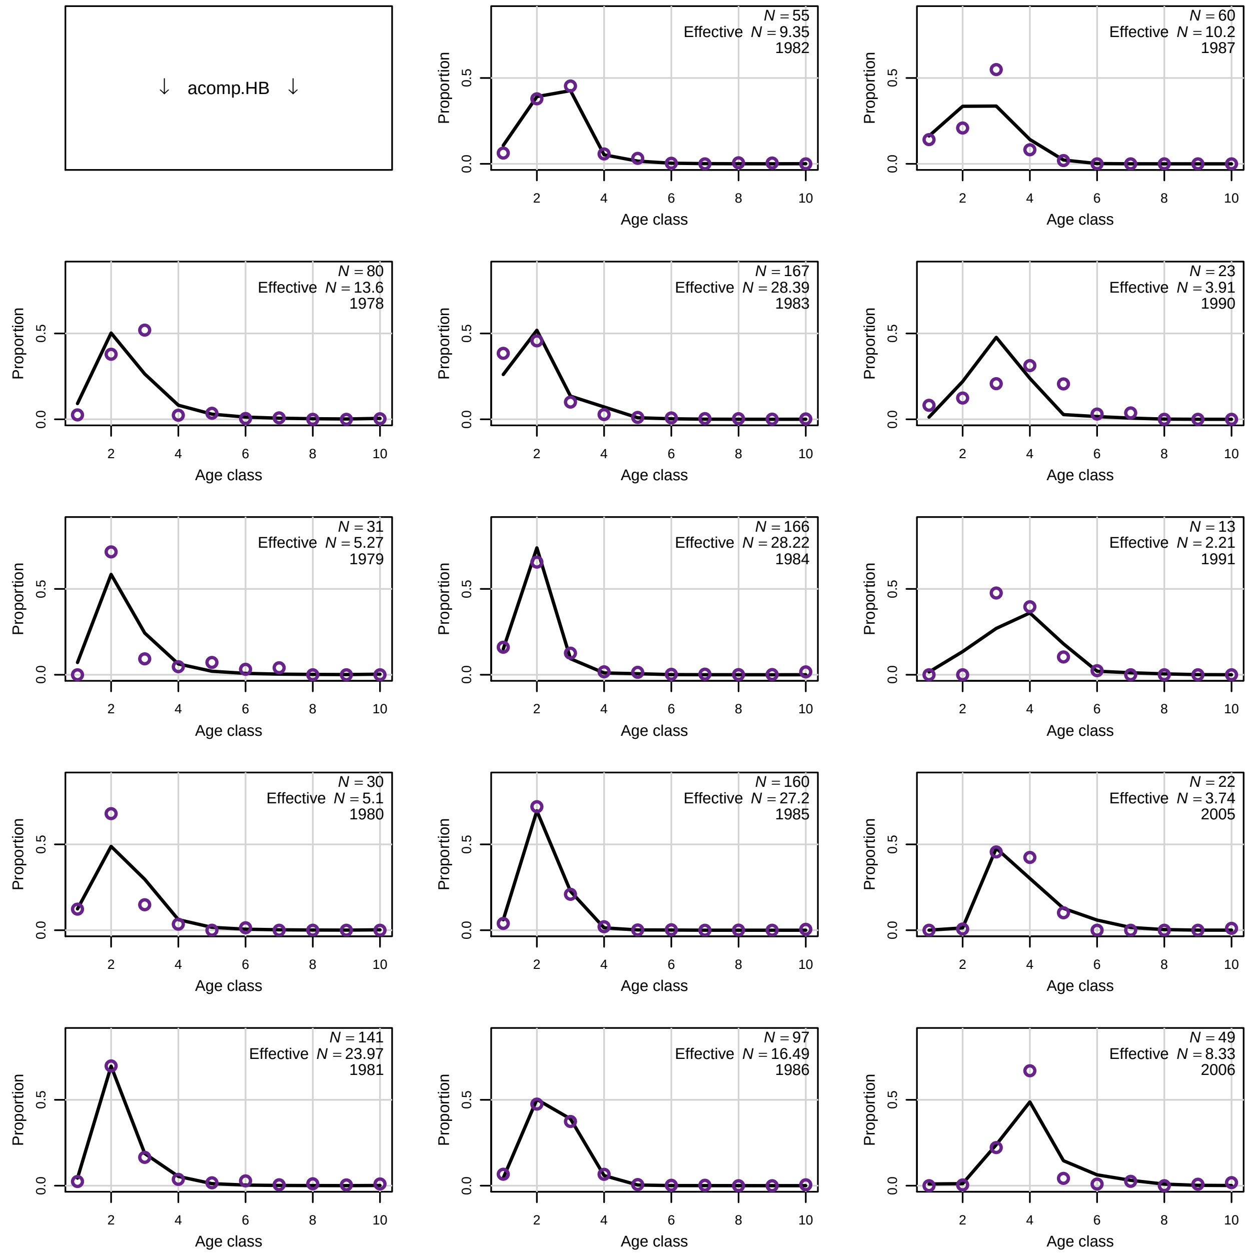

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey.

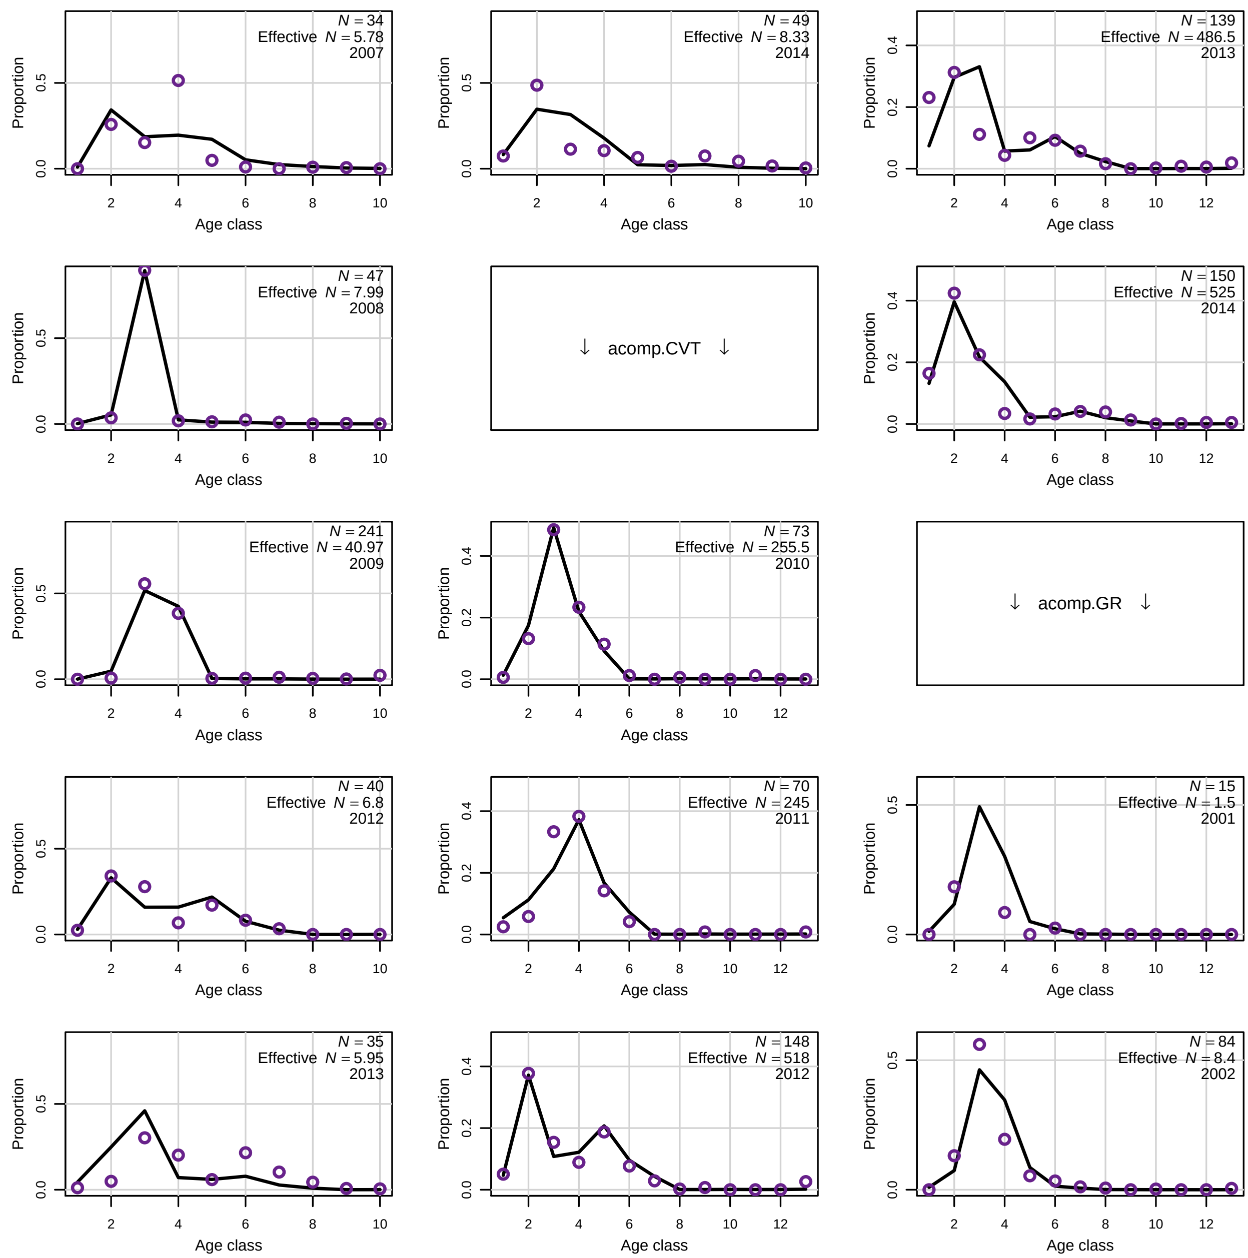

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey.

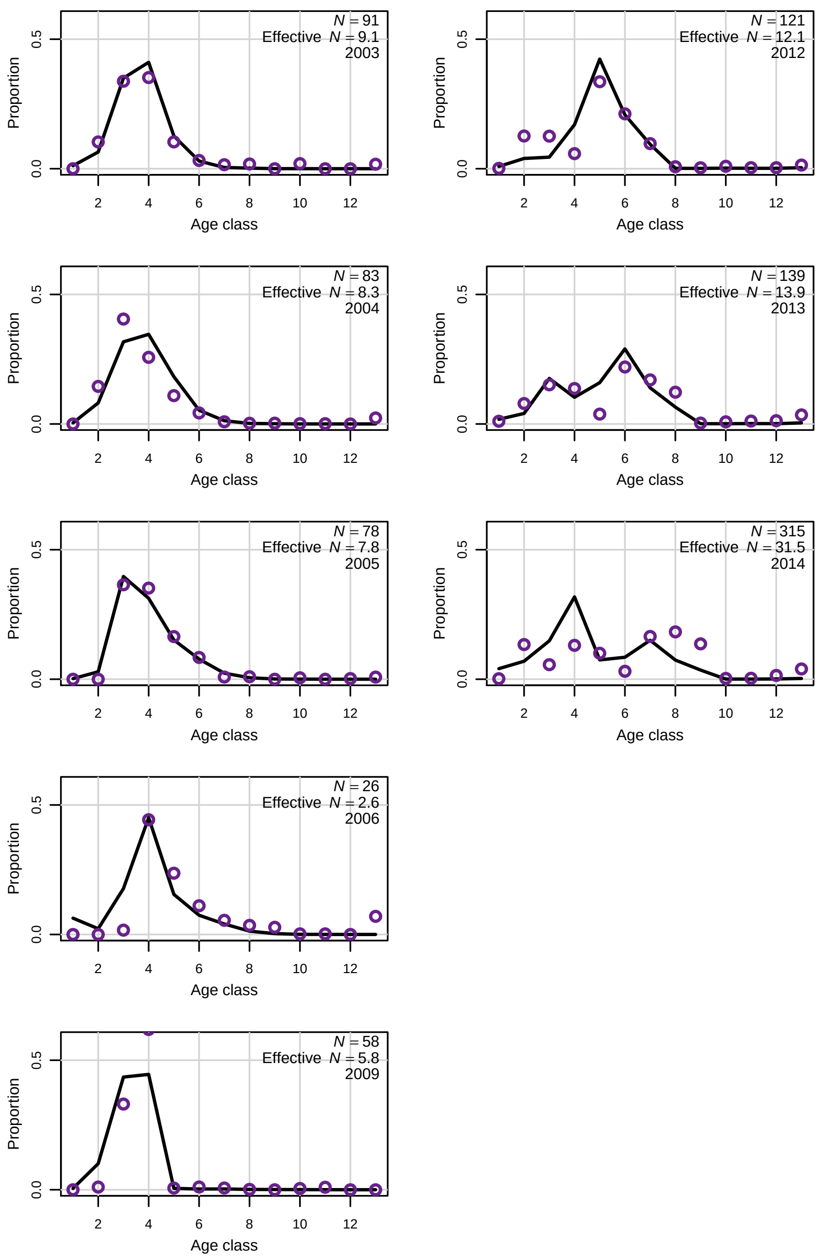

Figure 4. Observed (open circles) and estimated (solid line, circles) commercial handline landings in 1000 lb whole weight.

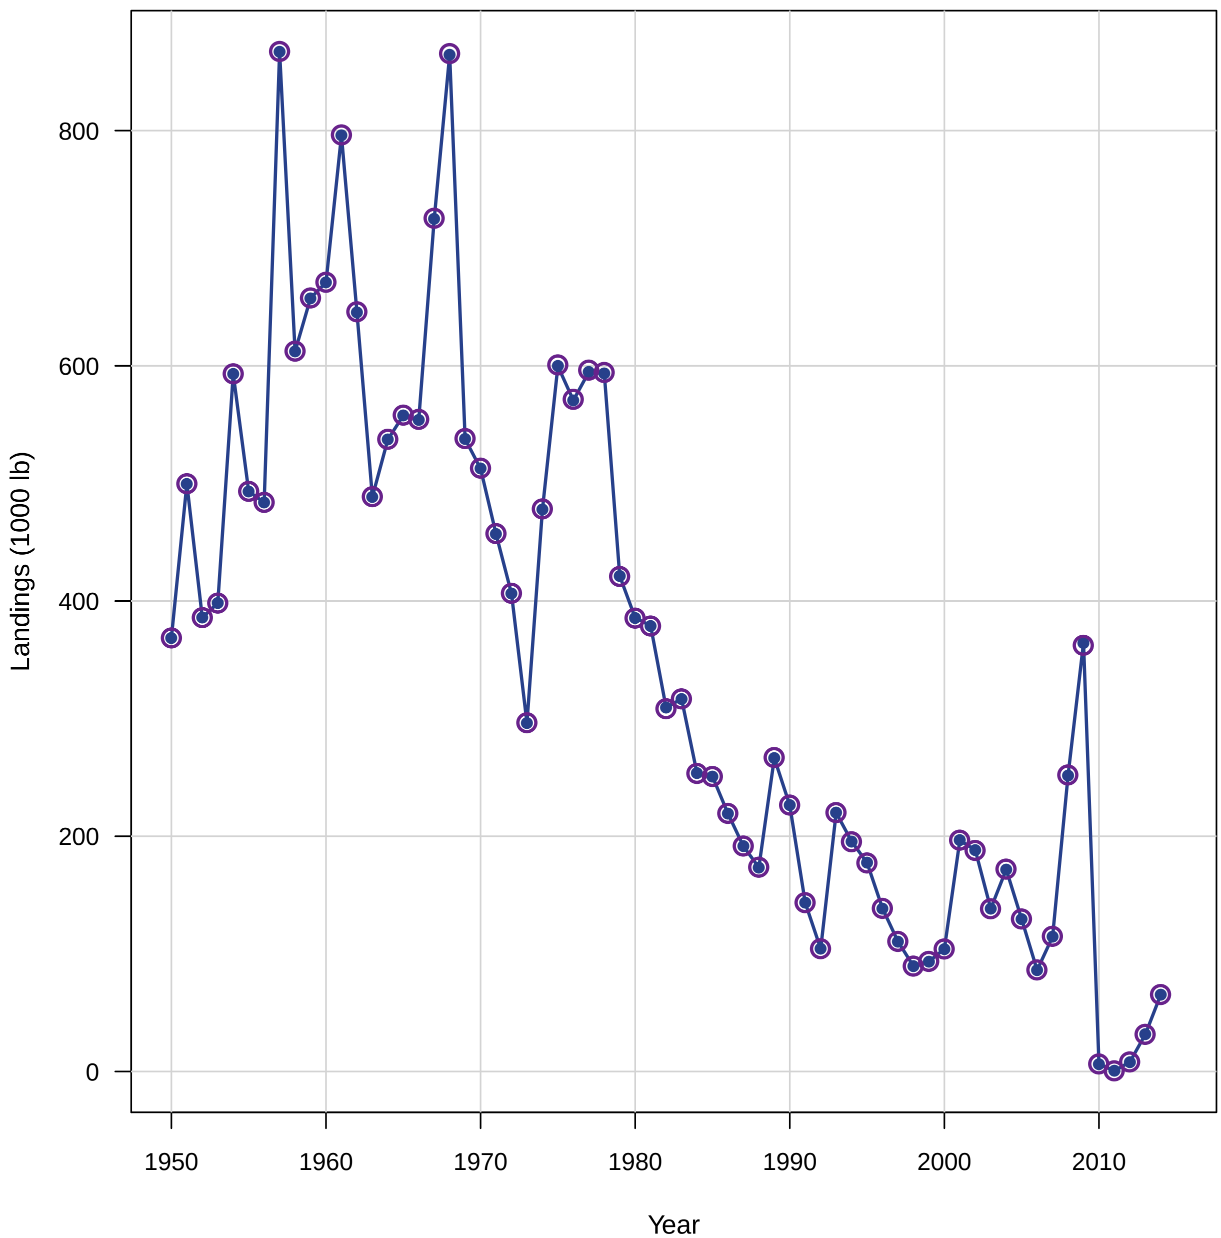

Figure 5. Observed (open circles) and estimated (solid line, circles) headboat landings in 1000s of fish.

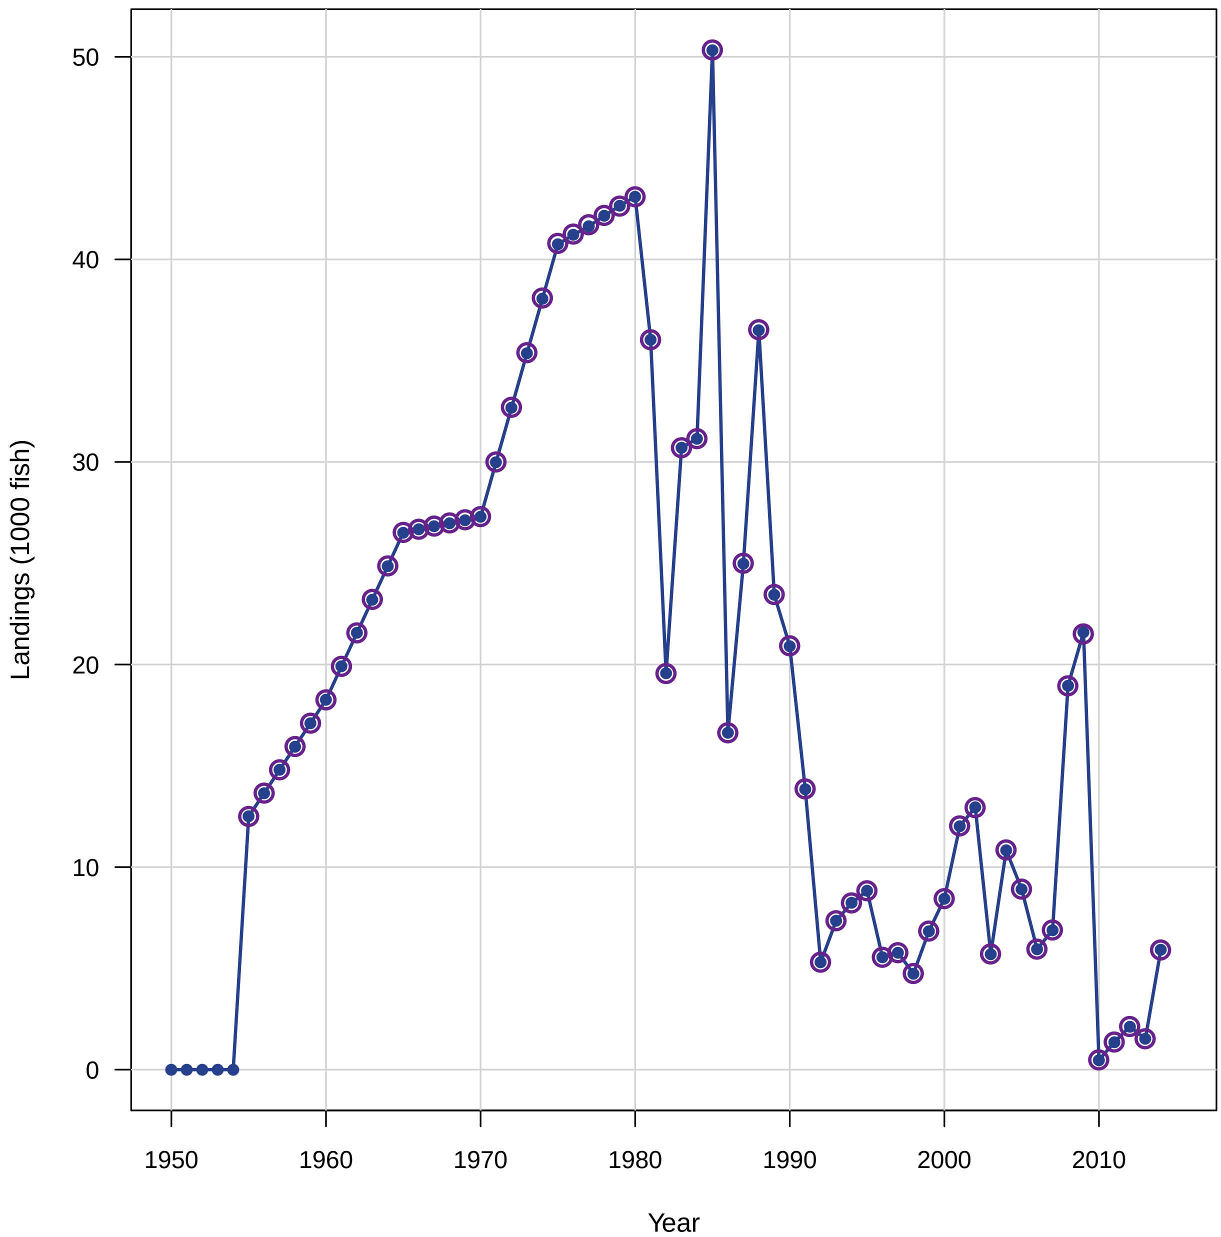

Figure 6. Observed (open circles) and estimated (solid line, circles) general recreational landings in 1000s of fish.

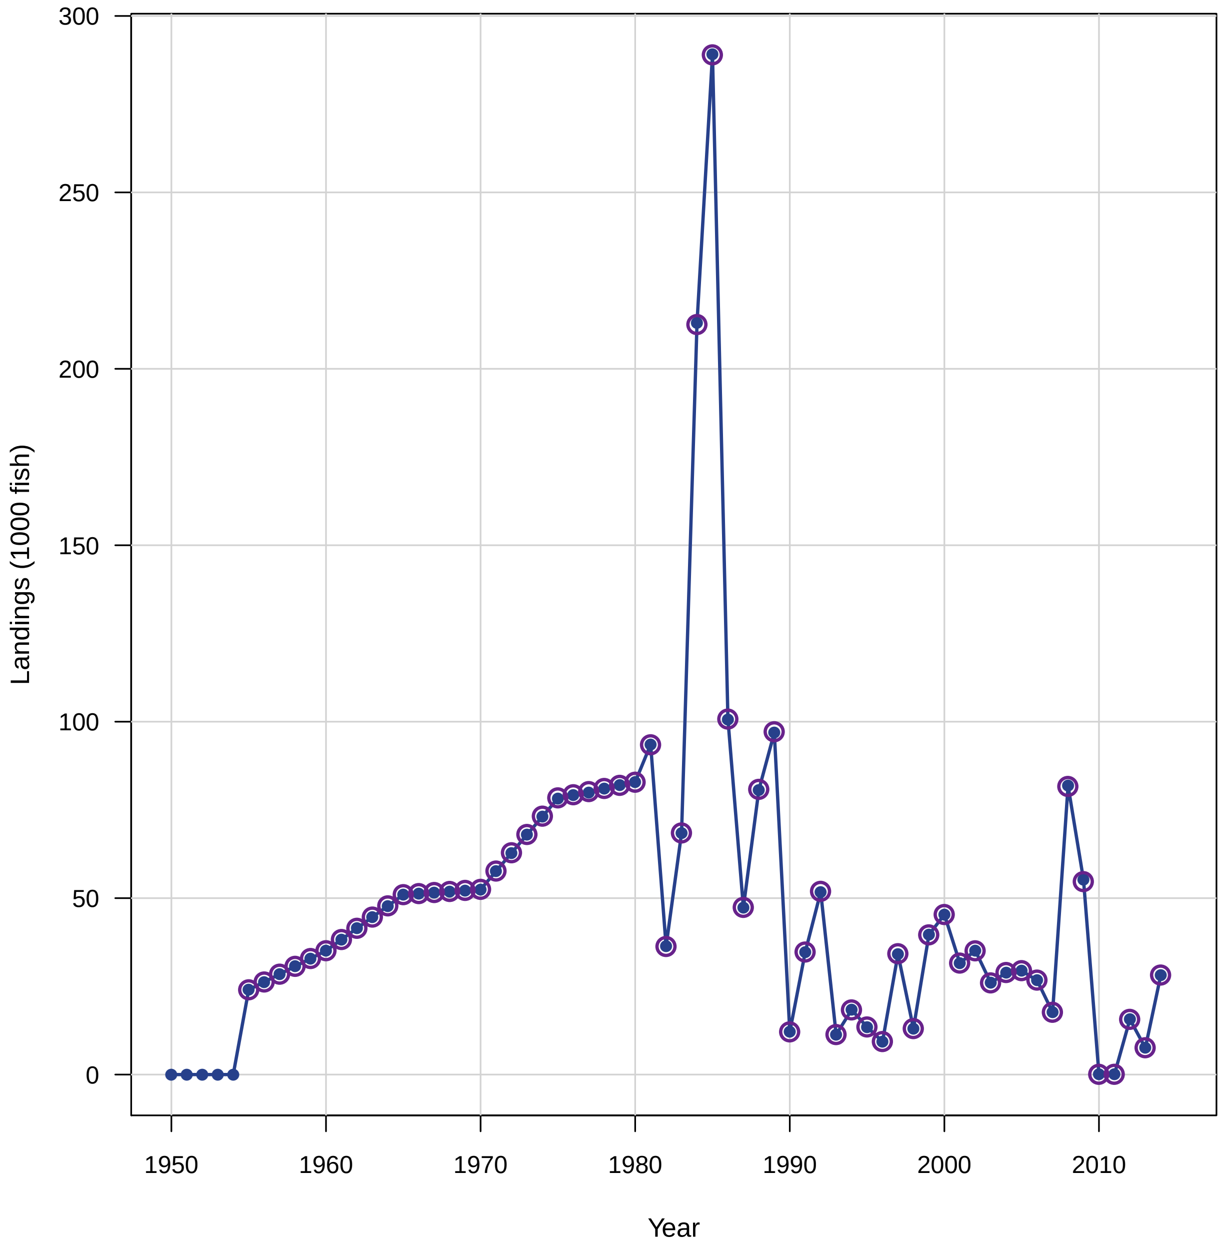

Figure 7. Observed (open circles) and estimated (solid line, circles) commercial handline discard mortalities.

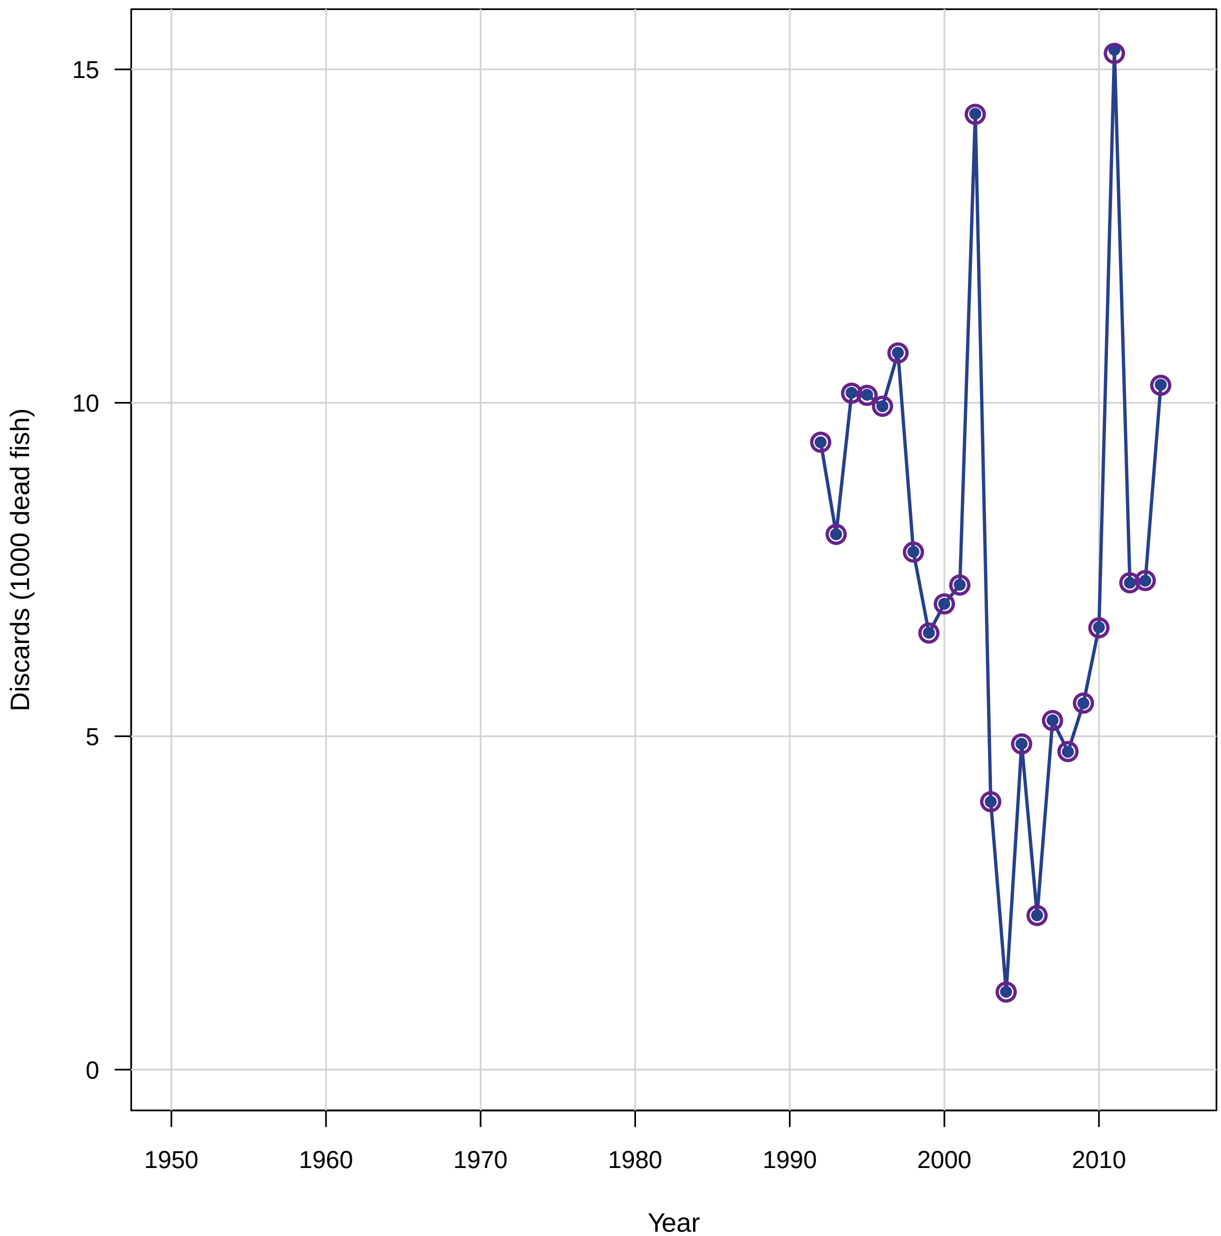

Figure 8. Observed (open circles) and estimated (solid line, circles) headboat discard mortalities.

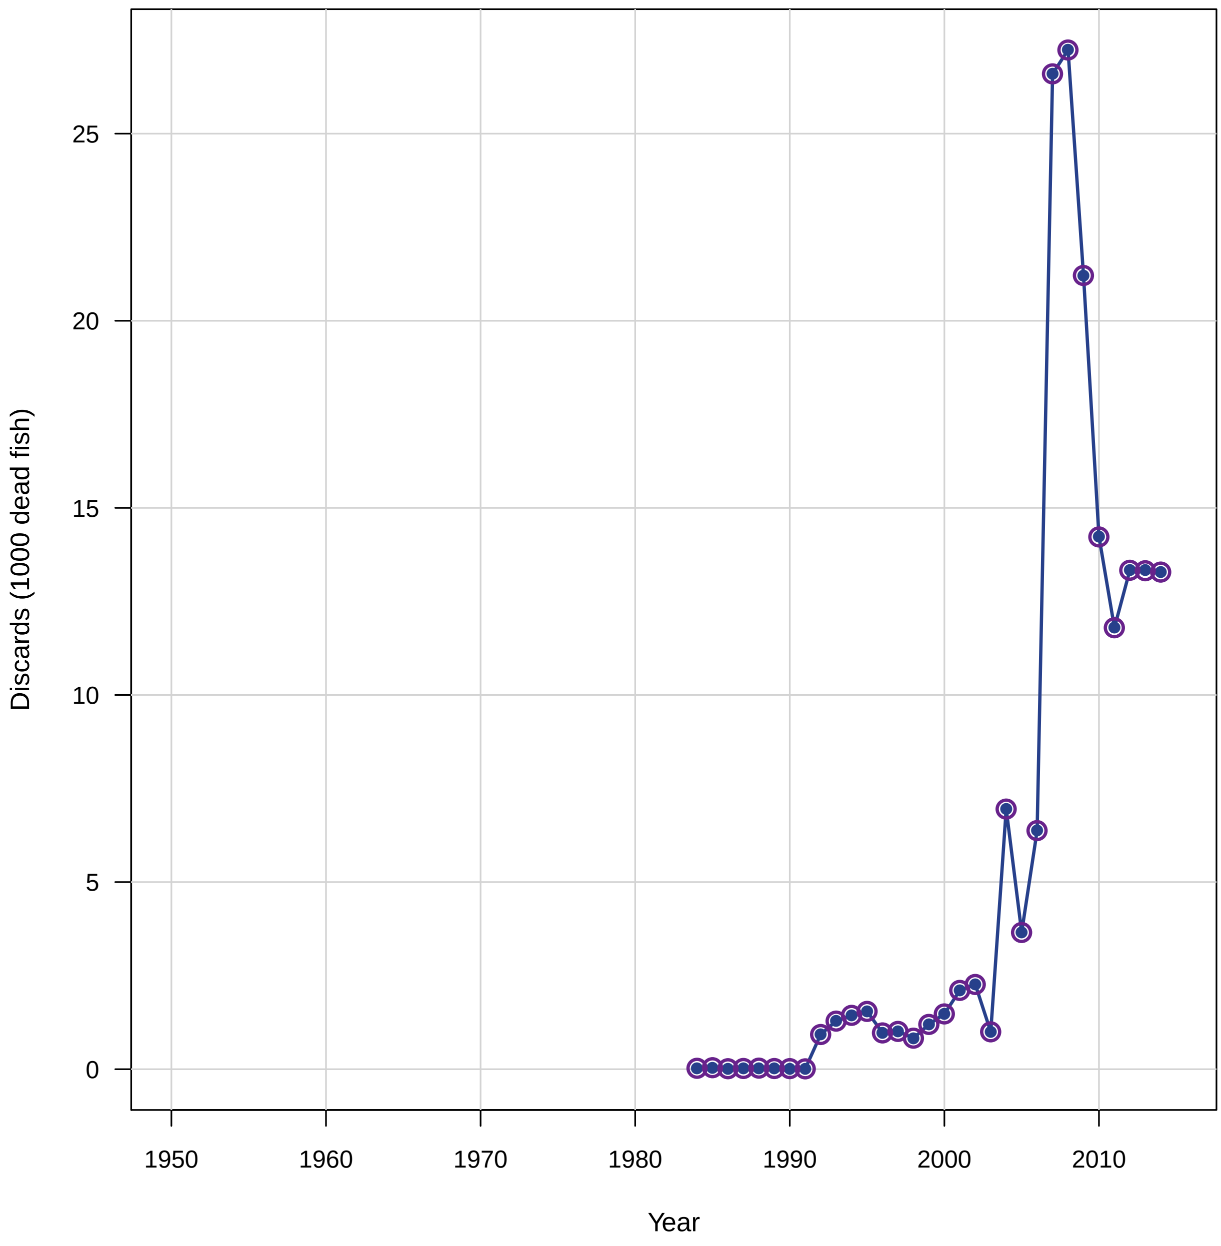

Figure 9. Observed (open circles) and estimated (solid line, circles) general recreational discard mortalities.

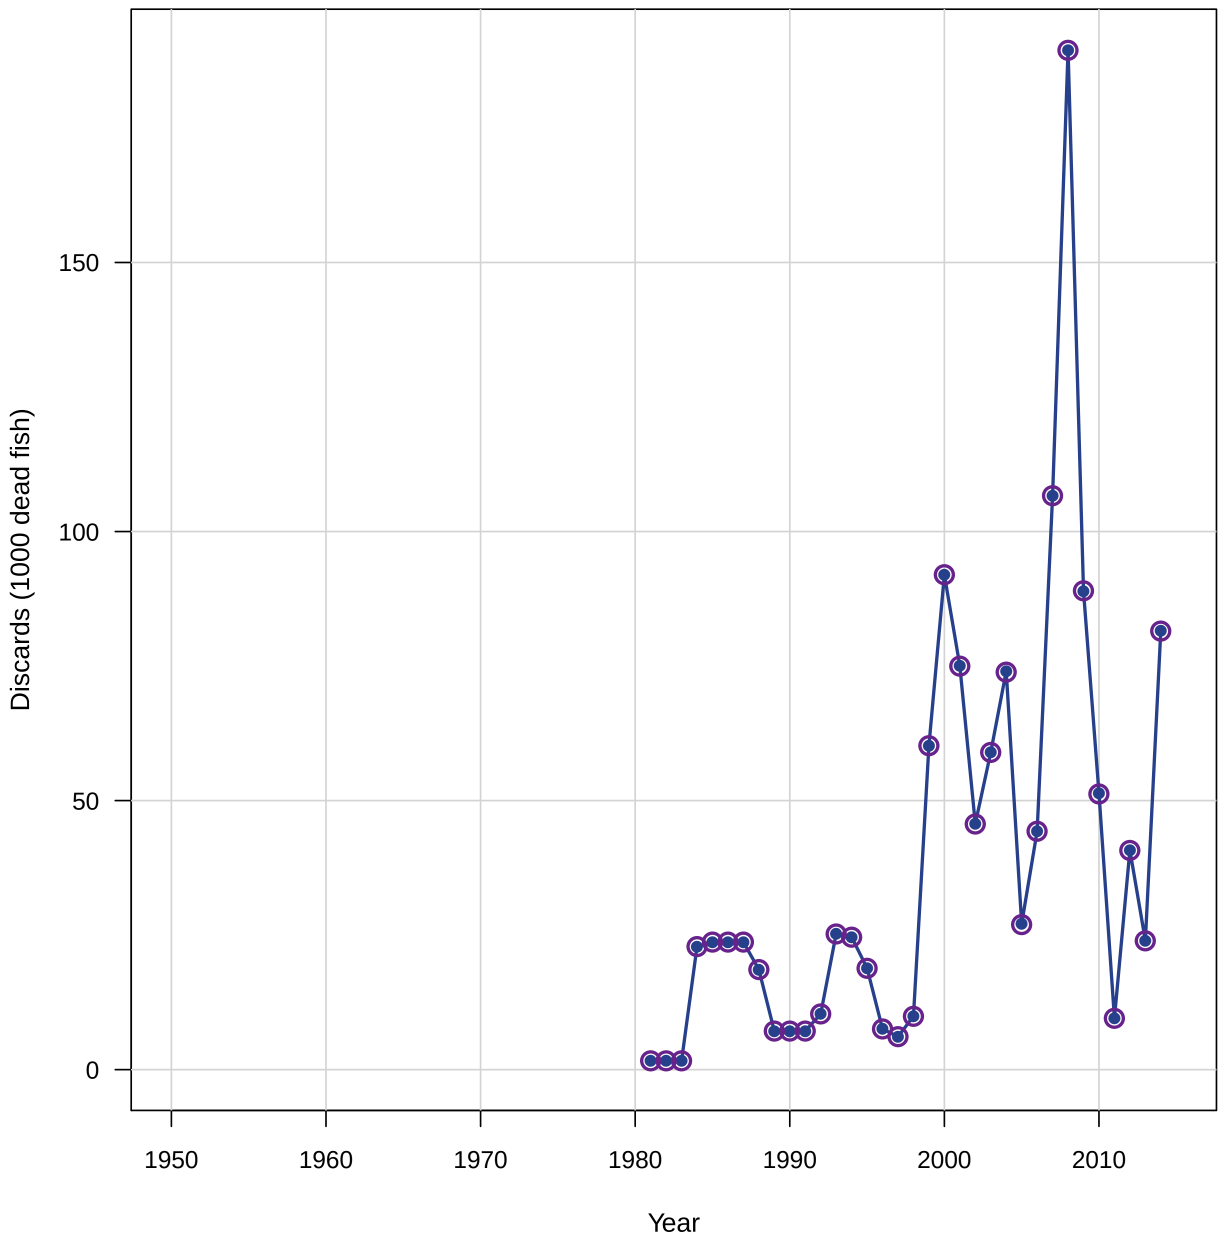

Figure 10. Observed (open circles) and estimated (solid line, circles) index of abundance from the SERFS combined trap and video index. The error bars represent the annual CV provided by the GLM standardization divided by the likelihood weight on the index.

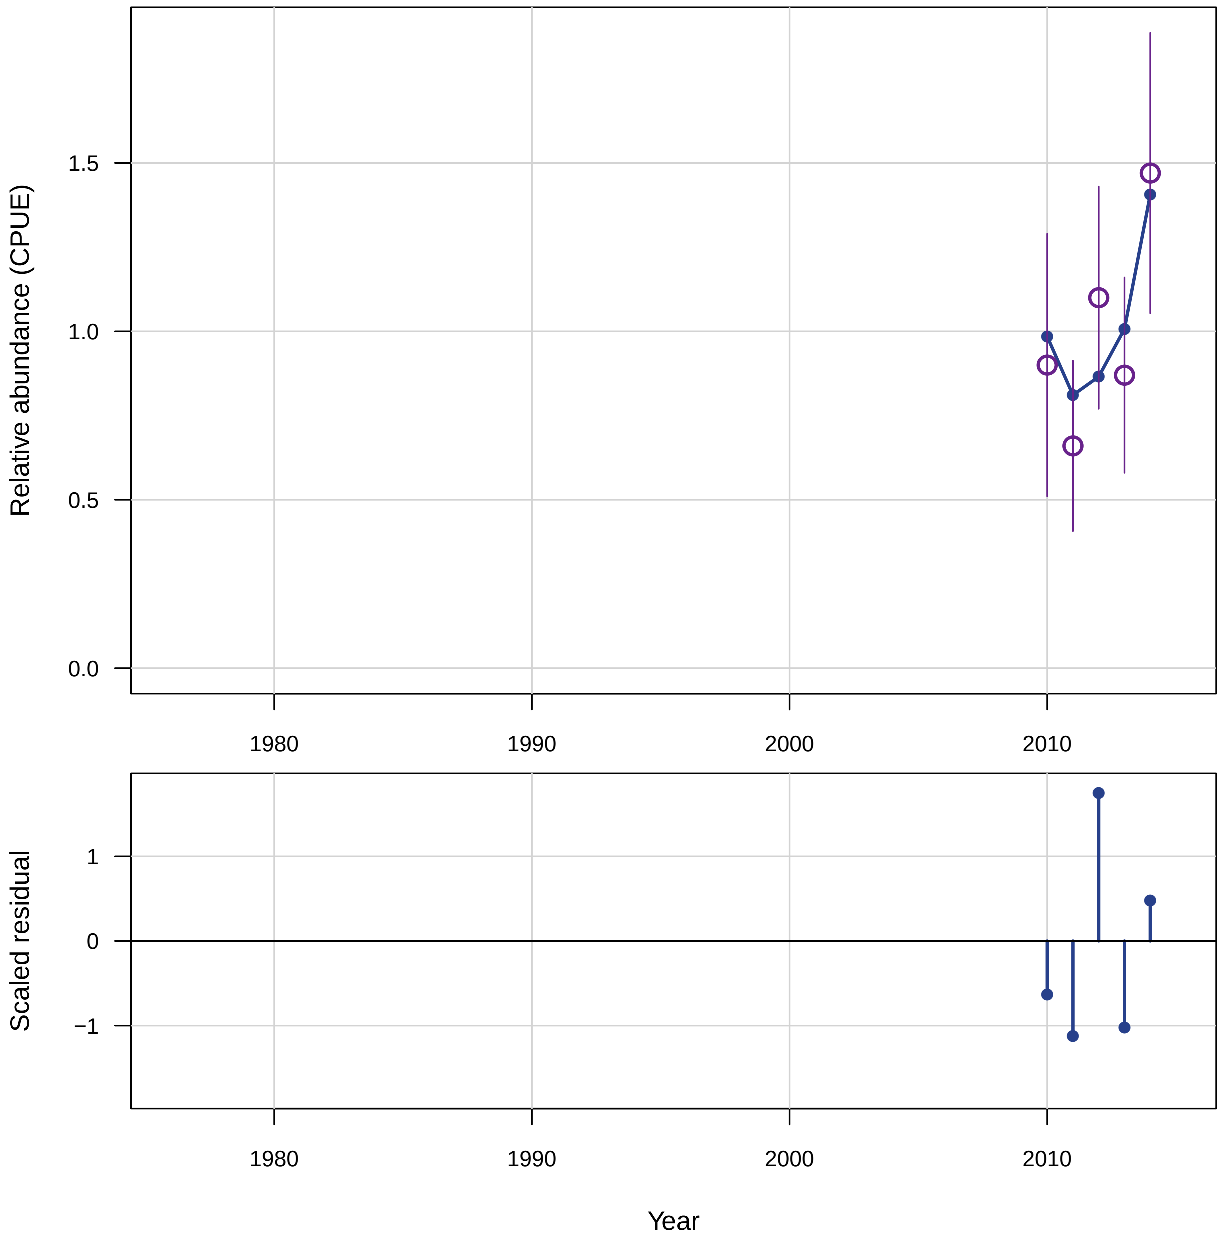

Figure 11. Observed (open circles) and estimated (solid line, circles) index of abundance from the commercial handline fleet. The error bars represent the annual CV of the index (0.2) divided by the likelihood weight on the index.

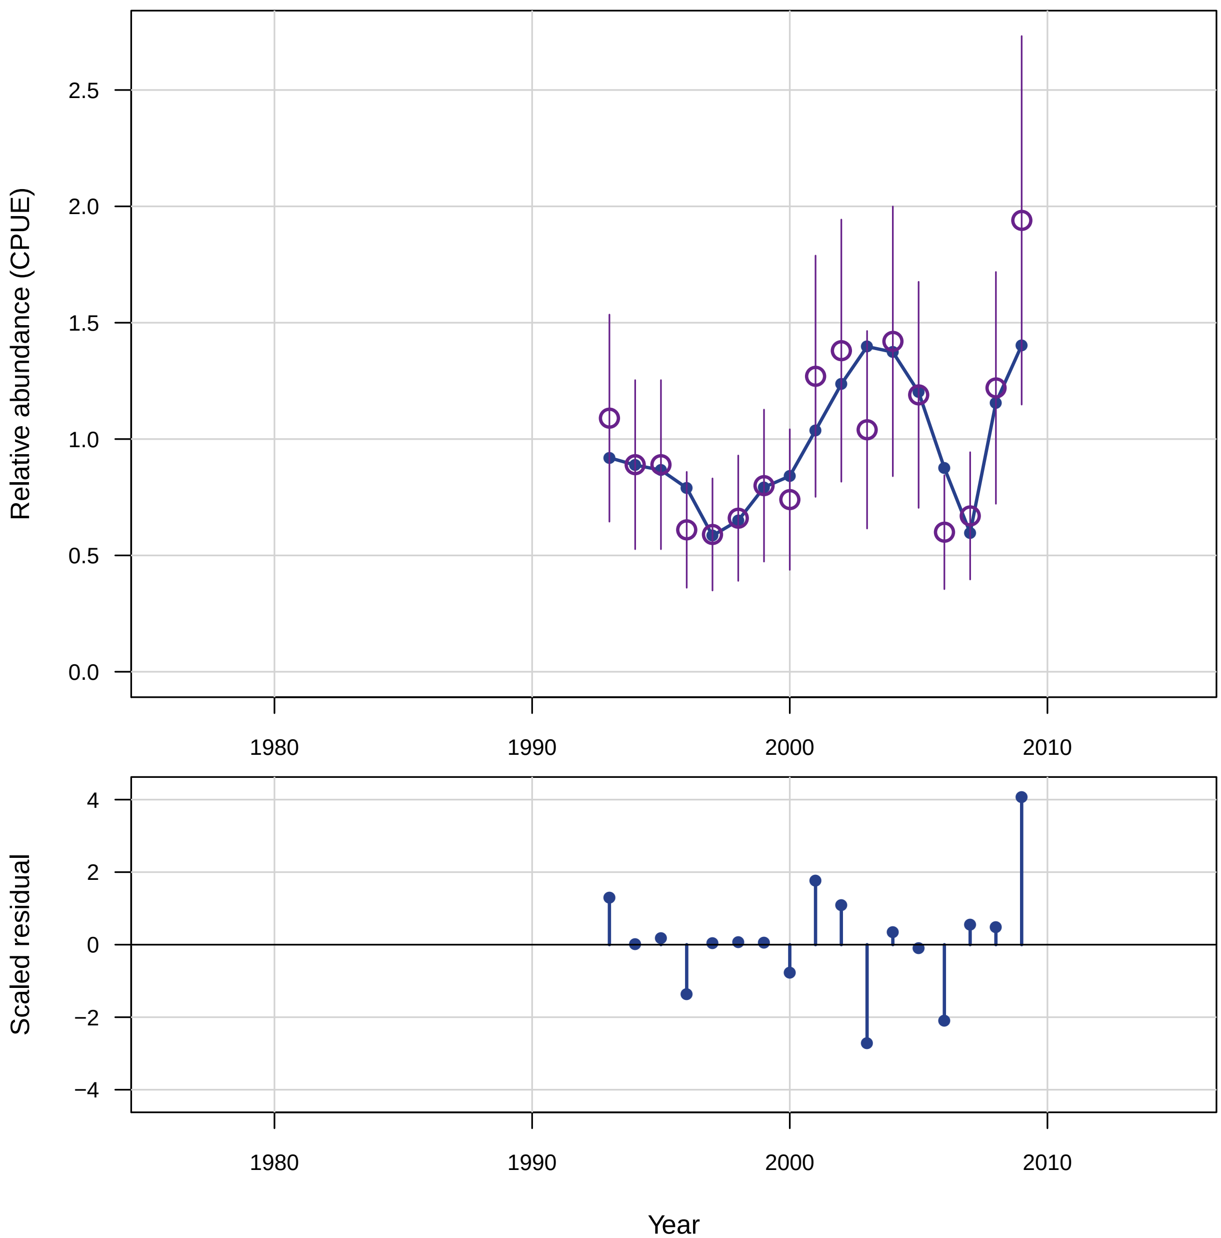

Figure 12. Observed (open circles) and estimated (solid line, circles) abundance from the headboat fleet. The error bars represent the annual CV of the index (0.2) divided by the likelihood weight on the index.

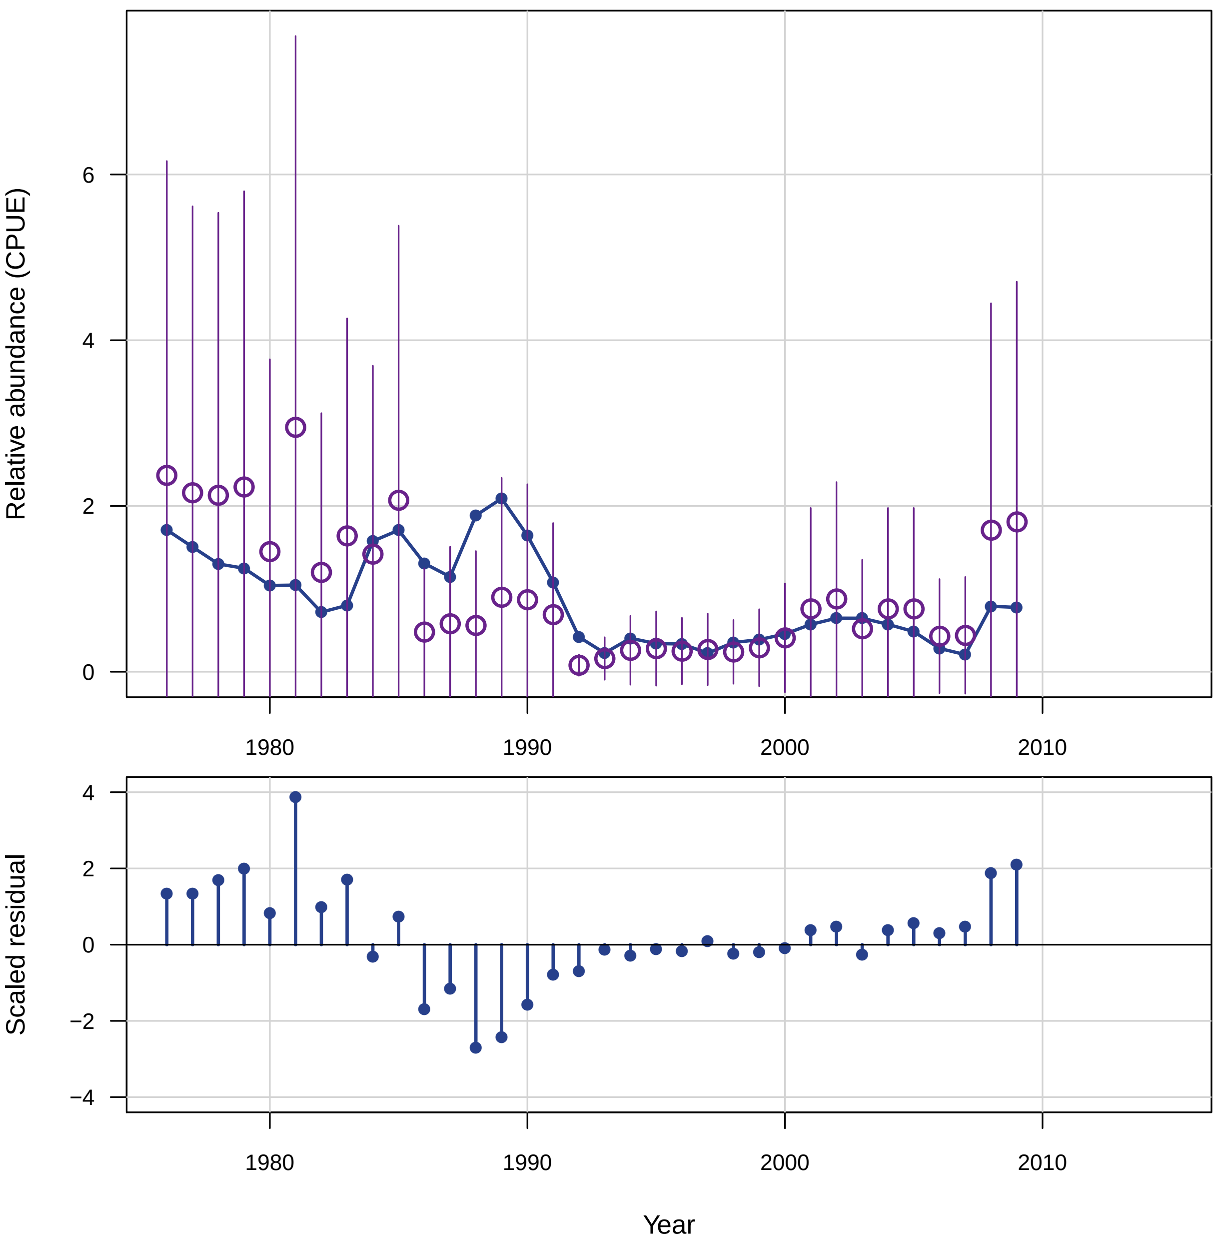

Figure 13. Observed (open circles) and estimated (solid line, circles) abundance from the headboat fleet (discards). The error bars represent the annual CV provided by the GLM standardization divided by the likelihood weight on the index.

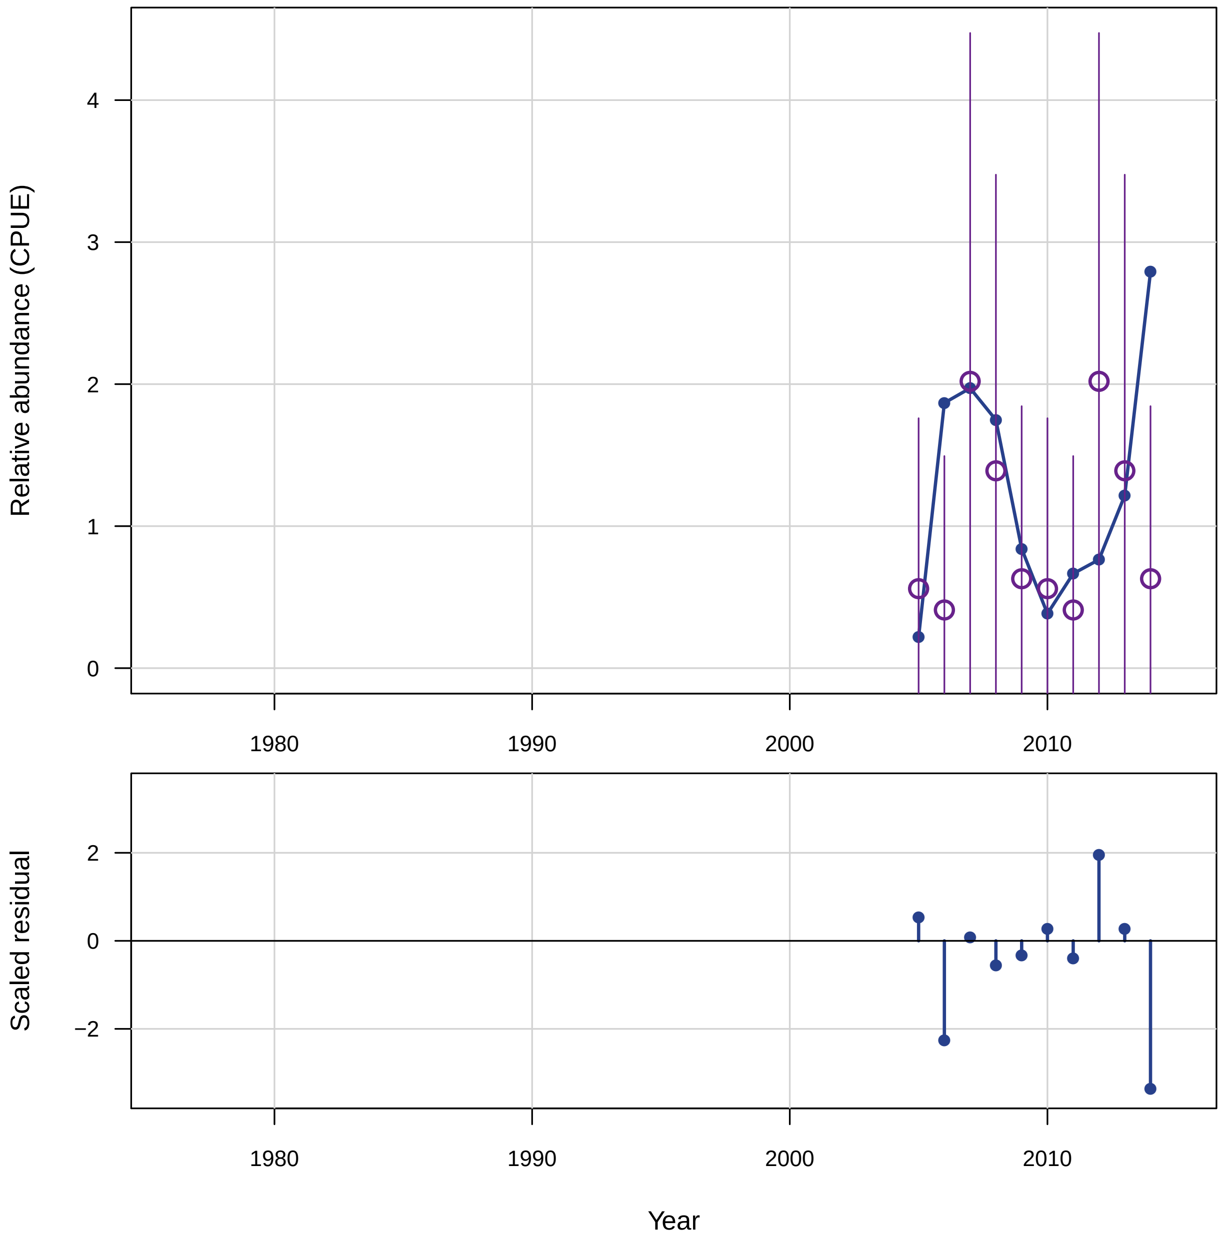

Figure 14. Estimated abundance at age at start of year.

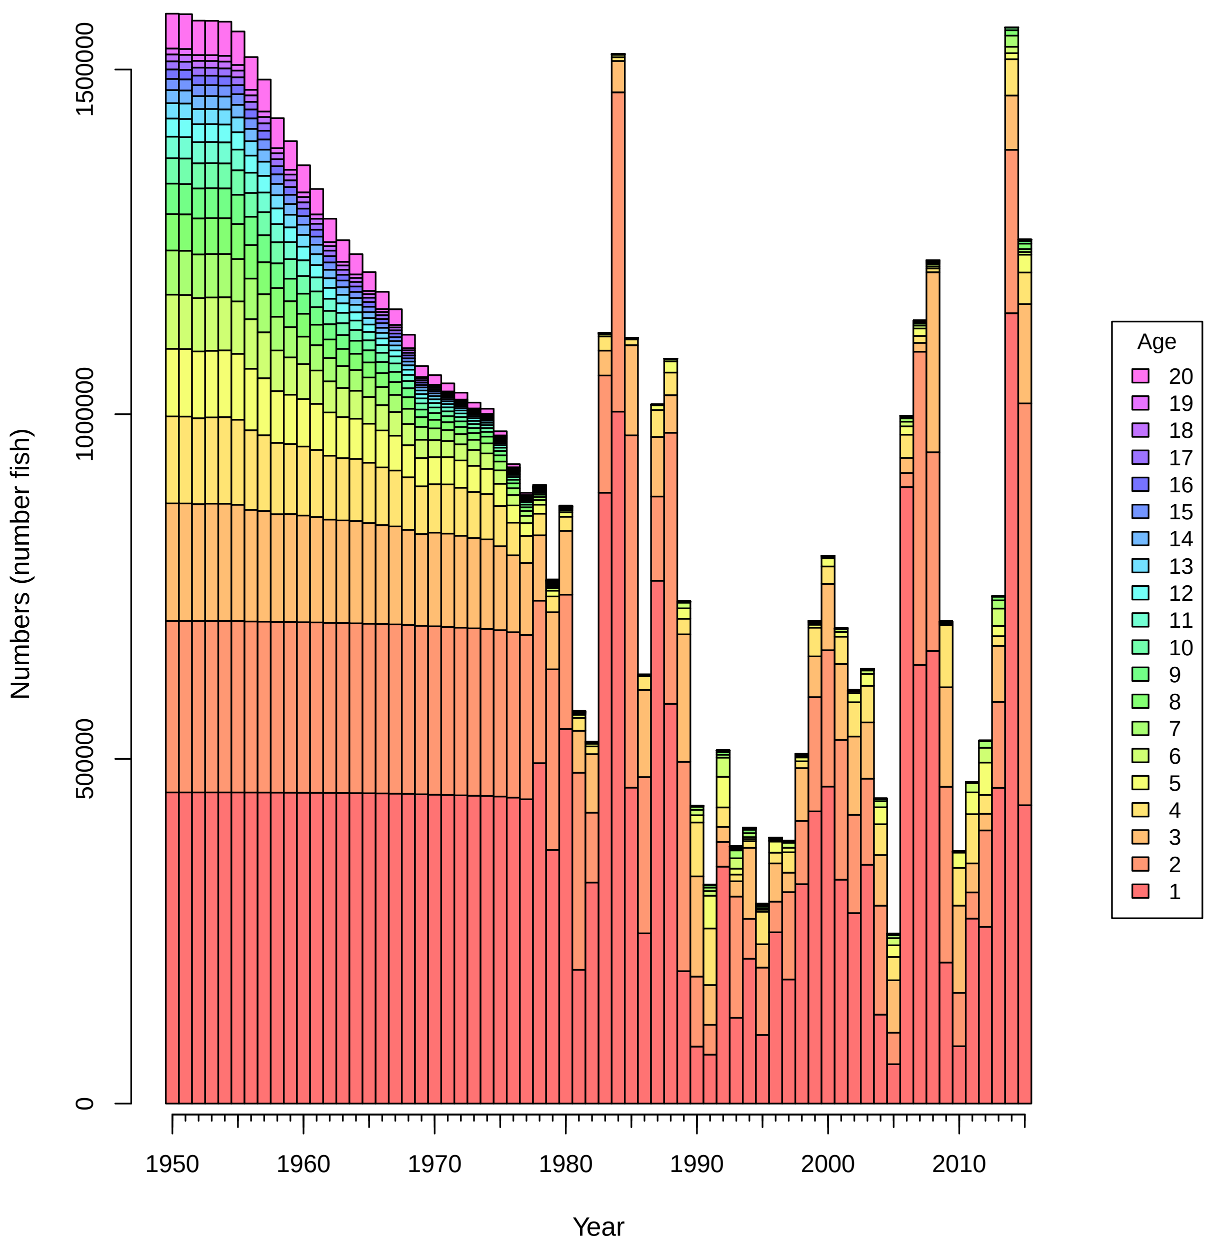

Figure 15. Top panel: Estimated recruitment of age-1 fish. Horizontal dashed line indicates $R_{F30\%}$. Bottom panel: log recruitment residuals.

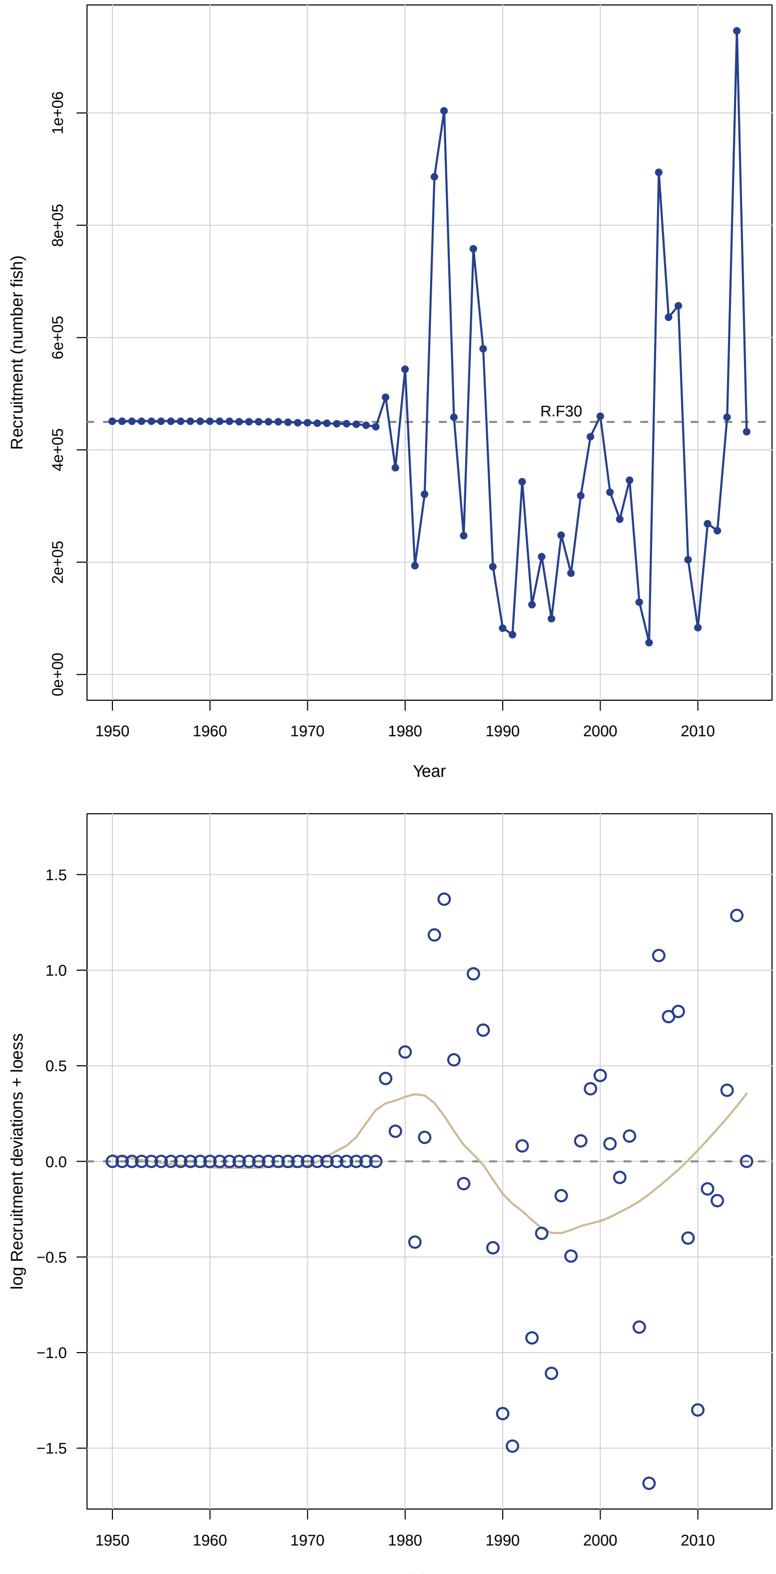

Figure 16. Estimated biomass at age at start of year.

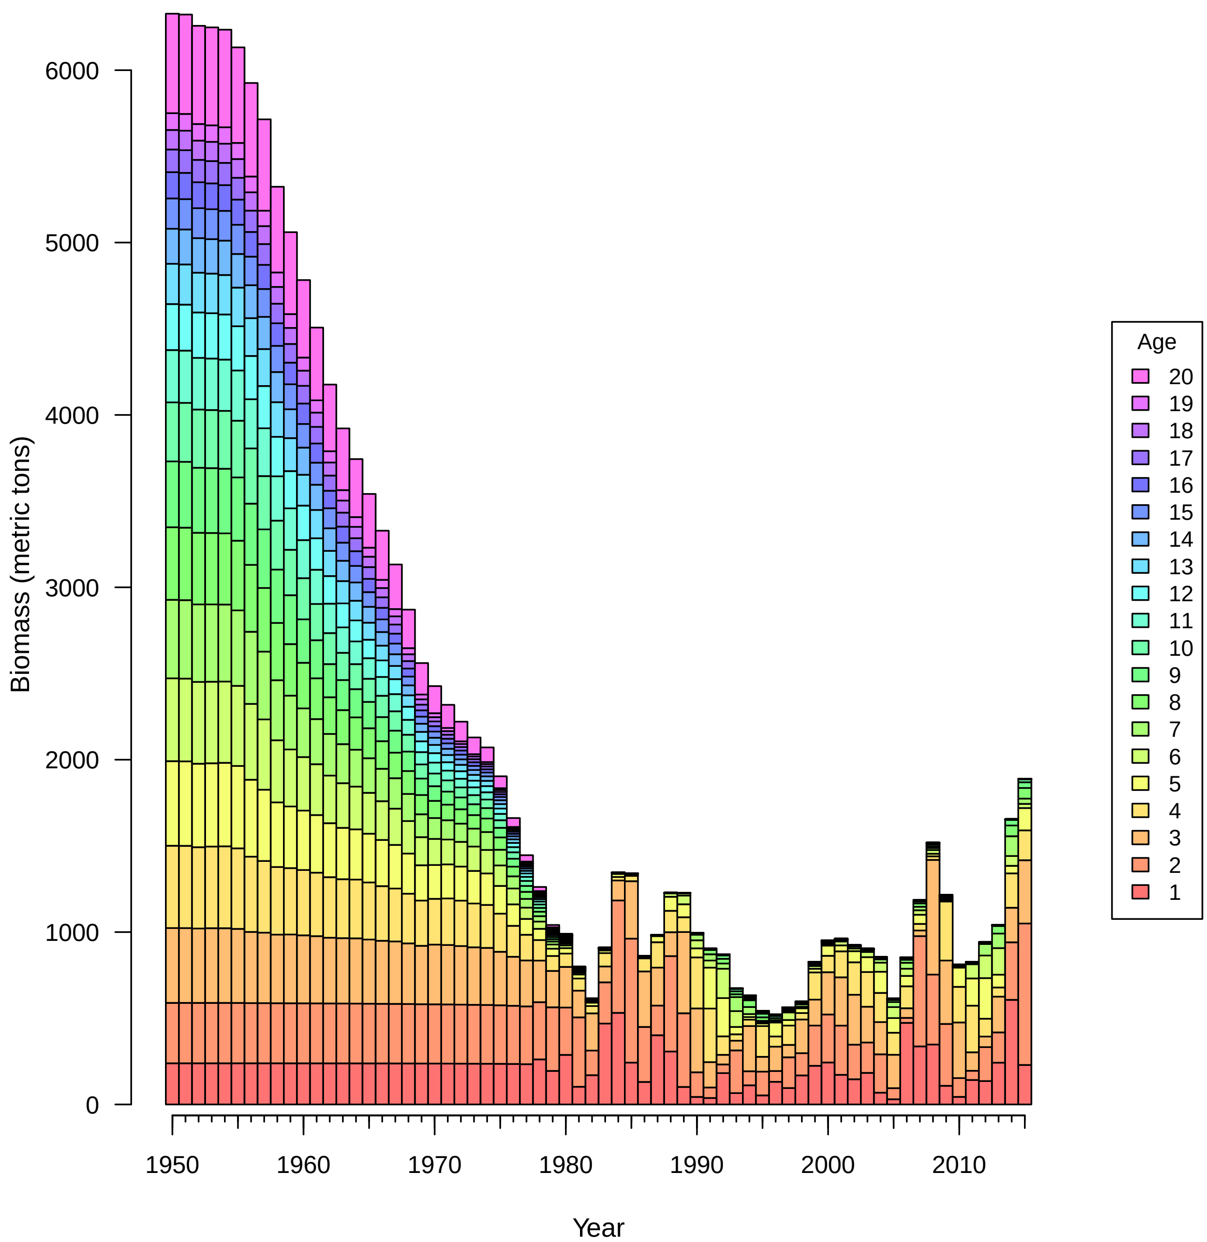

Figure 17. Top panel: Estimated total biomass (metric tons) at start of year. Horizontal dashed line indicates $B_{F30\%}$. Bottom panel: Estimated spawning stock (population fecundity) at time of peak spawning.

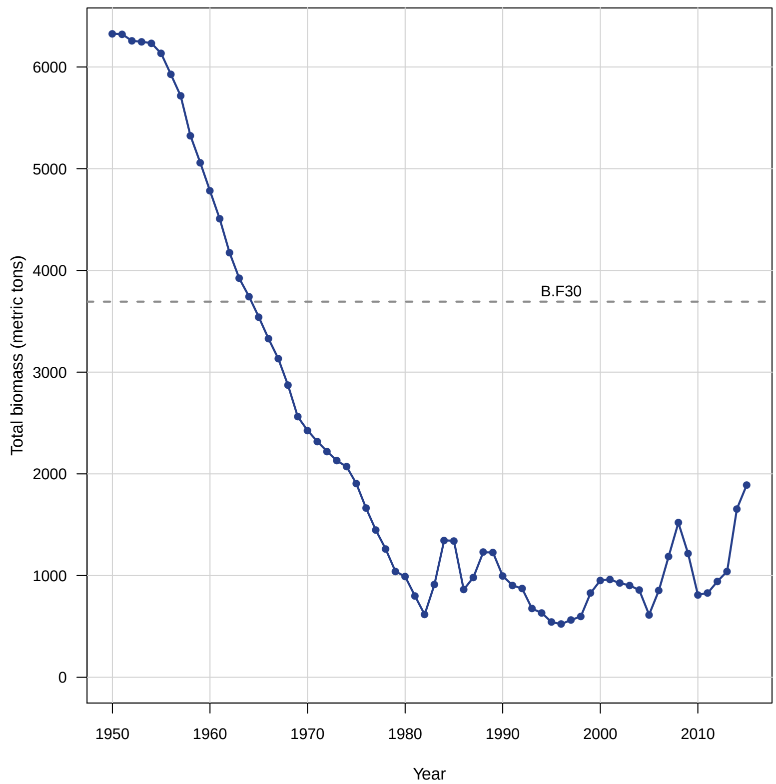

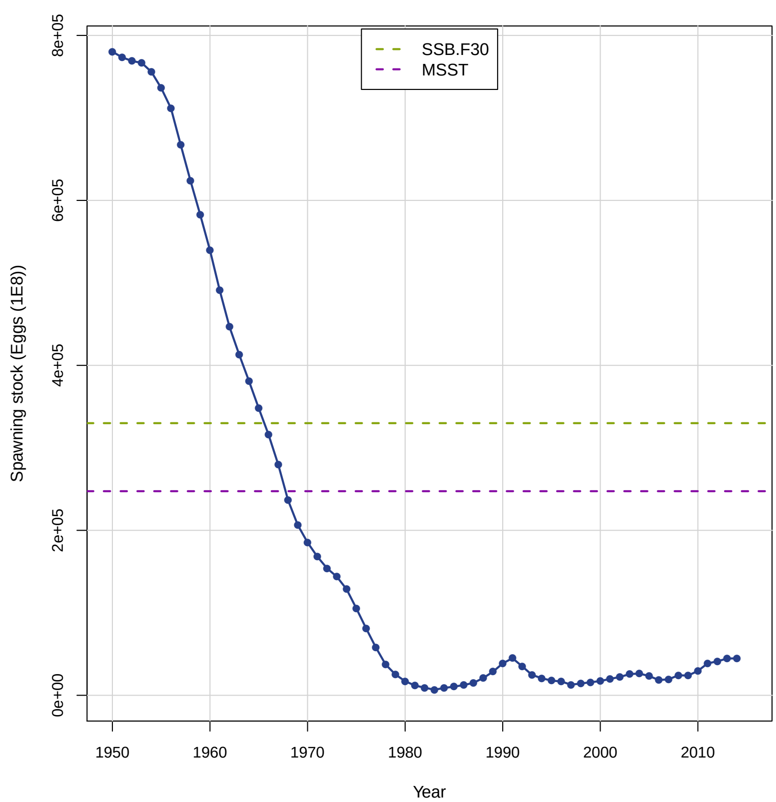

Figure 18. Monte Carlo Bootstrap estimates of population abundance. Top panel is all ages, and the bottom panel represents age 2+.

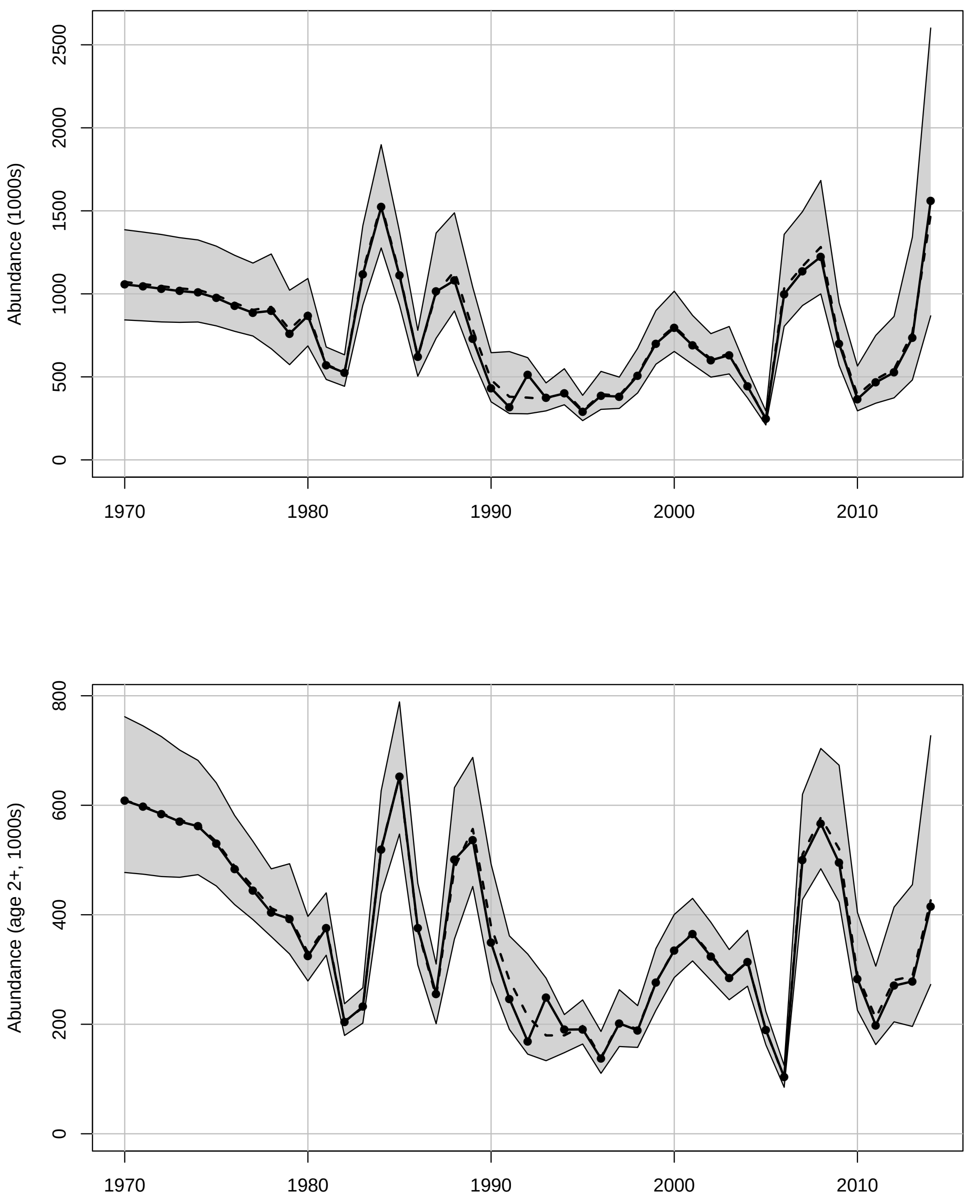

Figure 19. Selectivity of SERFS index.

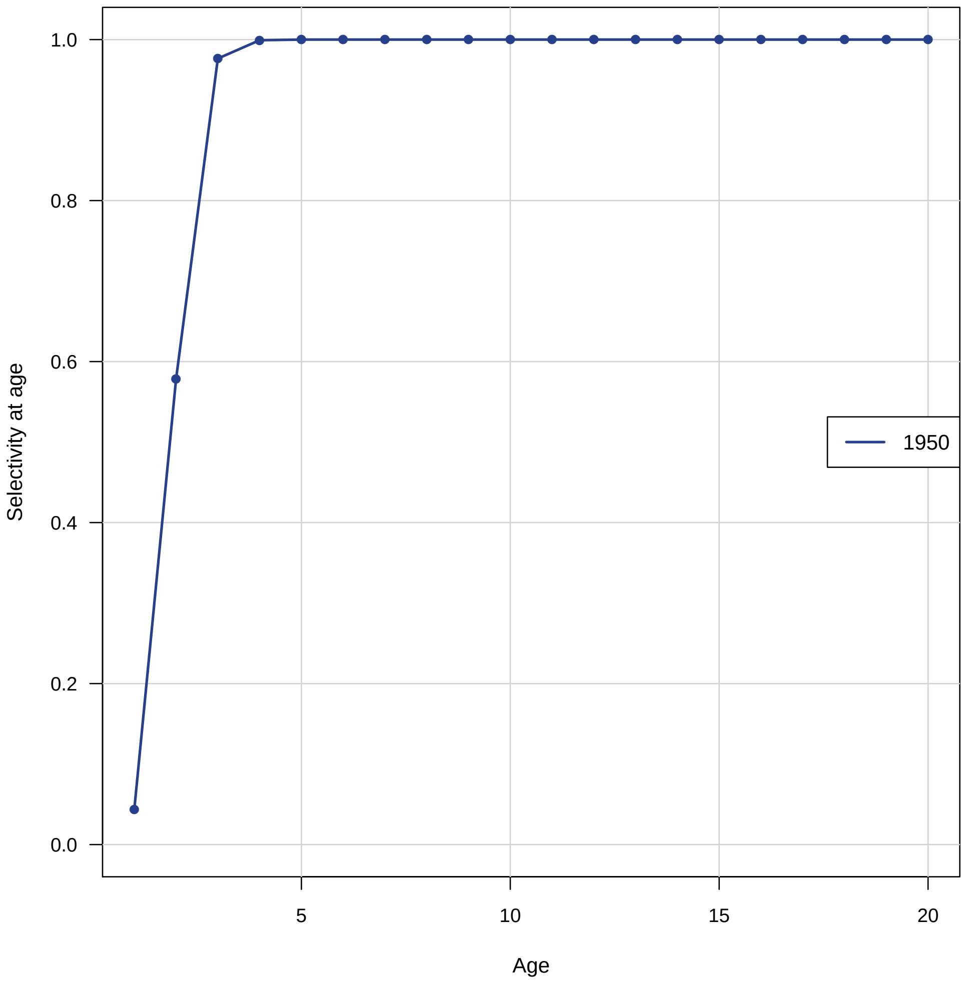

Figure 20. Selectivities of commercial handline landings. The legend indicates the first year each selectivity curve applies to the fleet.

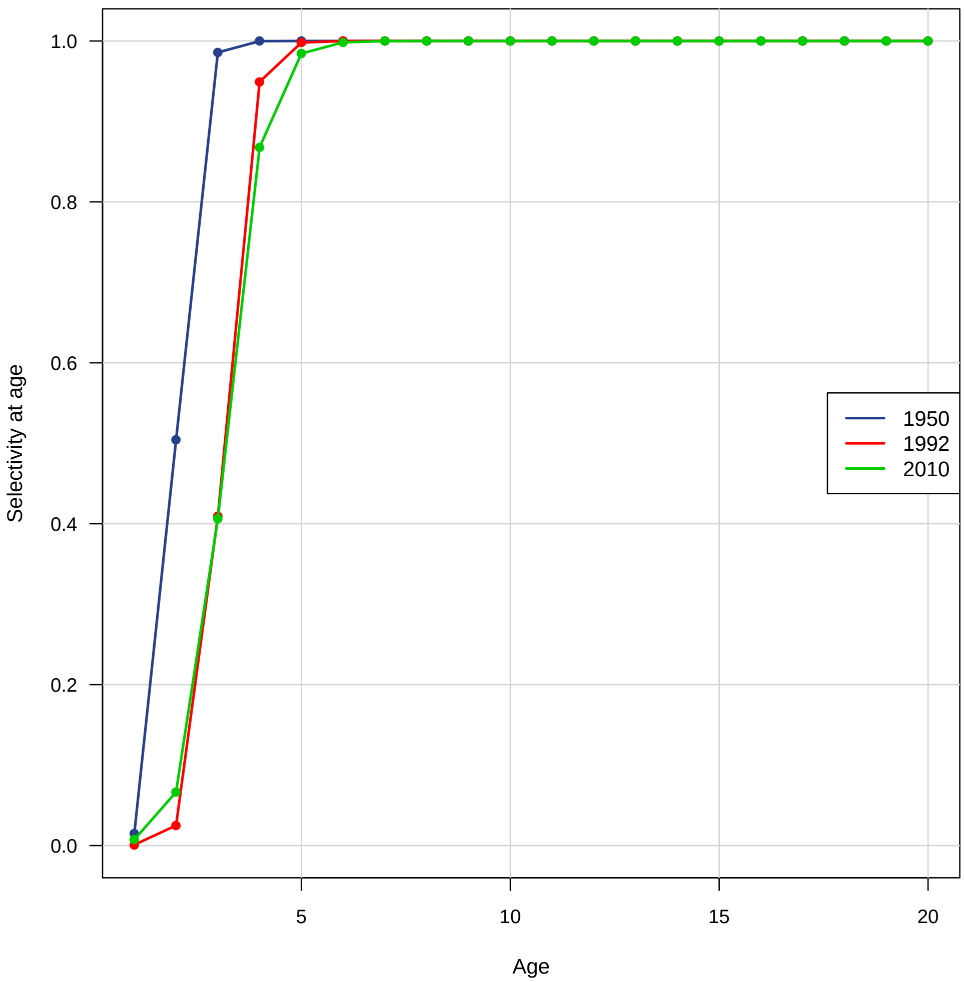

Figure 21. Selectivities of headboat landings. The legend indicates the first year each selectivity curve applies to the fleet.

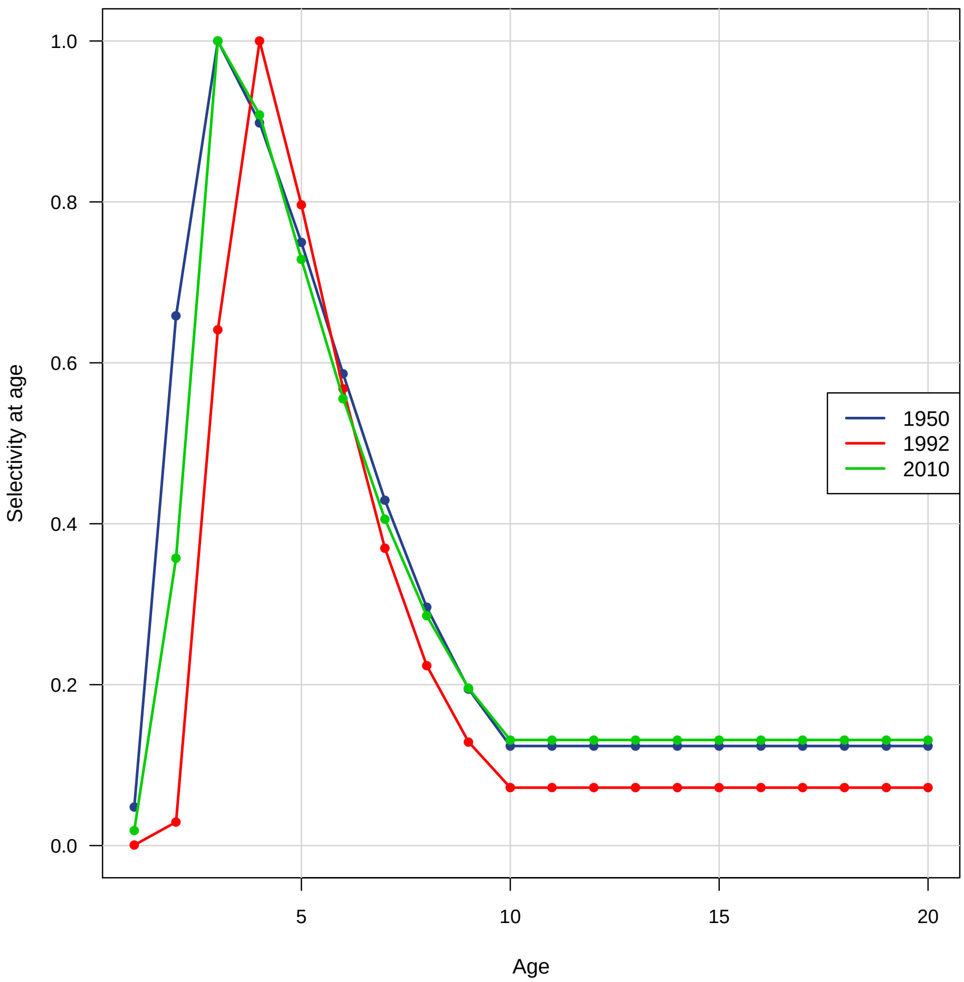

Figure 22. Selectivities of general recreational landings. The legend indicates the first year each selectivity curve applies to the fleet.

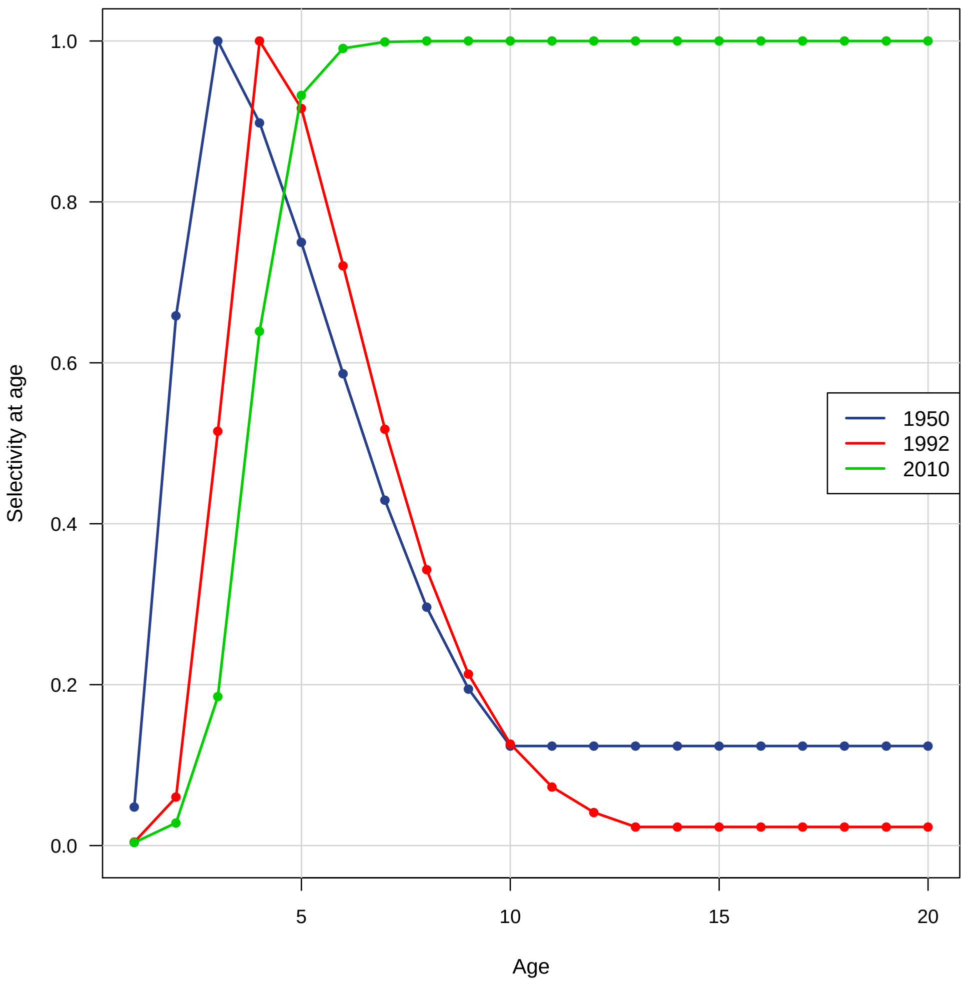

Figure 23. Selectivities of commercial handline discards. The legend indicates the first year each selectivity curve applies to the fleet.

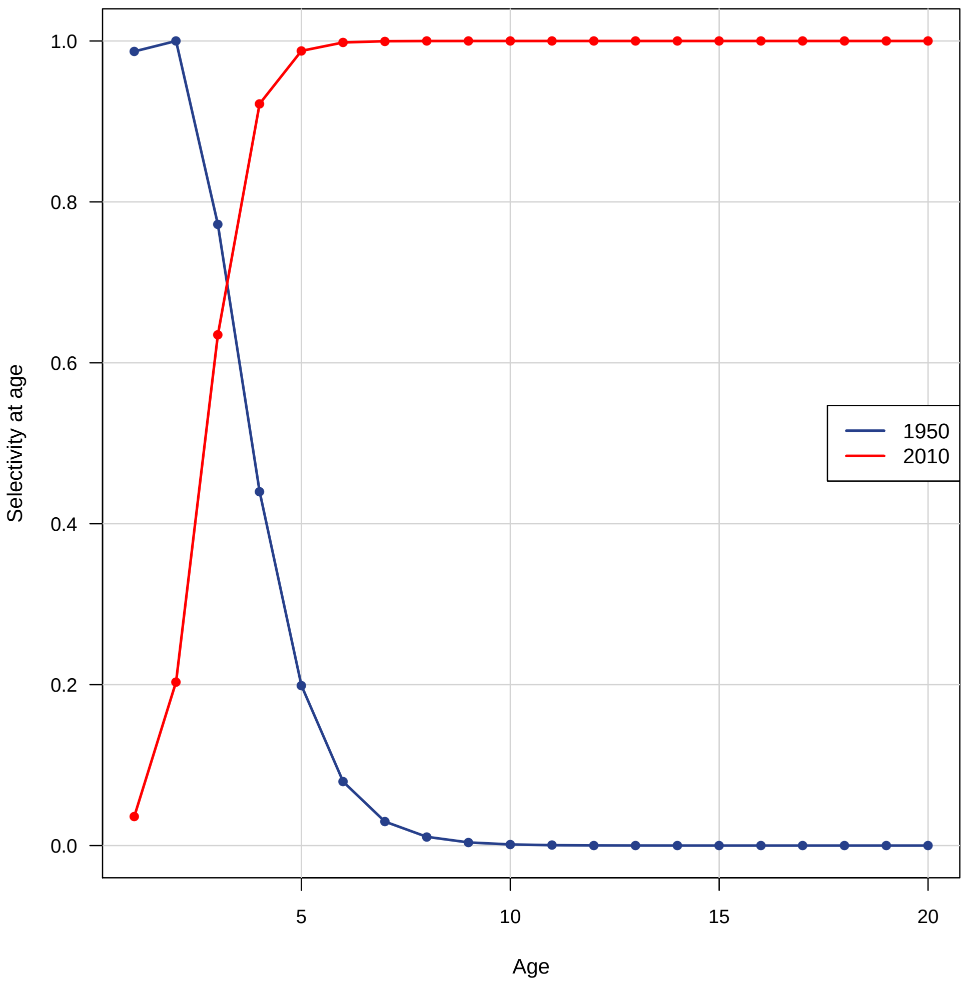

Figure 24. Selectivities of headboat discards. The legend indicates the first year each selectivity curve applies to the fleet.

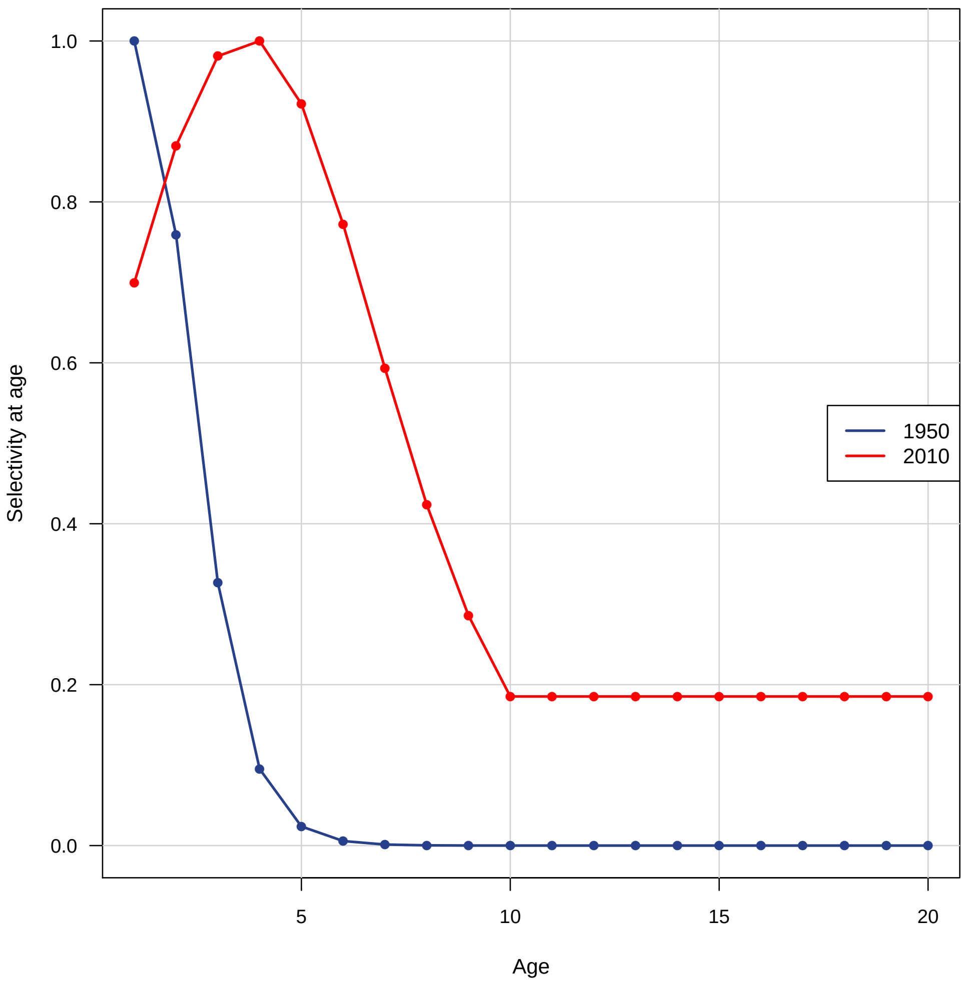

Figure 25. Selectivities of general recreational discards. The legend indicates the first year each selectivity curve applies to the fleet.

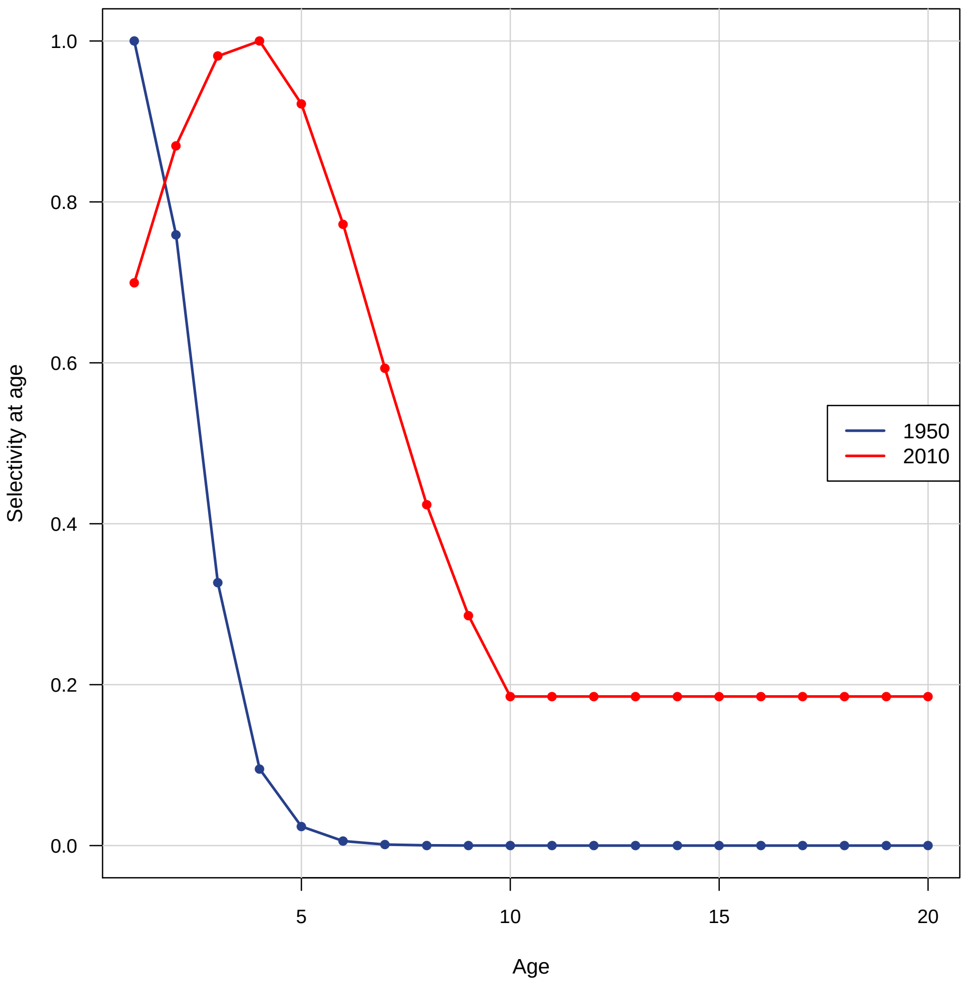

Figure 26. Average selectivity of discards(top left), landings (top right), and total weighted average (bottom) from the terminal assessment years, weighted by geometric mean F's from the last three assessment years, and used in computation of benchmarks and projections.

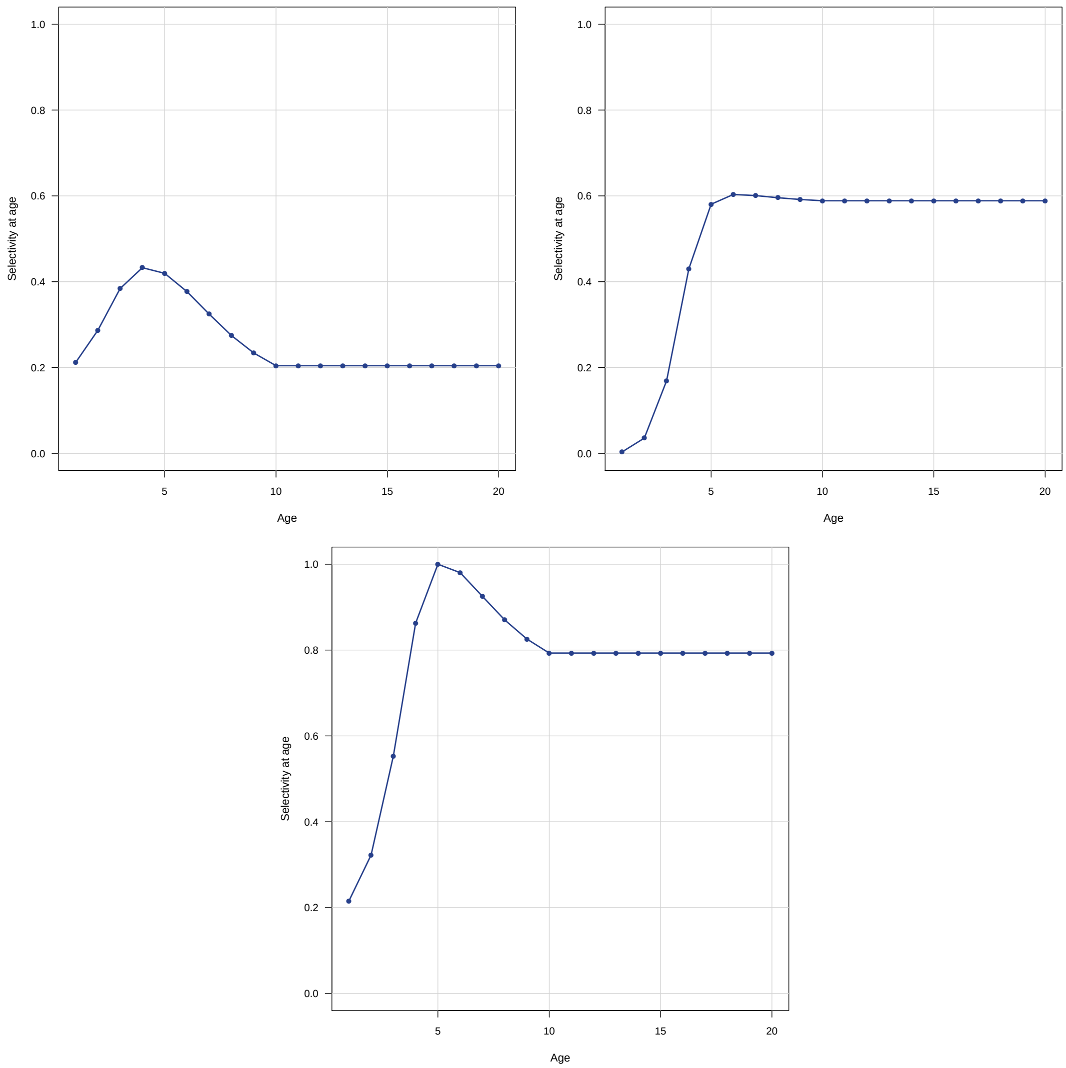

Figure 27. Estimated fully selected fishing mortality rate (per year) by fleet. cH refers to commercial handlines, HB to headboat, GR to general recreational, and D refers to discard mortality.

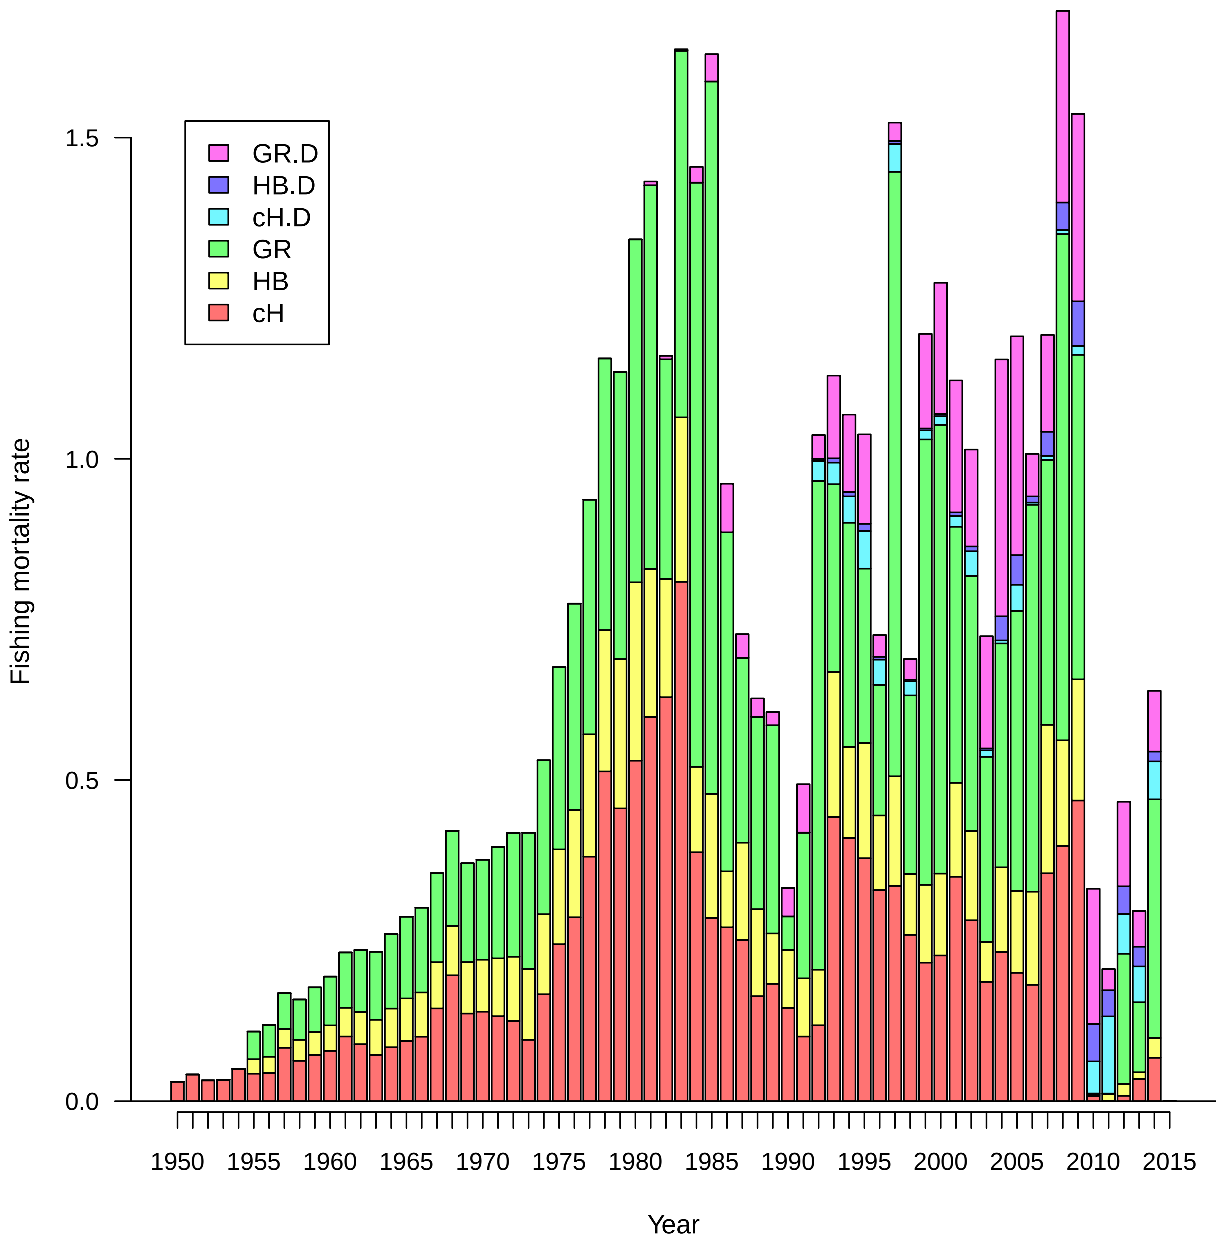

Figure 28. Estimated landings in numbers by fleet from the catch-age model. cH refers to commercial handlines, HB to headboat, and GR to general recreational. Horizontal dashed line in the top panel corresponds to the point estimate of $L_{\mathrm{F30\%}}$ *in numbers.*

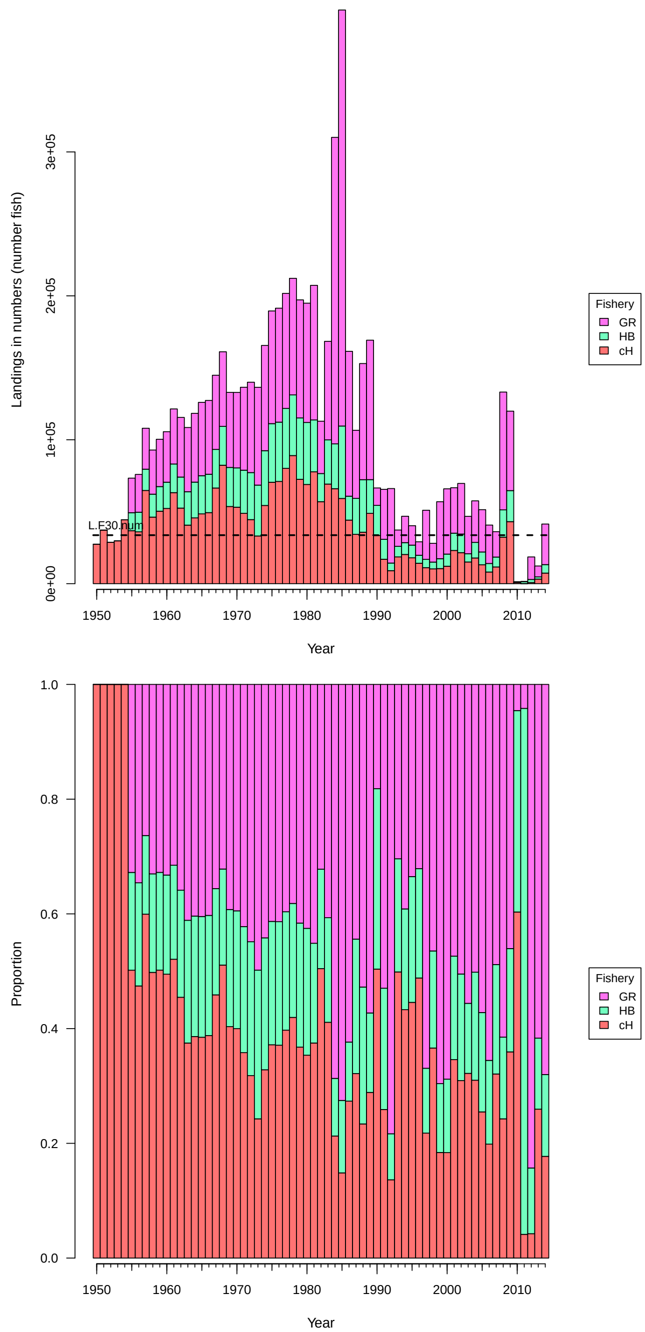

Figure 29. Estimated landings in whole weight by fleet from the catch-age model. cH refers to commercial handlines, HB to headboat, and GR to general recreational. Horizontal dashed line in the top panel corresponds to the point estimate of $L_{F30\%}$ in weight.

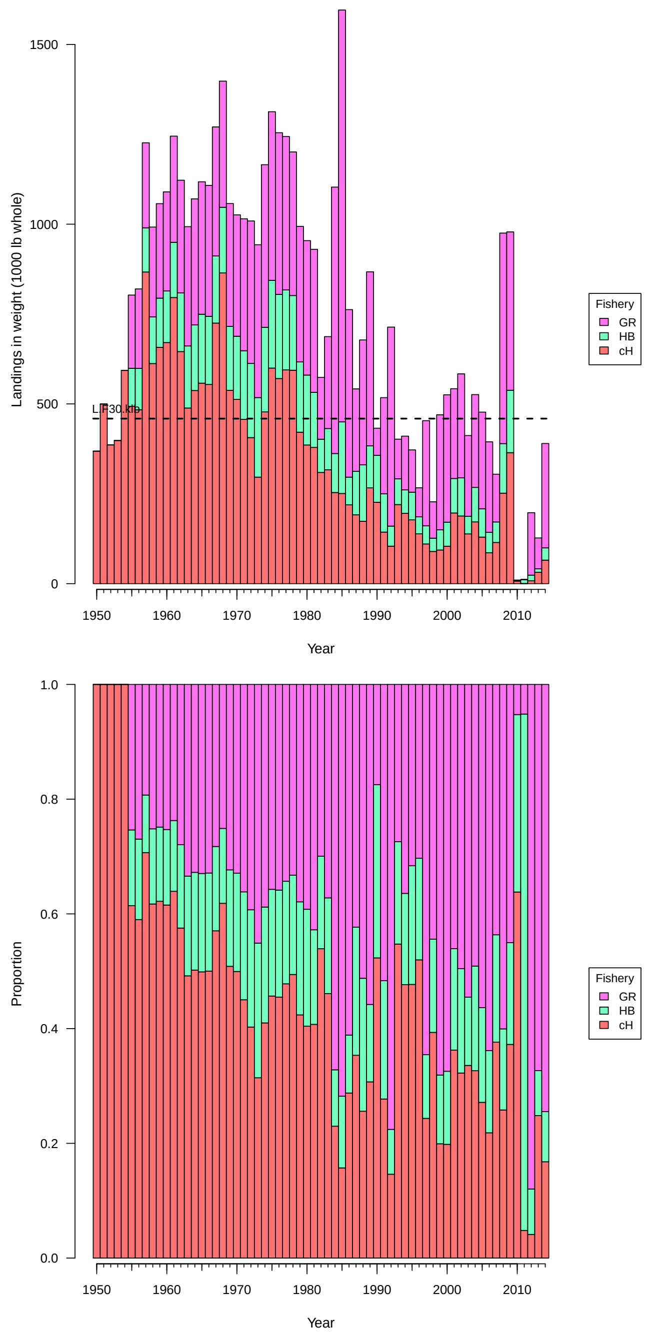

Figure 30. Estimated discard mortalities by fleet from the catch-age model. cH refers to commercial lines, hb to headboat, rec to general recreational. Horizontal dashed line in the top panel corresponds to the point estimate of $D_{F_{30\%}}$ in numbers.

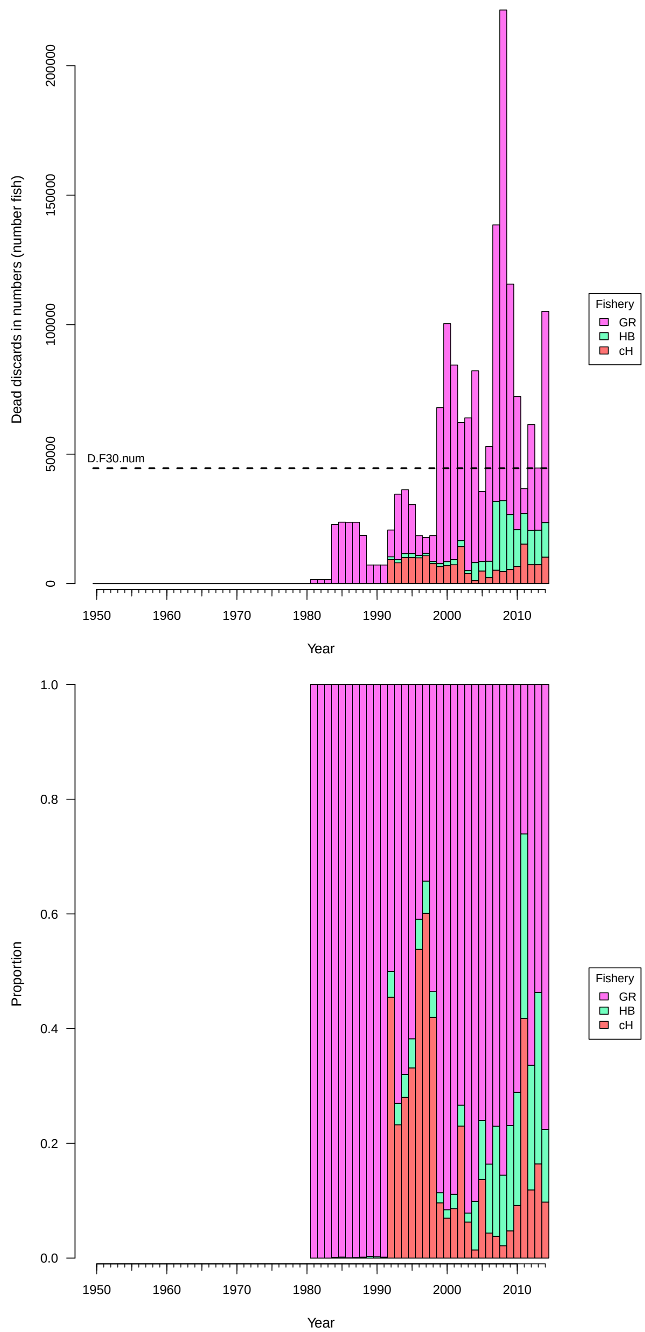

Figure 31. Top panel: Beverton–Holt spawner-recruit curves, with and without lognormal bias correction. The expected (upper) curve was used for computing management benchmarks. Bottom panel: log of recruits (number age-1 fish) per spawner as a function of spawners.

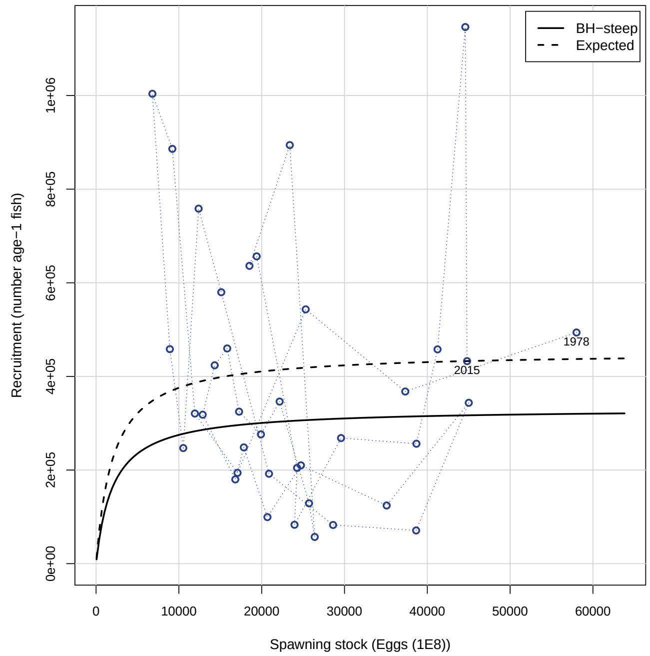

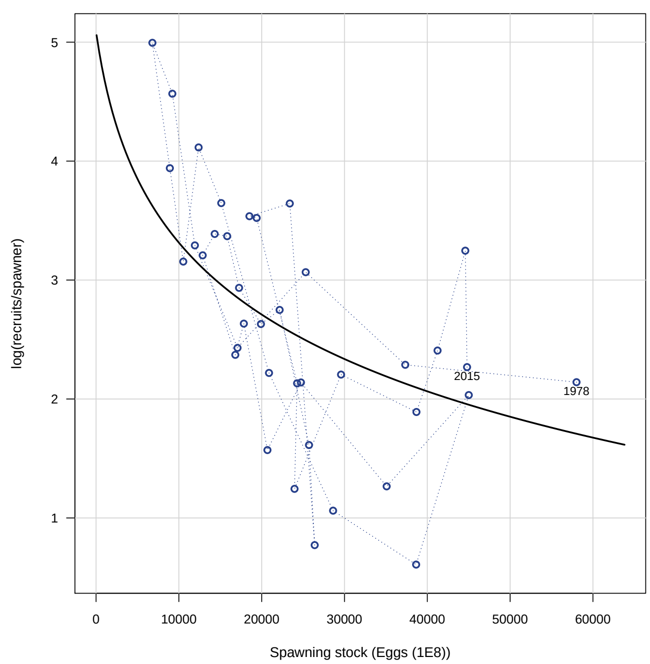

Figure 32. Probability densities of spawner-recruit quantities R0 (unfished recruitment of age-1 fish), steepness (fixed at 0.99), unfished spawners per recruit, and standard deviation of recruitment residuals in log space. Solid vertical lines represent point estimates or values from the base run of the Beaufort Assessment Model; dashed vertical lines represent medians from the MCB runs.

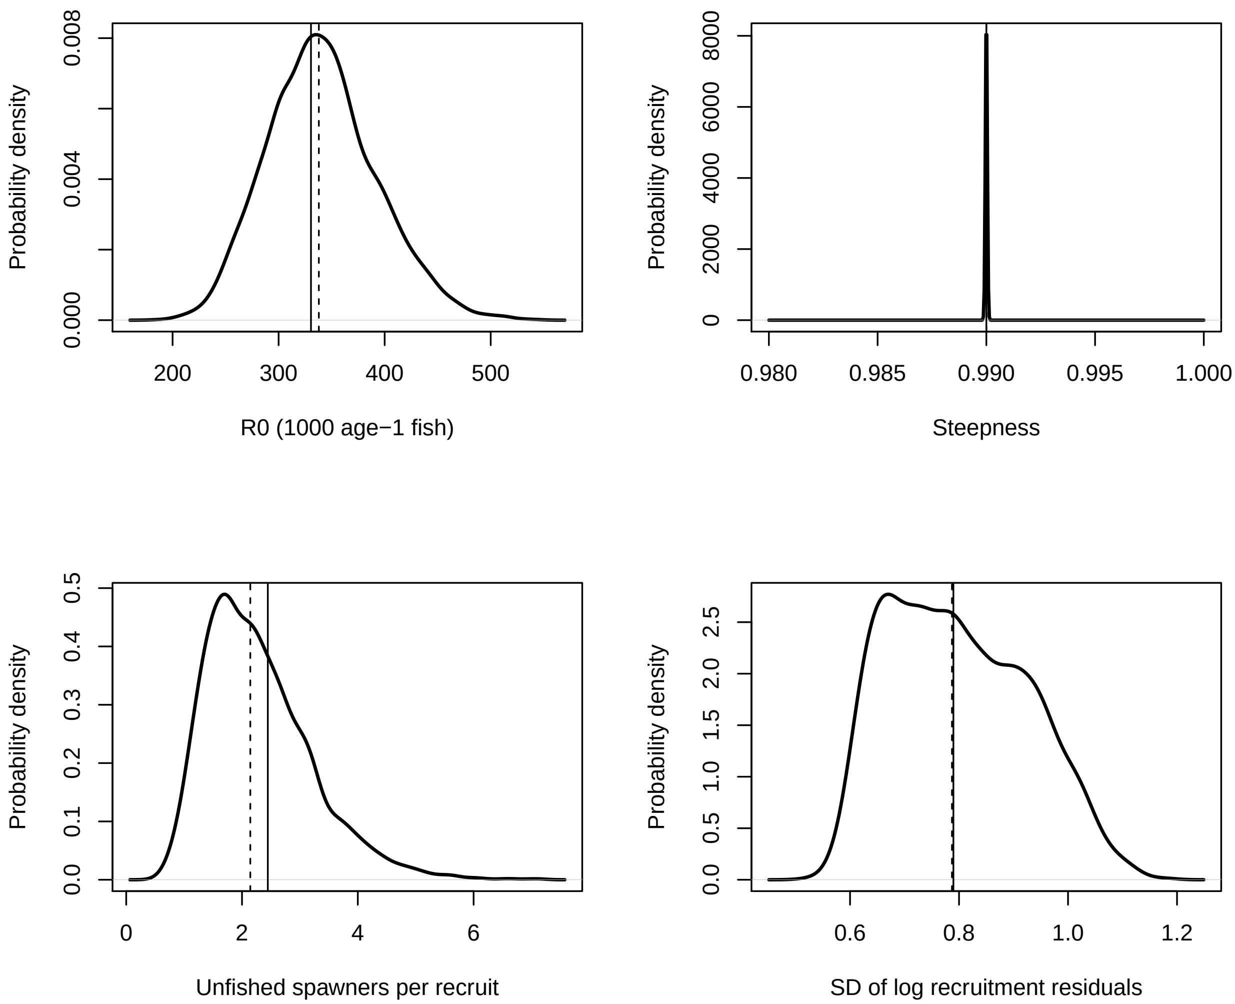

Figure 33. Yield per recruit based on average selectivity from the end of the assessment period.

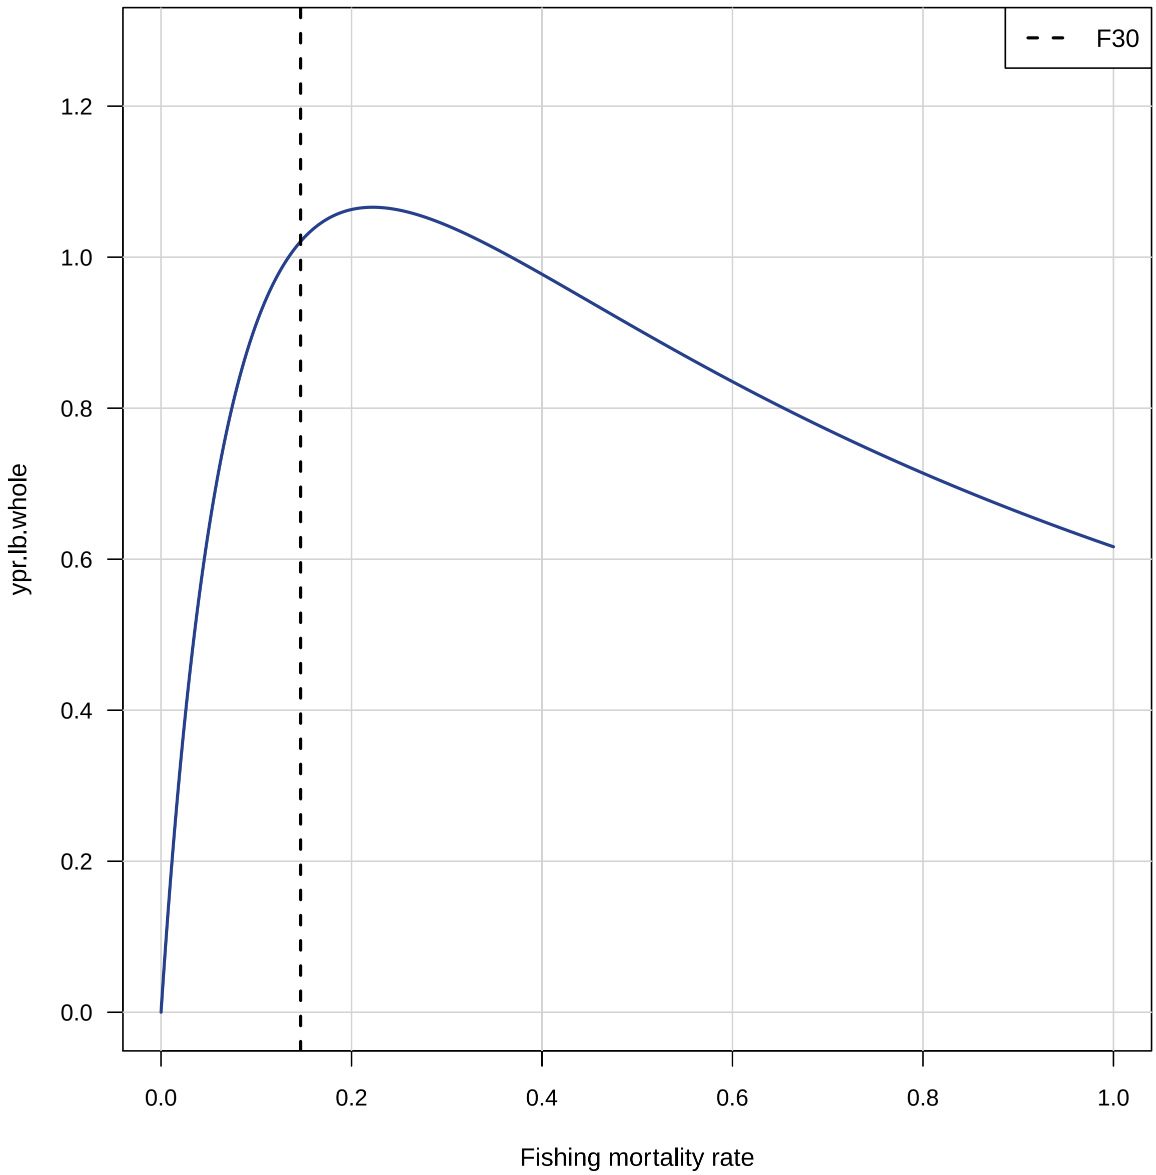

Figure 34. Spawning potential ratio (spawning biomass per recruit relative to that at the unfished level), from which the X% level of SPR provides $F_{X\%}$. SPR is based on average selectivity from the end of the assessment period.

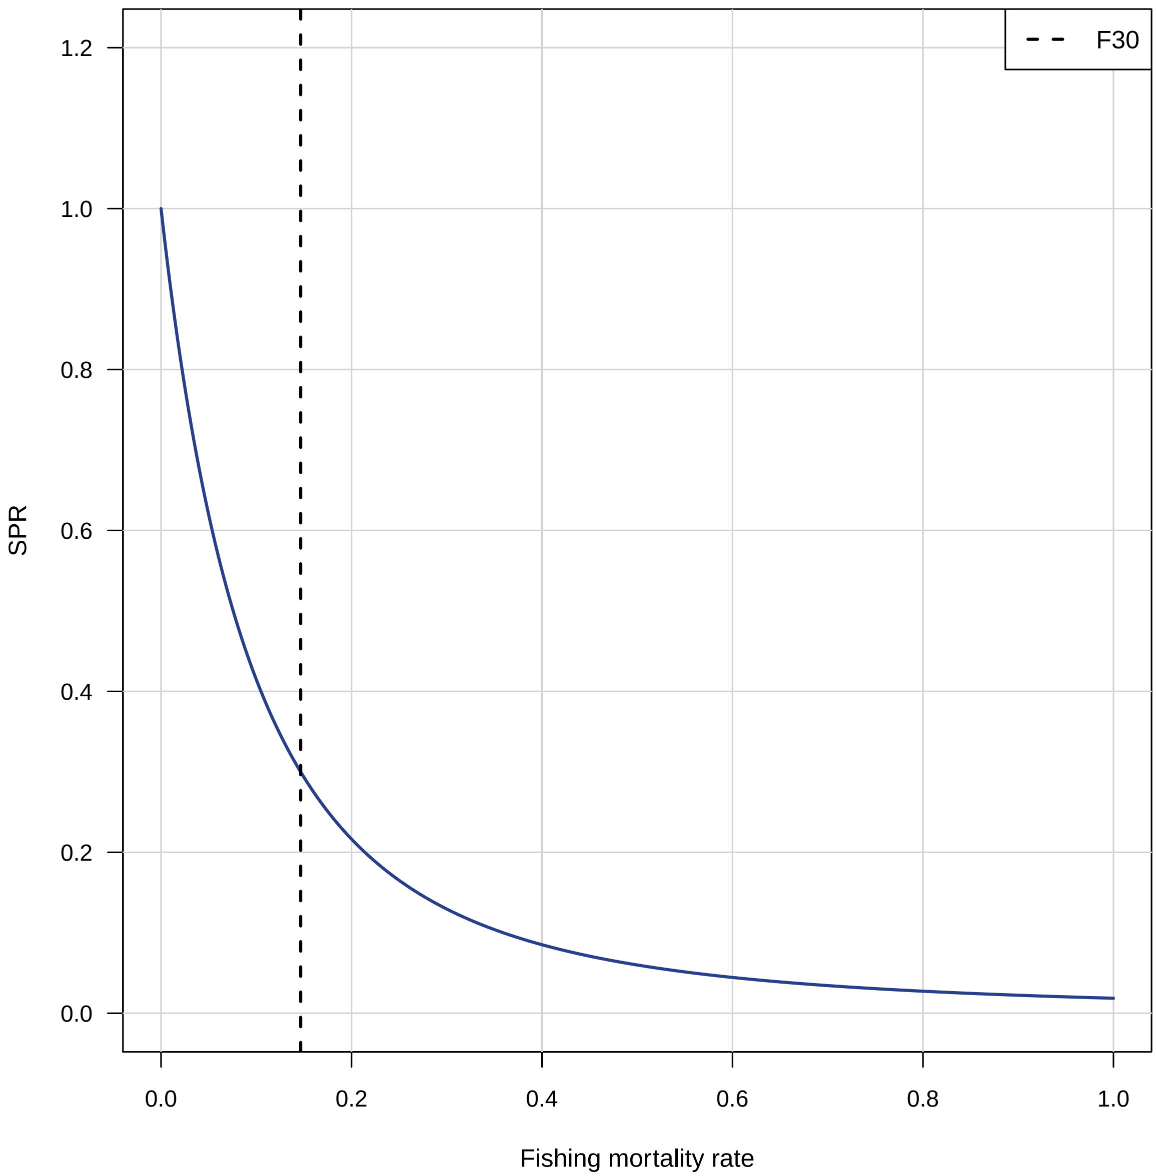

Figure 35. Equilibrium spawning biomass based on average selectivity from the end of the assessment period.

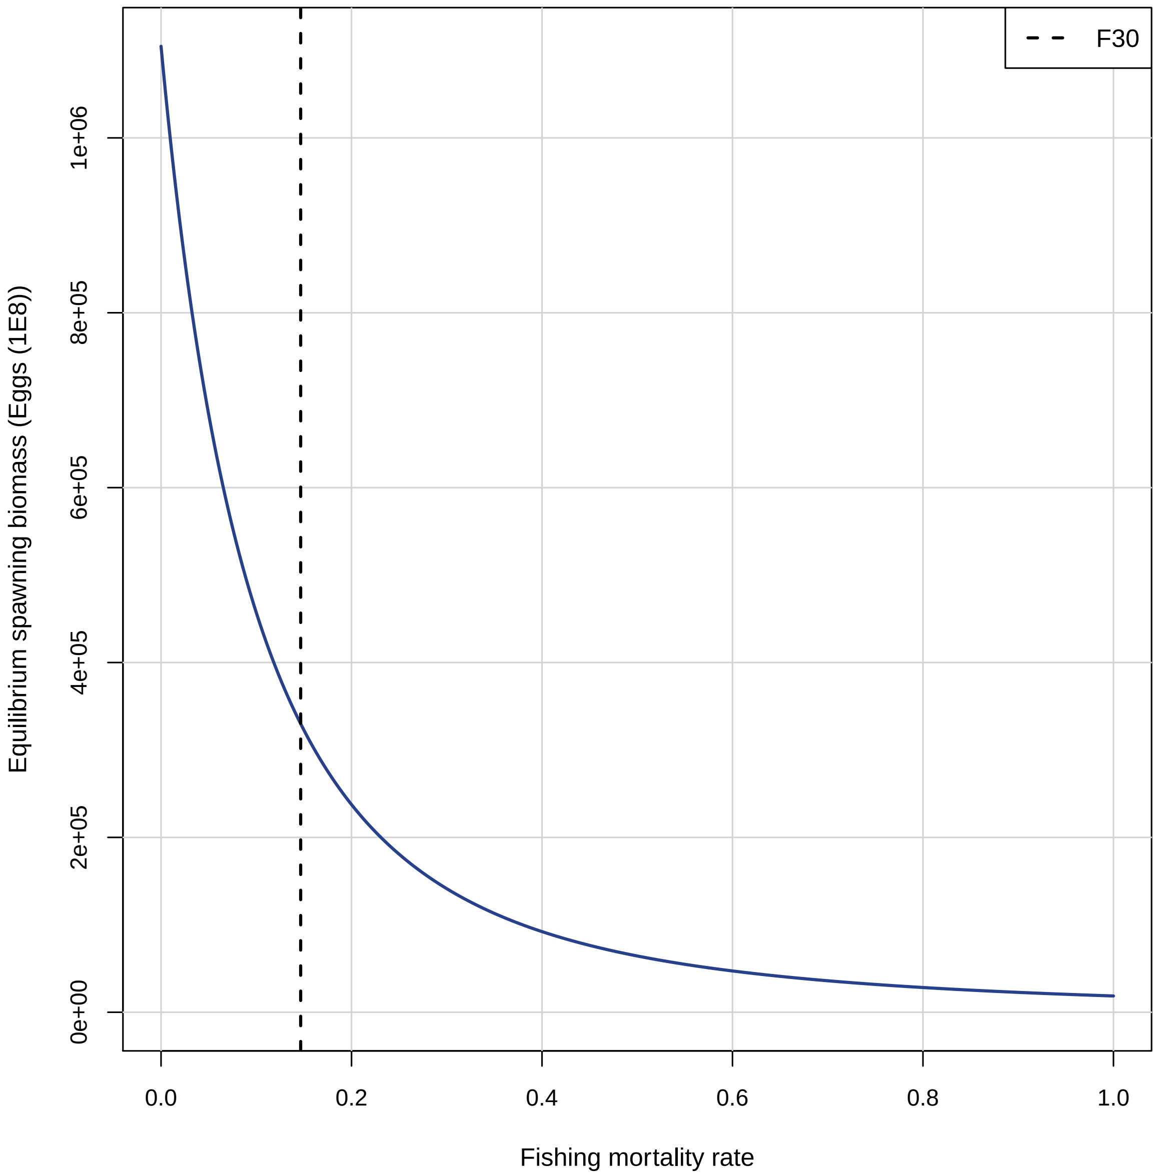

Figure 36. Probability densities of $F_{30\%}$-related benchmarks from MCB analysis of the Beaufort Assessment Model. Solid vertical lines represent point estimates from the base run; dashed vertical lines represent median values.

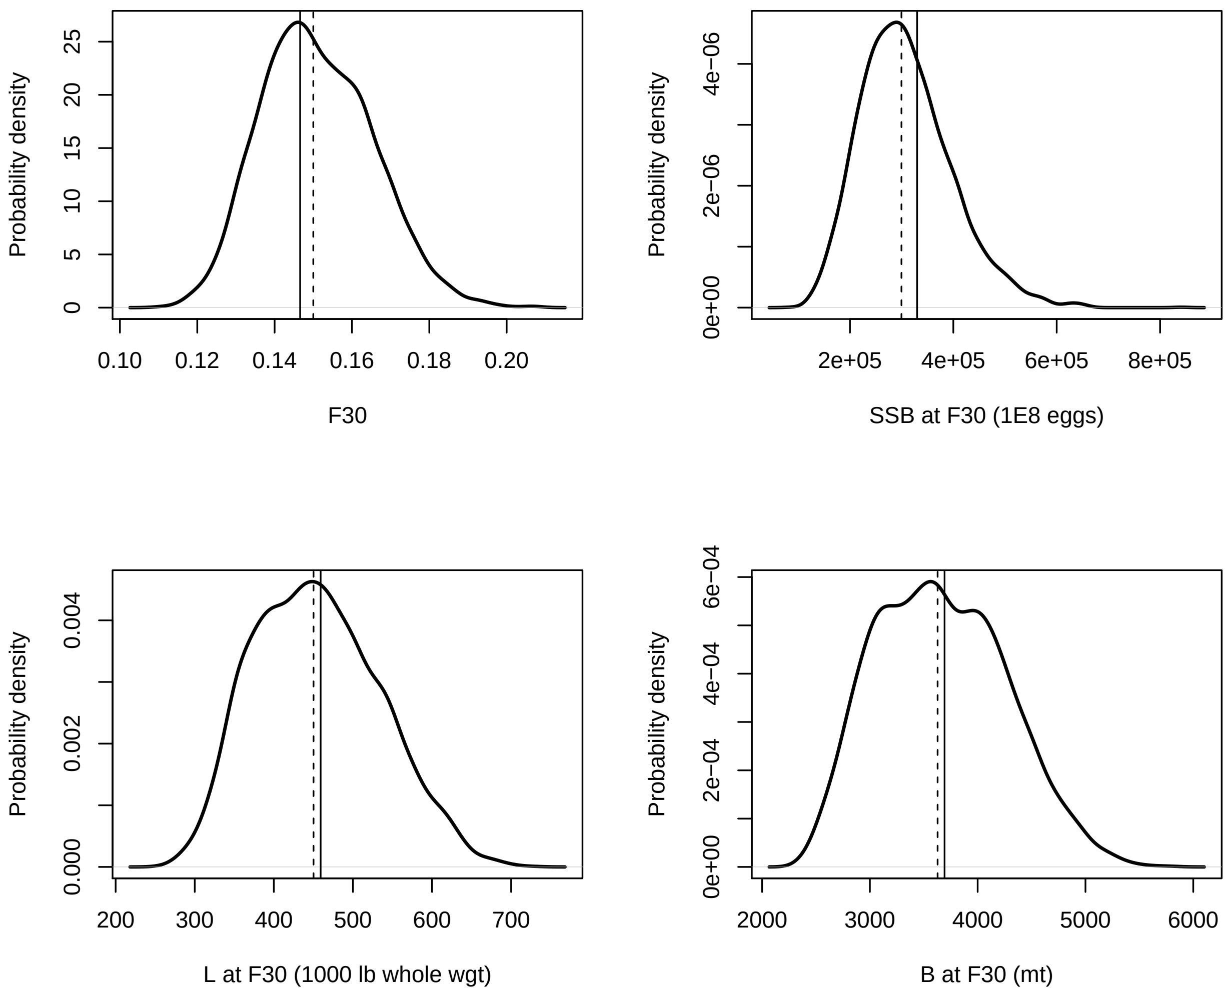

Figure 37. Estimated time series relative to benchmarks. Solid line indicates estimates from base run of the Beaufort Assessment Model; dashed lines represent median values; gray error bands indicate 5^{th} *and* 95^{th} *percentiles of the MCB trials. Top panel: spawning biomass relative to* $\mathrm{SSB}_{\mathrm{F30\%}}$*. Bottom panel: F relative to* $F_{30\%}$*.*

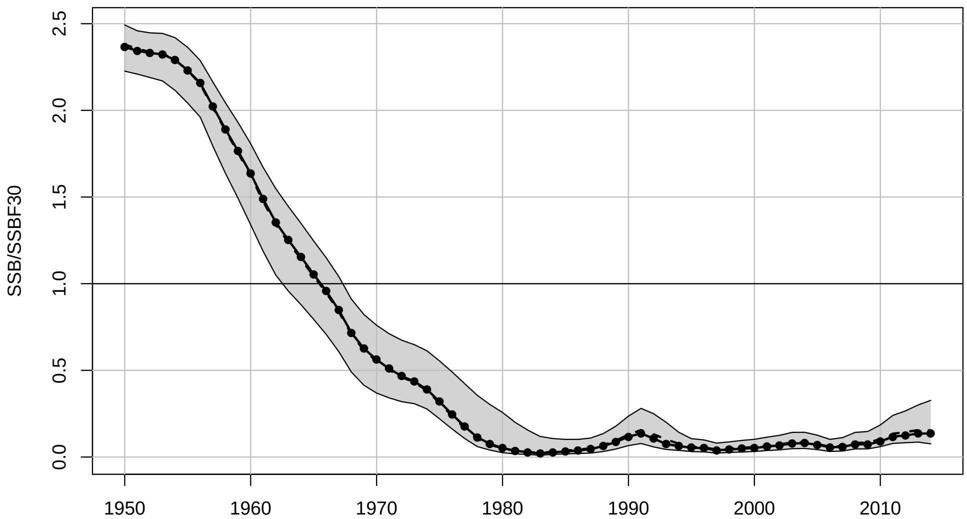

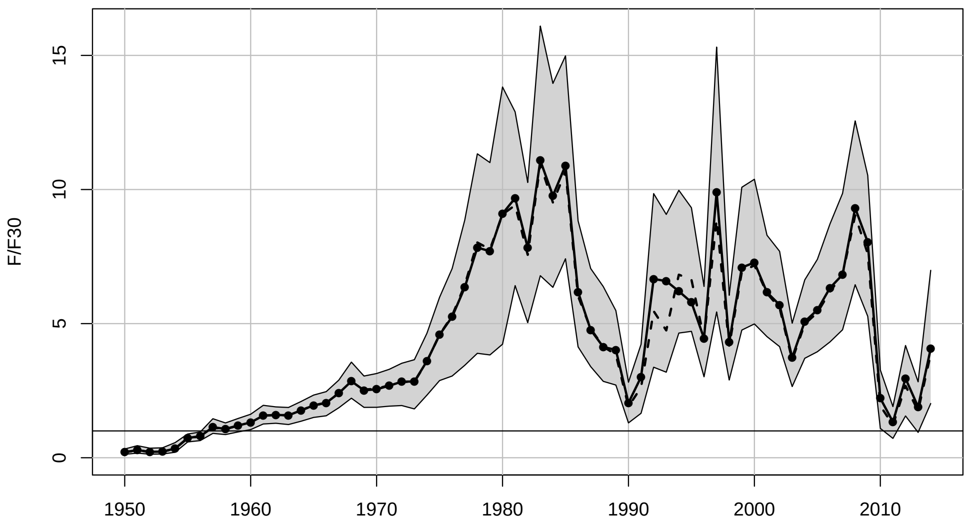

Figure 38. Probability densities of terminal status estimates from MCB analysis of the Beaufort Assessment Model. Solid vertical lines represent point estimates from the base run; dashed vertical lines represent median values.

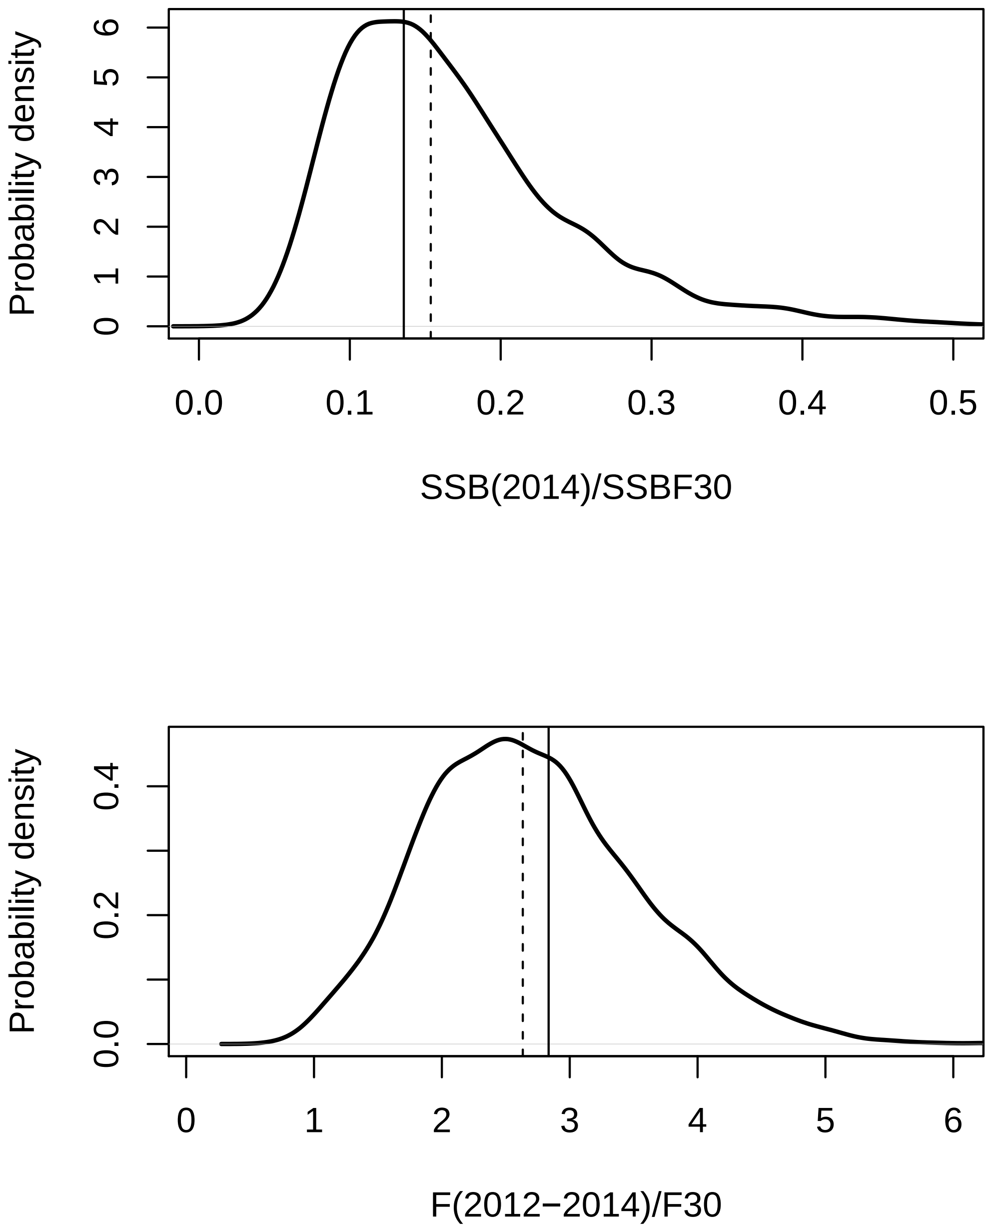

Figure 39. Phase plots of terminal status estimates from MCB analysis of the Beaufort Assessment Model. The intersection of crosshairs indicates estimates from the base run; lengths of crosshairs defined by 5^{th} and 95^{th} percentiles. Proportion of runs falling in each quadrant indicated.

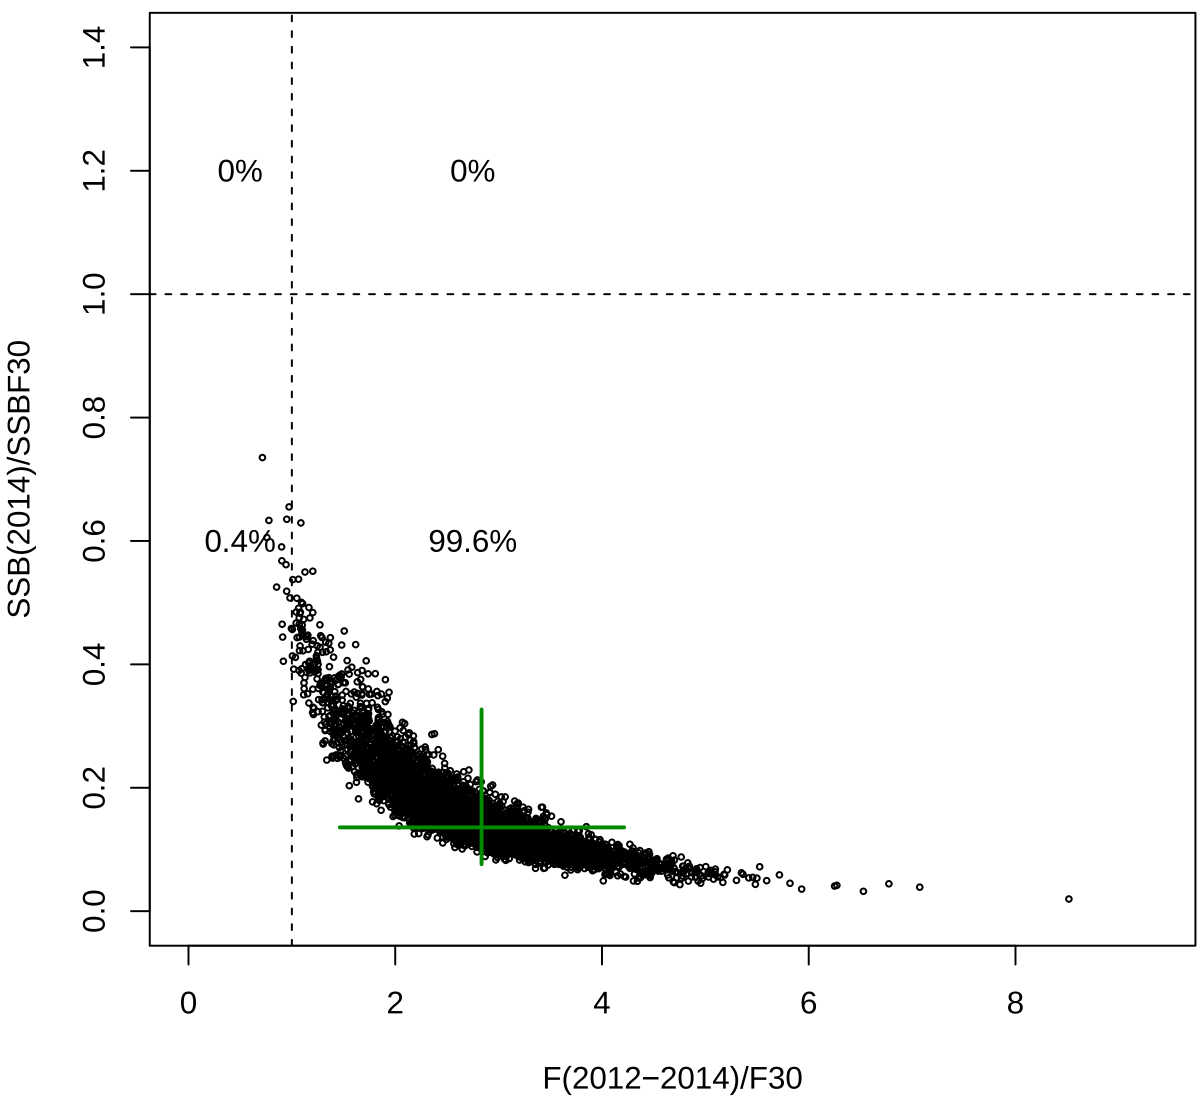

Figure 40. Sensitivity to changes in natural mortality (sensitivity runs S5 and S6). Top panel: Ratio of F to $F_{30\%}$. *Bottom panel: Ratio of* SSB *to* $SSB_{F30\%}$.

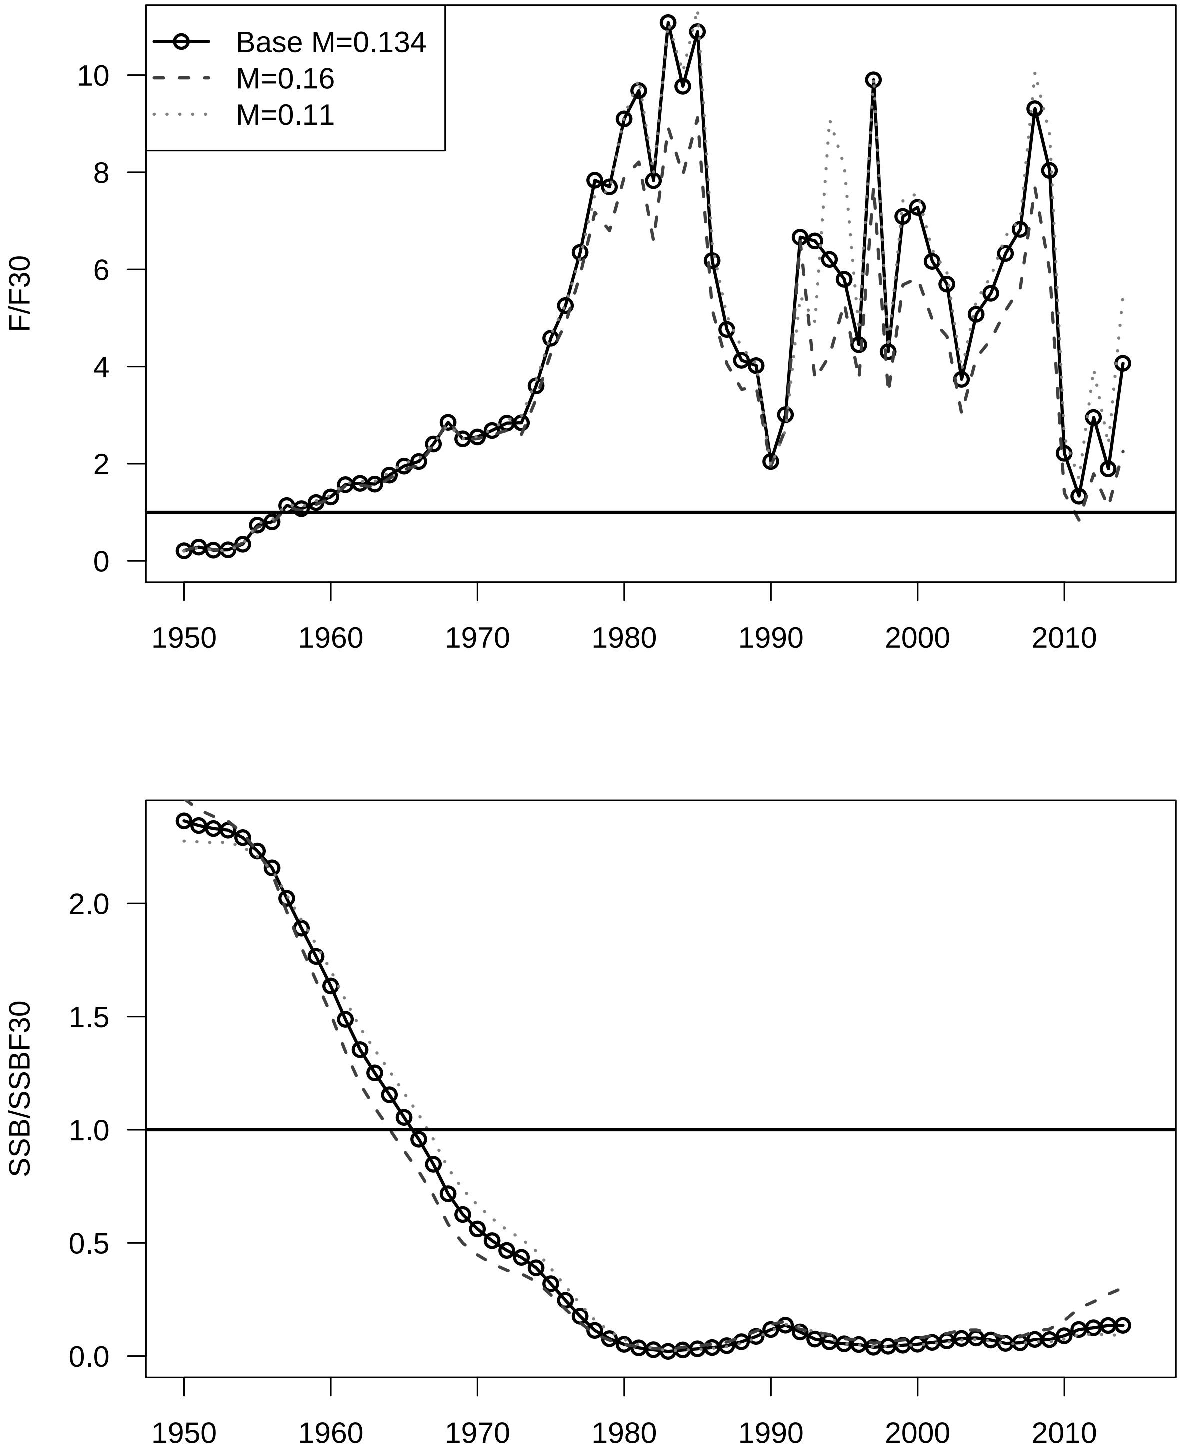

Figure 41. Sensitivity to steepness (sensitivity run S11). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

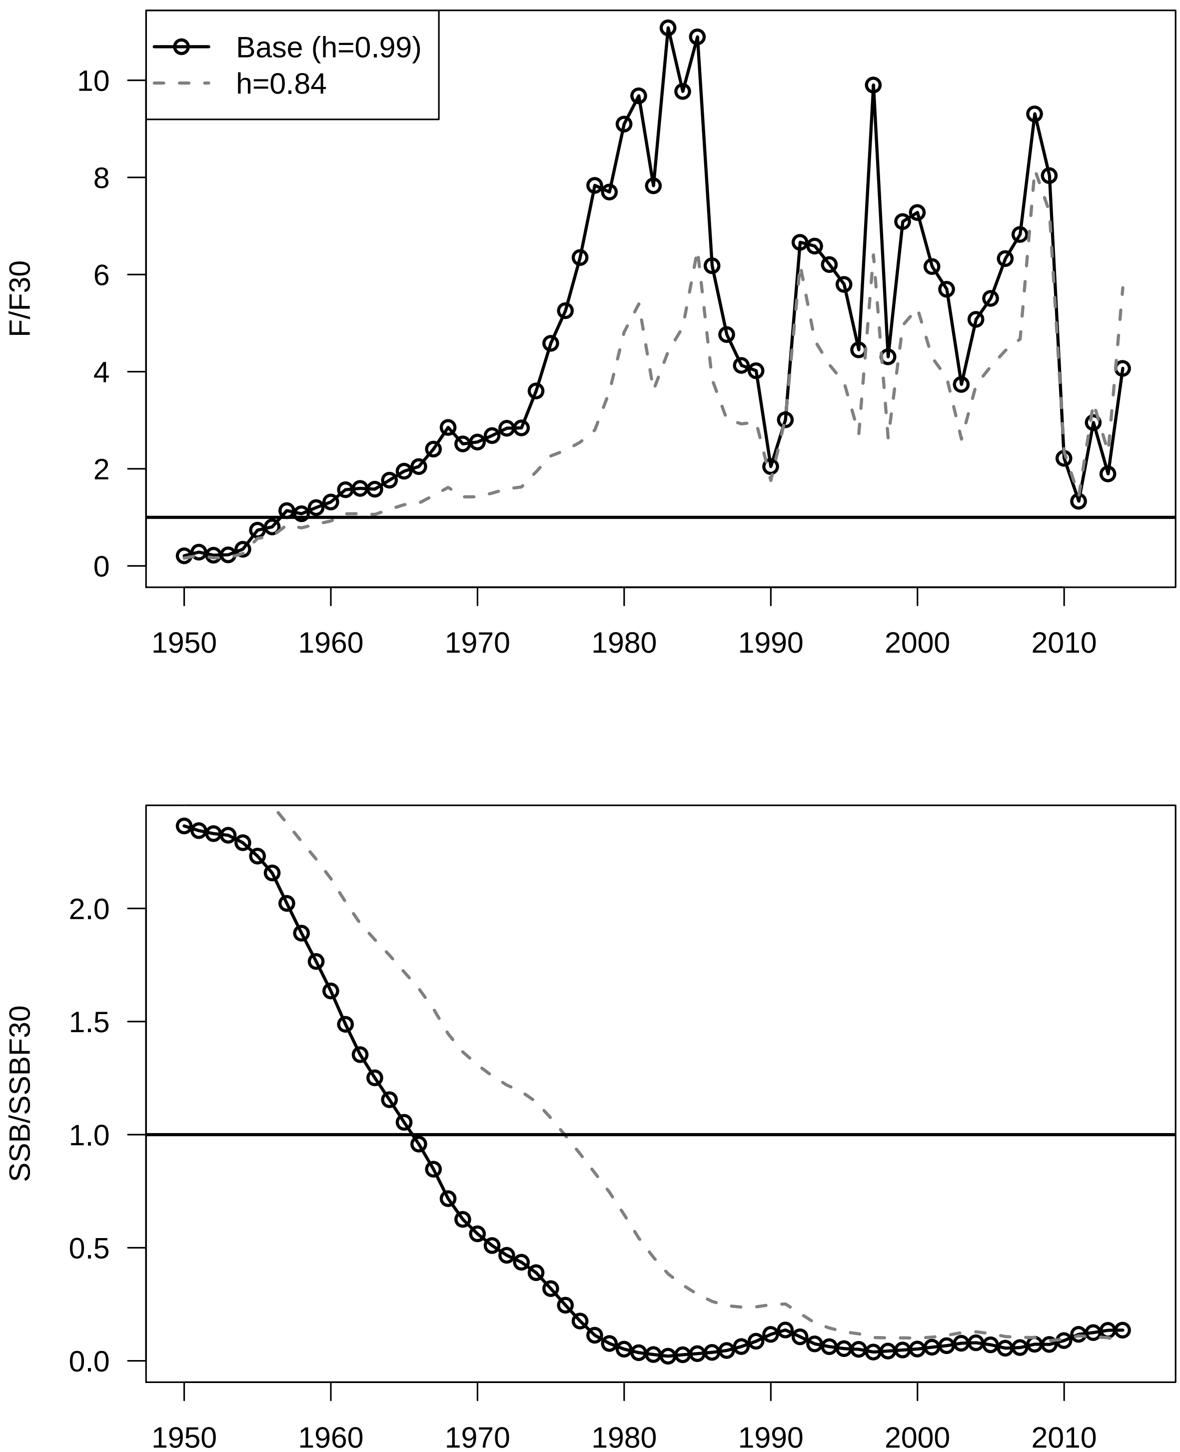

Figure 42. Sensitivity to start year (1978 compared to 1950) (sensitivity run S26). Top panel: Ratio of F to $F_{30\%}$. *Bottom panel: Ratio of* SSB *to* $SSB_{F30\%}$.

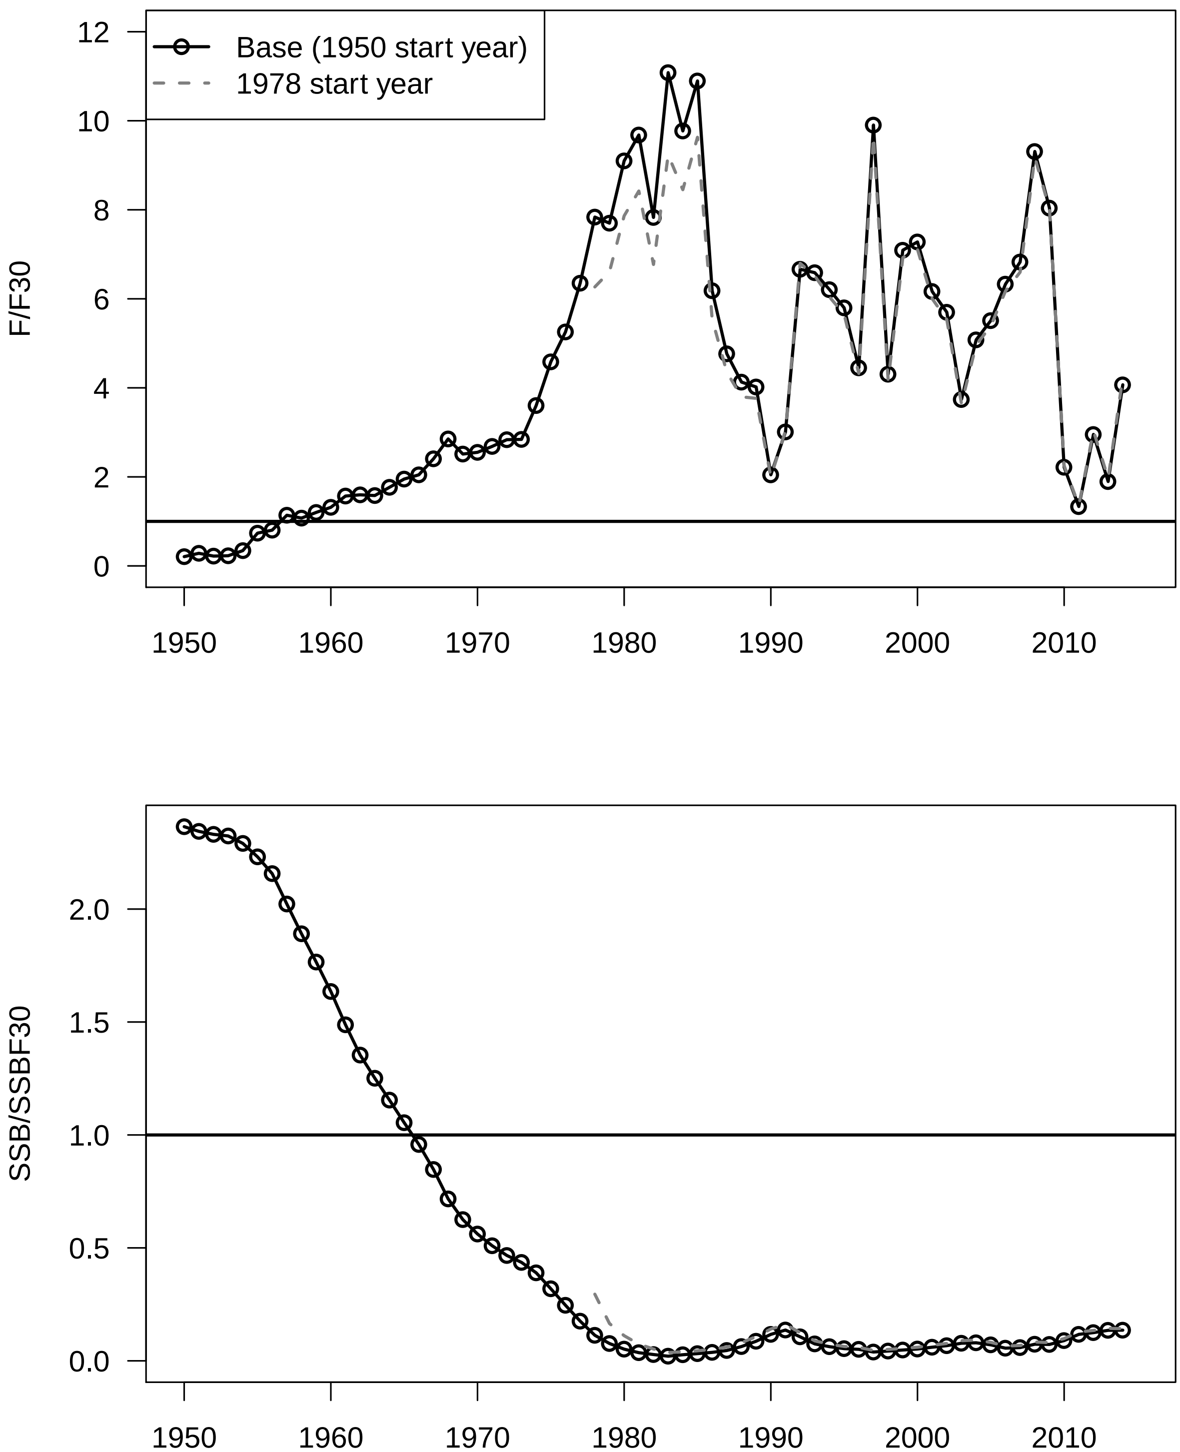

Figure 43. Sensitivity to aging error matrix (sensitivity run S13). Top panel: Ratio of F to $F_{30\%}$*. Bottom panel: Ratio of* SSB *to* $\mathrm{SSB}_{F30\%}$.

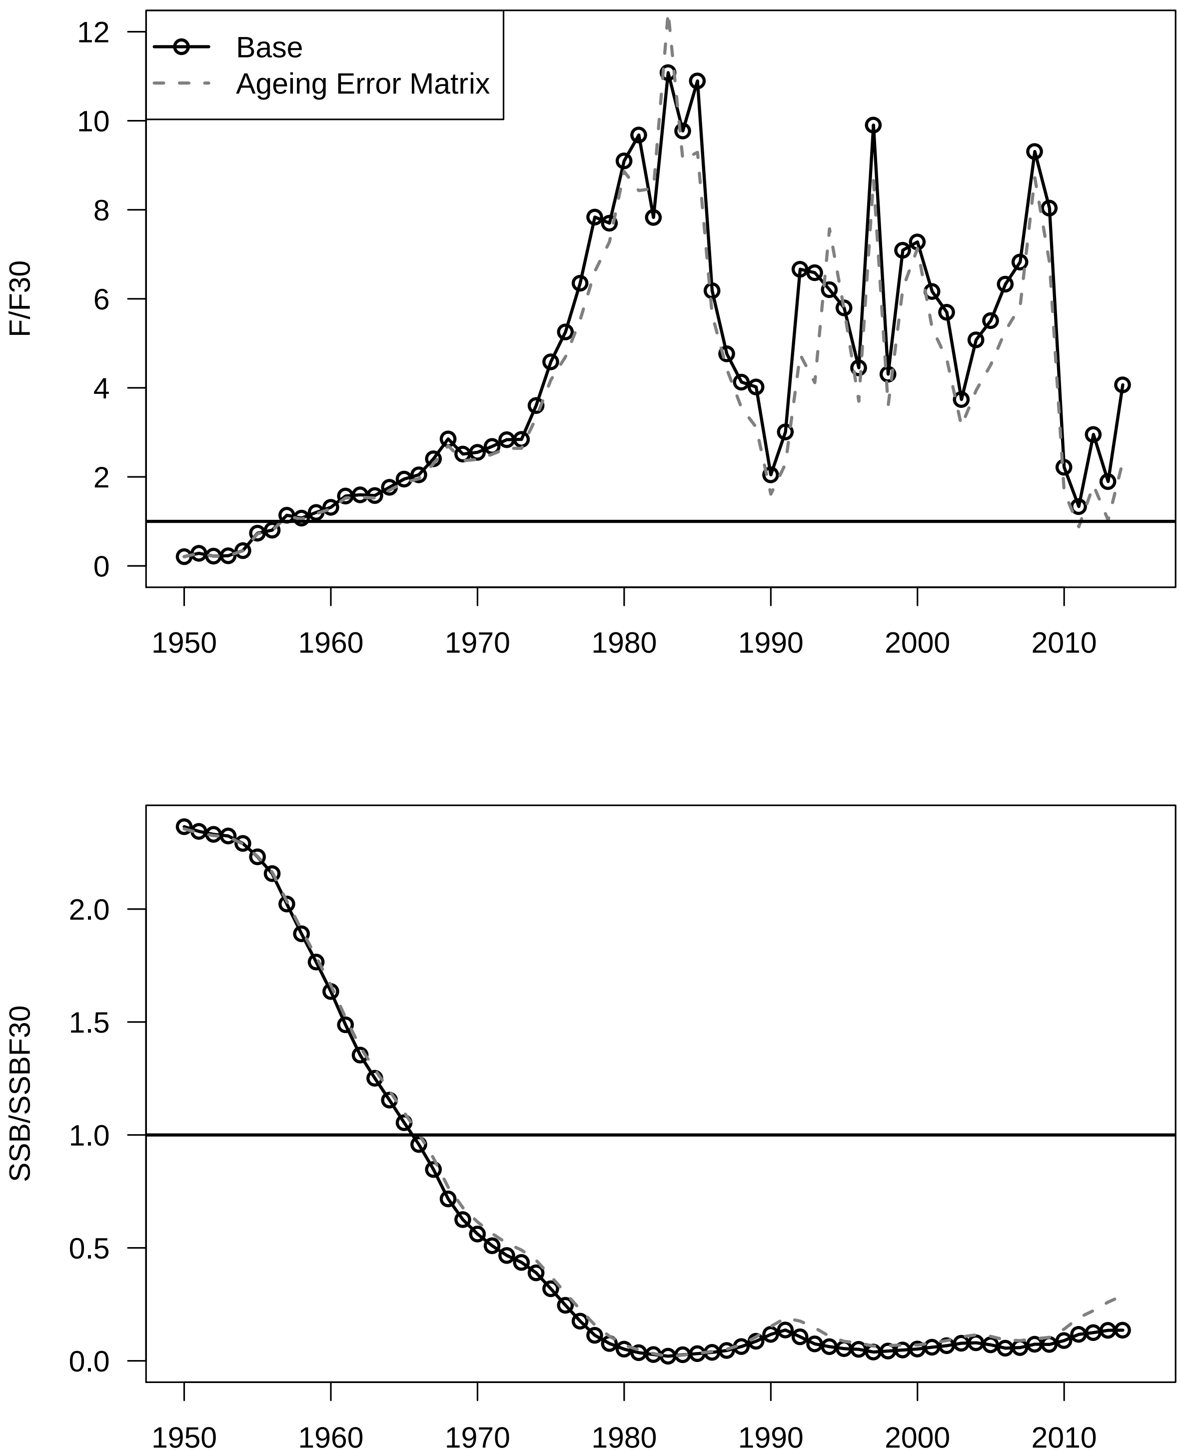

Figure 44. Sensitivity to batch number (sensitivity runs S14 and S15). Top panel: Ratio of F to $F_{30\%}$. *Bottom panel: Ratio of* SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

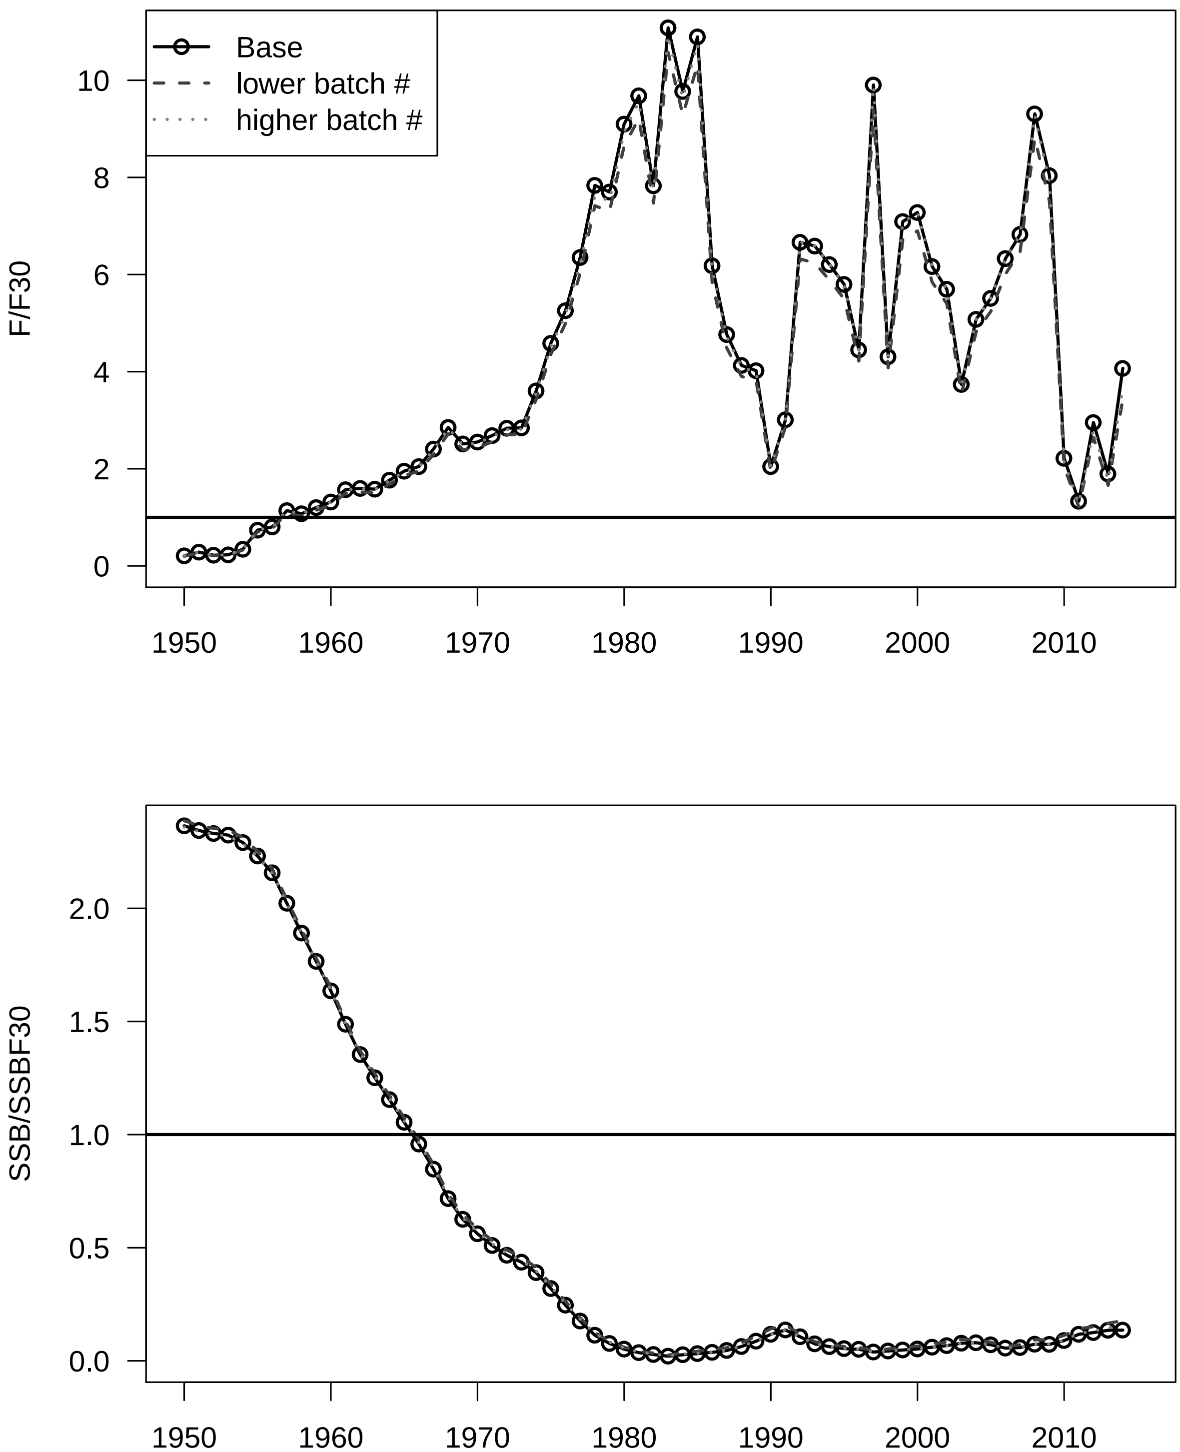

Figure 45. Sensitivity to various changes to SERFS video and trap indices (sensitivity runs S2, S9, S22 and S23). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\text{SSB}_{\text{F30\%}}$.

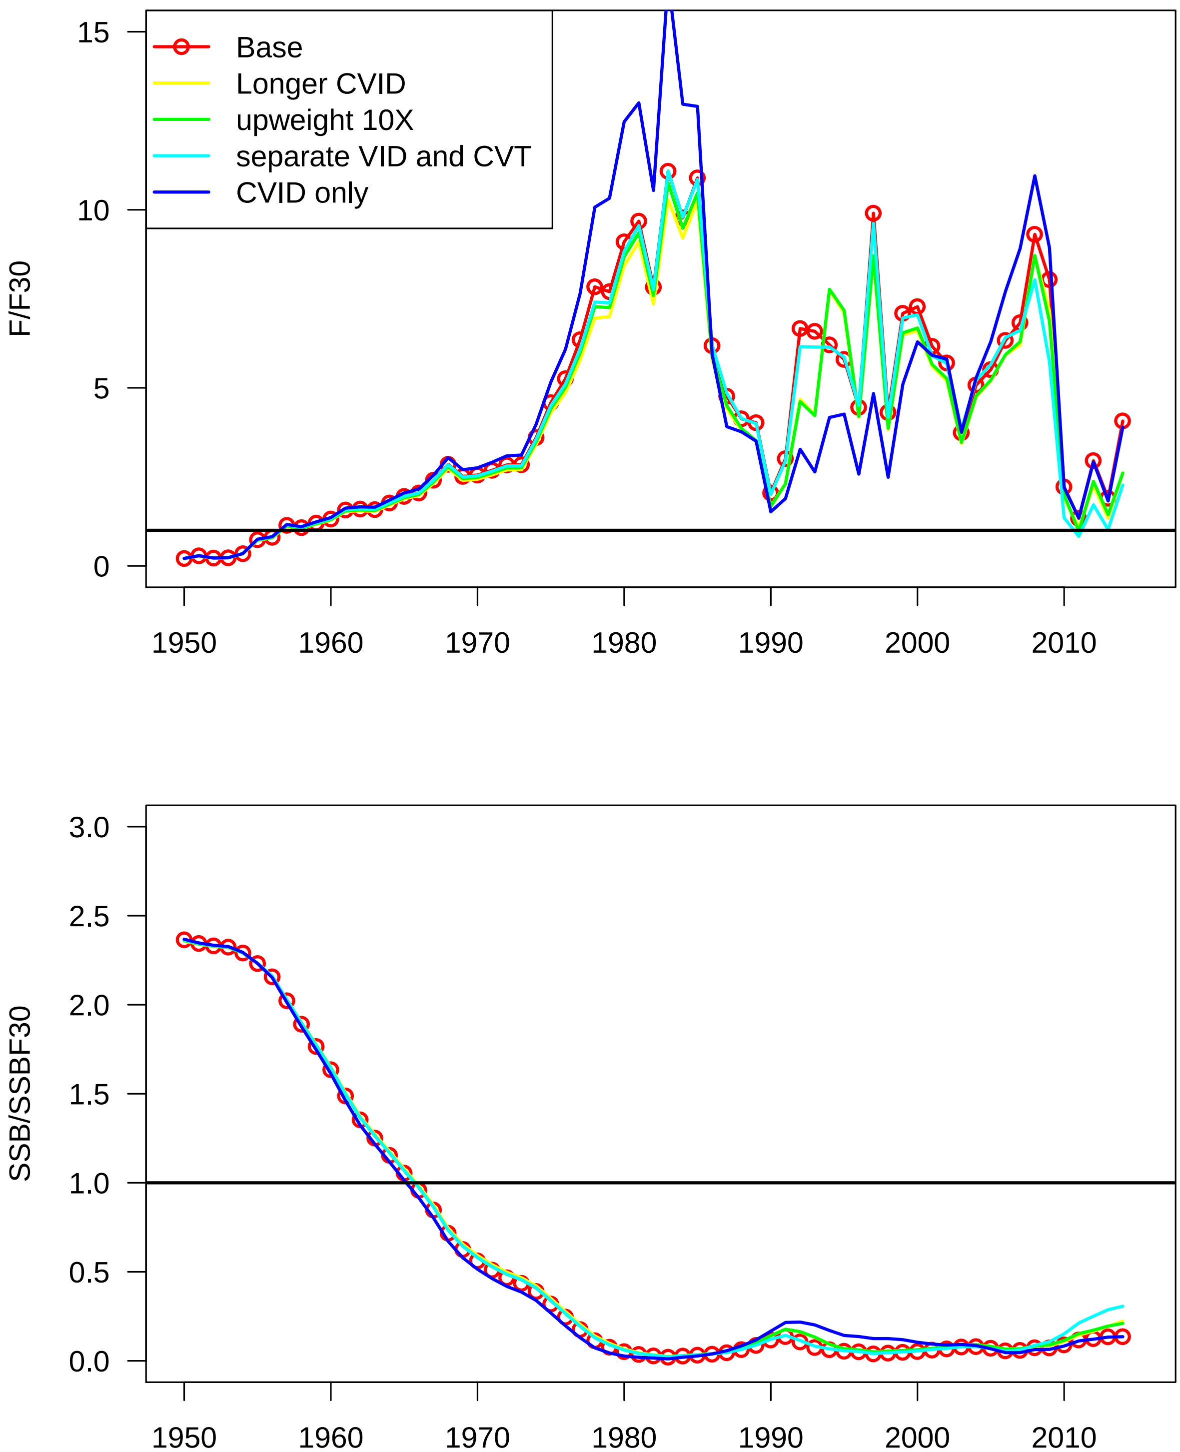

Figure 46. Sensitivity to discard mortality (sensitivity run S7 and S8). Top panel: Ratio of F to $F_{30\%}$. *Bottom panel: Ratio of* SSB *to* $SSB_{F30\%}$.

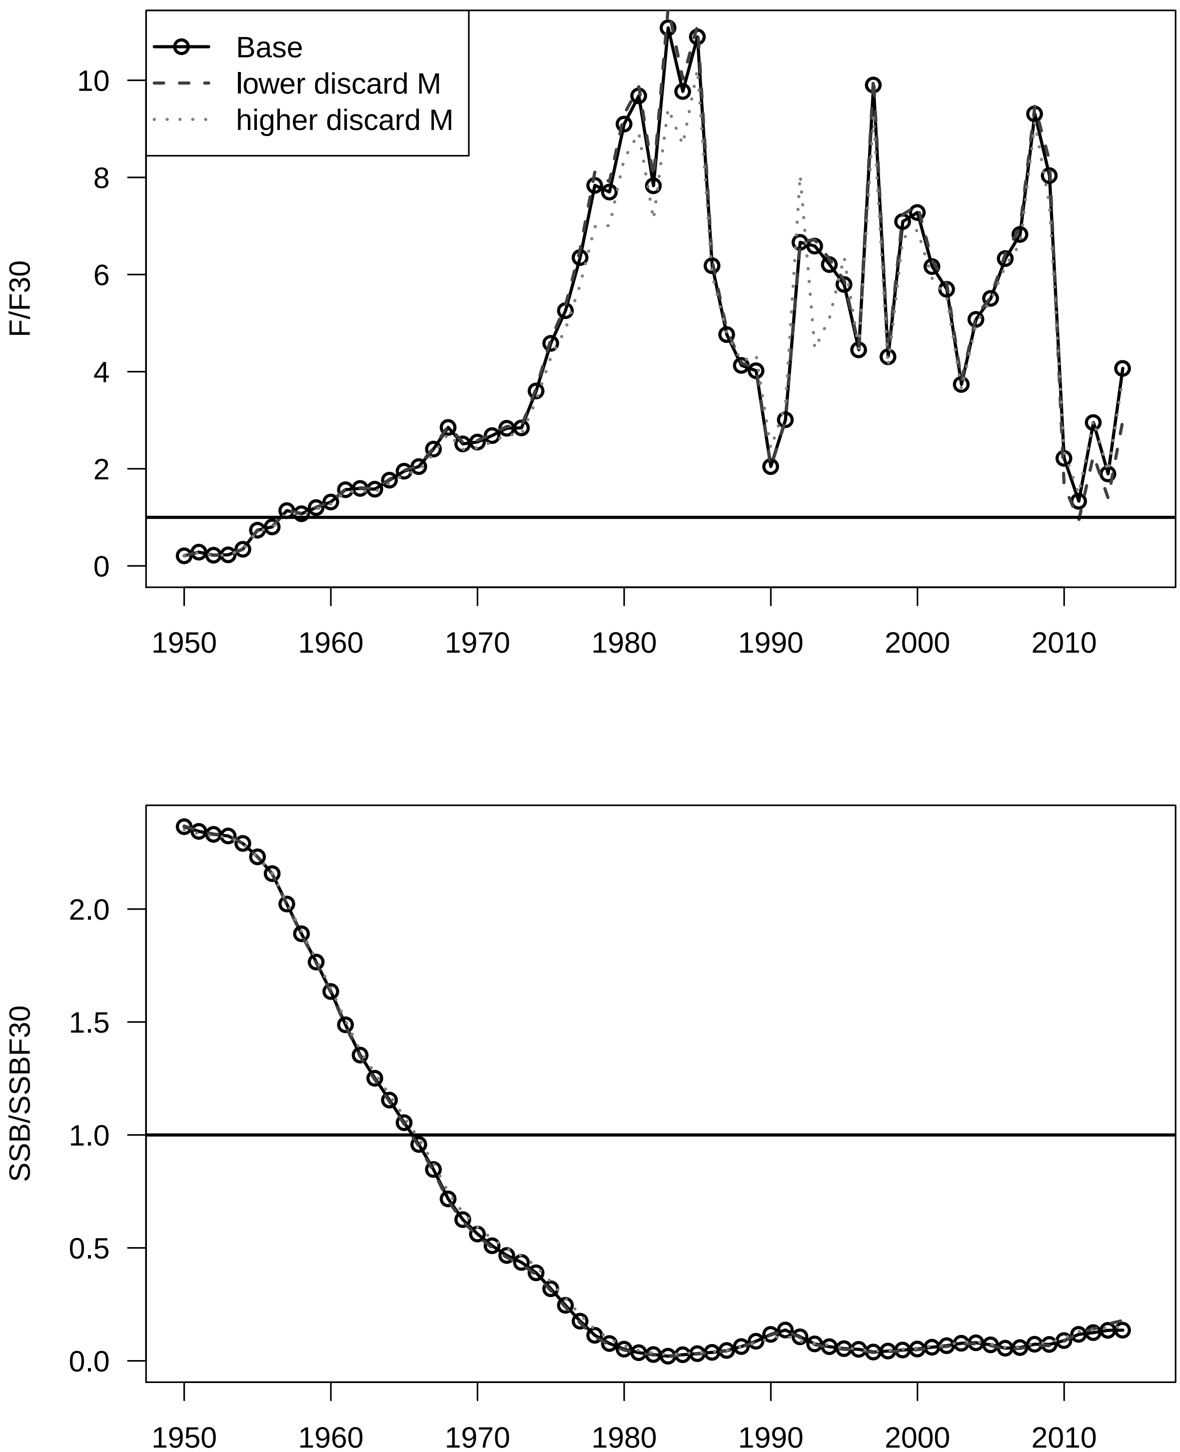

Figure 47. Sensitivity to dome-shaped selectivity for commercial handline (sensitivity run S21). Top panel: Ratio of F *to* $F_{30\%}$*. Bottom panel: Ratio of* SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$*.*

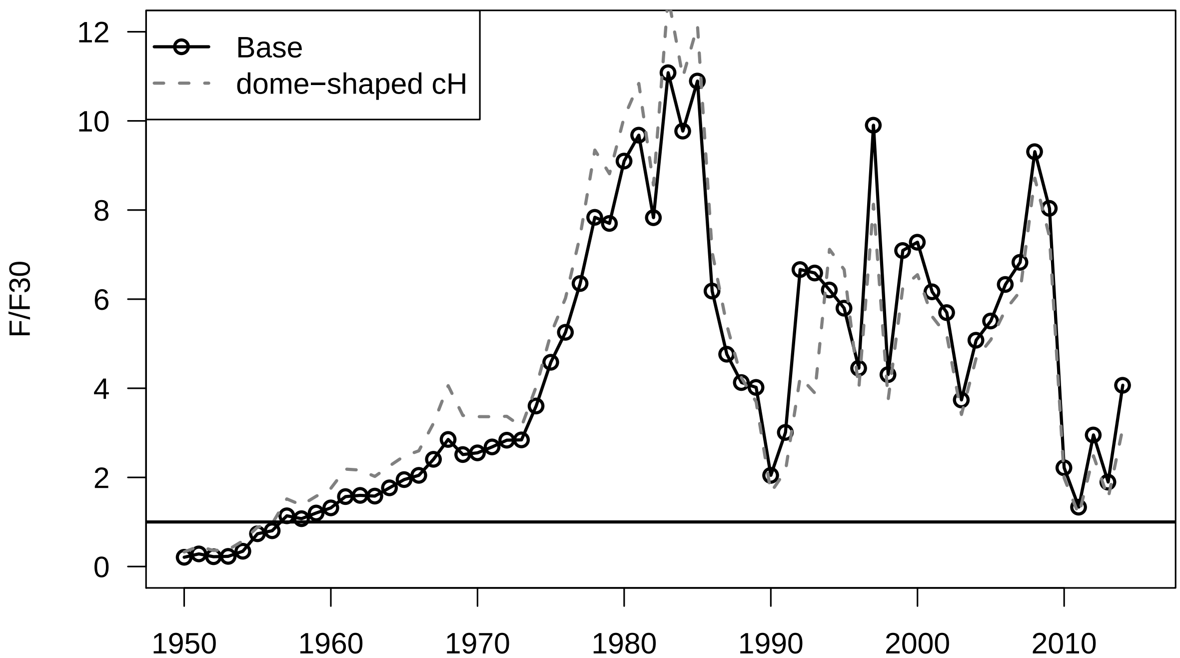

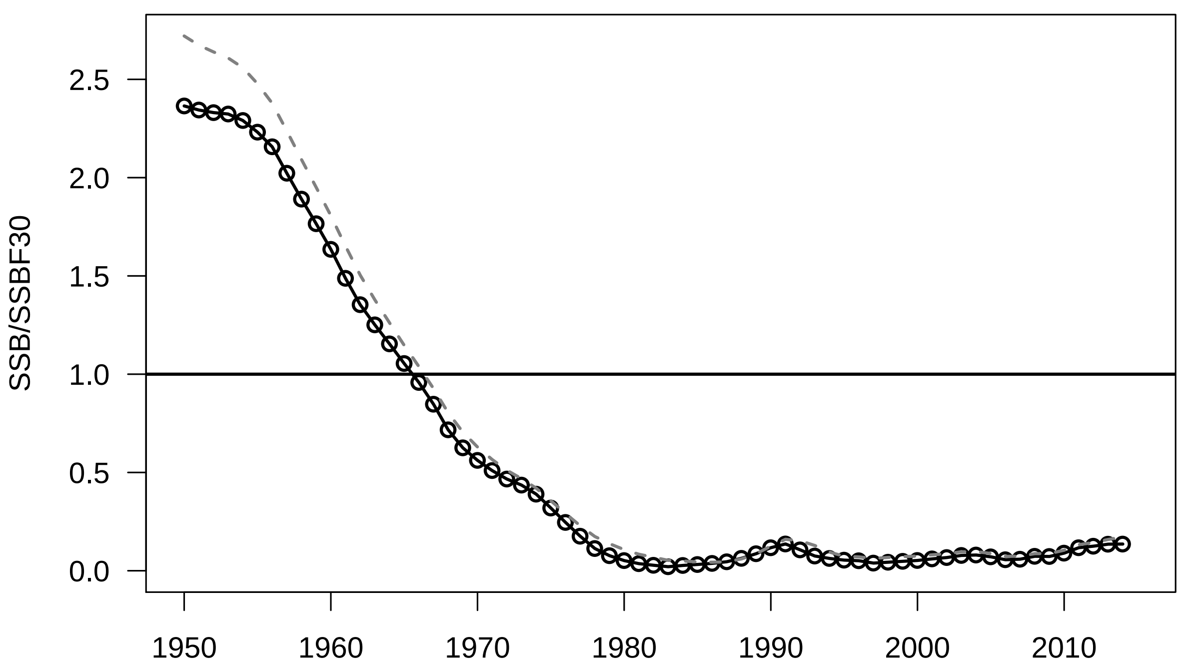

Figure 48. Sensitivity to various changes to fishery dependent indices (sensitivity runs S1, S3, S4, and S25). Top panel: Ratio of F *to* $F_{30\%}$*. Bottom panel: Ratio of* SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

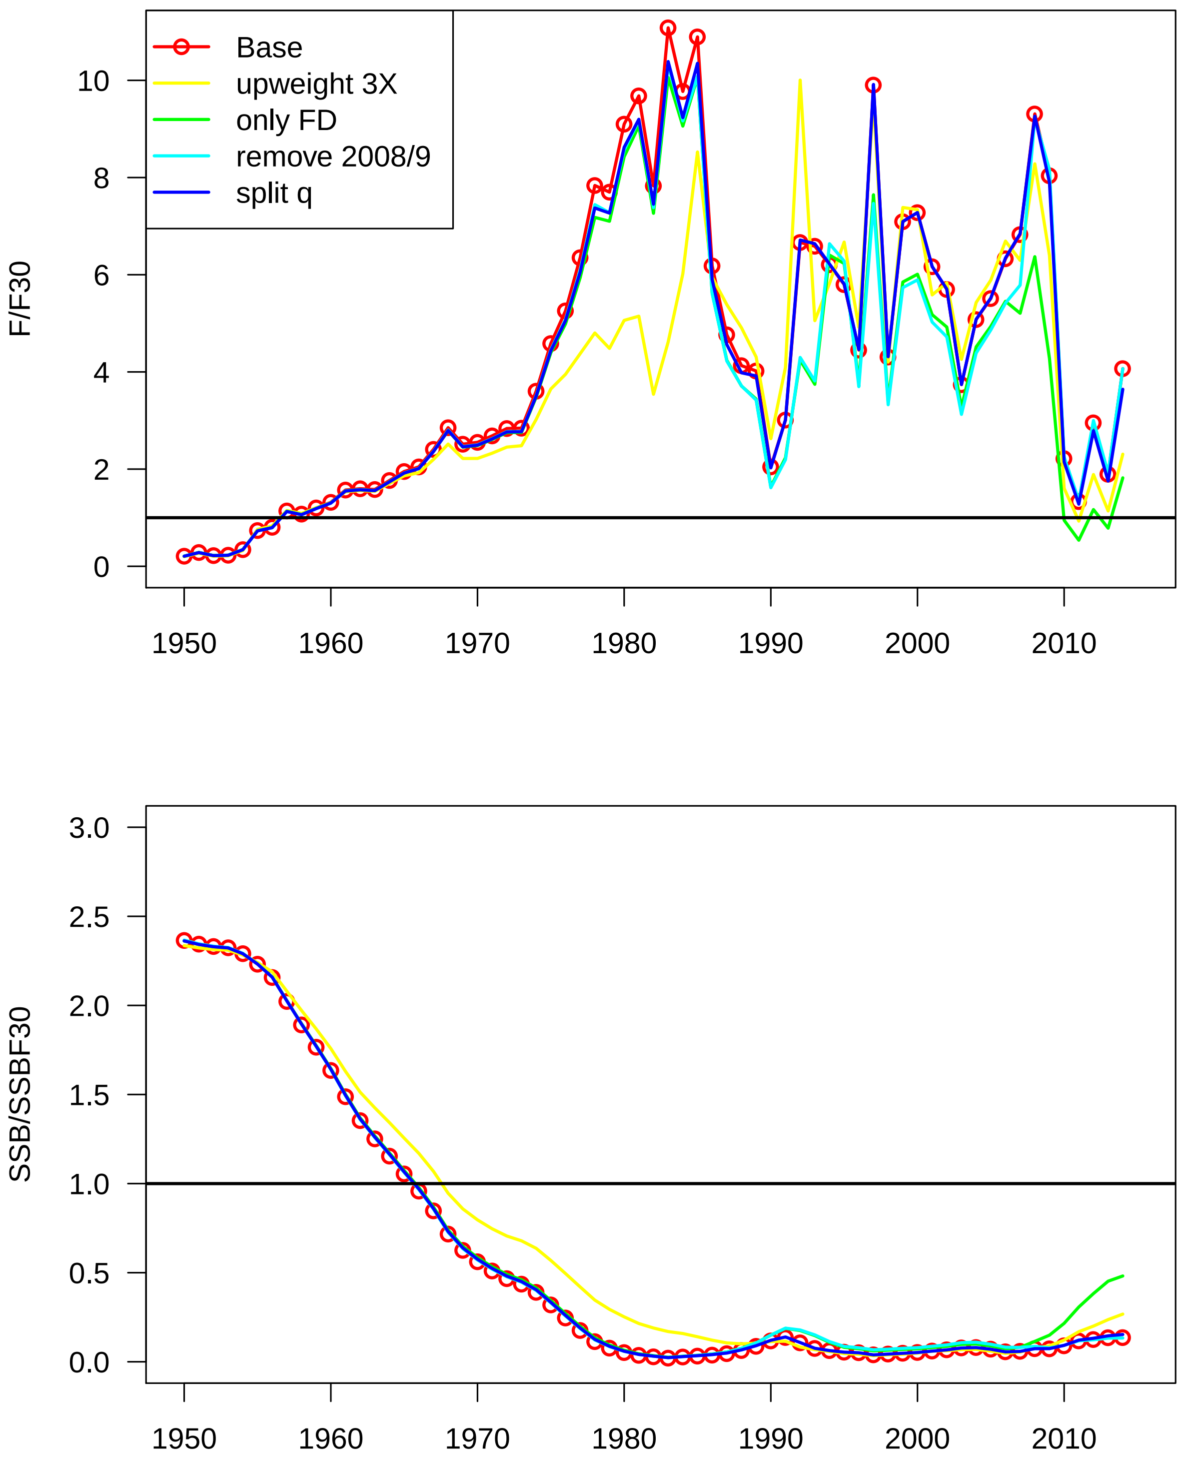

Figure 49. Sensitivity to not fixing selectivities (sensitivity run S27). Top panel: Ratio of F to $F_{30\%}$. *Bottom panel: Ratio of* SSB *to* $SSB_{F30\%}$.

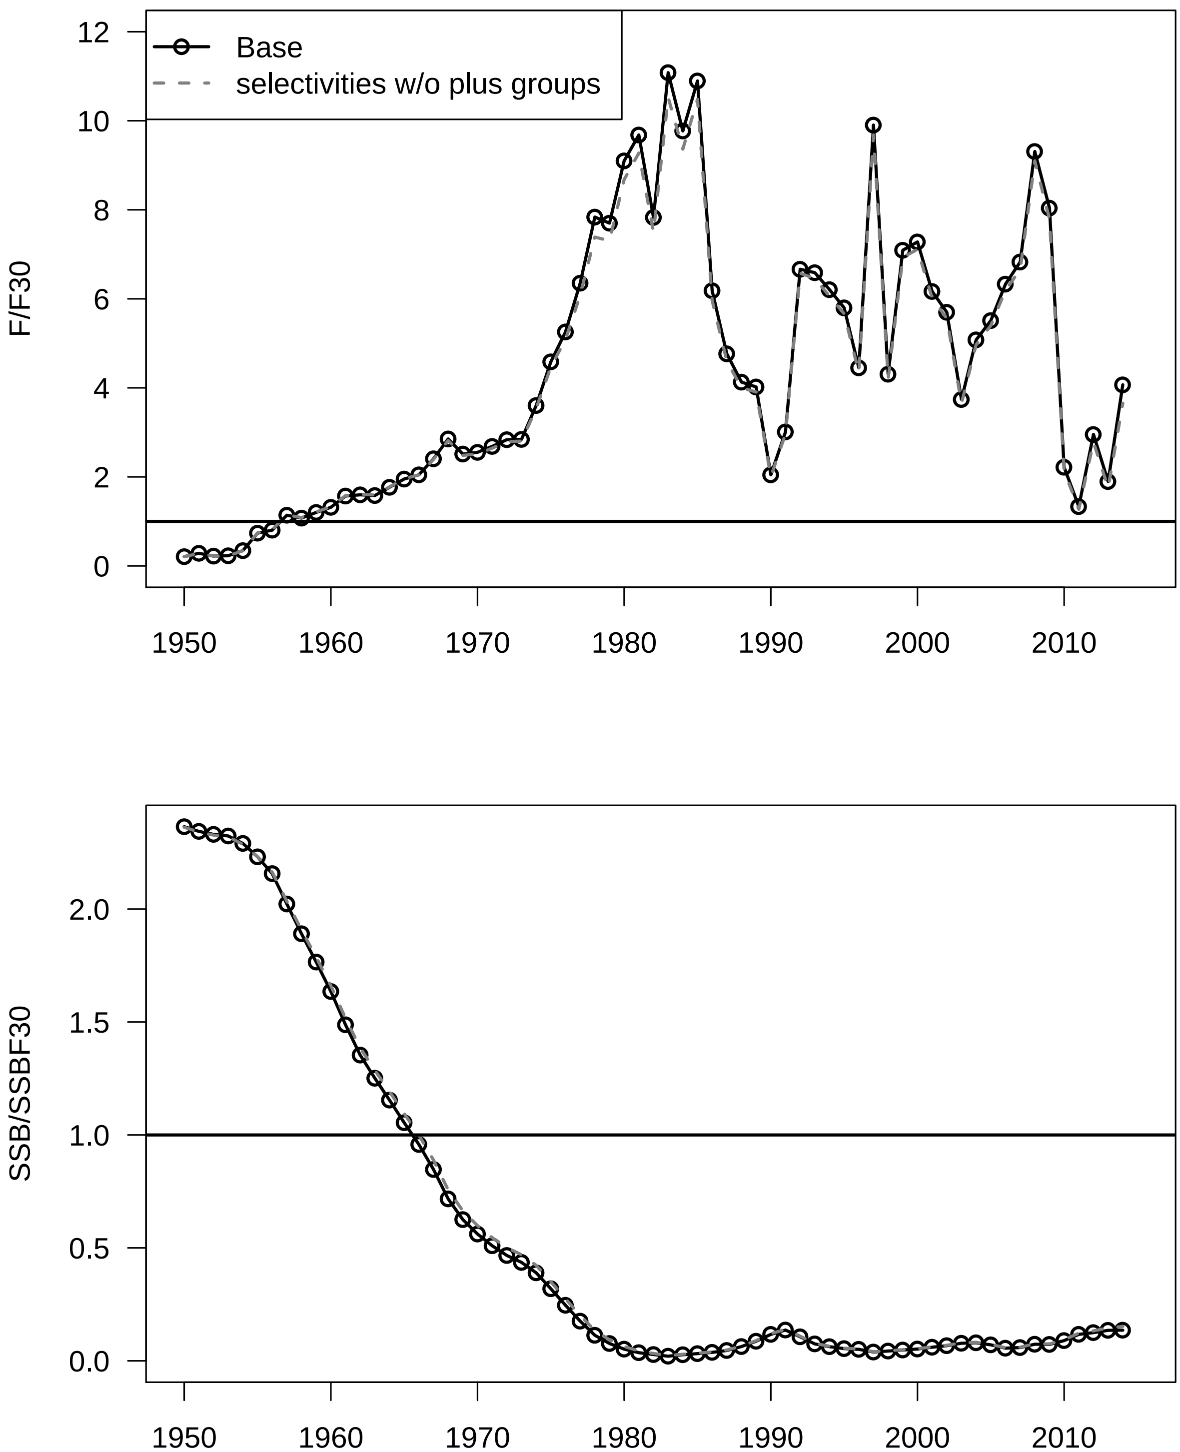

Figure 50. Sensitivity to dropping or truncating headboat discard index (sensitivity runs S12 and S16). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

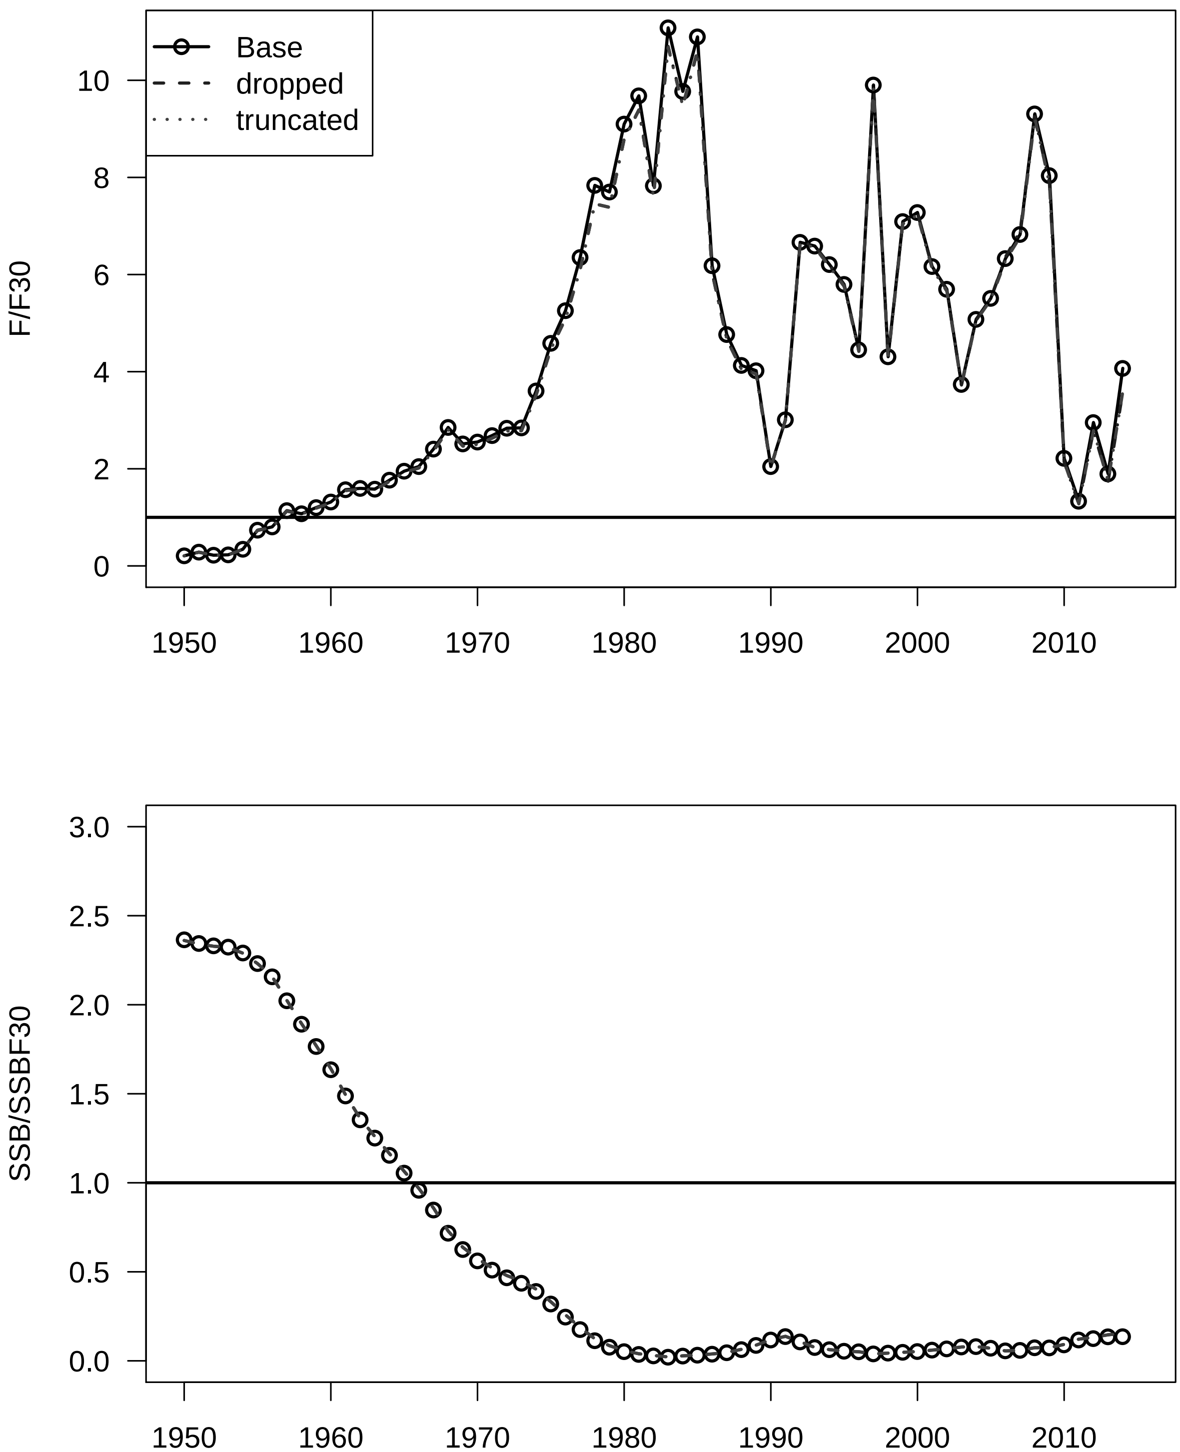

Figure 51. Sensitivity to higher or lower estimates of landings and discards (sensitivity runs S17–S20). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\text{SSB}_{\text{F30\%}}$.

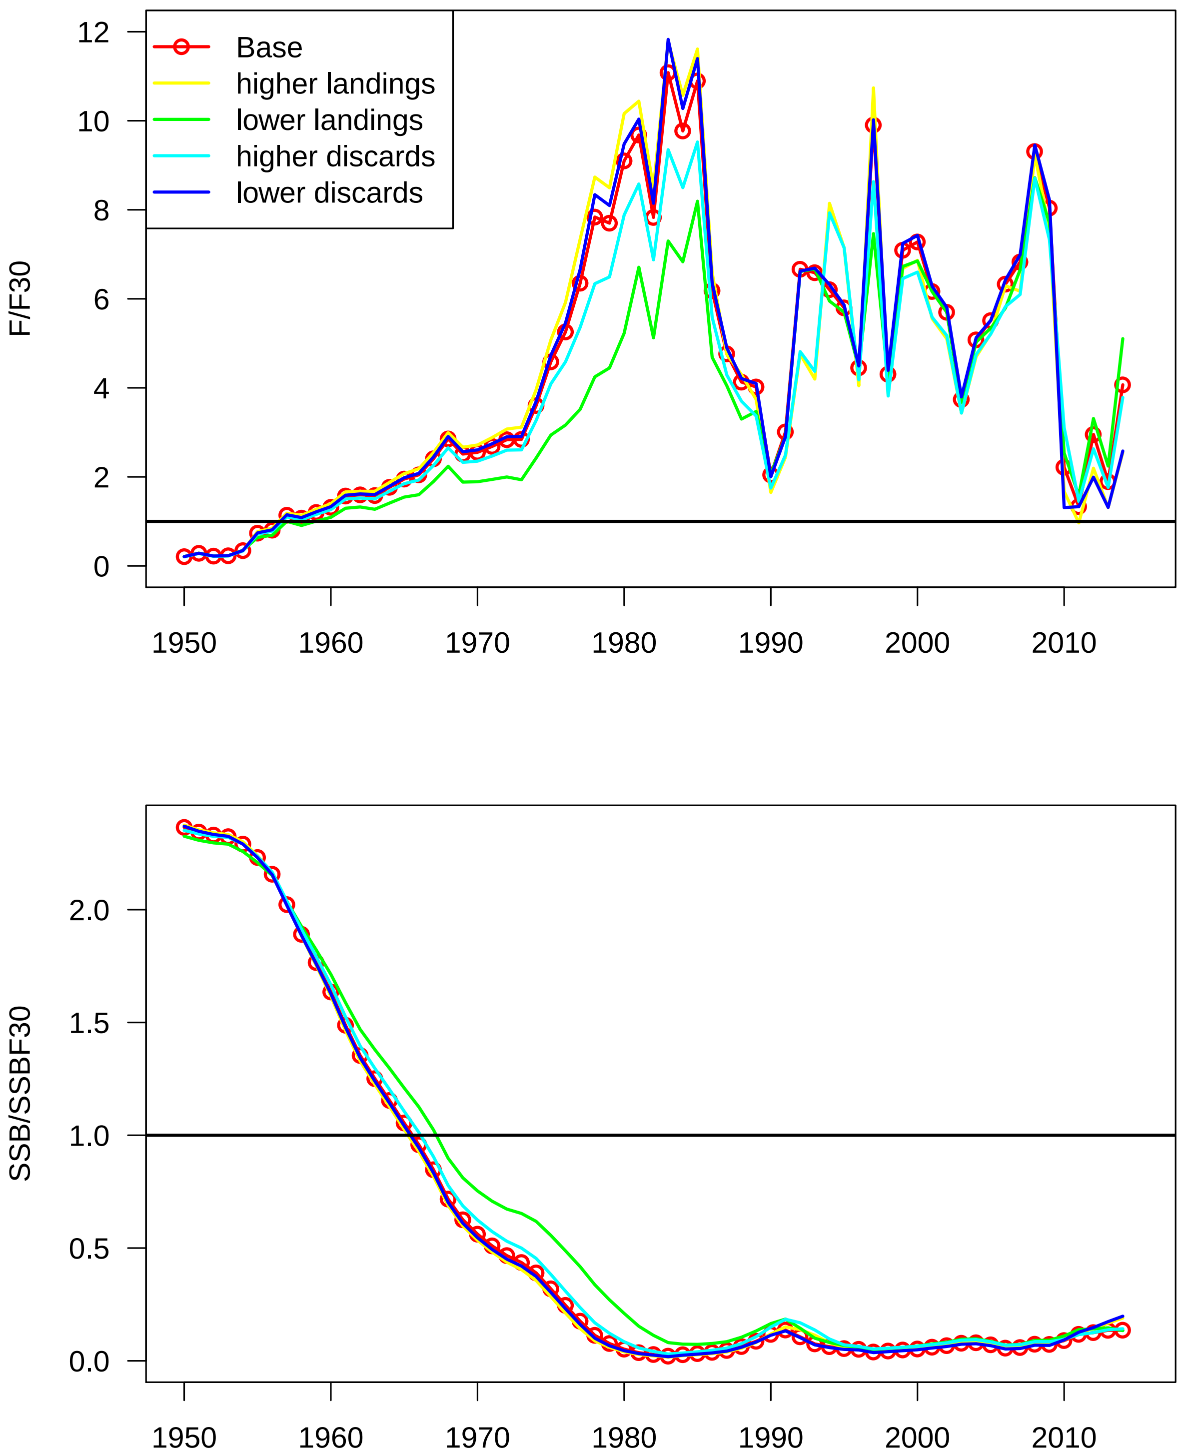

Figure 52. Sensitivity to smoothed 1984 and 1985 MRIP landings (sensitivity run S10). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

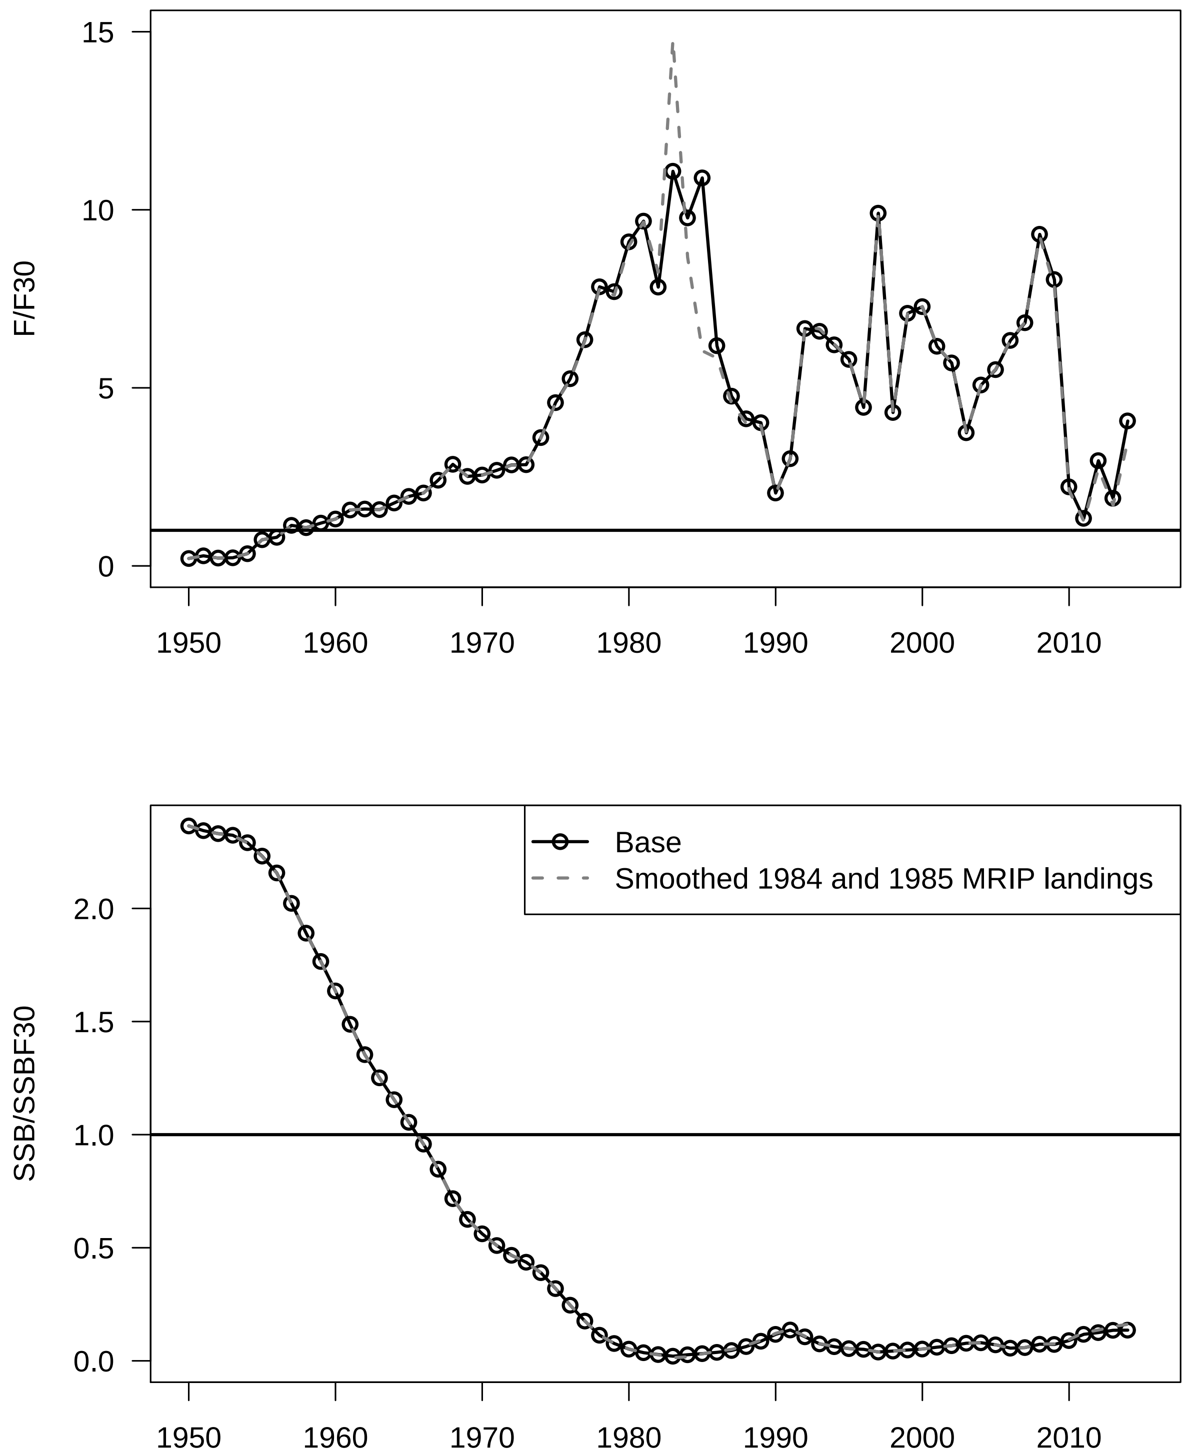

Figure 53. Sensitivity to continuity assumptions from SEDAR 24 (sensitivity run S24). Top panel: Ratio of F to $F_{30\%}$*. Bottom panel: Ratio of* SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

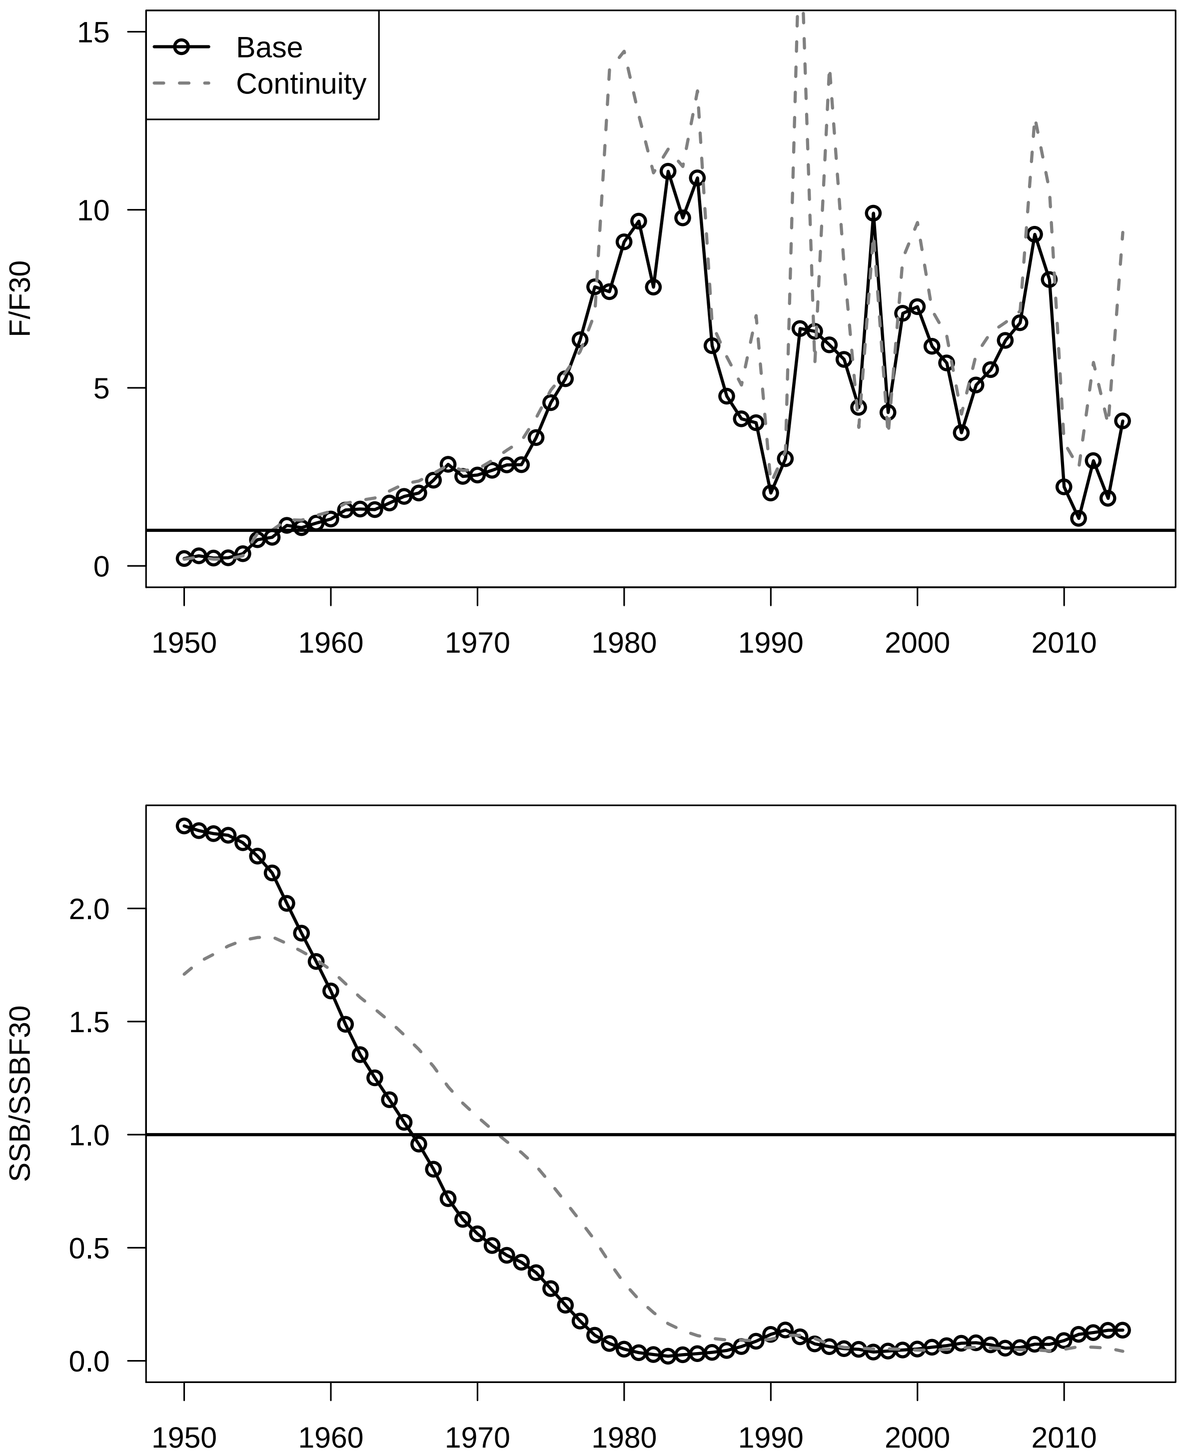

Figure 54. Phase plot of terminal status indicators from sensitivity runs of the Beaufort Assessment Model.

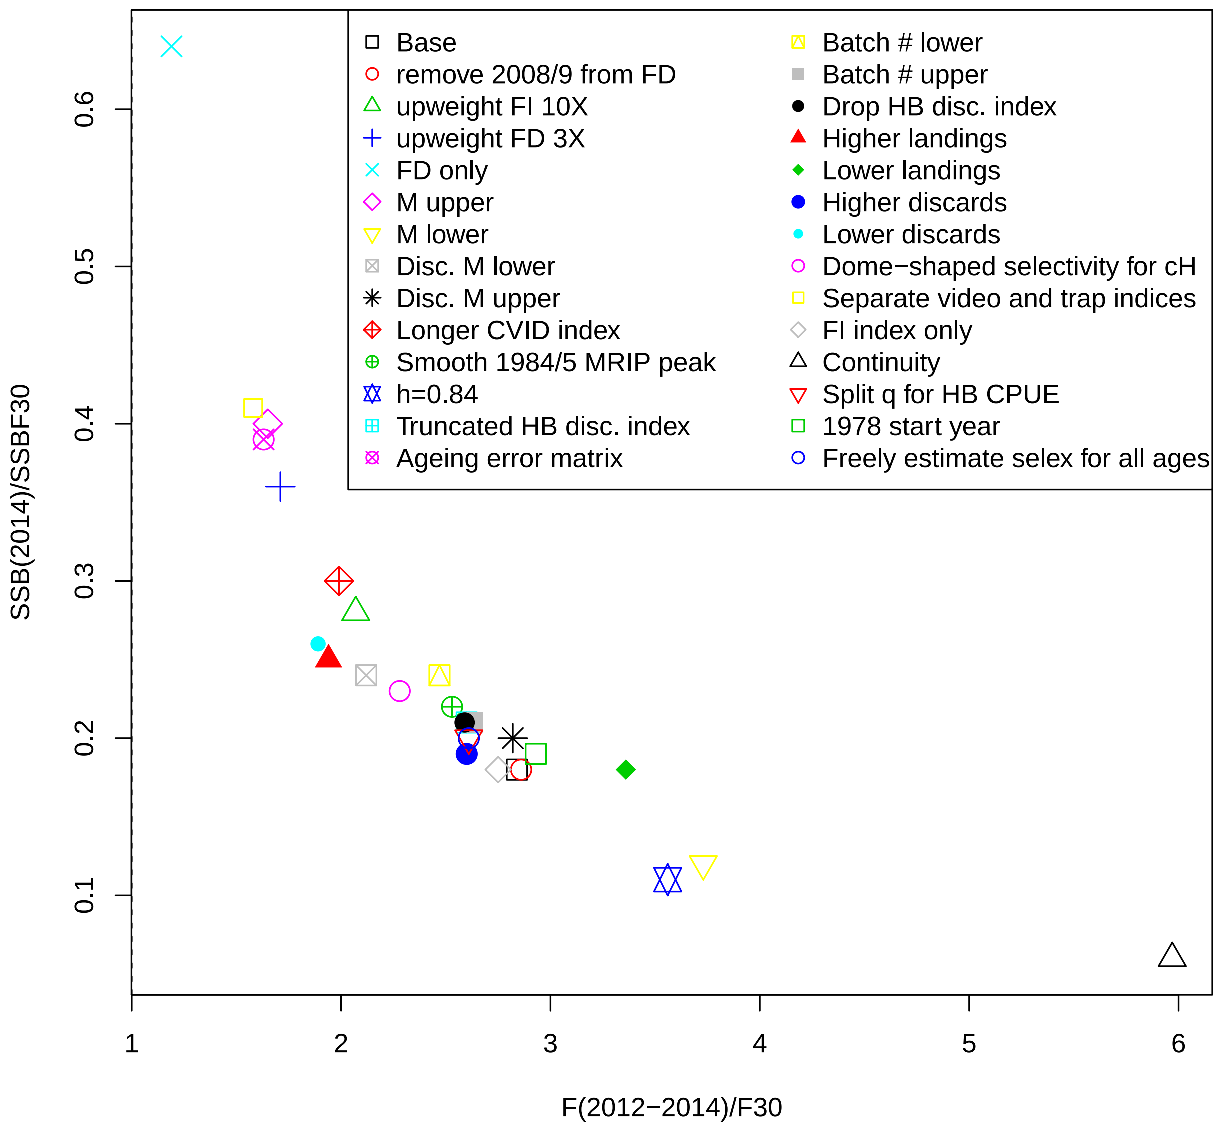

Figure 55. Retrospective analyses. Sensitivity to terminal year of data. Top panel: Fishing mortality rates. Middle panel: Recruits. Bottom panel: Spawning biomass. Closed circles show terminal-year estimates. Imperceptible lines overlap results of the base run.

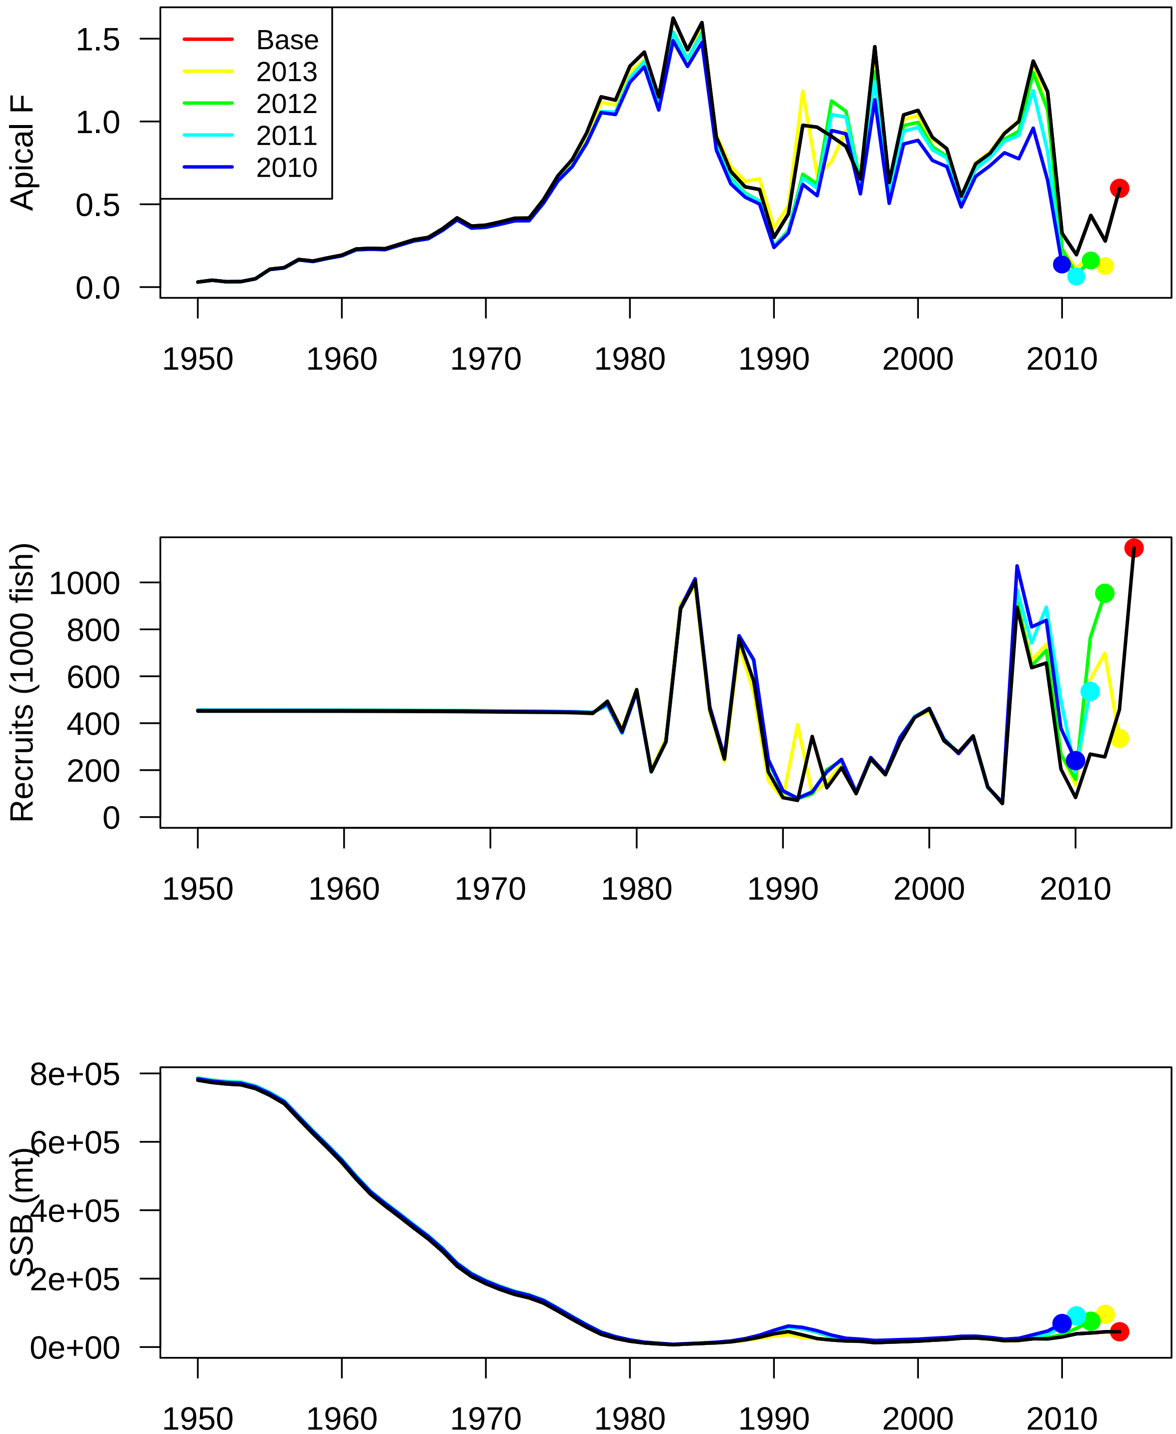

Figure 56. Projection results under scenario 1—fishing mortality rate at $F = 0$. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} and 95^{th} percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $SSB_{F30\%}$.

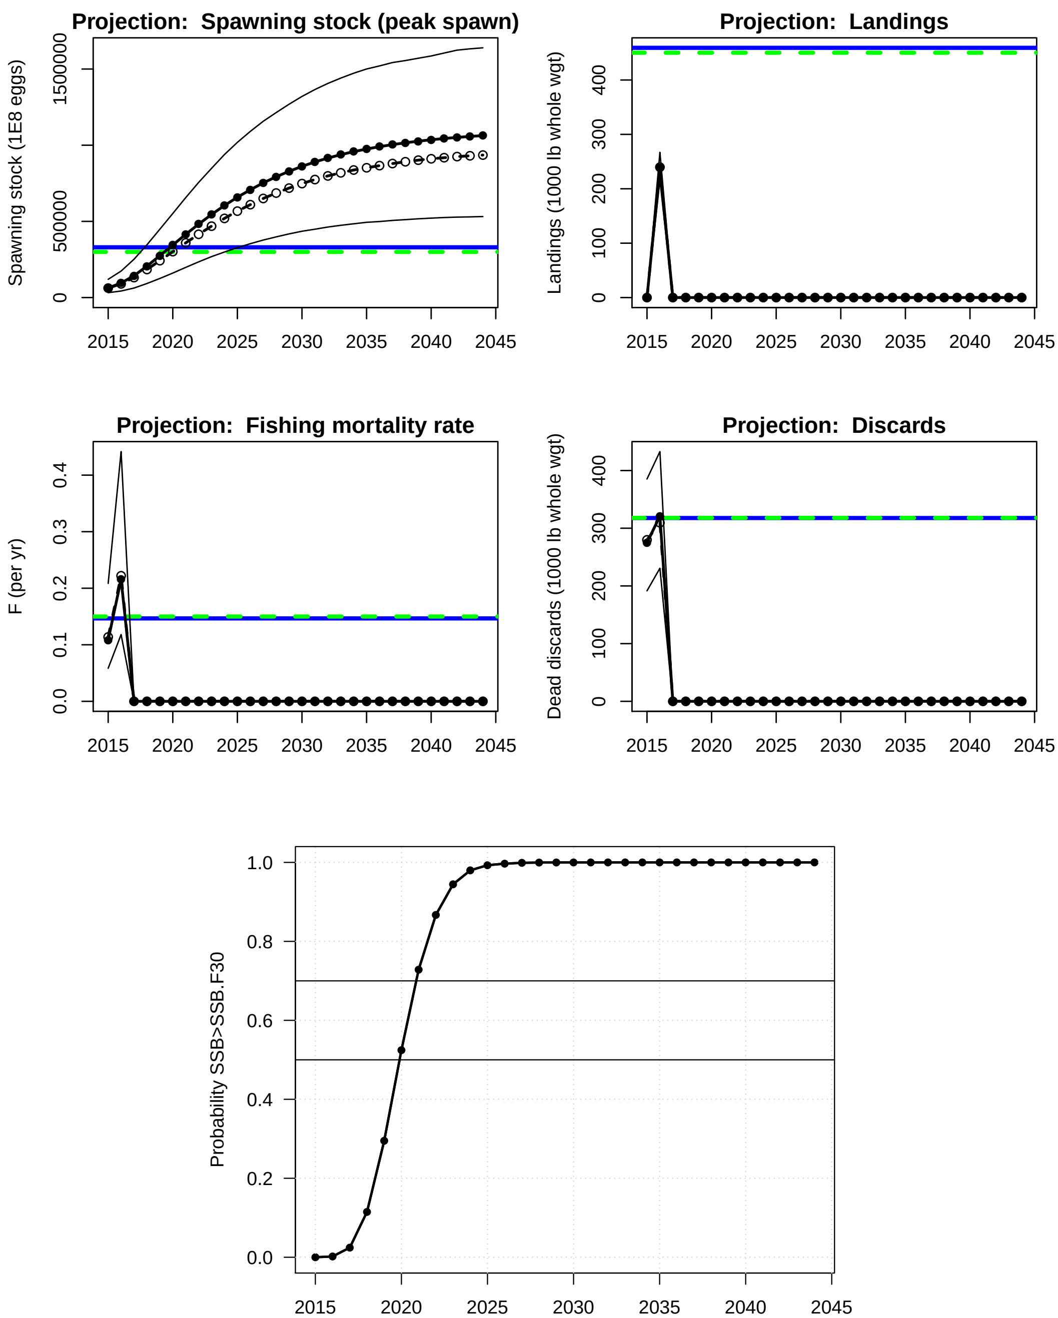

Figure 57. Projection results under scenario 2—fishing mortality rate at $F = F_{\text{current}}$. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} and 95^{th} percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $\text{SSB}_{\text{F30\%}}$.

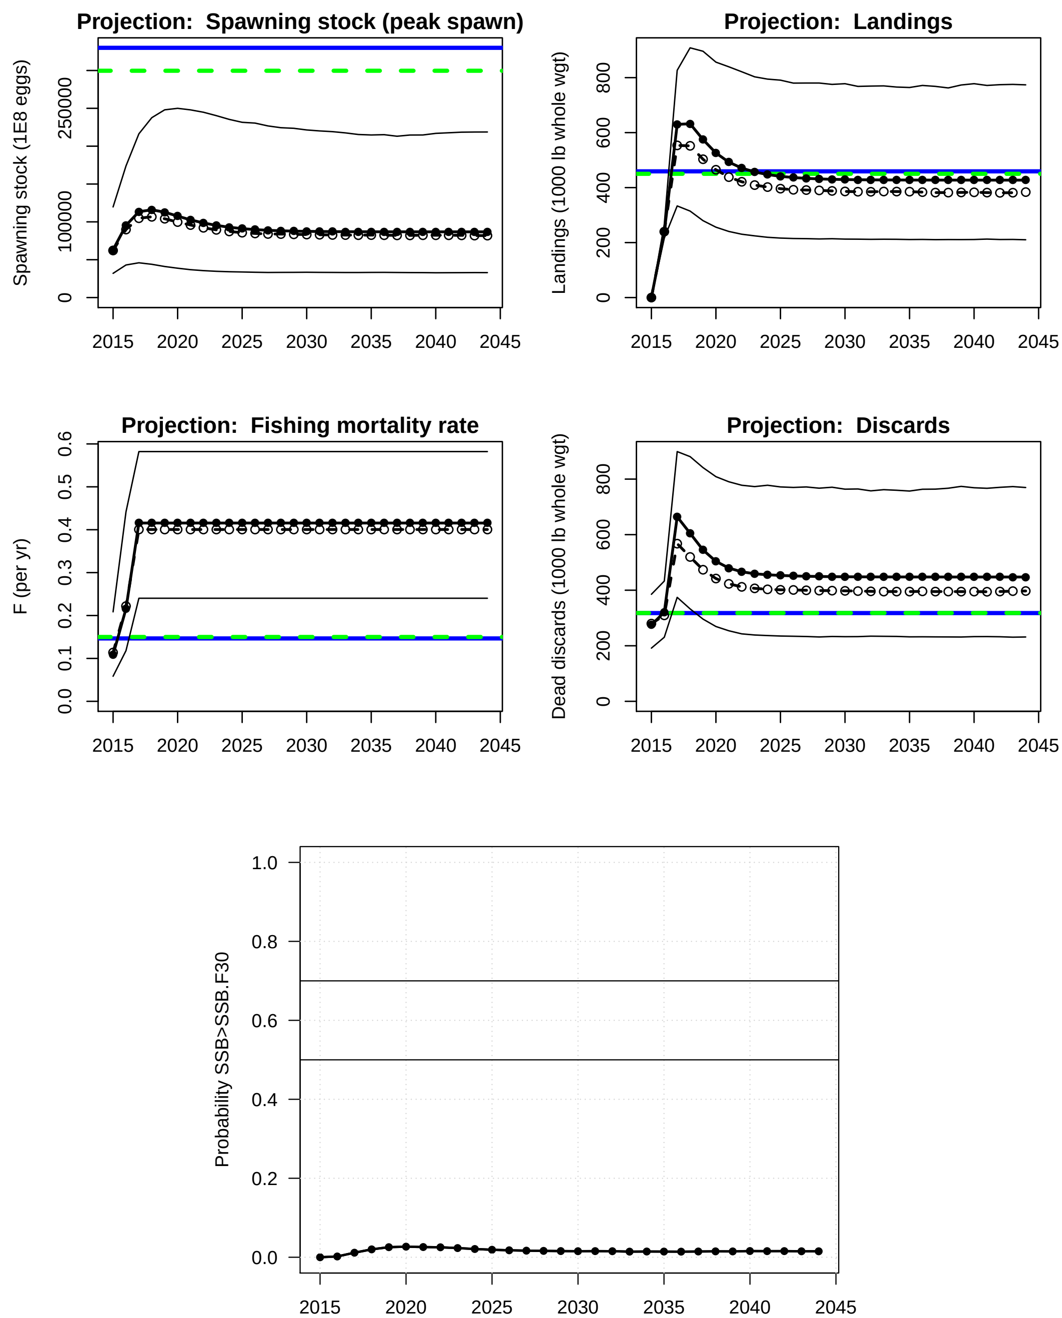

Figure 58. Projection results under scenario 3—fishing mortality rate at $F = F_{30\%}$. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} and 95^{th} percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $\mathrm{SSB}_{\mathrm{F30\%}}$.

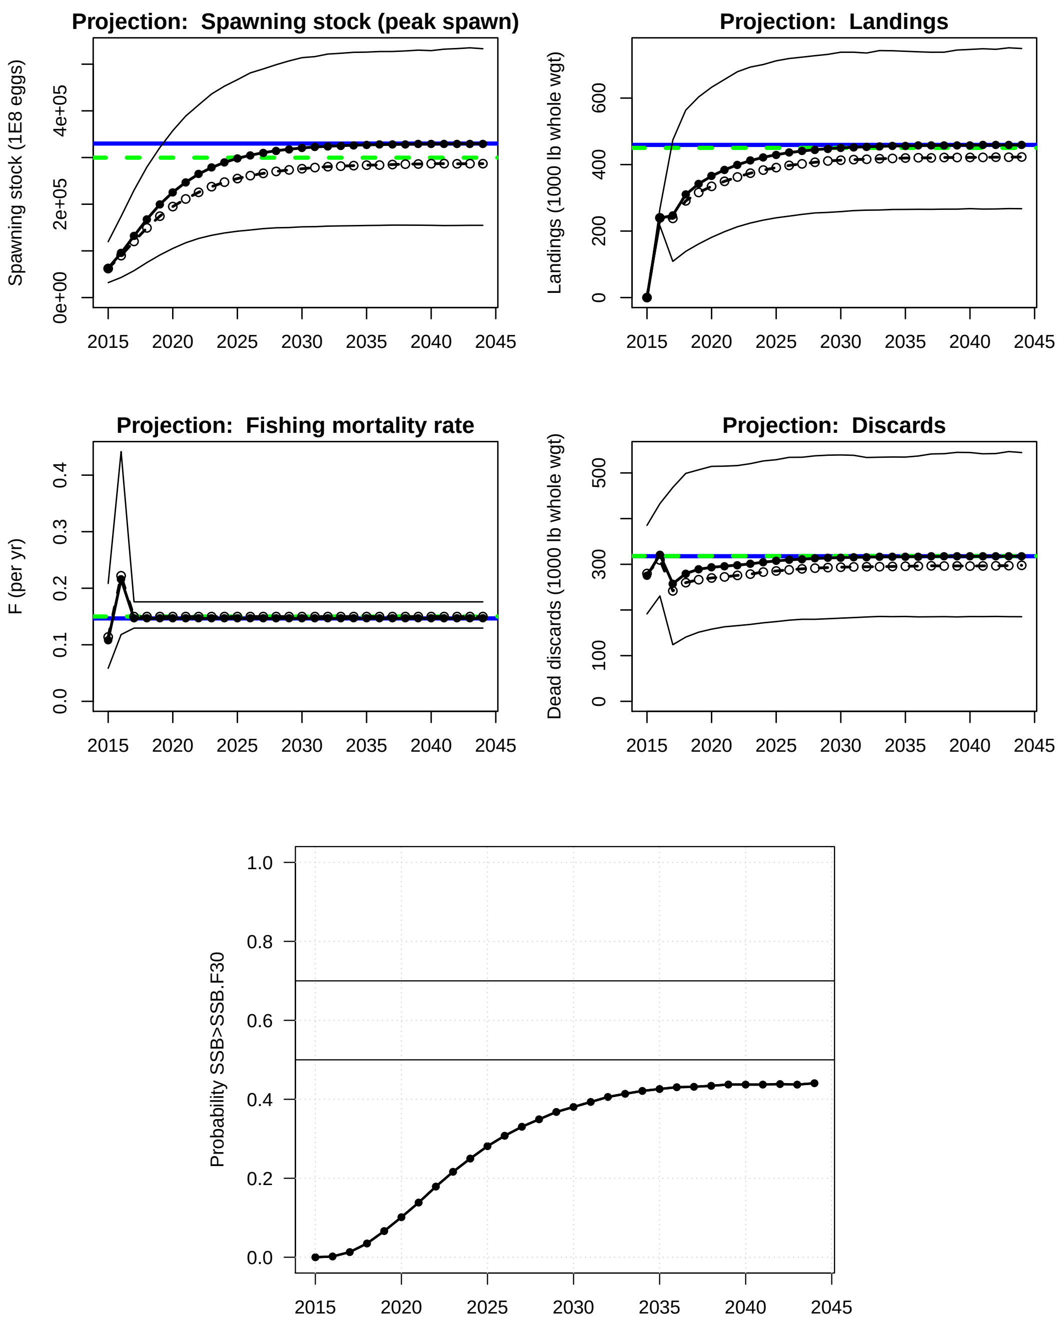

Figure 59. Projection results under scenario 4—fishing mortality rate at $F = 98\%F_{30\%}$. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} and 95^{th} percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $\mathrm{SSB}_{\mathrm{F30\%}}$.

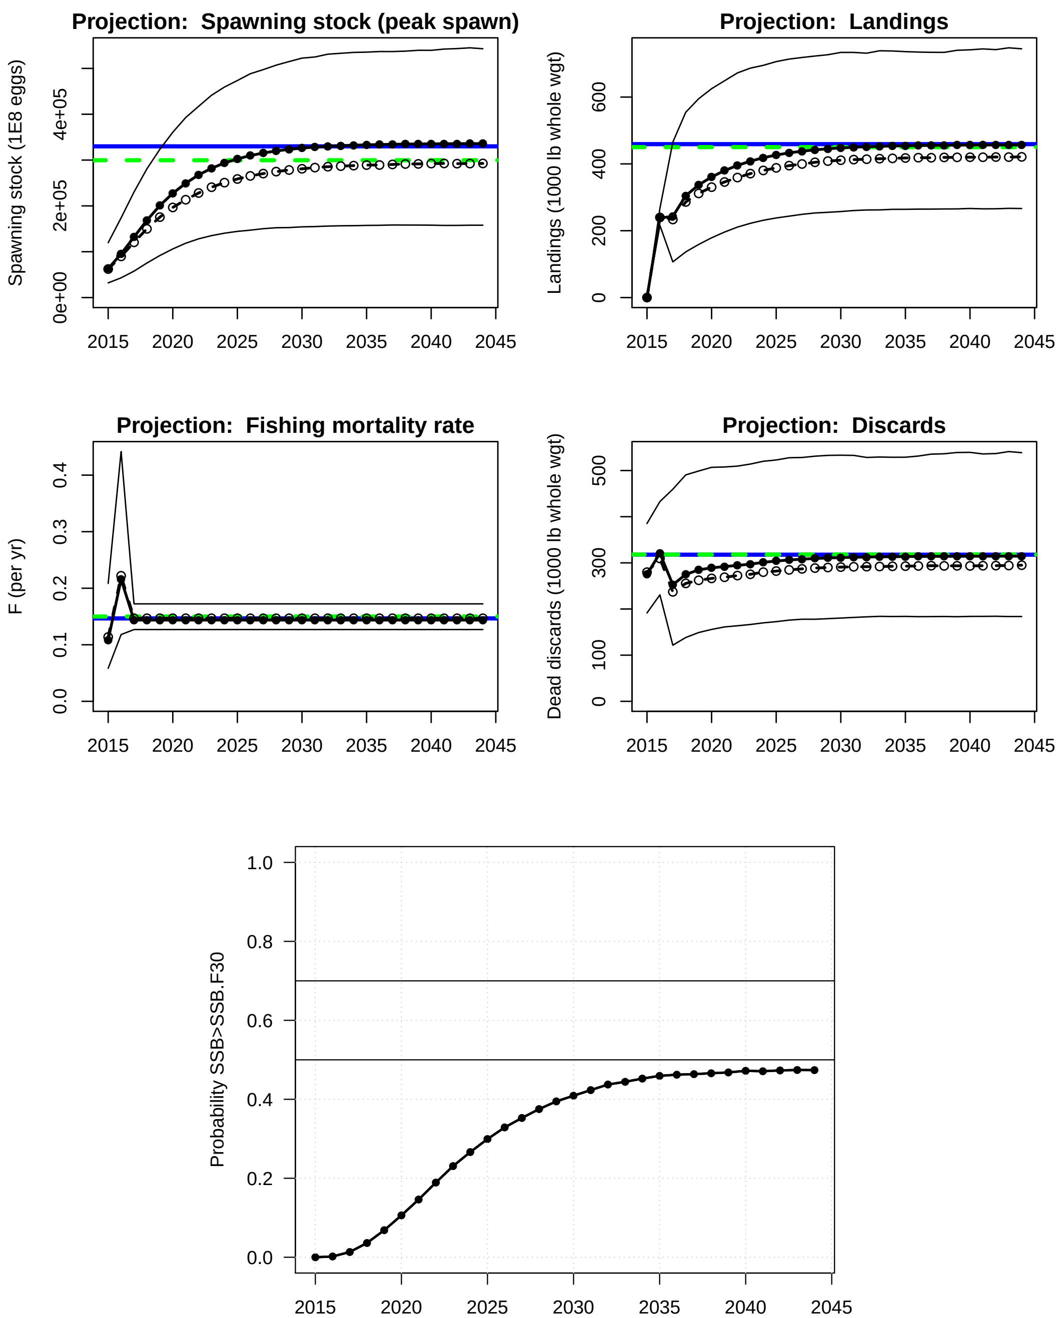

Figure 60. Projection results under scenario 5—fishing mortality rate at $F = F_{\text{rebuild}}$, with rebuilding probability of 0.5 in 2044. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} and 95^{th} percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $\text{SSB}_{\text{F30\%}}$.

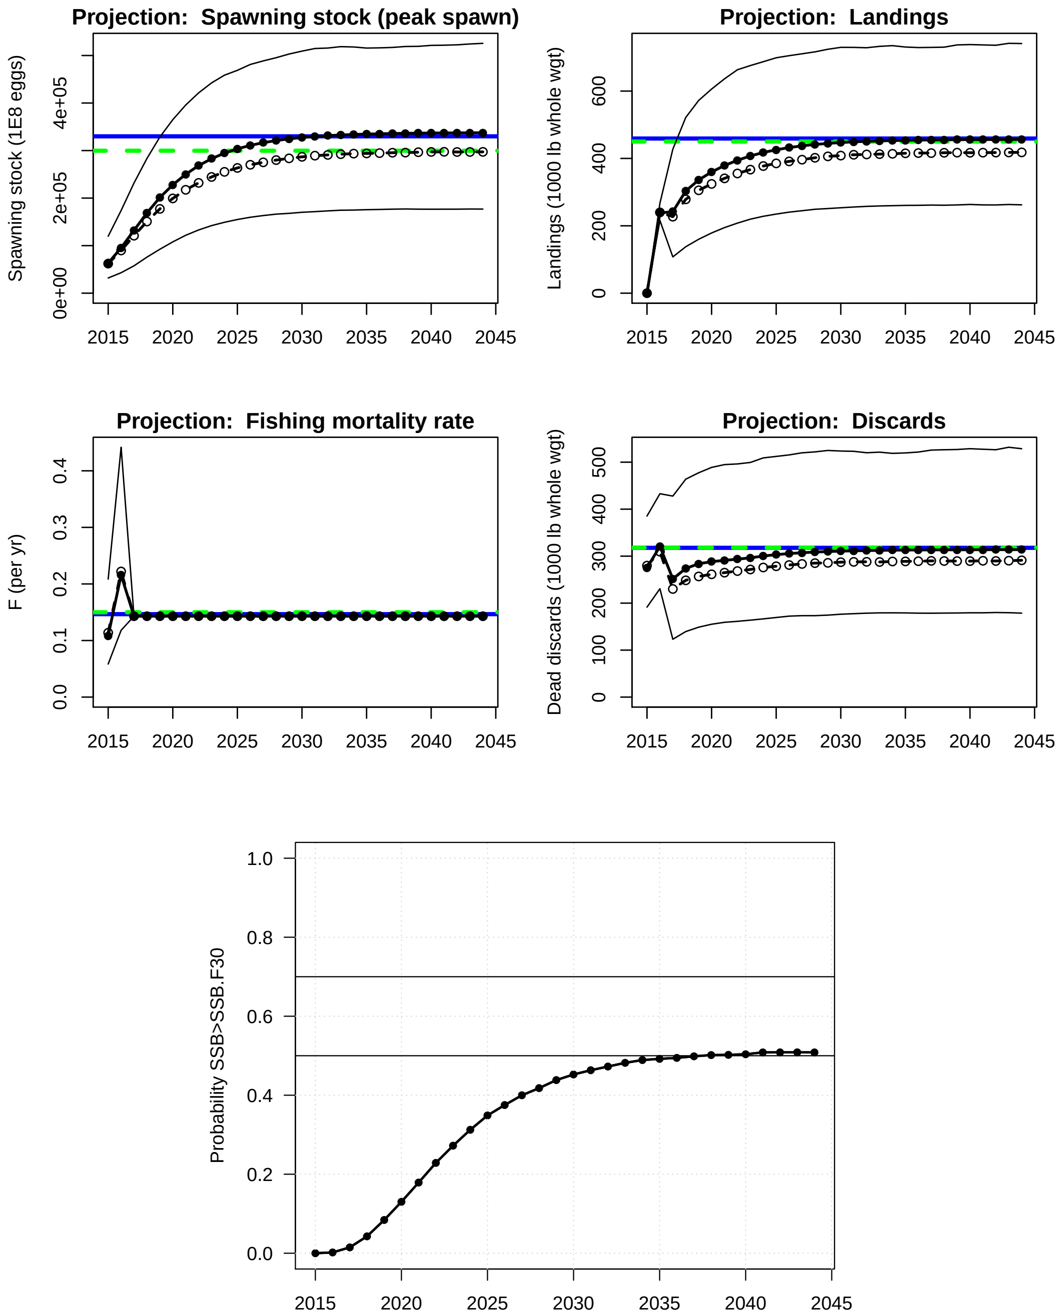

Figure 61. Projection results under scenario 6—fishing mortality rate set to average discard mortality rate only. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} *and* 95^{th} *percentiles of replicate projections. Solid horizontal lines mark* $F_{30\%}$*-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific* $\mathrm{SSB}_{\mathrm{F30\%}}$.

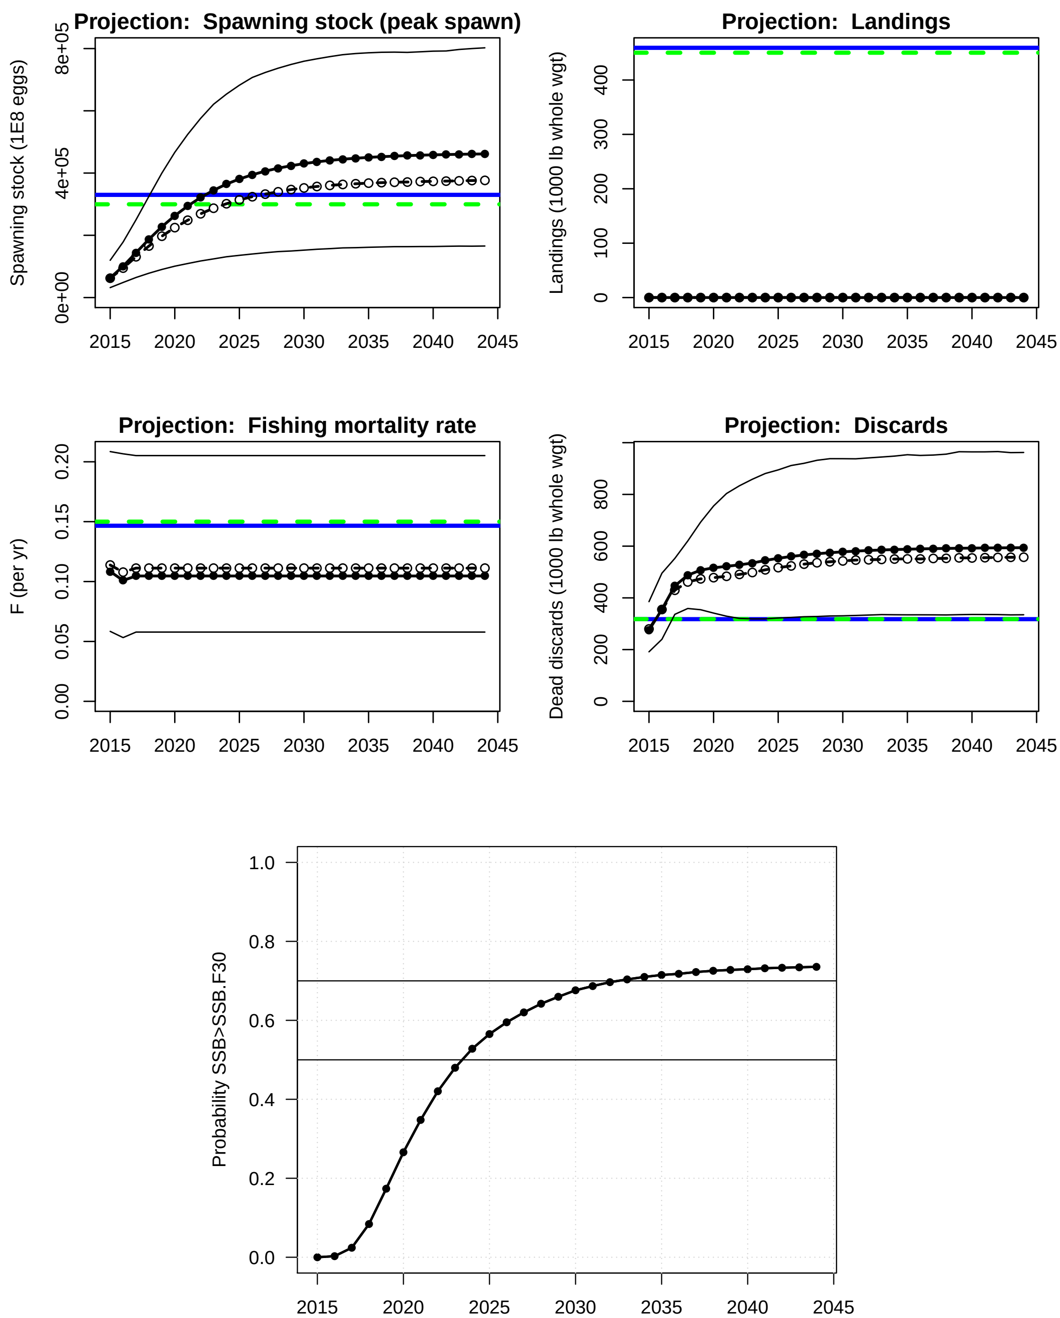

Figure 62. Abundance indices observed (obs.) and predicted (pred.) by the ASPIC surplus production model, and observed total removals (100,000 lbs) for South Atlantic red snapper. Comm = commercial, HB = headboat, HB.at.sea = headboat at sea discards, CVID = combined chevron trap-video index.

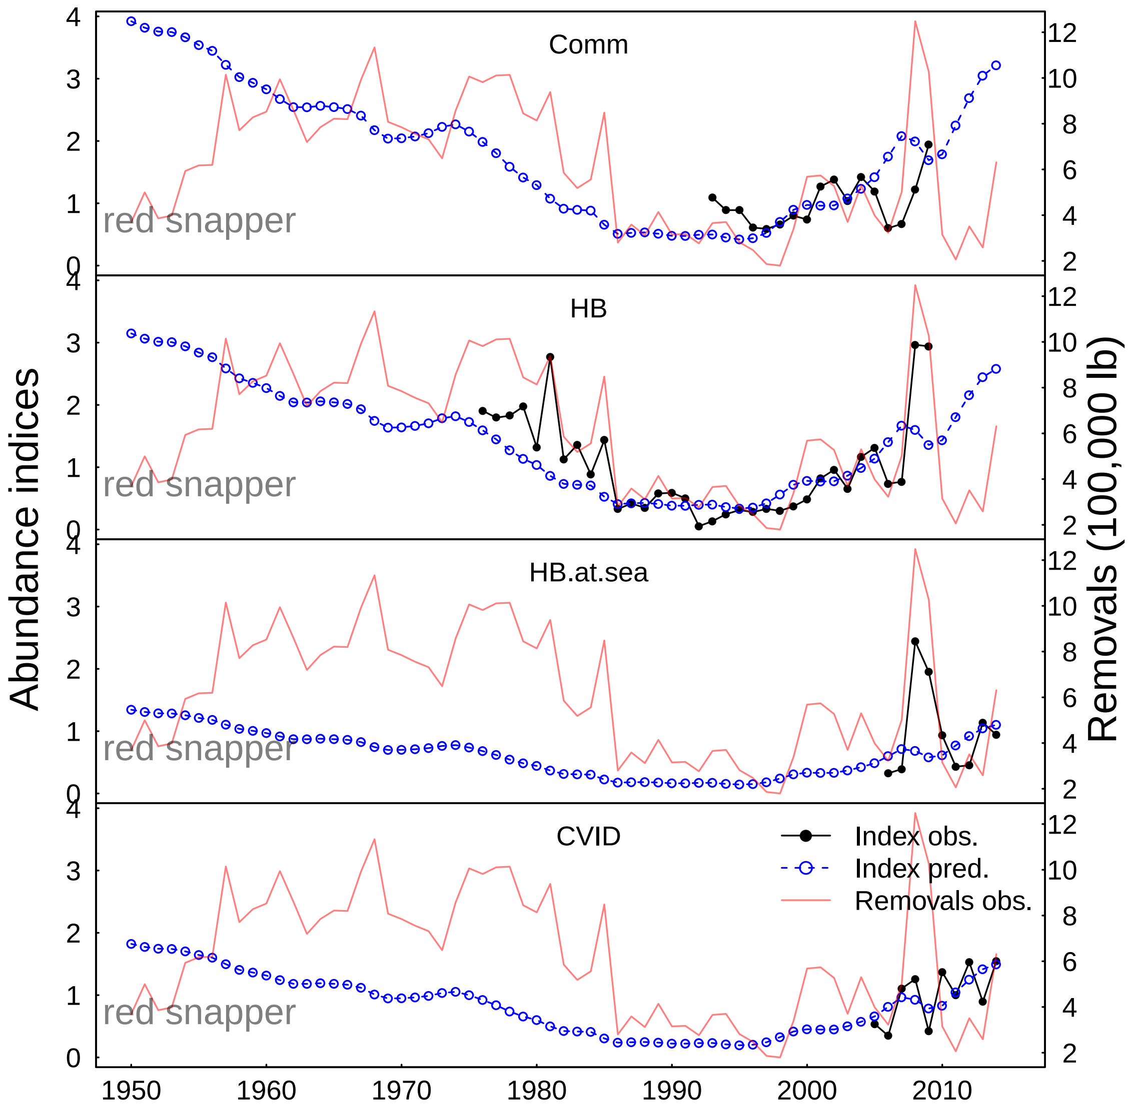

Figure 63. Prior distributions (blue shapes) and estimated parameter values (vertical black lines) for the South Atlantic red snapper ASPIC surplus production model.

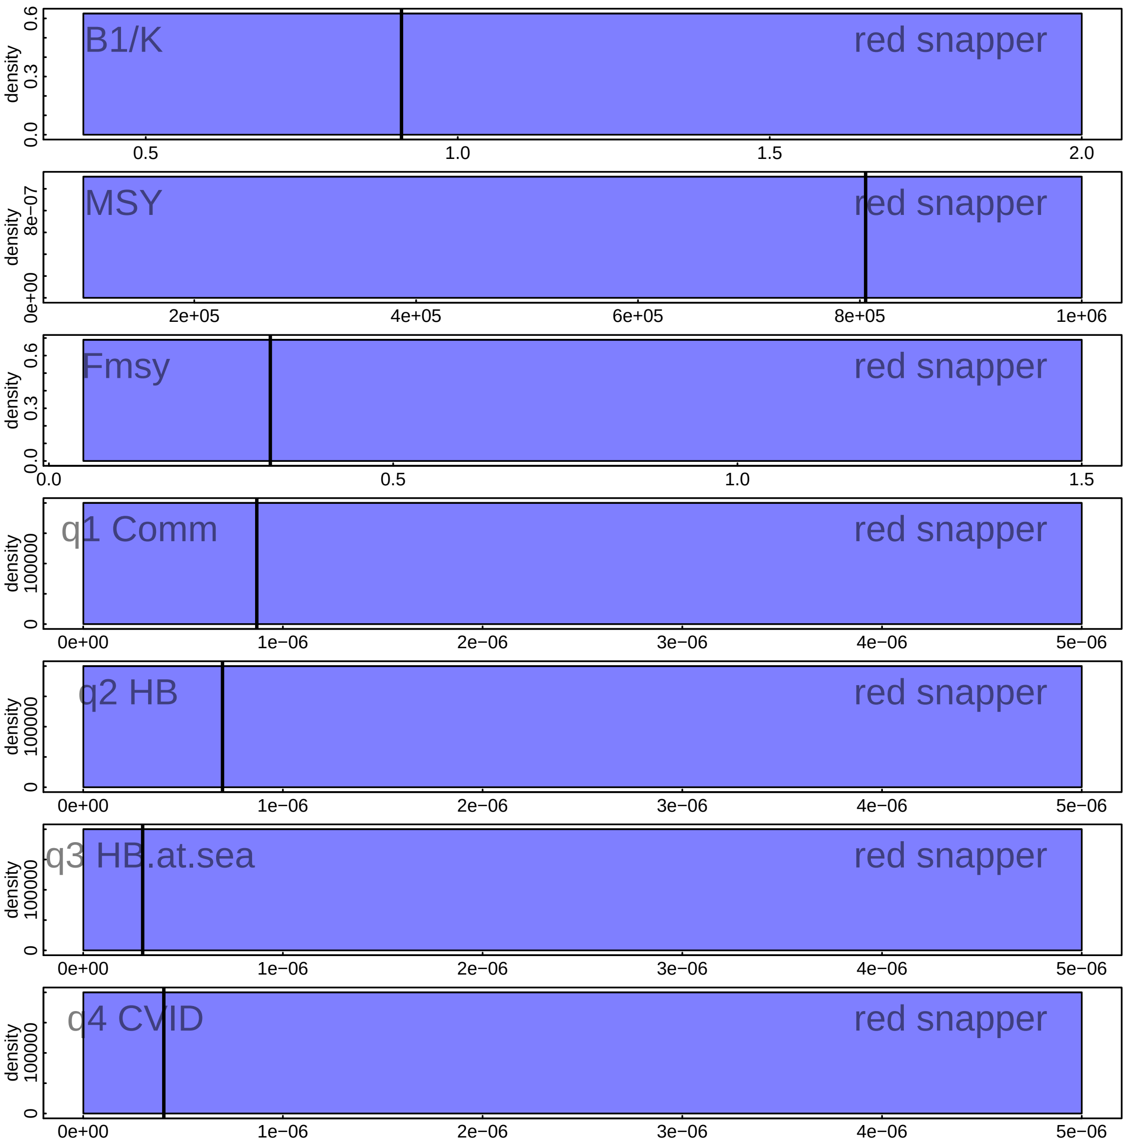

Figure 64. Bootstrap parameter values from ASPIC surplus production model run 320. Thick vertical lines represent ASPIC parameter estimates (solid) and 95% bootstrap percentile confidence intervals (dashed). Thin solid vertical lines are drawn at one in plots of F/F_{MSY} and B/B_{MSY} for reference.

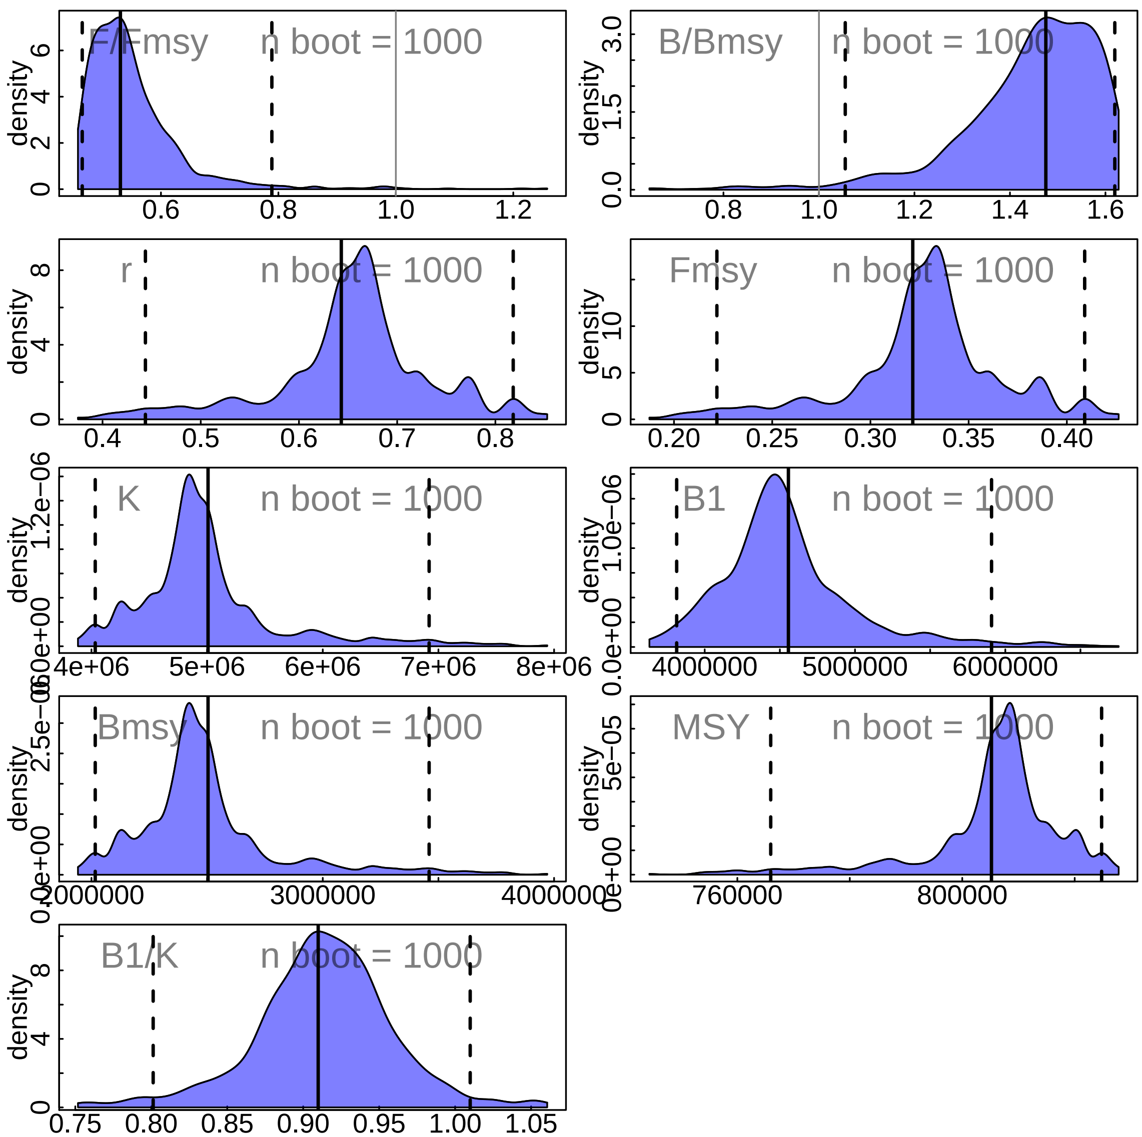

Figure 65. ASPIC surplus production model estimates of relative fishing rate (F/F_{MSY}) and biomass (B/B_{MSY}).

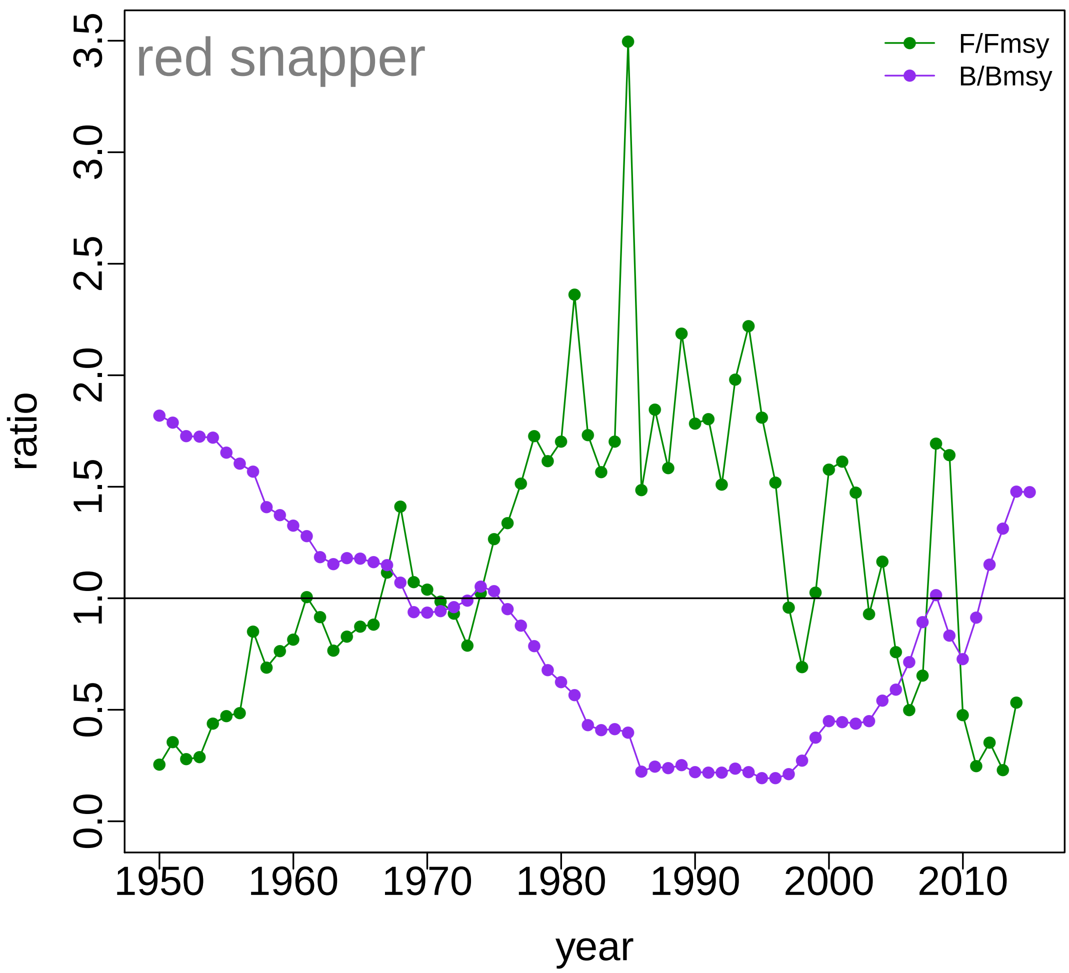

Appendix A Abbreviations and symbols

Table 31. Acronyms and abbreviations used in this report

Symbol	Meaning
ABC	Acceptable Biological Catch
AW	Assessment Workshop (here, for red snapper)
ASY	Average Sustainable Yield
B	Total biomass of stock, conventionally on January 1
BAM	Beaufort Assessment Model (a statistical catch-age formulation)
CPUE	Catch per unit effort; used after adjustment as an index of abundance
CV	Coefficient of variation
CVID	SERFS combined chevron trap and video survey
DW	Data Workshop (here, for red snapper)
F	Instantaneous rate of fishing mortality
$F_{30\%}$	Fishing mortality rate at which $F_{30\%}$ can be attained
F_{MSY}	Fishing mortality rate at which MSY can be attained
FL	State of Florida
FHWAR	The National Survey of Fishing, Hunting, and Wildlife-Associated Recreation Survey
GA	State of Georgia
GLM	Generalized linear model
K	Average size of stock when not exploited by man; carrying capacity
kg	Kilogram(s); 1 kg is about 2.2 lb.
klb	Thousand pounds; thousands of pounds
lb	Pound(s); 1 lb is about 0.454 kg
m	Meter(s); 1 m is about 3.28 feet.
M	Instantaneous rate of natural (non-fishing) mortality
MARMAP	Marine Resources Monitoring, Assessment, and Prediction Program, a fishery-independent data collection program of SCDNR
MCB	Monte Carlo/Bootstrap, an approach to quantifying uncertainty in model results
MFMT	Maximum fishing-mortality threshold; a limit reference point used in U.S. fishery management; often based on F_{MSY}
mm	Millimeter(s); 1 inch = 25.4 mm
MRFSS	Marine Recreational Fisheries Statistics Survey, a data-collection program of NMFS, predecessor of MRIP
MRIP	Marine Recreational Information Program, a data-collection program of NMFS, descended from MRFSS
MSST	Minimum stock-size threshold; a limit reference point used in U.S. fishery management. The SAFMC has defined MSST for red snapper as $(1 - M)\mathrm{SSB}_{\mathrm{MSY}} = 0.7\mathrm{SSB}_{\mathrm{MSY}}$.
MSY	Maximum sustainable yield (per year)
mt	Metric ton(s). One mt is 1000 kg, or about 2205 lb.
N	Number of fish in a stock, conventionally on January 1
NC	State of North Carolina
NMFS	National Marine Fisheries Service, same as “NOAA Fisheries Service”
NOAA	National Oceanic and Atmospheric Administration; parent agency of NMFS
OY	Optimum yield; SFA specifies that OY $\leq$ MSY.
PSE	Proportional standard error
R	Recruitment
SAFMC	South Atlantic Fishery Management Council (also, Council)
SC	State of South Carolina
SCDNR	Department of Natural Resources of SC
SDNR	Standard deviation of normalized residuals
SEDAR	SouthEast Data Assessment and Review process
SERFS	Southeast Regional Fishery-independent Sampling
SFA	Sustainable Fisheries Act; the Magnuson–Stevens Act, as amended
SL	Standard length (of a fish)
SRHS	Southeast Region Headboat Survey, conducted by NMFS-Beaufort laboratory
SPR	Spawning potential ratio
SSB	Spawning stock biomass; mature biomass of males and females
$\mathrm{SSB}_{\mathrm{MSY}}$	Level of SSB at which MSY can be attained
$\mathrm{SSB}_{\mathrm{F30\%}}$	Level of SSB at which $F_{30\%}$ can be attained
TIP	Trip Interview Program, a fishery-dependent biodata collection program of NMFS
TL	Total length (of a fish), as opposed to FL (fork length) or SL (standard length)
VPA	Virtual population analysis, an age-structured assessment
WW	Whole weight, as opposed to GW (gutted weight)
yr	Year(s)

9. South Atlantic and Gulf of Mexico Comparison (TOR #10)

This section addresses AW ToR 10: Compare and contrast productivity measures and assessment assumptions between the Gulf of Mexico and South Atlantic stocks. Comparisons are presented in Table 31.

A template of Table 31 was prepared by the SEDAR41 Assessment Panel, with guidance from SAFMC Council members attending the Assessment Workshop. Input for the South Atlantic stock was based on this (SEDAR41) assessment. Input for the Gulf of Mexico stock was based on the most recent (SEDAR31 update) assessment of that stock, and values were provided or reviewed by assessment scientists from the NMFS-Miami laboratory.

Table 31. Productivity measures and assessment assumptions from the South Atlantic (SA, SEDAR41) and Gulf of Mexico (GoM, SEDAR31 update) stocks of red snapper.

Productivity measure/assumption	SA	GoM	Comments
Reproductive output	Fecundity (eggs/female)	Fecundity (eggs/female)	SA units = $1X10^8$ eggs/female
Age at 50% maturity	1.2	NA	GoM: Age at 50% maturity was not used in the stock assessment model. Instead, a fixed vector of fecundity (eggs) at age was used.
Natural mortality	M=0.13	M=0.09	SA max age = 51. SA age dependent M was based on a scaled version of the Charnov estimator. GoM max age = 48. GoM age dependent M (ages 2+; age 0 and 1 M fixed) was based on a scaled version of the Lorenzen estimator.
Assessment model type	Statistical catch at age	Statistical catch at age	SA software = BAM (implemented in AD Model Builder) GoM software = Stock Synthesis (implemented in AD Model Builder; two areas modeled E and W of the Mississippi River; Single S/R relationship.
Assessment time frame	1950–2014	1872–2013	GoM: terminal year of data = 2013

			except for landings for which provisional 2014 estimates were available
Spawner-recruit model	Beverton-Holt	Beverton-Holt	SA: fixed steepness = 0.99 to model recruitment as variable around an average value. GoM: To fix projected recruitments at "recent" levels, steepness and σ_R were fixed.
Spawner-recruit model parameter values	h=0.99 log(R0)=12.71 σ_R=0.79	h=0.99 log(R0)=12.04 σ_R=0.3	SA: steepness fixed, R0 and σ_R estimated. R0 in number age-1 fish. GoM: There is evidence that observed recruitments have generally increased in recent years. Therefore, R0 was estimated for two time blocks (pre 1984 and 1984-present). Ln(R0) = 12.04 from recent time period. R0 in 1000s age-0 fish.
Modeled population recruitment age	Age=1	Age=0	GOM: Age 0 included in because of shrimp bycatch mortality.
Growth model	von Bertalanffy	von Bertalanffy	
Growth model parameter values	Linf=911.36mm (TL)	Linf=85.6374cm (Max TL) K=0.19	SA: Fixed in the assessment,

	K=0.24 t0=–0.33	t0=–0.39	estimated external to the model. Separate growth model applied to landings during the period of the 20-inch size limit. GoM: Fixed in the assessment; Parameters determined using a censored-regression approach to account for the effect of size limits (available data are generally from fishery dependent sources).
Scale of total removals over assessment time frame	Mean=0.82 mp Min=0.24 Max=1.64	Mean = 6.7 mp Min=0.52 mp Max = 18.45 mp	Total Removals (landings + dead discards) in millions of lb (mp)
MSY (or proxy)	0.46 mp	12.9 mp	SA: F30 proxy assuming average recruitment GoM: Equilibrium *Retained* Yield at $SSB_{SPR26\%}$
Fmsy (or proxy)	0.147	0.0494	SA: proxy=F30 GoM: $F_{SPR26\%}$ used as proxy
Bmsy (or proxy)	3692 mt	220.9 mp	SA: Total biomass (all ages 1+) at F30 GOM: Total biomass (all ages 0+) at $SSB_{SPR26\%}$
SSBmsy (or proxy)	3.3E+13 eggs	1.28E+12 eggs	SA: F30 proxy assuming average recruitment GoM: In units of

			1000s. Equilibirum SSB @ $F_{SPR26\%}$
F SPR values	$F_{SPR30\%}$=0.147	$F_{SPR26\%}$ = 0.0494	GOM: $F_{SPR26\%}$
Fleets/Indices modeled (selectivity assumptions)	Commercial handline (flat-topped), trap/video survey (flat-topped), headboat (domed), general recreational (domed, flat-topped since 2010)	**FLEETS:** COM_VL_E: ***RW*** COM_VL_W: ***RW*** COM_LL_E: ***RW*** COM_LL_W: ***RW*** MRIP(PB,CB)_E: ***RW*** MRIP(PB,CB)_W: ***RW*** HB_E: ***RW*** HB_W: ***RW*** COM_CLOSED SEASON_E: ***RW*** COM_CLOSED SEASON_W: ***RW*** REC_CLOSED SEASON_E: ***MIRROR MRIP(PB,CB)_E*** REC_CLOSED SEASON_W: ***MIRROR MRIP(PB,CB)_W*** SHRIMP BYCATCH_E: ***RW*** SHRIMP BYCATCH_W: ***RW*** **INDICES:** SEAMAP VIDEO_E: ***RW*** SEAMAP VIDEO_W: ***RW*** SEAMAP LARVAL_E: ***SSB*** SEAMAP LARVAL_W: ***SSB*** SUMMER GROUNDFISH_E: ***RW*** SUMMER GROUNDFISH_W: ***RW*** FALL GROUNDFISH_E: ***RW***	GOM: ***RW*** = Random Walk, Each age as random walk from previous age – can be dome shaped; ***MIRROR***: Use selectivity from another fleet; ***SSB:*** Sets expected survey selectivity such that abundance indexes spawning biomass; ***LOG***: Logistic or "Flat-topped".

		FALL GROUNDFISH_W: ***RW*** NMFS BOTTOM LL_E: ***MIRROR NMFS BOTTOM LL_W*** NMFS BOTTOM LL_W: ***LOG*** REM_OPER_VEHICLE_E: ***RW*** NMFS BOTTOM LL_E: ***RW*** COM_HL_E: ***MIRROR COM_HL_E Fleet*** COM_HL_W: ***MIRROR MRIP(PB,CB)_E Fleet*** MRIP(PB,CB)_E: ***MIRROR MRIP(PB,CB)_W Fleet*** MRIP(PB,CB)_W: ***MIRROR MRIP(PB,CB)_W Fleet*** HB_E: ***MIRROR HB_E Fleet*** HB_W: ***MIRROR HB_W Fleet***	
Fleet Modeled Retention Assumption	NA	Logistic: As a function of size.	SA: Dead discards modeled as having their own selectivities and fishing rates. GOM: For each fishery, retention was modeled using a logistic function. “Retained” fish are “landed.” Fish that were not retained were discarded. Dead

			discards were estimated by applying the relevant discard mortality rate. Retention does not apply to surveys.
Time varying catchability?	Y	N	SA: Explored in sensitivity analysis
Time varying selectivity?	Y	Y	SA: Three time blocks based on regulatory periods – 1950–1991, 1992–2009, 2010–current. GOM: 2007-2014; A new selectivity function was estimated for change in commercial selectivity with implementation of IFQ. GOM: 2008-2010 and 2011-2014; New selectivity functions were estimated for the recreational fisheries due to implementation of circle hooks and other regulatory effects (on fishing behavior).
Time varying retention?	NA	Y	GOM: Retention functions for recreational and commercial fisheries were re-estimated at all changes in size-limits. For the

			commercial fisheries, the asymptote (retention at sizes larger than the minimum size limit) was allowed to be <100% after the imposition of IFQ to account for regulatory discards not due to minimum size.

North Charleston, SC 29405

Contents

IV. Research Recommendations

1. Data Workshop

1.1 Life History

Red Snapper Mini Season

If this program, along with continued closure of the fishery, is to extend into future seasons, an exploration of methods to further incentivize angler participation would be useful. After brief interviews with participants from the recreational fishers group at SEDAR 41, the following suggestions were provided to increase angler participation:

- Free fish cleaning at donation site.
- As people may be tired after being out on the water all day and with busy boat ramps, short questionnaire from a biologist on-site could be used instead of the anglers filling the forms out or requiring fishermen to fill out a survey online after they return home.
- Advertise data collection at local bait & tackle shops.
- Use NOAA's announcement system on weather radio channel where they also announce season closures, etc. Since fishermen are frequently monitoring this channel for weather updates, it could be an effective communication route to announce the collection information (drop locations, reward information, etc.).
- Dry storage areas are a good place to sample; many people store boats there instead of trailering home.

Life History Research

- More research on red snapper movements and migrations in Atlantic waters is needed. Available data and the results of studies in the Gulf of Mexico indicate high site fidelity, but that tropical storms may cause greater than normal movement that might help dispersal to depleted areas. This needs to be confirmed in the South Atlantic. Additional acoustic and traditional tagging is needed on known spawning locations to document spawning migrations or aggregations, and return of fish to non-spawning areas.
- Evaluate more thoroughly the data/sample collection during the mini-season to improve utility for assessments. This should include what samples should be collected (e.g. reproductive information).
- Possible changes in life history parameters, in particular relative to reproduction, need to be further investigated.
- Much is unknown about the early life history of Red Snapper, in particular relative to spawning areas, larval and juvenile stages, including habitat and dispersal.
- Alternative methods of reproductive output. The methods described in Klibansky's SEDAR41-DW49 may provide a more accurate estimate of reproductive output than

previously used. Further investigation into this modeling effort and use for future assessments should be investigated.
- Duration of spawning indicators. The definition of spawning indicators has received significant discussion recently. As this has significant implications for the estimates of reproductive output, further research is needed to define consistent criteria for spawning indicators in finfish.
- Continuing the age reading comparisons and calibrations between labs on a reference collection of known age fish would be beneficial for determining a more accurate aging error matrix and would provide accuracy to the age composition data.

1.2 Commercial Statistics

Landings

- Improve gear and effort data for each trip.
- Standardize methodology for developing average proportions to parse out unclassified landings.

Discards

- Investigate the validity and magnitude of “no discard” trips. This may include fisher interviews throughout the region.
- Examine potential impacts of “no discard” trips on estimated discards.
- Improve discard logbook data collections via program expansion or more detailed reporting (i.e. electronic logbooks, etc.)
- Establish an observer program that is representative of the fisheries in the South Atlantic

Biosampling

- Establish an observer program that is representative of the fisheries in the South Atlantic.
- Angler education with regards to recording depths on paper logbooks (i.e. standardized units); validation of additions to the logbook form still needed.
- Standardize TIP sampling protocol to get representative samples at the species level.
- Standardize TIP data extraction.

1.3 Recreational Statistics

- Complete analysis of available historic photos for trends in CPUE and mean size of landed Red Snapper and Gray Triggerfish for pre-1981 time period. (Ultimately all species).
- Formally archive data and photos for all other SEDAR target species.
- For Hire Survey (FHS) should collect additional variables (e.g. depth fished).
- Increasing sample sizes for at-sea headboat observers (i.e. number of trips sampled).

- Compute variance estimate for headboat landings.
- Mandatory logbooks for all federally permitted for-hire vessels.

1.4 Indices

- Compare existing methods and/or develop new methods to define effective effort in fishery dependent data.
- Estimate selectivity of video gear in the SERFS.
    - Tagging, stereo cameras
- For video reading, evaluate methods to score water clarity and habitat.
- Evaluate effect of (non) independence between chevron traps and videos, including methods to combine the indices.
- Continue exploring the use of continuous predictor variables (e.g., splines or polynomials) for ZIP and ZINB standardization models.
- Headboat at-sea observer program needs depth data from all states (not just FL) and increased coverage overall.
- SCDNR charterboat logbook program should be replicated by other states.
- Develop fishery independent hook-gear index (S41-DW08).

2. Assessment Workshop

- Increased fishery independent information, in particular reliable indices of abundance and age compositions.
- Red Snapper were modeled in this assessment as a unit stock off the southeastern U.S. For any stock, variation in exploitation and life-history characteristics might be expected at finer geographic scales. Modeling such sub-stock structure would require more data, such as information on the movements and migrations of adults and juveniles, as well as spatial patterns of larval dispersal and recruitment. In addition, it is unknown whether a spatial model would improve the assessment.
- More research to describe the life history of Red Snapper is needed, including more work to identify the location of juveniles before they recruit to the fishery.
- The effects on environmental variation on the changes in recruitment or survivorship.
- The Florida sampling program, during the mini-season in particular, provided invaluable data to this assessment. Programs such as these would be useful in all South Atlantic states, particularly if the management regulations continue to make established methods of index development or composition sampling from fleets less regular or possible.

3. Review Workshop

The Review Panel considers the first three of the following bullets to be the highest priority for assessment improvement.

- Increased fishery independent information, particularly maintaining reliable indices of abundance and composition data streams.
- Improve the reliability of discard data as an abundance index by improving knowledge of private recreational fisherman behavior.
- Research to determine the spatial distribution (horizontal and vertical) of large adult Red Snapper using tracking and telemetry.
- The Review Panel reiterates various research recommendations focused on Red Snapper population structure in the South Atlantic. Red Snapper were modeled in this assessment as a unit stock off the southeastern U.S. For any stock, variation in exploitation and life-history characteristics might be expected at finer geographic scales. Modeling such sub-stock structure would require more data, such as information on the movements and migrations of adults and juveniles, as well as spatial patterns of larval dispersal and recruitment, and spatially-explicit data of all types used in the assessment model. It is unclear whether a spatially-explicit model would improve the assessment. Given the robust ocean circulation in the South Atlantic Bight conditions creating population sub-structure. The research effort necessary to support such an effort would be extensive and probably unjustified on stock assessment improvement grounds, however, it would be needed to support MPA placement, performance evaluation, etc.
- More research to describe the juvenile life history of Red Snapper is needed, including more work to identify the location of juveniles before they recruit to the fishery.
- The effects of environmental variation on the changes in recruitment or survivorship.
- Investigate possible historical changes in sexual maturity. The current estimate of age of sexual maturity is low and unusual for other Lutjanids. Is it right or a compensatory response to heavy exploitation?
- Continue conducting studies to develop a time series of batch fecundity to obtain information on the inter-annual variation in reproductive output.

South Atlantic Red Snapper

SECTION V: Review Workshop Report

April 2016

SEDAR
4055 Faber Place Drive, Suite 201
North Charleston, SC 29405

Table of Contents

1. Introduction

1.1 Workshop Time and Place

The SEDAR 41 Review Workshop for South Atlantic Red Snapper (*Lutjanus campechanus*) was held March 15-18, 2016 in North Charleston, SC. Review Panel members were presented all information generated throughout the Data (DW) and Assessment (AW) Workshops and webinars, and the Review Workshop (RW) Panel then developed a consensus review and analysis of the stock assessment model and inputs according to a number of SEDAR Terms of Reference.

1.2 Terms of Reference

1. Evaluate the data used in the assessment, including discussion of the strengths and weaknesses of data sources and decisions, and consider the following:
    a) Are data decisions made by the DW and AW sound and robust?
    b) Are data uncertainties acknowledged, reported, and within the normal or expected levels?
    c) Are data properly applied within the assessment model?
    d) Are data input series reliable and sufficient to support the assessment approach and findings?

2. Evaluate and discuss the strengths and weaknesses of the methods used to assess the stock, taking into account the available data, and consider the following:
    a) Are methods scientifically sound and robust?
    b) Are assessment models configured properly and used consistent with standard practices?
    c) Are the methods appropriate for the available data?

3. Evaluate the assessment findings and consider the following:
    a) Are abundance, exploitation, and biomass estimates reliable, consistent with input data and population biological characteristics, and useful to support status inferences?
    b) Is the stock overfished? What information helps you to reach this conclusion?
    c) Is the stock undergoing overfishing? What information helps you reach this conclusion?
    d) Is there an informative stock recruitment relationship? Is the stock recruitment curve reliable and useful for evaluation of productivity and future stock conditions?
    e) Are the quantitative estimates of the status determination criteria for this stock reliable? If not, are there other indicators that may be used to inform managers about stock trends and conditions?

4. Evaluate the stock projections, including discussing the strengths and weaknesses, and consider the following:
   a) Are the methods consistent with accepted practices and available data?
   b) Are the methods appropriate for the assessment model and outputs?
   c) Are the results informative and robust, and are they useful to support inferences of probably future conditions?
   d) Are key uncertainties acknowledged, discussed, and reflected in the projection results?

5. Consider how uncertainties in the assessment, and their potential consequences, are addressed.
   a) Comment on the degree to which methods used to evaluate uncertainty reflect and capture the significant sources of uncertainty in the population, data sources, and assessment methods.
   b) Ensure that the implications of uncertainty in technical conclusions are clearly stated.

6. Consider the research recommendations provided by the Data and Assessment workshops and make any additional recommendations or prioritizations warranted.
   a) Clearly denote research and monitoring that could improve the reliability of, and information provided by, future assessments.
   b) Provide recommendations on possible ways to improve the SEDAR process.

7. Consider whether the stock assessment constitutes the best scientific information available using the following criteria as appropriate: relevance, inclusiveness, objectivity, transparency, timeliness, verification, validation, and peer review of fishery management information.

8. Compare and contrast assessment uncertainties between the Gulf of Mexico and South Atlantic stocks.

9. Provide guidance on key improvements in data or modeling approaches which should be considered when scheduling the next assessment.

10. Prepare a Peer Review Summary summarizing the Panel's evaluation of the stock assessment and addressing each Term of Reference. Develop a list of tasks to be completed following the workshop. Complete and submit the Peer Review Summary Report in accordance with the project guidelines.

1.3 List of Participants

REVIEW WORKSHOP PANELISTS

Luiz Barbieri	Review Panel Chair	SAFMC SSC
Mike Armstrong	Reviewer	CIE
Jon Helge Vølstad	Reviewer	CIE
Stephen Smith	Reviewer	CIE
Steve Cadrin	Reviewer	SAFMC SSC
Churchill Grimes	Reviewer	SAFMC SSC

ANALYTICAL REPRESENTATIVES

Kevin Craig	Lead Analyst, GTF	SEFSC Beaufort
Kate Siegfried	Lead Analyst, RS	SEFSC Beaufort
Kyle Shertzer	Assessment Team	SEFSC Beaufort
Erik Williams	Assessment Team	SEFSC Beaufort
Rob Cheshire*	Assessment Team	SEFSC Beaufort
Eric Fitzpatrick*	Assessment Team	SEFSC Beaufort

APPOINTED OBSERVERS

Rusty Hudson	Recreational/Commercial	FL / SFA
Robert Johnson	For-Hire	FL

APPOINTED COUNCIL REPRESENTATIVES

Zack Bowen	Council Member	SAFMC
Mark Brown	Council Member	SAFMC
Chris Conklin	Council Member	SAFMC

COUNCIL AND AGENCY STAFF

Julia Byrd	Coordinator	SEDAR
Julie O'Dell	Admin	SEDAR / SAFMC
Chip Collier	Fishery Biologist	SAMFC
Mike Errigo	Fishery Biologist	SAFMC
Nick Farmer	Fishery Biologist	SERO

WORKSHOP ATTENDEES

Joey Ballenger, SCDNR
Peter Barile, SFA
Myra Brouwer, SAFMC
John Carmichael, SAFMC
Brian Cheuvront, SAFMC
Lora Clarke, PEW

Amy Dukes, SCDNR
Jimmy Hull, FL fisherman
Julie Neer, SAFMC
Adam Nelson, FL fisherman
David Nelson, FL fisherman
Michael Nelson, FL fisherman
Paul Nelson, FL fisherman
Marcel Reichert, SCDNR
Tracey Smart, SCDNR

*Appointees marked with a * were appointed to the workshop panel but did not attend the workshop.

1.4 Document List

SEDAR 41 review workshop working papers and reference documents.

Document #	Title	Authors
	Documents Prepared for the Review Workshop	
SEDAR41-RW01	Addendum to SEDAR41-DW16: Report on Life History of South Atlantic Gray Triggerfish, *Balistes capriscus*, from Fishery-Independent Sources: UPDATE on analyses of maturity, spawning fraction, and sex ratio	Kolmos et al. 2016

2. Review Panel Report

Executive Summary

The Review Workshop (RW) Panel was presented outputs and results of the SEDAR 41 South Atlantic Red Snapper stock assessment. The primary assessment model used was the Beaufort Assessment Model (BAM), a software package that implements a statistical catch-at-age framework. The formulation is an age-structured population model that is fit using standard statistical methods to data available from surveys and fishing fleets, such as landings, discards, indices of abundance, age compositions, and length compositions. The modeling framework is nearly identical to other common assessment packages, such Age Structure Assessment Program (ASAP) and Stock Synthesis (SS), and the programming language (AD Model Builder) is the same across all three. A secondary, surplus-production model (Stock Production Model Incorporating Covariates, ASPIC) provided a comparison of model results. The Review Panel concluded that the data used in the assessment were generally sound and robust. Likewise, data generally were applied properly and uncertainty in data inputs was appropriately acknowledged. Numerous sensitivity analyses and exploration of alternative scenarios were also presented during the RW, all of which agreed with the base model run conclusions of stock status. Note that a follow-up webinar on 8 April 2016 was necessary to continue discussion of projections and finalize the SEDAR 41 RW process. Based on these results the Review Panel concluded that the stock is overfished and overfishing is occurring. The current level of spawning stock biomass (SSB_{2014}) is estimated to be about 22% of MSST (SSB_{2014}/MSST= 0.22), and the current level of fishing mortality is about 2 ½ times $F_{30\%SPR}$ ($F_{2012-2014}/F_{30\%SPR}$= 2.52). Although the Review Panel concluded that assessment results represent the best available science, there were significant areas of uncertainty identified in both the data and in components to the model. The most significant sources of this uncertainty include: the stock-recruitment relationship, the composition and magnitude of recreational discards, potential changes in CPUE catchability, and the selectivities for the different fishery fleets. The Review Panel recognized that the perception of current selectivity used to derive reference points and projections is conditional on poorly-informed assumptions regarding recent fishing behavior. During the most recent years of the stock assessment series (i.e., the 2010-2014 moratorium), recreational discards are one of the most important and most uncertain sources of information. Also, a strong retrospective pattern in apical F indicates the base BAM model is very sensitive to terminal year of data and suggests higher uncertainty in exploitation status.

2.1 Statements Addressing Each ToR

1. Evaluate the data used in the assessment, including discussion of the strengths and weaknesses of data sources and decisions, and consider the following:
    e) Are data decisions made by the DW and AW sound and robust?

f) Are data uncertainties acknowledged, reported, and within the normal or expected levels?
g) Are data properly applied within the assessment model?
h) Are data input series reliable and sufficient to support the assessment approach and findings?

General comments

Data decisions made by the DW and AW were sound and robust. The Review Panel acknowledges the considerable efforts of the DW and AW to compile the data and evaluate their strengths and weaknesses. The development of input data and parameters for the BAM and ASPIC models required an extremely thorough compilation and evaluation of all available data at the DW. Modifications made subsequently by the AW were fully explained.

Data uncertainties were acknowledged, reported, and were within the normal or expected levels. Where this could be ascertained from information provided to the RW. Data on fishery catches and length/age compositions, and fishery-dependent and independent relative abundance indices, varied widely in coverage and quality. Complex manipulations and standardisation methods were often required to try and develop coherent time series from diverse data sources of differing designs, coverage and accuracy, and the combined data will have biases that in some cases are poorly understood especially in earlier years of the time series. All decisions made by the DW and AW in compiling data were explained and justified in detail. Data quality metrics were provided by the DW in terms of numbers of samples, CVs, or alternative plausible data series or biological parameter values. These were used by the AW to weight data series in the assessment model, estimate the uncertainty in the assessment results using the Monte Carlo/bootstrap method, or to explore the sensitivity of the assessment to data decisions and uncertainty. The sensitivity analyses were carried out altering one input at a time, and did not explore the impact of combinations of adjustments.

The data were properly applied within the assessment model. Any issues with application of the data such as time periods for fitting, use of length and age data from the same sampling schemes, or weighting of data according to data quality metrics, were explored at the SEDAR-41 RW if not previously evaluated by the DW and AW.

Data input series were applied if considered reliable and sufficient to support the assessment approach and findings. Reliability and sufficiency was evaluated based on a-priori criteria where possible, supported by data quality metrics such as numbers of samples or CVs and by model fits. The assessment is supported primarily by a wide range of fishery-dependent data covering landings and discards, and therefore is heavily driven by these data and assumptions related to their reliability and use. An additional fishery-independent trap survey data set unfortunately covers only the period since 2010 due to very low incidence of Red Snapper catches prior to the recent increase in abundance due to strong year classes.

An evaluation of the strengths and weaknesses of the data sources and decisions is given below for each type of data used.

Life history parameters

Life history data and assumptions used in the Red Snapper assessment include stock structure, reproductive biology and natural mortality. The assessment was sensitive to estimates of natural mortality (M) as is generally the case, although sensitivity to trends in M could not be evaluated as there is no information on this. An age-dependent, year-invariant estimate of M was determined by a meta-analysis approach using growth parameters and maximum observed age. Reproductive biology was included in the model by computing total annual egg production at age based on maturity, length, number of batches and batch fecundity, thus allowing the effect of age structure on reproductive output to be reflected in setting SSB reference points and stock status. This represents a significant change from previous assessments. Interannual variation in fecundity, a possible source of uncertainty, was not able to be included as historical information was not available. The low estimate of age at first maturity in females (43% at age 1) was considered by the RW to be unusual for snappers, and it was speculated if it has declined as a compensatory response to heavy exploitation. Annual maturity data from the SERFS chevron trap survey could not be used to test this because sample collections have been from different areas in different time periods.

Fishery removals

Reconstruction of a historical series of commercial and recreational fishery removals (landings and dead discards) was made back to 1950 to allow a sufficient burn-in period for the BAM model as well as to establish a period of stable age structure and low fishing mortality. Creation of a series of removals estimates since 1950 required a large number of decisions to infer historical values from more recent data or to calibrate data series where design has changed. This included calibration factors to adjust NMFS Marine Recreational Fisheries Statistics Survey (MRFSS) surveys catch estimates from 1981 to 2003 to be consistent with catches from the Marine Recreational Information Programme (MRIP: 2004 to present), and to develop combined recreational landings back to 1955 using effort data from the National Survey of Fishing, Hunting, and Wildlife-Associated Recreation Survey (FHWAR: SEDAR41-DW17) combined with average MRFSS and SRHS CPUE data for 1981-83.

The recording of landings of the commercial handline fleets have improved in accuracy over time, and the DW proposed CVs that could be used for MCB uncertainty analysis in the assessment. Recreational landings of headboats are estimated from the Southeast Region Headboat Survey (SRHS) logbook scheme which has improved in quality over time due to introduction of mandatory reporting in 1996 and improved logbook supply from 2008 onwards. Private boat and charter boat landings since early 1980s were estimated from MRFSS/MRIP, which has a robust and peer-reviewed statistical design that has substantially reduced bias and improved precision over time, and for which CVs are estimated directly based on efficient estimators.

Discards estimates are inherently less reliable than landings for both the commercial and recreational fleets, and for the commercial handline fleet involved extrapolating observations for 2002-2009 to other years back to 1992, with zero discards assumed prior to that due to low minimum landing size. Similarly, headboat discard estimates are available from logbooks and some at-sea observation since 2004 but had to be extrapolated back in time based on changes in length frequencies recorded by dockside sampling before and after changes in minimum landing sizes, with zero discards assumed pre-1984. All these data manipulations introduce additional error in the time series. Discards estimates from MRFSS/MRIP are self-reported by anglers intercepted at landing sites and are not verified.

Sample sizes and allocation in MRIP have not been sufficient to provide reliable estimates of Red Snapper landings or discards for the very brief mini-seasons since 2012, and alternative data sources from State surveys were also used for these periods, based on collaboration between MRIP staff and State laboratories which the Review Panel was advised is continuing to develop options for future sampling, which the Review Panel encourages.

Discarding of Red Snapper has increased over time due to changes in minimum landing size to 20 inches in 1992 and increases in abundance of young fish from above-average year classes in some recent years. The introduction of the moratorium in 2010 and 2011, and the small commercial catch limits and recreational bag limits in the mini seasons for 2012 onwards, have resulted in most of the catch now being discarded. Estimates of discards are of poorer quality than for landings, and are often self-reported with no verification although some data are available from at-sea observations. The Review Panel notes that under the current management regime the quality of total fishery removals estimates may therefore have deteriorated significantly. The BAM model has estimated a very strong 2013 year class, based mainly on recreational discards data and CVID Chevron trap survey data. Preliminary 2015 CVID data shown to the Review Panel confirmed this by showing increased numbers of 2-year-olds. The accuracy of future BAM estimates for this year class, and projections of its contribution to future biomass and fishery catches will depend on quality of discard estimates to quantify the fishery removals. The Review Panel supports any initiatives to improve quality of discards estimates particularly as the BAM model requires these and any landings estimates to be treated as precise.

Length and age compositions

The AW used age composition data in preference to length composition data in BAM where both data exist, and length composition data were fitted only for commercial handline from 1984 to 1992, commercial discards in 2009 and 2013, and headboat discards from 2005 to 2014. Age compositions were fitted for commercial handline landings from 1990 onwards, for headboat landings in two widely separated blocks in the 1980s and 2000s, for general recreational landings since 2001, and for the CVID survey from 2010. The CVID age data were found towards the end of the Review Workshop to have not been converted to calendar ages, and revised data were provided along with some preliminary assessment results which indicated some relatively small changes to the overall assessment results and stock status.

The Review Panel heard testimony from recreational and commercial fishermen, documented also in SEDAR 41-RW6, expressing concern that the BAM assessment underestimates the numbers of large, older Red Snappers. In their experience these fish occur more frequently in midwater than is the case for smaller snappers, which are strongly benthic and therefore are less likely to enter traps, and also have behaviour and distribution that makes them less probable to be caught by commercial handline, suggesting that all fisheries have domed selectivity. The scientific sampling of fishery catches shows that the incidence of large snappers is lowest in headboats operating inshore, highest in commercial lines operating in deeper water on average, and intermediate in recreational private and charter boats which typically operate in intermediate depths. The age composition of Red Snappers caught in the Chevron trap survey, which extends across a wide depth range, is closer to the composition of commercial handline. Broad spatial coverage of the commercial fishery and survey has been used by the DW and AW to justify asymptotic selectivity for these catches. The relative selectivity of the different fisheries is shown clearly by the size and age compositions in samples collected over time, but it is more difficult to prove that the commercial fishery and Chevron trap survey have asymptotic selectivity based purely on model diagnostics or spatial fishery distribution. The Review Panel did not see any empirical data from independent studies to confirm the selection pattern for commercial handline or chevron traps. Studies are needed to provide independent data showing how Red Snapper behaviour and depth distribution affects the probability of encounter with a fishing operation or trap, and the probability of being caught when encountering the gear, to help define selectivity patterns and resolve the different perspectives on abundance of large snappers during the rebuilding period. The Review Panel suggests some approaches later in this report.

Relative abundance indices

The Review Panel considers the rationale for including abundance indices from the fisheries-independent combined CVID trap/video survey (2010-2014) and data from three fisheries-dependent CPUE series in the BAM stock assessment model to be reasonable. The combination of trap/video survey indices of abundance for the years 2010-2014 is clearly supported since the video camera is mounted on the traps, and thus cannot be considered independent observations. The three fishery dependent indices of relative abundance consisted of data from headboat logbooks (1976–2009), headboat discards (2005–2014), and commercial handline logbooks (1993–2009). The CPUE series were standardized to account for potential biases related to spatial and temporal coverage, and trip type, among other factors. The application of the method of Stephens and MacCall (2004), which takes into account other species than Red Snapper to subset trips in Red Snapper habitats, seems reasonable. The CPUE series had data gaps that required imputations to fill in the missing data points. The pragmatic method of indexing recreational catches against commercial landings and then applying a multiplier to back calculate historic landings, and the imputed values for years with zero discards based on averaging across the current and two adjacent years were considered to be reasonable. The CPUE values from commercial handline and headboat fisheries are likely to be biased indices of abundance for the stock since relatively more fishing effort will be spent in areas with high catch rates (before the 2010 moratorium) , and since the spatial coverage cannot be controlled like in a fishery-independent survey. HB CPUE series cover shallower waters where younger and smaller Red Snapper occur disproportionately more than in the deeper water where the commercial handline fishery spends more effort. A combination of the CPUE series external to the model based on their spatial/depth coverage is an alternative that might be explored in future assessments.

The various sources of systematic errors (e.g., spatial coverage, selectivity) and random errors (e.g., sample sizes) in each individual relative abundance series are well documented. There is some indication of lower discards in the HB fishery immediately following the moratorium (Figure 1; SEDAR41-DW14), which could suggest changes in fishing patterns to avoid snapper catches. The Review Panel is of the opinion that changes in management actions such as the moratorium, mini-season and reductions in bag limits that are expected to alter fishing behavior and hence catchability in fishery-dependent indices should inform decisions on inclusion of data or periods of data in assessments. A member of the SAFMC stated on record that the behavior of anglers has changed substantially since the moratorium, to avoid catching and discarding Red Snapper. The Review Panel, therefore, considers the fishery CPUE series to be applicable only to 2009, the year before the moratorium. CPUE series are also likely to be affected by technology creep in catchability due to improvements in fishing gear, positioning (GPS) and communication systems, and also by rising fuel costs in recent years.

The application of the data in the model follows common practice and appears sound. However, since the CPUE indices of abundance partly cover different depths/areas it should be noted that they do not individually cover the entire stock. Of particular concern is that the age and length composition of data from the headboat fishery likely differ from the data from the commercial fishery that tends to operate in deeper waters. Also, the precision of the CPUE series differs depending on survey design and sample sizes. The results of the stock assessment modeling depend on the relative weights assigned to different data sets. However, there is no consensus amongst practitioners as to the best approach to data weighting. This stock assessment follows the common practice of weighting compositional catch data and abundance indices in two stages. The input data are first assigned relative weights before the model is run, and then iteratively weighted during a model run to improve model fit. Ideally, stage 1 weighting would use information about sample sizes (primary sampling units, and lower level sample sizes) and the way in which the data were collected (i.e., multi-stage survey designs), through calculated precision and effective sample sizes (Francis 2011; Pennington and Vølstad 1994). In particular, abundance indices by cohorts are likely to have different precision due to differences in the number of primary sampling units (e.g., trips, or trap-sets) where the cohorts are caught (Aanes and Vølstad 2015). In general, the multi-stage sampling can introduce complex correlation structures among cohorts, and drastically reduce the effective sample sizes for estimating compositions, and indices of cohorts (Aanes and Vølstad 2015). This would allow different weighting to each data point. The current assessment appears to largely apply ad-hoc weighting of input data. In particular weighting of the fishery-independent abundance indices (across cohorts) in the base model is poorly justified. The inclusion of CPUE indices with fixed CVs (relative standard error) of 0.2 (i.e., equal weights) follows Francis (2003), based on the argument that the CVs of the fishery dependent indices do not reflect true variation in abundance. However, since sample sizes vary over the years, a fixed CV could cause bias. An estimate of the variance of CPUE indices based only on the between-trip variability in CPUE may indeed underestimate the true variance of the CPUE abundance indices if catchability varies over time, which is likely. Pennington and Godø (1995) estimated the actual variance of survey abundance indices by cross-calibrating independent VPA estimates and survey catch per tow indices. For the current BAM assessment, the fishery-independent trap data could potentially be used for cross-calibration of CPUE indices, but since the fishery-independent index only is considered to be from 2010 onwards this is problematic. A pragmatic alternative to the fixed CV of 0.2 for the CPUE series could be to apply this value for an average sample size (number of trips) for each series, and then adjust the CV for actual sample sizes every year.

The input data series appears adequate to support the assessment results and findings. However, the CPUE series are likely to have large uncertainties as measures of abundance, and the trap/video index only covers the recent years. In particular, the fishery-dependent CPUE abundance indices after 2010 are based on discards, and may be biased downwards if the HB and commercial fishery successfully avoids areas with high abundance of snappers.

2. Evaluate and discuss the strengths and weaknesses of the methods used to assess the stock, taking into account the available data, and consider the following:
    d) Are methods scientifically sound and robust?
    e) Are assessment models configured properly and used consistent with standard practices?
    f) Are the methods appropriate for the available data?

The Review Panel agrees with the DW and AW decisions and confirms that the methods are sound and relatively robust. Many stock assessment decisions are somewhat subjective, but alternative decisions were considered and the final decisions were generally well justified. Sensitivity analyses explored a wide range of data decisions, model assumptions and model configurations to examine the robustness of stock status determination. The Monte Carlo Bootstrap procedure also explored many combinations of alternative data and model assumptions.

The Review Panel concluded that the assessment models were reasonably configured and are consistent with standard practices. The BAM is the approved assessment method for many stocks in the South Atlantic Snapper-Grouper complex and is well suited to the fishery-dependent and fishery-independent information available (e.g., life history information, commercial landings and discards, recreational landings and discards, standardized CPUE indices, trap survey indices, length and age sampling). The model has many assumptions and many estimated parameters, but the base model configuration appears to have reasonable assumptions and parameter estimates. The ASPIC model and an Age-Structured Production Model were also applied to aggregate catch and stock biomass indices to provide alternative perspectives on stock status. However, the age-aggregate models do not consider length and age composition data. Although the interpretation of length and age composition data are conditional on assumed forms of selectivity and estimates of selectivity at age, the Review Panel agrees with the AW that length and age composition information is an important source of information. Catch curves of age composition data were provided as exploratory information on trends in maturity, but results are not considered to be a valid basis for status determination, because estimates are imprecise and the implicit assumption of constant mortality rate at age do not appear to be valid. The BAM base configuration is considered to be the most appropriate basis for status determination, because it fully considers important information on demographic structure, including regulated changes in selectivity, age-based maturity and fecundity, and variable recruitment of new age classes. The base configuration of BAM from the AW (‘base’) was revised with corrected age compositions of the Chevron Trap survey. Results and diagnostics from the AW base model and the corrected base model (‘newbase’) were similar. The review of methods was based on the Assessment Workshop report and the corrected base model, but conclusions from the RW were confirmed with corrected results.

During the most recent years of the stock assessment series (i.e., the 2010-2014 moratorium), recreational discards are one of the most important sources of information for the assessment. Unfortunately, recreational discards are also one of the most uncertain sources of information. Despite the imprecision in estimates of recreational catch, the BAM base configuration is conditional on catch estimates (e.g., the input CV for catch was 0.05). Exploratory analyses that allow error in landings could not produce a solution, but the Review Panel requested an exploratory analysis that allowed error in the estimates of recreational discards, assuming the MRIP estimates of CV. Exploratory assessment models with more or less catch had similar estimates for the last 30 years (BAM runs S17–S20).

Fishery CPUE indices suggest a greater recent increase in stock biomass and lower mortality (BAM run S4). However, the Review Panel agrees that the fishery-independent index is informative and should be included in the assessment model. Considering the Chevron Trap Survey and Video Survey as separate indices (BAM run S22) also estimates a greater recent increase in stock biomass and lower mortality, but the Review Panel agrees that the two series are not independent and should not be considered as separate indicators of stock trends. An alternative model configuration that included the entire series of Chevron Trap Survey provided similar estimates as the base model.

Accurate interpretation of length and age composition data relies on accurate assumptions about the form of selectivity and estimates of selectivity at age in the fisheries and the survey. The commercial fishery is assumed to be asymptotic (i.e., ‘flat topped’), and the model estimated that all Red Snapper older than age-4 have been fully vulnerable to the commercial fishery since the minimum legal size regulation in 1992. The Review Panel agrees that the flat-topped selectivity assumption for the commercial fishery is justified, because the commercial fishery covers the entire resource area and targets large fish. Assuming ‘dome-shaped’ selectivity (i.e., oldest ages are not full vulnerable) for the commercial fishery (BAM run S21) produced similar results as the base model.

Selectivity of the headboat fleet was assumed to be dome-shaped, and the model estimated full selectivity at ages 3-4 and low selectivity of ages 10+. Selectivity of the general recreational fleet was also assumed to be dome shaped until 2010, with full selectivity at ages 3-4 and low selectivity of ages 10+. Results were not sensitive to how selectivity was estimated for ages 10+ (BAM run S31).

Since 2010 (during the moratorium, mini-seasons and 1-fish bag limit), selectivity of the general recreational fleet was assumed to be flat-topped, with full selection at ages 6+. The Review Panel could not agree on whether the flat-topped assumption is well-justified. The Review Panel requested a sensitivity analysis in which selectivity of the recent general recreational fleet was assumed to be the same as the recent headboat fleet.

Results suggest that the model does not fit age composition data well, underestimating catch at older ages, and estimates are not sensitive to the selectivity assumption of the recent general recreational fleet (Appendix A).

The Review Panel recognizes that the perception of current selectivity used to derive reference points and projections is conditional on poorly-informed assumptions regarding recent fishing behavior, and projections of alternative management scenarios should consider alternative selectivity assumptions that are consistent with each scenario. For example, alternatives that do not allow recreational landings (e.g., moratoria with no mini-seasons) should not assume the *status quo* composite selectivity that includes a flat-topped selectivity for general recreational landings.

The form of selectivity of the Chevron Trap Survey was assumed to be flat topped, and the model estimated that all Red Snapper older than age-3 are fully vulnerable to the trap survey. Public comment suggested that traps may not catch large Red Snapper as efficiently as small Red Snapper. However, some of the largest and oldest samples available are from the trap survey, and efforts to estimate lower selectivity of older ages produced estimates near full selectivity.

The flat-topped selectivity assumption for the Chevron Trap survey implies that relative abundance of old fish is represented by the survey. The assumed shift from dome-shaped selectivity to flat-topped selectivity of the general recreational fishery implies that the recent increase in catch of larger and older fish reflects a shift in selectivity, rather than a proportional increase in the abundance of older fish in the population. Alternative interpretations would require evidence that larger, older Red Snapper are not fully vulnerable to the fishery or the survey.

Attempts to sample larger and older Red Snapper than sampled in the fisheries or trap survey have not been successful. Mitchell et al. (2014 Marine and Coastal Fisheries 6: 142-155 and SEDAR41-RD34) investigated length-specific depth distributions of Red Snapper in the South Atlantic region from two fishery-independent surveys targeting hard-bottom habitats, and reported "*no evidence of a positive relationship between depth and age or length. Additionally, age and length distributions of Red Snapper ≥ 50 cm FL did not differ between fishery-independent surveys and the commercial hook-and-line fishery. These results provide no support for assertions of greater abundances of older and larger Red Snapper in deeper SE USA waters*."

The information available on size selectivity of Red Snapper by survey traps is equivocal on the form of selectivity. Wells et al. (2008, Fisheries Research 89: 294–299 and SEDAR31-RD36) compared catch rates of trawls, small fish traps, chevron traps, and underwater video for sampling Red Snapper in the Gulf of Mexico. They concluded that "*the chevron trap is most effective for sampling adults, while trawls were the most effective gear for sampling age-0 fish*." DeVries et al. (2012, SEDAR31-DW28) compared size samples of Red Snapper from traps and cameras and found that "*the traps* *do select against most Red Snapper >650 mm TL, although fish that large appear to be uncommon in the survey area based on the few stereo measurements obtained*" and "*distributions of the trap fish and that from the stereo images, like in 2011, were very similar*." Therefore, there is insufficient evidence to reject the selectivity assumptions in the assessment. However, the assumptions of asymptotic selectivity of the trap survey and recent recreational fishery should be investigated further in future assessments.

3. Evaluate the assessment findings and consider the following:
    a) Are abundance, exploitation, and biomass estimates reliable, consistent with input data and population biological characteristics, and useful to support status inferences?

The Review panel accepted the new base model with the corrected age compositions for the CVID survey index as the best available model to provide advice for the South Atlantic red snapper fishery. However, the review panel did have concerns such as those discussed below.

The recent Red Snapper fishery comprises two periods of distinct exploitation patterns where the period up to and including 2009 consist of commercial and recreational fisheries with a moratorium on fishing from 2010 to the present. Since 2010 removals albeit reduced have continued through mini-seasons and discard mortality from the headboat and general recreational fishery. This change in the fishery has complicated the monitoring of the fishery because the fishery dependent indices (catch rates from the commercial handline, general recreational and headboat fleets) end in 2009. The SERFS combined video and trap survey index, CVID was introduced in this assessment to cover the moratorium period from 2010 to the present. The annual Red Snapper discard rate from the headboat fleet for 2005 to the present is used to link the fishery dependent indices in the earlier period with the CVID during the moratorium period.

The reliability of model estimates of abundance, biomass and exploitation depend on how well the monitoring indices included in the model track the population trends over time. In this assessment fishery dependent catch rates were used for the pre-moratorium period and were replaced by the CVID survey index for 2010 to the present. The MRIP annual red snapper discard rate from the headboat fleet for 2005 to the present was the only index that spanned the two time periods.

The consistency of the stock status determinations for this combination of monitoring indices was evaluated through a series of sensitivity runs. These runs indicated that the determination of stock status was actually fairly insensitive to changes such as using the longer time series for the CVID (S9), removing the CVID (S4), up-weighting the fishery dependent indices (S3), dropping the headboat discard index for 2010 to the present (S12), dropping the headboat discard index altogether (S16) or only using the CVID

(S23). All indices were well fit by the data, except for the headboat discard rate in the most recent years (Figure 13 of document).

All of these results suggest that the population trends in the model results probably have as much or more to do with the very close fit of the model to the landings, discard data, and associated age compositions as they do with the trends in the monitoring data. CVs were set to 0.05 for the landings and discards, which seems unreasonably low for the MRIP estimates of the latter but a higher CV of 0.20 for discards was investigated in MCB study and the results did not indicate a change in stock status from the base case.

b) Is the stock overfished? What information helps you reach this conclusion?

The estimated abundance for 2014 was at levels not seen in the model since the mid-1960s (Fig. 14 in the assessment report) however the 2014 population mainly consisted of ages 1-4 years (96% by number). Despite these high abundance levels the stock is overfished as $SSB_{2014}/SSB_{F30\%}$ =0.16 due to the lack of older fish in the population.

c) Is the stock undergoing overfishing? What information helps you reach this conclusion?

The review panel could not find any evidence against the overfishing determination in the assessment but did have a number serious concerns that are discussed below. The panel also reflected on issues with using apical fishing mortality to monitor the impact of the fishery on the stock over time (*see item e below*)

The determination of overfishing in the assessment relies on the geometric mean of apical F summed across fleets each year over 2012–2014 period. Currently, $F_{2012-2104}/F_{30\%}$=2.52. The retrospective analysis indicated that there was a substantial increase in apical F for 2010 to 2013 with the addition of the 2014 data (Figure 55 in the assessment report). The individual results for the different runs were not presented and it is not known whether the ages at which the apical F's occurred changed with the addition of 2014 data.

Given the retrospective pattern, it is likely that had the red snapper assessment been done a year ago, evidence for overfishing would have been much weaker than presented here. The main change between 2013 and 2014 was that landings and discards by the general recreational fleet were much higher in 2014 vs. 2013 by about 3.7 times for numbers landed and 3.4 times for discard numbers. Estimated increase in weight landed by the general recreational fleet was 3.4 times the 2013 landings. Fishing mortalities associated with general recreational landings and discards make up 78% of the 2014 apical F estimate (Table 14 in the assessment report). The mini-season in 2014 was longer than in previous years and recruits in 2014 were the highest in the time series.

The current determination that overfishing is occurring while the fishery is under moratorium generated much discussion during the panel review. The moratorium has not resulted in a complete closure as there have been landings from mini-seasons in 2011–2014 and removals due to discards during these seasons and throughout the year for recreational fisheries. The estimated fishing mortalities (Figure 27, in the assessment report) reflect the large decrease expected with the introduction of the moratorium in 2010. However since 2010 fishing mortalities have increased from this low point mainly due to discard mortalities and catches from the general recreational fishery. A comparison of mean Fs at ages 1, 2, 3, 4, and 5+ indicates that while fishing mortality was greatly reduced on all age groups in 2010, fishing mortality greatly increased on the older age 4 and 5+ group by 2014 while the Fs for the younger group ages level continued to be lower. The moratorium appears to have been a benefit to the younger fish but not so for fish 4 years and older as interpreted by the selectivity curves used for the moratorium years.

The panel asked for a sensitivity run to investigate the impact of the flat topped selectivity curve assumed for the general recreational fishery by substituting the domed curve used for headboats for 2010–2014. The domed selectivity did not result in any substantial change in stock status from the base case. The fishing mortalities-at-age were not presented by gear so it was not possible to see which age corresponded to apical F for the general recreational landings or discards for either selectivity curve.

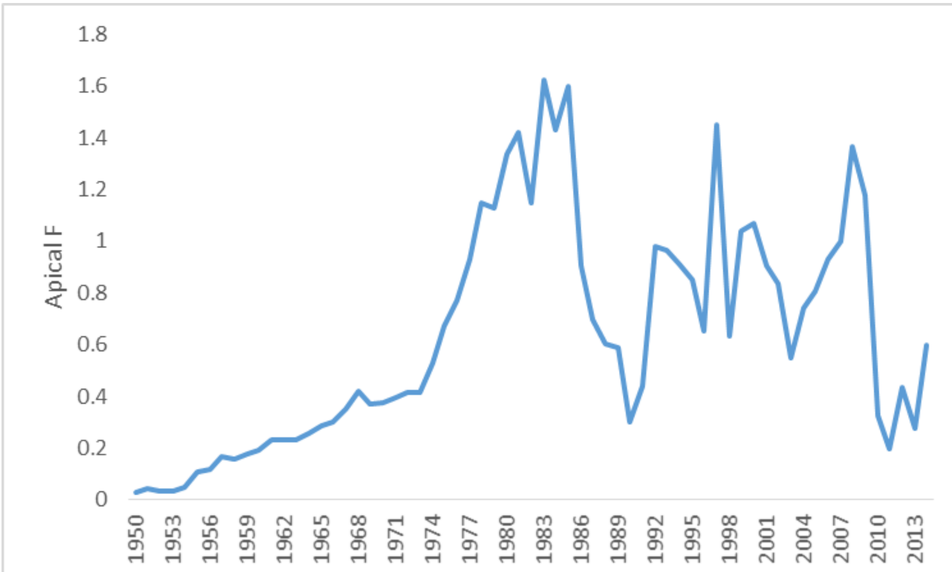
d) Is there an informative stock recruitment relationship? Is the stock recruitment curve reliable and useful for evaluation of productivity and future stock conditions?

The stock recruitment curve was not informative and inference was based on setting steepness to 0.99 and assuming average recruitment. Mean annual recruitment was assumed and lognormal deviations around that mean were estimated in the model.

Recruitment is typically not well estimated in the last year of stock assessments, because there is little information to inform the estimate. The estimate of strong recruitment in the last year of the assessment is supported by the high CVID index as well as the length composition of the headboat fleet. Review Workshop participants reported continued signals of strong recruitment in 2015 fishery and survey data. The Review Panel recognizes that projections are largely dependent on the estimate of recent recruitment, but the estimates of abundance at age from the base model is the most reliable basis for stock status determination and projection.

e) Are the quantitative estimates of the status determination criteria for this stock reliable? If not, are there other indicators that may be used to inform managers about stock trends and conditions?

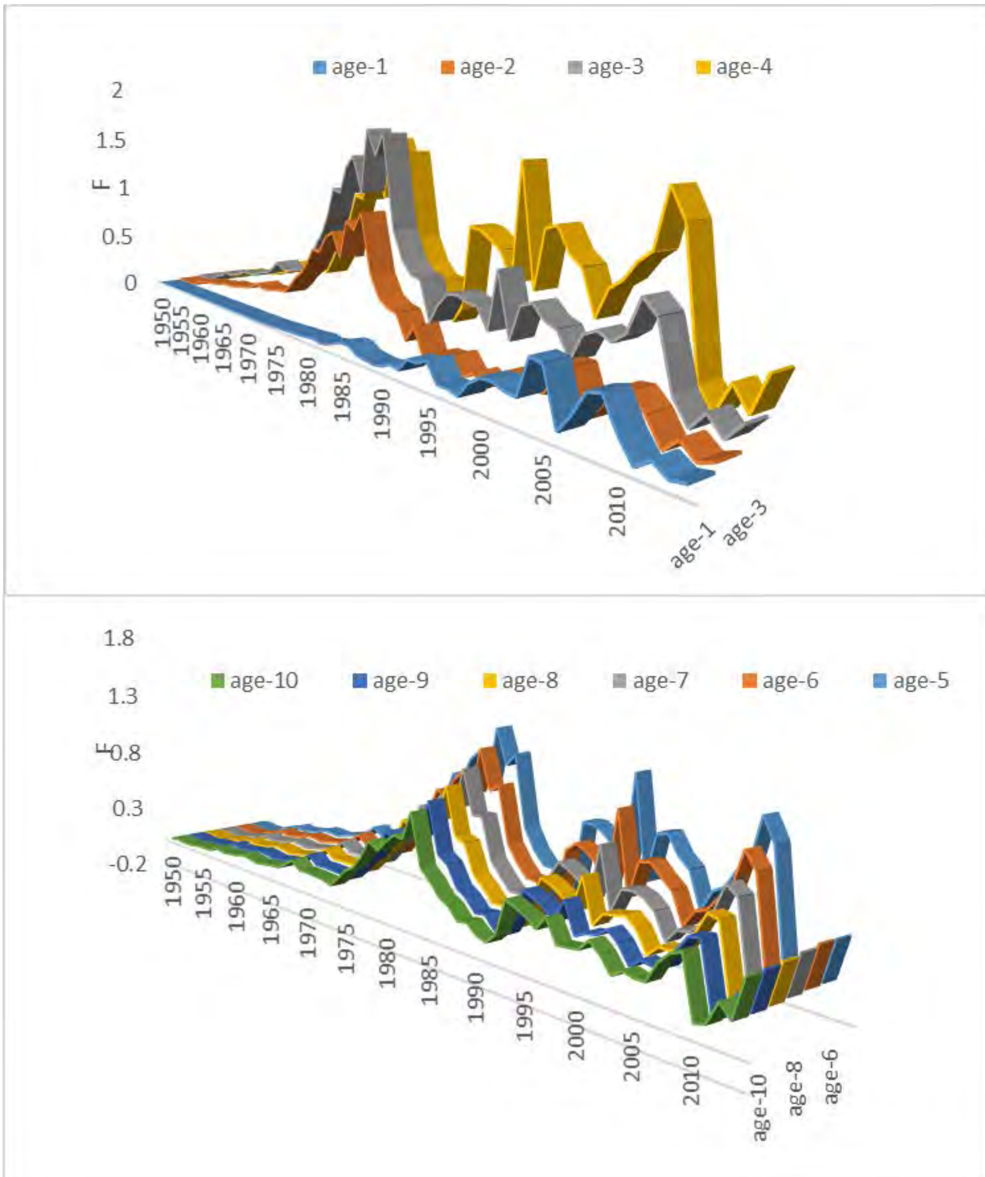
Evaluating trends in F over time requires a metric that is comparable among years and reflects exploitation across a range of ages. Apical F (maximum F at age, Figure 1) is based on a different range of ages among years, because of changing fleet contributions and fleet selectivities. Apical F also does not reflect F for partially selected ages.



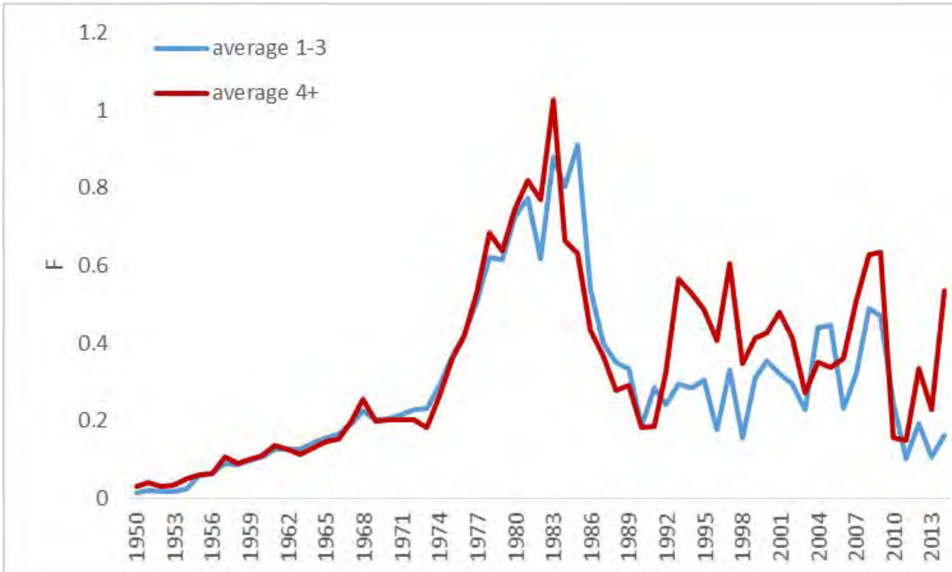
Deciding on a more appropriate metric of F for Red Snapper is challenging because of the complexity of patterns in estimated F at age:

- Age-1 F has one peak in 2004. F was negligible until the mid-1990s, peaked at 0.4 in 2004, then decreased to ~0.1 since 2010.
- Age-2 F had one peak at 1.0 in 1985. F decreased to ~0.1 in the late 1990s, increased to 0.2-0.3 from 1999 to 2010, then decreased to ~0.1 since 2010.
- Age-3 F also had a major peak at 1.6 in the early 1980s, decreased to 0.3-0.5 in the early 1990s, increased to a minor peak of 0.8 in 2008 and decreased to 0.2-0.3 since 2010.
- Age-4 F had three peaks at >1.0 in the early 1980s, 1.5 in 1997 and 1.4 in 2008, then increasing from 0.2 in 2010 to 0.5 in 2014.
- Ages 5 and older have similar patterns in F (three peaks in the early 1980s, 1997 and 2008-2009, then increasing from 2010 to 2014). For most of the time series F

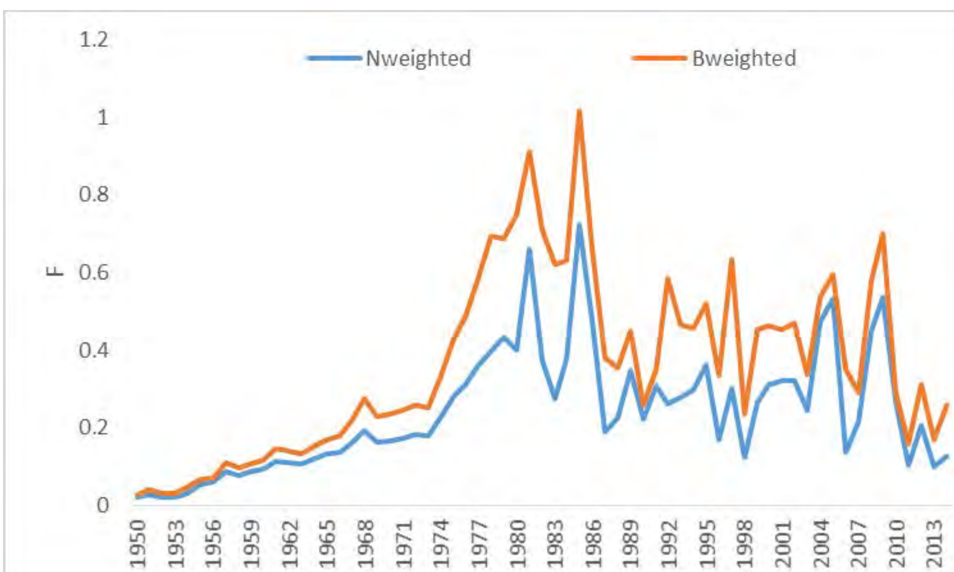
decreases with age, but since 2010, F at ages 5+ is similar, increasing from ~0.2 in 2010 to ~0.5 in 2014.



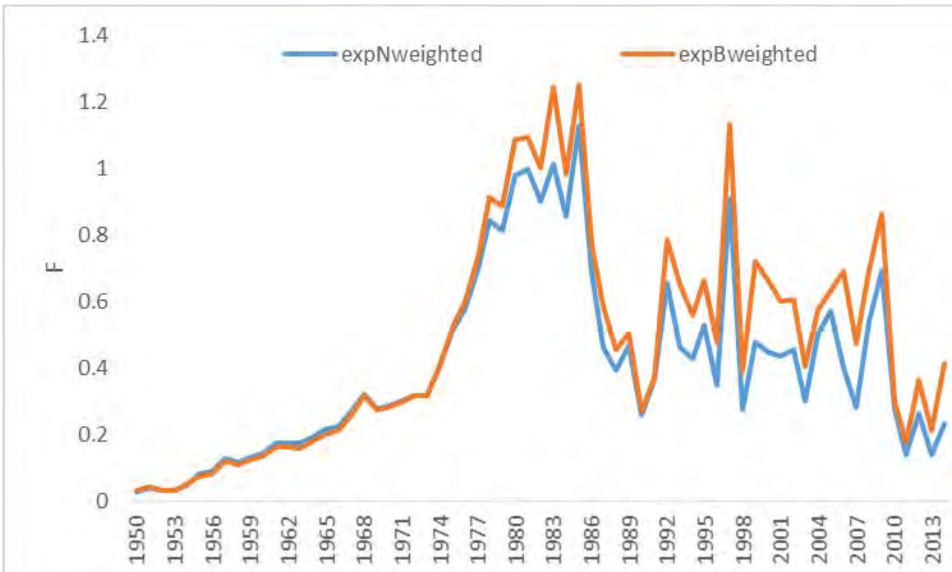
Alternative metrics of F will reflect these patterns differently. Simple average F at age can reflect trends for similar ages (e.g., ages 2-3, ages 4+), and show different recent trends. During the moratorium, F remained low for ages 1-3, but more than tripled for ages 4+.



Average F can be weighted by abundance at age or biomass at age to measure the average F exerted on the entire stock. With young ages typically having greater abundance, abundance weighted average F reflects patterns of F at young ages. Biomass peaks at different ages over the assessment time series (age-20 in 1950, age-2 in 2014), so biomass weighted average F reflects a varying age range.



Average F can also be weighted by exploitable abundance (the product of abundance at age and selectivity at age) or exploitable biomass (the product of biomass at age and selectivity at age) to measure the average F exerted on the exploitable stock. The two exploitable stock average F's are similar, but the exploitable biomass weighted F reflects older ages (e.g., more than doubles during the moratorium) and the exploitable abundance weighted F reflects younger ages (e.g., remains low during the moratorium.



The overfishing limit ($F_{30\%SPR}$) can be expressed in the same currency as the measure of F from the stock assessment. $F_{30\%}$ is currently expressed as Apical F, assuming the average selectivity for the last three years of the stock assessment, which peaks at age-5 (e.g., $F_{30\%}$ expressed as age-5 F is 0.15). All forms of $F_{30\%SPR}$ expressed as an average F are less than age-5 F, because they include some partially recruited ages. According to all of the alternative F metrics considered, overfishing is occurring, but to varying degrees.

Metric	2012-2014 Geo.Mean	F30%	F/F30%
F(age-5)	0.43	0.15	2.8
F(ages 1-3)	0.15	0.06	2.7
F(age-4+)	0.35	0.12	2.8
F(Nwtd)	0.14	0.08	1.8
F(Bwtd)	0.24	0.11	2.1
F(expNwtd)	0.20	0.10	2.0
F(expBwtd)	0.31	0.12	2.5

In conclusion, despite the Review Panel's concurrence that the base BAM configuration can be used for stock status determination the Panel has clearly expressed caveats on some key aspects such as selectivity changes, given the number of parameters being fitted vs. data quality. All the assessment runs clearly show a stock that is abundant at younger ages but overfished in terms of egg production and very slowly recovering. However it is of some concern that the retrospective analysis indicates a substantial upward adjustment of recent F's with addition of 2014 data. Remove 2014 data and the recent Fs are down to around the $F_{30\%}$ reference point (apical values). SSB's are correspondingly adjusted down. The recent strong year classes (age 1 in 2006-2008) appear more stable, but these are feeding progressively into the 5+ age groups from 2010 onwards, the period for which the model sees more adult fish and "wants" to estimate asymptotic selectivity for the general recreational fishery. The Panel expressed concerns that no diagnostics (e.g. parameter correlation tables) were provided to evaluate whether the model has an issue estimating fully selected F's in 2014 vs. recruitment estimates for the strong year classes. There is a potential large uncertainty in the F estimates from the assessment including 2014 data. Some of the age composition data are very well fitted in 2014 – the CVID comps are fitted extremely closely (perhaps too closely!) in 2012 and 2014 and close in 2013, whilst the general recreational age comps are fitted very poorly in 2014 despite a very large sample size and may be an indication of problems with the data for this fishery in 2014. Further, the retrospective analysis indicated that there was a substantial increase in apical F for 2010 to 2013 with the addition of the 2014 data. It is likely that had the red snapper assessment been done up to and including 2013 data, that evidence for overfishing would have been very much weaker than presented here.

4. Evaluate the stock projections, including discussing the strengths and weaknesses, and consider the following:
    e) Are the methods consistent with accepted practices and available data?
    f) Are the methods appropriate for the assessment model and outputs?
    g) Are the results informative and robust, and are they useful to support inferences of probably future conditions?
    h) Are key uncertainties acknowledged, discussed, and reflected in the projection results?

Projections were run to predict stock status in years after the assessment, 2015–2044. The structure of the projection model was the same as that of the assessment model, and parameter estimates were those from the assessment. A single selectivity curve was applied to calculate landings and one for discards, averaged across fleets using geometric mean F's from the last three years of the assessment period, similar to computation of $LF_{30\%}$ benchmarks (§3.22). Expected values of SSB (time of peak spawning), F, recruits, and removals were represented by deterministic projections using parameter estimates from the base run. These projections were built on the spawner-recruit relationship (h =

0.99) with bias correction, and were thus consistent with estimated benchmarks in the sense that long-term fishing at $F_{30\%}$ would yield $LF_{30\%}$ from a stock size at $SSB_{30\%}$. Uncertainty in future time series was quantified through stochastic projections that extended the Monte Carlo/Bootstrap (MCB) fits of the stock assessment model.

The projection method is consistent with those used widely in SEDAR assessments based on statistical models such as BAM and Stock Synthesis, and is consistent with the available data. The method used stochastic projections that extended the Monte Carlo/ Bootstrap (MCB) fits of the assessment model with added stochasticity in recruitment, and hence the propagation of uncertainty from the assessment into the projection period is internally consistent.

The Review Panel concluded that the Red Snapper stock projections provided for SEDAR 41 are appropriate for the BAM assessment model and outputs. The results of the projections are informative and robust, and are useful to support inferences of probable future conditions. The projections provide the information needed to develop management advice, showing projections for F=0; $F=F_{CURRENT}$ (geometric mean of the last 3 years); $F=F_{30\%}$; $F=F_{TARGET}$; $F=F_{REBUILD}$ (max exploitation that rebuilds in greatest allowed time (2044). An additional projection was carried out with F from discards only. Each projection shows the 10th and 90th percentiles of the replicate projections allowing an evaluation of the probability of overfishing occurring, or the stock being overfished, for each year in the rebuilding time frame up to 2044. The projections are robust in terms of propagating realistic levels of uncertainty from the accepted base model run.

Key uncertainties in the projections are acknowledged, discussed, and reflected in the projection results. The MCB runs included ranges of values of natural mortality, discard mortality and fecundity at age agreed by the AW, together with bootstrap selection of data using well-justified error distributions and additional random process error in recruitment conditional on the fitted stock recruit pattern with steepness fixed at 0.99. Initial age structure at the start of 2015 was computed by the assessment model, and fishing rates for the projection started in 2017 following an initialization period in 2015-2016 where fishing mortality rates were derived to represent the management measures in place.

5. Consider how uncertainties in the assessment, and their potential consequences, are addressed.
    c) Comment on the degree to which methods used to evaluate uncertainty reflect and capture the significant sources of uncertainty in the population, data sources, and assessment methods.
    d) Ensure that the implications of uncertainty in technical conclusions are clearly stated.

The Review Panel is concerned that many of the reported uncertainties on quantities of interest are a consequence of the assumed (and fixed) observation variance parameters. No clear evidence of the appropriateness of these assumed values has been presented.

Because of the large number of parameters in BAM a thorough evaluation of convergence and model sensitivity is necessary, but difficult. Uncertainties in the assessment were explored through (1) a mixed Monte Carlo and bootstrap (MCB) analysis to quantify random errors in the assessment output; (2) sensitivity analysis around the base BAM run; and (3) the use of alternative assessment models. The Monte Carlo Bootstrap procedure also explored many combinations of alternative data and model assumptions. In the bootstrapping of observed data on landings, information from the headboat program was used to specify a decreasing CV by time blocks (i.e. CV = 0.15 for 1981-1995, CV = 0.1 for 1996-2007, and CV = 0.05 thereafter). These CVs reflect random errors. However, landings from the headboat fishery are monitored through mandatory logbooks, and thus should in principle have zero sampling errors for the vessels in the sampling frame. The CVs may reasonably reflect random errors in reporting. However, various sources of systematic errors (bias) are not reflected through these CVs. It is known that under-reporting of trips does occur, that catch data may not always be 100% accurate (for example due to recall bias if logbooks are not filled in immediately after each trip), and that other variations in reporting likely occur. Because the distribution of such systematic errors is unknown, it is not possible to quantify the magnitude of the resulting uncertainty in the landings.

The input data on catch composition and abundance indices by cohort are obtained from multi-stage sampling programs where fishing trips typically are the primary sampling units (PSUs) for fisheries data, and locations/standardizes trap catches (90 min soak time) are the PSUs for the chevron trap. Substantial correlations can be expected in age or length composition data sets that are constructed from samples/sub-samples from multiple catches (whether from fisheries-independent surveys or fisheries) (e.g., Aanes and Vølstad 2015). The BAM model itself and the MCB is not likely to realistically account for complex error structure in data weighting without prior estimates of the actual variance-covariance matrices for the input data. The robust multinomial approach with number of PSU's as proxy effective sample sizes employed in the uncertainty evaluation of the BAM can only partly reflect the complex error structure. Ideally, it would be possible to run bootstrap resampling on the PSU's to create replicated BAM runs that reflect the complexity in input data, but given the complexity and configuration of BAM this is not possible. The Review Panel therefore considers the uncertainty in the assessment to be appropriately addressed given these restrictions.

The sensitivity analyses were used to explore a wide range of data decisions, model assumptions and model configurations to examine the robustness of stock status determination. The model was run for a plausible range of values for each factor. The

Review Panel noted that the sensitivity testing by alternating one factor at a time, although commonly done, may not fully reflect the uncertainty in model outputs from a complex model such as BAM with a large number of parameters where many are likely to be correlated (e.g., Saltelli and Annoni (2010). Global sensitivity analysis (Saltelli et al. 2008) may be used to untangle the contribution of single factors/parameters and interactions between parameters to the overall variability in model output. Anderson et al. (2011) provide an excellent overview of the literature, and many examples of applications of global sensitivity analysis to Integrated Assessment Models in climate research, and some of these are likely to be applicable to the BAM model. The following is a description of each of the model runs provided to the reviewers during the course of the RW:

S12: (based on the old base model) The headboat discard index was truncated to only include years 2005-2009.

S16: (based on the old base model) The headboat discard index was dropped entirely.

S32: (based on the old base model) The general recreational fleet was set to have the same selectivity as headboat in the last time block (dome-shaped, 2010-2014).

DroppedHBdiscindex: same as S16, except starting with the new base model (corrected chevron trap age compositions).

TruncatedHBdiscindex: same as S12, except starting with the new base model (corrected chevron trap age compositions).

Model uncertainty was mainly explored by running ASPIC (Version 7.03, 2005) that relies on length-age aggregated catch and CPUE indices, with no compositional catch being included. The ASPIC runs resulted in biomass estimates above B_{MSY} and estimates of F below F_{MSY}, and hence do not place the stock in the "overfished-overfishing" category. The difference between the ASPIC and the BAM results can however be explained by the fact that ASPIC does not take into account the age-structure of the catches and the stock. Thus, a biomass made up largely by recruits can result in a stock status of not overfished-overfishing. In addition to ASPIC, a simple catch curve analysis was performed that tended to support the Z values estimated from the BAM. Therefore, despite the many uncertainties and the concerns expressed above the BAM base configuration is therefore considered to provide the most appropriate basis for status determination, despite many sources of uncertainty.

6. Consider the research recommendations provided by the Data and Assessment workshops and make any additional recommendations or prioritizations warranted.
   a) Clearly denote research and monitoring that could improve the reliability of, and information provided by, future assessments.
   b) Provide recommendations on possible ways to improve the SEDAR process.

The Review Panel considers the first three of the following bullets to be the highest priority for assessment improvement.

- Increased fishery independent information, particularly maintaining reliable indices of abundance and composition data streams.
- Improve the reliability of discard data as an abundance index by improving knowledge of private recreational fisherman behavior.
- Research to determine the spatial distribution (horizontal and vertical) of large adult Red Snapper using tracking and telemetry.
- The Review Panel reiterates various research recommendations focused on Red Snapper population structure in the South Atlantic. Red Snapper were modeled in this assessment as a unit stock off the southeastern U.S. For any stock, variation in exploitation and life-history characteristics might be expected at finer geographic scales. Modeling such sub-stock structure would require more data, such as information on the movements and migrations of adults and juveniles, as well as spatial patterns of larval dispersal and recruitment, and spatially-explicit data of all types used in the assessment model. It is unclear whether a spatially-explicit model would improve the assessment. Given the robust ocean circulation in the South Atlantic Bight conditions creating population sub-structure. The research effort necessary to support such an effort would be extensive and probably unjustified on stock assessment improvement grounds, however, it would be needed to support MPA placement, performance evaluation, etc.
- More research to describe the juvenile life history of Red Snapper is needed, including more work to identify the location of juveniles before they recruit to the fishery.
- The effects of environmental variation on the changes in recruitment or survivorship.
- Investigate possible historical changes in sexual maturity. The current estimate of age of sexual maturity is low and unusual for other Lutjanids. Is it right or a compensatory response to heavy exploitation?
- Continue conducting studies to develop a time series of batch fecundity to obtain information on the inter-annual variation in reproductive output.

7. Consider whether the stock assessment constitutes the best scientific information available using the following criteria as appropriate: relevance, inclusiveness, objectivity, transparency, timeliness, verification, validation, and peer review of fishery management information.

The Review Panel considers that the BAM assessment for Red Snapper constitutes the best scientific information available, and fulfils the following criteria:

Relevance: The SEDAR 41 assessment is highly relevant as the Red Snapper stock is depleted and undergoing rebuilding under a moratorium with limited landings permitted and most catches being discarded. The data and assessment provide the best means of establishing the rate of recovery of the stock, determining if measures are preventing overfishing, and providing information that can be used to adjust management actions where appropriate.

Inclusiveness: The SEDAR 41 assessment includes all data that have been quality assured and proved adequate for use in the assessment. This includes data from State as well as Federal sampling schemes where needed, for example to estimate discards during the mini-season where MRIP sampling is too limited for such a short season length.

Objectivity: The SEDAR 41 BAM model is a highly objective procedure based on well-tested statistical modeling principles, and using data sets and assumptions that have been rigorously documented and reviewed through the SEDAR data, assessment and peer-review process. Where fully objective decisions are difficult to make, such as some decisions on scenarios for historic catches where evidence is lacking, the uncertainties around the decisions made have been explored and included in sensitivity analyses and the Monte Carlo Bootstrap evaluation of assessment uncertainty.

Transparency: All outputs of the data, assessment and review workshops in SEDAR 41 are fully documented and publicly available. The discussions at the review workshop are also recorded for record. All data sets are thoroughly explored and the quality of data on which the assessment is based is documented and transparent, as are all decisions related to the choice of assessment model, how it is implemented, and the results of the base run and sensitivity and uncertainty analyses.

Timeliness: The SEDAR process in general is arranged to provide timely fishery management advice where it is needed, and to ensure that assessments are benchmarked and reviewed at appropriate intervals.

Verification: The SEDAR 41 assessment process and deliverables comply with legal requirements under the Magnuson Stevens Act (2007) for developing and monitoring of fishery management plans and providing information on stock status.

Validation: The SEDAR 41 process is designed to meet the needs of fishery managers for peer-reviewed stock assessments and associated advice on stock status and future catches, and the process is open and fully transparent to the fishery managers and to stakeholders from commercial and recreational fisheries, conservation groups or others with a stake in the outcomes and who have opportunity to give their views on record.

Peer review: The SEDAR 41 process includes full peer-review by experts appointed by the Center for Independent Experts (CIE, University of Miami) and by reviewers from the SAFMC SSC. The review panel report and the independent CIE reviews are publicly available

8. Compare and contrast assessment uncertainties between the Gulf of Mexico and South Atlantic stocks.

   Both the South Atlantic and Gulf of Mexico Red Snapper stock assessments have multiple uncertainties. The table below summarizes the significant sources of assessment uncertainty in the population, data sources, and assessment methods for both stocks.

Sources of Uncertainty	**South Atlantic (SEDAR 41)**	**Gulf of Mexico (SEDAR 31)**
Population	• Juvenile life history, including the location of juveniles before they recruit to the fishery • Spatial distribution (horizontal and vertical) of large adult Red Snapper • Variability in batch fecundity and spawning frequency with size and age • Effects of environmental variation on changes in recruitment • Density-dependent changes in growth, reproduction, and natural mortality	• Population structure and connectivity between eastern and western Gulf (for both adults and juveniles) • The use and effect of artificial reef structures on red snapper population abundance, age and length composition, and spatial distribution Effects of environmental variation on changes in recruitment • Density-dependent changes in growth, reproduction, and natural mortality
	• Limited fishery independent indices of abundance • No fishery independent index of abundance for early juveniles	• Limited fishery independent index of abundance for early juveniles • Limited information on the magnitude, size, and age composition of discards

Data Sources	• Changes in selectivity, catch, and discard data due to changes in fisher behavior within and outside the mini-season • Poor information on the magnitude, size, and age composition of discards • Poorly-informed selectivity functions for most fleets	• Poorly-informed selectivity functions for most fleets
Assessment Methods	• Uninformative Stock-Recruitment relationship (had to use proxy reference points) • Uncertainty for certain parameters and data inputs was fixed to chosen values that could be considered arbitrary (e.g., CV for landings and discards set = 0.05) • Model uncertainty was mainly explored by running an alternative Stock Production Model	• Uninformative Stock-Recruitment relationship (had to use proxy reference points) • Uncertainty for certain parameters and data inputs was fixed to chosen values that could be considered arbitrary (e.g., CV for landings set = 0.05 and for discards = 0.5) • Model uncertainty was not explicitly explored by the use of different models

9. Provide guidance on key improvements in data or modeling approaches which should be considered when scheduling the next assessment.

The RW Panel recommends that given the data and model complexities inherently associated with stock assessment of South Atlantic Red Snapper, more realistic timelines be considered for the next assessment.

Additionally, given that the input data on catch-at-age and abundance indices by cohort are likely to be cluster-correlated (Nelson 2014), and therefore have low effective sample sizes, it is problematic that the BAM model has a very large number of parameters. It would therefore make sense to provide alternative runs using more parsimonious models to get a wider evaluation of the robustness of the assessment. One recommended candidate is a statistical assessment model (XSAM) (Sondre Aanes, Norwegian Computing Center) recently applied in the ICES Benchmark Assessment for Norwegian Spring Spawning Herring, and approved as the standard assessment model. This model template is based on a state-space model and structural time series models for fish stock assessment (inspired by Gudmundsson 1994), and includes the DTU Aqua SAM model (Nielsen and Berg 2014) that is widely used in ICES as a special case. The main advantage of this XSAM model template is that it can utilize the sampling distributions derived from analysis of sample survey data (estimated catch-at-age, and abundance indices at age) by giving appropriate weights to input-data points. It is coded in TMB (R library) which is efficient for nonlinear models with latent variables.

Another important point in addressing future assessments of South Atlantic Red Snapper is that it would be extremely useful for the Review Panel to see direct estimates of total removals by age-class across fleets (each fleet is essentially a stratum when it comes to estimating the age-composition of removals). This would allow the Panel to see how well cohorts are tracked in the fisheries data. The selectivity by fleet is only relevant when trying to use the fishery-dependent data as indices of abundance. However, selectivity in this context is muddled by the spatial coverage of each fleet. For example, two fleets using same gear (with same selectivity) would end up with different age-compositions if they operate in different areas (depths), if in fact the population by age-class differs by area (depths), which seems to the case for Red Snapper. Therefore, the Review Panel has struggled to understand how multiple abundance indices from fisheries-dependent data that each only covers portions of the stock can be pooled within the BAM model to yield representative indices for the entire stock. In the suggestions made above regarding the use of alternative assessment models (Gudmundsson 1994, and refinements by Aanes), input data from fisheries are total estimates across fleets of yearly removals by age-class and have an associated variance-covariance matrix that reflects the complex cluster sampling.

Another recommendation from the Review Panel concerns the process used for standardization of the CVID index of abundance. The CVID index was derived from fitting a Zero-Inflated Negative Binomial (ZINB) generalized linear model to individual catches with polynomials (degree) of depth (3), temperature (2) and Latitude (7) fit to catches greater than zero and polynomials (degree) of depth (3) and Latitude (4) fit to the zero-inflation portion of the model. Standardized index for each year was based on converting each covariate (all continuous except year) to a sequence of a small number of evenly space values over the range of each covariate over all the years. These converted covariates were used to predict catches over all years with the effect added and then averaged within each year to give annual indices. The variances of these indices were estimated by bootstrapping observed catches and associated covariates and running each bootstrap through the above process. This standardization approach amounts to predicting the catch expected for the mean of the converted covariates. Bootstrapping the individual Chevron trap sets implicitly assumes that the covariates are a random sample from a population of potential covariate values. In this case, the range of covariate values will vary over bootstrap samples and so will mean of the converted covariates. This may be appropriate in a case of a one-off analysis of the survey data for any one year but the focus of standardization is to have a fixed set of covariate variables. In addition, changes in the range of the covariates in the bootstrap samples may not support the original fitted model, especially for coefficients of high degree polynomials.

As an alternative, bootstrapping of the residuals from the original model fit to the data may be more appropriately estimate the variance of the standardized survey index. In this case the residuals (in the appropriate scale) are randomly combined with the predicted values to give new observations that are then used to fit the ZINB model. The range of the covariates and mean of the converted covariates will stay the same over all of the bootstrap replications and the variances of the annual indices will be a function of the variability of the residuals from the fitted model.

10. Prepare a Peer Review Summary summarizing the Panel's evaluation of the stock assessment and addressing each Term of Reference. Develop a list of tasks to be completed following the workshop. Complete and submit the Peer Review Summary Report in accordance with the project guidelines.

    This report constitutes the Review Panel's summary evaluation of the stock assessment and discussion of the Terms of Reference. The Review Panel will complete edits to its report and submit a final document to the SEDAR program for inclusion in the full set of documents associated with SEDAR 41.

National Marine Fisheries Service

Last revision: April, 2016

Document History

February, 2016 Original release.

March, 2016 This release incorporates some of the corrections made during the Review Workshop, including corrected age composition data from the MARMAP program.

April, 2016 This release incorporates all of the corrections made during the Review Workshop, including corrected chevron trap age composition data. The corrections resulted in a new base run, for which iterative reweighting of the likelihood components and the starting value analysis were re-run. The new base run results, including updated uncertainty analyses and projections are included. The sensitivities and retrospectives, however, are unchanged. The Reviewers did not request that sensitivities or retrospectives be re-run because the base run changes were relatively small.

2 Data Review and Update

The input data for this assessment are described below, with focus on modifications from the SEDAR41 DW.

2.1 Data Review

In this benchmark assessment, the Beaufort assessment model (BAM) was fitted to data sources developed during the SEDAR 41 DW with some modifications and additions.

Model input compiled during the DW

- Life history: Life history meristics, population growth, female maturity, proportion female, number of batches at age, size-dependent batch fecundity, and discard mortality
- Landings and discards: Commercial handline landings and discards, Headboat landings and discards, Recreational landings and discards
- Indices of abundance: Commercial handline, Headboat, Headboat discards, SERFS chevron trap, SERFS video

Model input modified or developed after the DW

- Life history: Fishery-dependent growth estimates, Growth estimates during the 20 inch size regulation, Age–specific natural mortality
- Landings and discards: changes to the recreational discards
- Indices of abundance: Fishery–independent indices combined (Chevron trap and Video)
- Length compositions: Commercial handline, Headboat, Recreational
- Age compositions: Commercial handline, Headboat, Recreational, Chevron trap

2.2 Data Update

2.2.1 Life History

Estimates of the von Bertalanffy growth parameters were provided by the DW for the population as a whole: (911mm, 0.24yr^{-1}, and -0.33yr). Two alternative von Bertalanffy curves were generated: one for all fisheries when no size limit was in place, and another to represent the fish captured by all fisheries under a 20 inch size limit regulation. Age-specific mortality was updated due to an error in the original calculation which forced the t_0 value to 0. Life-history information is summarized in Tables 1 and 2.

2.2.2 Landings and Discards

The fleet structure to be modeled was decided after the DW. The general recreational fleet comprises the charterboat and private boat fleets, while the headboat fleet stands alone. The decision was made to separate headboat from all other recreational fishing modes because length compositions diverge later in the time series. The general recreational fleet discards contained some zeros (years 1982, 1986, and 1990) that the panel considered unlikely to be accurate due to the magnitude of the surrounding years' values. The decision was made by the panel to fill in the zeros with the lowest observed discards in the regulatory time block of the zero value. Total removals as used in the assessment are in Table 3.

2.2.3 Indices of Abundance

The DW provided a SERFS chevron trap and video index separately. However, because the data are collected from the same sampling platforms (i.e. cameras mounted on the chevron traps), the two indices are not independent measures of abundance. Therefore, the panel decided to combine the two using the Conn (2010) method for combining indices. All indices and their corresponding CVs are shown in Table 4, and Figure 1 shows the indices as recommended by the data workshop plotted with the new CVID index for comparison. Fishery dependent indices of abundance were assumed to have CVs of 0.2, which is consistent with Francis (2003).

2.2.4 Length Compositions

Length compositions for all data sources were developed in 3-cm bins over the range 21–99 cm (labeled at bin center). All lengths below and above the minimum and maximum bins were pooled. The commercial handline, general recreational and headboat lengths were weighted by the region and landings (SEDAR41-AW05 2015). For inclusion, length compositions in any given year had to meet the sample size criteria of $nfish > 30$ and $ntrips \geq 10$ (Table 5). Furthermore, the AW panel decided to eliminate length comps where age comps were available. There were conflicts between the length compositions and age compositions, and the panel thought, given the relative ease of ageing this species and the fact the model is age-structured, the age compositions would provide more informative signals of year-class strength and better represent the catch in each fleet or survey.

2.2.5 Age Compositions

For age composition data, the upper range was pooled at 13 years old because a very small proportion of the data exist past age 13. The age compositions were weighted by the length compositions in attempt to address bias in selection of fish to be aged. For inclusion, age compositions in any given year had to meet the sample size criteria of $nfish > 10$ and $ntrips \geq 10$ (Table 5). Age composition was preferred over length composition when both were available from a given fleet in a given year. Age compositions were further corrected at the Review Workshop (SEDAR41-RW07 2016).

2.2.6 Additional Data Considerations

Size limits were in place beginning in 1983 (12 inch minimum size limit TL), and changed in 1992 (20 inch minimum size limit TL). A moratorium was put in place for Red Snapper in 2010, and three subsequent mini-seasons were allowed (2011-2014) with no size limit. The panel examined size composition data and determined that three time blocks should be used to account for size limits, or the lack thereof: 1950-1991, 1992-2009, and 2010-2014. Data available for this assessment are summarized in Tables 1–5.

3 Stock Assessment Methods

3.1 Overview

The primary model discussed during the Assessment Workshop (AW) was a statistical catch-age model implemented using the Beaufort Assessment Model (BAM) software (Williams and Shertzer 2015). BAM applies a statistical catch-age formulation, coded using AD Model Builder (Fournier et al. 2012). BAM is referred to as an integrated analysis because it uses all population dynamics-relevant data (e.g. removals, length and age compositions, and indices of abundance) in a single modeling framework. In contrast, production models (e.g. ASPIC or ASPM) or catch curve analyses only use subsets of the available data and often require simplifying assumptions. In essence, the catch-age model simulates a population forward in time while including fishing processes (Quinn and Deriso 1999; Shertzer et al. 2008). Quantities to be estimated are systematically varied until characteristics of the simulated population matches available data on the real population. The model is similar in structure to Stock Synthesis (Methot 1989; 2009). Versions of BAM have been used in previous SEDAR assessments of reef fishes in the U.S. South Atlantic, such as Red Porgy, Black Sea Bass, Tilefish, Blueline Tilefish, Gag, Greater Amberjack, Red Grouper, Snowy Grouper, and Vermilion Snapper, as well as in the previous SEDAR assessments of Red Snapper (SEDAR24 2010). In addition, a surplus production model implemented using ASPIC and a catch curve analysis (SEDAR41-AW08 2015) were used to provide supplementary information.

3.2 Data Sources

The catch-age model included data from three fleets that caught Red Snapper in southeastern U.S. waters: general recreational (charter and private boat), commercial handlines (hook-and-line), and recreational headboats. The model was fitted to data on annual landings (in numbers for the recreational fleets, in whole weight for commercial fleet); annual discards (in numbers for all fleets), annual length compositions of removals; annual age compositions of landings and surveys; three fishery dependent indices of abundance (commercial handlines, headboat, and headboat discards); and one fishery independent index of abundance (combined SERFS chevron trap and SERFS video index). Removals included landings and dead discards, assuming the mortality rates provided by the Data Workshop. Data used in the model are tabulated in §2 of this report.

3.3 Model Configuration

The assessment time period was 1950–2014. A general description of the assessment model follows.

3.4 Stock dynamics

In the assessment model, new biomass was acquired through growth and recruitment, while abundance of existing cohorts experienced exponential decay from fishing and natural mortality. The population was assumed closed to immigration and emigration. The model included age classes $1 - 20^+$, where the oldest age class 20^+ allowed for the accumulation of fish (i.e., plus group).

3.5 Initialization

Initial (1950) numbers at age assumed the stable age structure computed from expected recruitment and the initial, age-specific total mortality rate. That initial mortality was the sum of natural mortality and fishing mortality, where fishing mortality was the product of an initial fishing rate (F_{init}) and F-weighted average selectivity. The initial fishing rate was estimated using a prior centered around $F_{\text{init}} = 0.03$. The assumption matches what was used for SEDAR24 with the justification that the value should be small given the relatively low volume of landings prior to the assessment period. The initial recruitment in 1950 was assumed to be the expected value from the spawner-recruit curve. For the remainder of the initialization period (1950–1977), recruitment was assumed equal to expected values. Without sufficient age/length composition data prior to 1978, there is little information to estimate those historic recruitment deviations with accuracy.

3.6 Natural mortality rate

The natural mortality rate (M) was assumed constant over time, but decreasing with age. The form of M as a function of age was based on Charnov et al. (2013), a change from SEDAR24 which based natural mortality on the findings of Lorenzen (1996). The Charnov et al. (2013) approach inversely relates the natural mortality at age to somatic growth. As in previous SEDAR assessments, the age-dependent estimates of M_a were rescaled to provide the same fraction of fish surviving from age 4 through the oldest observed age (51 yr) as would occur with constant $M = 0.134$. This approach using cumulative mortality allows that fraction at the oldest age to be consistent with the findings of Then et al. (2014).

3.7 Growth

Mean size at age of the population, fishery removals under no size limit, and fishery removals under a 20 inch size limit (total length, TL) were modeled with the von Bertalanffy equation, and weight at age (whole weight, WW) was modeled as a function of total length (Figure 2, Table 2). Parameters of growth and conversions (TL-WW) were treated as input to the assessment model. For fitting length composition data, the distribution of size at age was assumed normal with a CV estimated by the assessment model for each growth curve.

3.8 Female maturity and sex ratio

Female maturity was modeled with a logistic function; parameters for this model and a vector of maturity at age were provided by the DW and treated as input to the assessment model (Table 2). The sex ratio was assumed to be 50:50, as recommended by the DW.

3.9 Spawning stock

Spawning biomass was modeled as population fecundity (number of eggs). For Red Snapper, peak spawning was considered to occur at the end of June. This included information on batch size as a function of age, as well as information on the number of annual batches as a function of age (SEDAR41-DW49 (2015) and Fitzhugh et al. (2012)).

3.10 Recruitment

Expected recruitment of age-1 fish was predicted from spawning biomass using the Beverton–Holt spawner-recruit model. Steepness, h, is a key parameter of this model, and unfortunately it is often difficult to estimate reliably (Conn et al. 2010). In this assessment, many initial attempts to estimate steepness resulted in a value near its upper bound of 1.0, indicating that the data were insufficient for estimation. Likelihood profiling showed that the value was likely above 0.92, and was unreliably estimated between 0.92 and 0.98. The AW Panel decided to assume an average annual recruitment while estimating lognormal deviations around that average. This was achieved by fixing steepness at $h = 0.99$.

3.11 Landings

Time series of landings from three fleets were modeled: commercial handline (1950–2014), general recreational (1955–2014), and headboat (1955–2014). Landings were modeled with the Baranov catch equation (Baranov 1918) and were fitted in either weight or numbers, depending on how the data were collected (1000 lb whole weight for commercial fleets, and 1000 fish for recreational). The DW provided observed landings back to the first assessment year (1950) for the commercial fleet and back to 1955 for the recreational fleets. However, sampling of headboats began in 1972 and other recreational sectors in 1981. Thus, historic landings of the recreational fleets were estimated indirectly by the DW using the FHWAR ratio method (SEDAR41 41dw17). Historic landings were considered (and treated) in this assessment as a primary source of uncertainty.

3.12 Discards

As with landings, discard mortalities (in units of 1000 fish) were modeled with the Baranov catch equation (Baranov 1918), which required estimates of discard selectivities and release mortality probabilities. Discards were assumed to have fleet-specific, year-specific mortality probabilities, as suggested by the DW. Until 2007, the rate for commercial handlines was 0.48, and 0.38 thereafter. Until 2011, the general recreational and headboat rate was 0.37, with 0.285 thereafter. Annual discard mortalities, as fit by the model, were computed by multiplying total discards (tabulated in the DW report) by the fleet-specific and year-specific discard mortality rate. For general recreational and headboat fleets, discard time series were assumed to begin in 1981; for the commercial handlines fleet, discards were modeled starting in 1992 corresponding to the implementation of the 20-inch size limit.

3.13 Fishing

For each time series of removals (landings and discards), the assessment model estimated a separate full fishing mortality rate (F). Age-specific rates were then computed as the product of full F and selectivity at age. The across-fleet annual F was represented by apical F, computed as the maximum of F at age summed across fleets.

3.14 Selectivities

Selectivity curves applied to landings were estimated using a parametric approach. This approach applies plausible structure on the shape of the curves, and achieves greater parsimony than occurs with unique parameters for each age. Flat-topped selectivities were modeled as a two-parameter logistic function. Dome-shaped selectivities were modeled by combining two logistic functions: a two-parameter logistic function to describe the ascending limb of the curve, and a two-parameter logistic function to describe the descending limb. To model landings, the AW Panel recommended flat-topped selectivity for commercial handlines and dome-shaped selectivity for headboat and the general recreational fleets.

The assessment panel devoted substantial discussion and exploration to the pattern (flat-topped or dome-shaped) of selectivity at age. Several working papers and scientific literature (SEDAR24-AW05, SEDAR24-AW09, SEDAR24-AW12, SEDAR31-AW04, SEDAR31-AW12, SEDAR41-DW50, SEDAR41-DW08, Patterson et al. (2012), Wells et al. (2008), and Mitchell et al. (2014)) helped guide the panel's decisions by providing insight into selectivity based on length and age compositions, depth distributions of fishing effort, skill levels of fishermen, and how circumstances contrasted between the Atlantic and Gulf of Mexico. The choice of flat-topped selectivity for commercial handlines landings and dome-shaped for all others was based on several criteria. Two related considerations were the fleet-specific depths of fishing effort and the distribution of age at depth. In general, the commercial handlines fleet fish

in deeper water than other fleets, and although there was only weak correlation between depth and age of older fish (5^+), younger fish (1–5) were more readily caught in shallower depths (SEDAR24-AW05, and Mitchell et al. (2014)). It was also suggested that commercial gear and fishermen can better handle larger fish (SEDAR24-AW12). Catch curve data were consistent with the hypothesis that older fish are more vulnerable to the commercial handlines fleet than to recreational fleets (SEDAR41-AW08 2015).

Selectivity of each fleet was fixed within each block of size-limit regulations, but was permitted to vary among blocks where possible or reasonable. Fisheries experienced four blocks of size-limit regulations (no limit prior to 1983, 12-inch limit during 1983–1991, 20-inch limit during 1992–2009, and no size limit during the moratorium/miniseasons 2010–2014). However, the panel combined blocks one and two after seeing that the 12-inch size limit had a negligible effect on the selectivity pattern. Age and length composition data are critical for estimating selectivity parameters, and ideally, a model would have sufficient composition data from each fleet over time to estimate distinct selectivities in each period of regulations. That was not the case here, and thus additional assumptions were applied to define selectivities, as follows. Because the general recreational fleet had little age or length composition data prior to 1998, this fleet mirrored the headboat fleet until the final time block. All domed-shaped selectivities meant to characterize landings were configured so as not to allow a selectivity of 0 at older ages, which was considered implausible. Size and age composition data show larger, older fish are caught by all fleets. However, the selectivity functions would reach zero before the plus group age of 20. Therefore, the panel examined the age composition data and used the information they contained to create a plus group for the selectivities. Headboat selectivities were fixed as constant after age 10 at the value estimated for age 10. For the general recreational fleet, the constant age at which we fixed selectivity was 13. These plus groups were consistent with how the age composition data were fitted.

Selectivities of discards were estimated in a similar fashion to the landings in that the general recreational fleet discards mirrored the headboat fleet discards. Both the commercial handline discards and the headboat discards had sufficient length composition to estimate selectivities.

Selectivities of fishery dependent indices were the same as those of the relevant fleet. The fishery independent CVID index selectivity was assumed logistic and informed by the SERFS chevron trap age compositions.

3.15 Indices of abundance

The model was fit to three fishery dependent indices of relative abundance (headboat 1976–2009; headboat discards 2005–2014; and commercial handlines 1993–2009), and one fishery independent index of abundance (SERFS combined video and trap, CVID). Predicted indices were conditional on selectivity of the corresponding fleet or survey, and were computed from abundance at the midpoint of the year or, in the case of commercial handlines, biomass. The headboat discard index tracks small fish (less than 20 inches) and was included as a measure of recruitment strength.

3.16 Catchability

In the BAM, catchability scales indices of relative abundance to the estimated population at large. For the base model, the AW Panel recommended a time-invariant catchability.

A sensitivity run adopted a time-varying catchability for the headboat index. In this formulation, catchability was estimated in two stanzas, pre- and post-1992. Choice of the year 1992 was based on the implementation of a fishery management plan that may have changed fishing behavior.

3.17 Biological reference points

Biological reference points (benchmarks) were calculated based on the fishing rate that would allow a stock to attain 30% of the maximum spawning potential which would have been obtained in the absence of fishing mortality. Computed benchmarks included the MSY proxy, fishing mortality rate at $F_{30\%}$, total biomass at $F_{30\%}$, and spawning stock at $F_{30\%}$ (Gabriel and Mace 1999). In this assessment, spawning stock measures total eggs of the mature stock. These benchmarks are conditional on the estimated selectivity functions and the relative contributions of each fleet's fishing mortality. The selectivity pattern used here was the effort-weighted selectivities at age, with effort from each fleet estimated as the full F averaged over the last three years of the assessment.

3.18 Fitting criterion

The fitting criterion was a penalized likelihood approach in which observed removals (landings and discards) were fit closely, and observed composition data and abundance indices were fit to the degree that they were compatible. Removals and index data were fit using lognormal likelihoods. Length and age composition data were fit using robust multinomial likelihoods (Francis 2011), and only from years that met minimum sample size criteria ($nfish > 30$ and $ntrips \geq 10$) for length compositions and ($nfish > 10$ and $ntrips \geq 10$) for age compositions. Commercial and headboat discard length composition minimum sample size threshold was set lower ($nfish > 10$) due to the fact that the discard composition data were the only information available to estimate selectivity.

The model includes the capability for each component of the likelihood to be weighted by user-supplied values. For data components, these weights were applied by either adjusting CVs (lognormal components) or adjusting effective sample sizes (multinomial components). In this application to Red Snapper, CVs of landings and discards (in arithmetic space) were assumed equal to 0.05, to achieve a close fit to these time series yet allowing some imprecision. In practice, the small CVs are a matter of computational convenience, as they help achieve the desired result of close fits to the landings, while avoiding having to solve the Baranov equation iteratively (which is complex when there are multiple fisheries). Weights on other data components (indices, age/length compositions) were adjusted iteratively, starting from initial weights as follows. The CVs of indices were set equal to the values estimated by the GLMs used for standardization or at the fixed value of 0.2 for the headboat and commercial handline indices. Effective sample sizes of the multinomial components were assumed equal to the number of trips sampled annually, rather than the number of fish measured, reflecting the belief that the basic sampling unit occurs at the level of trip. These initial weights were then adjusted until standard deviations of normalized residuals were near 1.0 (Francis 2011). In sensitivity runs, weights on the fishery dependent indices were adjusted upward to explore their effects (not because up-weighted runs were considered equally plausible).

For parameters defining selectivities, CV of size at age, and σ_R, normal priors were applied to maintain parameter estimates near reasonable values, and to prevent the optimization routine from drifting into parameter space with negligible gradient in the likelihood. For σ_R, the prior mean (0.6) and standard deviation (0.25) were based on Beddington and Cooke (1983) and Mertz and Myers (1996).

3.19 Configuration of a base run

The base run was configured as described above. This configuration does not necessarily represent reality better than all other possible configurations, and thus this assessment attempted to portray uncertainty in point estimates through sensitivity analyses and through a Monte-Carlo/bootstrap approach (described below).

3.20 Sensitivity analyses

Sensitivity runs were chosen to investigate issues that arose specifically with this benchmark assessment. They were intended to demonstrate directionality of results with changes in inputs or simply to explore model behavior, and not all were considered equally plausible. These model runs vary from the base run as follows:

- S1: Remove the 2008 and 2009 years from the handline and headboat indices
- S2: Upweight fishery independent index further than was explored in the Assessment Workshop (10X likelihood weight after the iterative reweighting)
- S3: Upweight handline and headboat indices (3X likelihood weight after iterative reweighting)
- S4: Fishery dependent indices only
- S5: High value of M
- S6: Low value of M
- S7: Low discard mortality probabilities (commercial handlines rate set to 0.38 or 0.28, all recreational set to 0.27 or 0.20)
- S8: High discard mortality probabilities (commercial handlines rate set to 0.58 or 0.48, all recreational set 0.45 or 0.36)
- S9: Longer combined chevron trap and video (CVID) index (2005-2014)
- S10: Reduced general recreational landings in 1984 and 1985 by taking the geometric mean of surrounding years
- S11: Steepness $h = 0.84$
- S12: Headboat discard index excluded after 2009
- S13: Ageing error matrix included
- S14: Low value for age-specific number of batches
- S15: High value for age-specific number of batches
- S16: Headboat discard index dropped
- S17: High landings
- S18: Low landings
- S19: High discards
- S20: Low discards
- S21: Dome-shaped selectivity for commercial handline fleet
- S22: Separate video and trap index rather than a single CVID index
- S23: Fishery independent index only
- S24: Continuity run: changes include SEDAR24 values such as M, steepness, maturity, and SSB
- S25: Two time blocks for Headboat logbook index catchability (pre- and post-1992)
- S26: Retrospective - 1 year of data
- S27: Retrospective - 2 years of data
- S28: Retrospective - 3 years of data
- S29: Retrospective - 4 years of data

- S30: Use 1978 as the starting year, applied a loose prior to the estimation of F_{init} that corresponds to the geometric mean of the fishing mortality for 1950-1977
- S31: Estimate selectivities without fixing a plus group (for the selectivity estimation)

Sensitivities 5, 6, 14, 15, and 17-20 used the 10th and 90th quantiles (as the low and the high respectively) from the bootstraps of the observed data described in the uncertainty analysis methods (Section 3.24).

3.21 Parameters Estimated

The model estimated annual fishing mortality rates of each fleet, selectivity parameters, catchability coefficients associated with indices, parameters of the spawner-recruit model (except steepness), annual recruitment deviations, and CV of size at age for each age and growth relationship.

3.22 Per Recruit and Equilibrium Analyses

Yield per recruit and spawning potential ratio were computed as functions of F, as were equilibrium landings and spawning biomass. Equilibrium landings and discards were also computed as functions of biomass B, which itself is a function of F. As in the computation of benchmarks (described in §3.23), per recruit and equilibrium analyses applied the most recent selectivity patterns averaged across fleets, weighted by each fleet's F from the last three years of the assessment (2012–2014).

3.23 Benchmark/Reference Point Methods

In this assessment of Red Snapper, the quantities $F_{30\%}$, $\mathrm{SSB}_{\mathrm{F30\%}}$, $B_{\mathrm{F30\%}}$, and $L_{\mathrm{F30\%}}$ were estimated as proxies for MSY-based reference points. Steepness was not reliably estimable, so the stock-recruit relationship was not used to identify a maximum yield. Instead, steepness was fixed at 0.99 in order to assume an average level of recruitment while estimating deviations around the mean. $F_{30\%}$ was used in the rebuilding plan for Red Snapper, therefore, it was used here to generate fishing benchmarks. However, because the stock-recruitment relationship was not estimated, assumptions about recruitment are required to generate biomass benchmarks. Here, equilibrium recruitment was assumed equal to expected recruitment (arithmetic average). On average, expected recruitment is higher than that estimated directly from the spawner-recruit curve, because of lognormal deviation in recruitment. Thus, in this assessment, the method of benchmark estimation accounted for lognormal deviation by including a bias correction in equilibrium recruitment. The bias correction (ς) was computed from the variance (σ_R^2) of recruitment deviation in log space: $\varsigma = \exp(\sigma_R^2/2)$. Then, equilibrium recruitment (R_{eq}) associated with any F is,

$$R_{eq} = \frac{R_0 \left[\varsigma 0.8 h \Phi_F - 0.2(1-h)\right]}{(h-0.2)\Phi_F} \tag{1}$$

where R_0 is virgin recruitment, h is steepness which is fixed in this assessment, and $\Phi_F = \phi_F/\phi_0$ is spawning potential ratio given growth, maturity, and total mortality at age (including natural and fishing mortality rates). Because steepness is fixed at 0.99, R_{eq} as a function of F is approximately a straight line. The R_{eq} and mortality schedule imply an equilibrium age structure and an average sustainable yield (ASY). The estimate of $F_{30\%}$ is the F giving 30% of the SPR, and the estimate of $L_{\mathrm{F30\%}}$ is that ASY. The estimate of $\mathrm{SSB}_{\mathrm{F30\%}}$ follows from the corresponding equilibrium age structure, as does the estimate of discard mortalities $D_{F30\%\}}$, here separated from ASY (and consequently, $L_{\mathrm{F30\%}}$).

Estimates of $L_{\mathrm{F30\%}}$ and related benchmarks are conditional on selectivity pattern. The selectivity pattern used here was an average of terminal-year selectivities from each fleet, where each fleet-specific selectivity was weighted in proportion to its corresponding estimate of F averaged over the last three years (2012–2014). If the selectivities or relative fishing mortalities among fleets were to change, so would the estimates of $L_{\mathrm{F30\%}}$ and related benchmarks.

The maximum fishing mortality threshold (MFMT) is defined by the SAFMC as $F_{30\%}$, and the minimum stock size threshold (MSST) as 75%$\mathrm{SSB_{F30\%}}$. Overfishing is defined as $F >$ MFMT and overfished as SSB < MSST. However, because this stock is currently under a rebuilding plan, increased emphasis is given to SSB relative to $\mathrm{SSB_{F30\%}}$ (rather than MSST), as $\mathrm{SSB_{F30\%}}$ is the rebuilding target. Current status of the stock is represented by SSB in the latest assessment year (2014), and current status of the fishery is represented by the geometric mean of F from the latest three years (2012–2014). Recent SEDAR assessments have considered the mean over the terminal three years to be a more robust metric.

3.24 Uncertainty and Measures of Precision

As in SEDAR24, this assessment used a mixed Monte Carlo and bootstrap (MCB) approach to characterize uncertainty in results of the base run. Monte Carlo and bootstrap methods (Efron and Tibshirani 1993; Manly 1997) are often used to characterize uncertainty in ecological studies, and the mixed approach has been applied successfully in stock assessment, including Restrepo et al. (1992), Legault et al. (2001), SEDAR4 (2004), and many South Atlantic SEDAR assessments since SEDAR19 (2009). The approach is among those recommended for use in SEDAR assessments (SEDAR Procedural Guidance 2010).

The approach translates uncertainty in model input into uncertainty in model output, by fitting the model many times with different values of "observed" data and key input parameters. A chief advantage of the approach is that the results describe a range of possible outcomes, so that uncertainty is characterized more thoroughly than it could be by any single fit or handful of sensitivity runs. A minor disadvantage of the approach is that computational demands are relatively high.

In this assessment, the BAM was successively re-fit in $n = 4000$ trials that differed from the original inputs by bootstrapping on data sources, and by Monte Carlo sampling of several key input parameters. The value of $n = 4000$ was chosen because a minimum of 3000 runs were desired, and it was anticipated that not all runs would converge or otherwise be valid. Of the 4000 trials, approximately 5.2% were discarded, because the model did not properly converge (in most cases, an estimated quantity was at its upper bound). This left $n = 3791$ MCB trials used to characterize uncertainty, which was sufficient for convergence of standard errors in management quantities.

The MCB analysis should be interpreted as providing an approximation to the uncertainty associated with each output. The results are approximate for two related reasons. First, not all combinations of Monte Carlo parameter inputs are equally likely, as biological parameters might be correlated. Second, all runs are given equal weight in the results, yet some might provide better fits to data than others.

3.24.1 Bootstrap of observed data

To include uncertainty in the indices of abundance, multiplicative lognormal errors were applied through a parametric bootstrap. To implement this approach in the MCB trials, random variables ($x_{s,y}$) were drawn for each year y of time series s from a normal distribution with mean 0 and variance $\sigma^2_{s,y}$ [that is, $x_{s,y} \sim N(0, \sigma^2_{s,y})$]. Annual observations were then perturbed from their original values ($\hat{O}_{s,y}$),

$$O_{s,y} = \hat{O}_{s,y}[\exp(x_{s,y} - \sigma^2_{s,y}/2)] \qquad (2)$$

The term $\sigma^2_{s,y}/2$ is a bias correction that centers the multiplicative error on the value of 1.0. Standard deviations in log space were computed from CVs in arithmetic space, $\sigma_{s,y} = \sqrt{\log(1.0 + CV^2_{s,y})}$. As used for fitting the base run, CVs of indices of abundance were those provided by, or modified from, the data providers (tabulated in Table 4 of this assessment report).

Uncertainty was modeled for historical commercial landings similarly to the indices, and by the CVs provided by the commercial working group at the DW. No commercial discard CVs, headboat landings CVs, or headboat discard CVs by year were provided, therefore the panel had to make some assumptions. We assumed a value of $CV = 0.20$ for commercial discards and headboat discards. For headboat landings, we used information from the headboat program to assume a decreasing CV by time blocks (i.e. $CV = 0.15$ 1981-1995, $CV = 0.1$ for 1996-2007, and $CV = 0.05$ thereafter). General recreational landings and discards had complementary CVs, and those were used as provided except in a few instances. A CV greater than 1 was capped at 1, which was sufficiently large to represent high uncertainty but not so high that bootstrapped values caused implausible time series. The panel thought the resulting draws sufficiently represented uncertainty in spite of the dampening of a few years' CVs (Table 6).

Uncertainty in age and length compositions were included by drawing new distributions for each year of each data source, following a multinomial sampling process. Ages (or lengths) of individual fish were drawn at random with replacement using the cell probabilities of the original data. For each year of each data source, the number of fish sampled was the same as in the original data.

3.24.2 Monte Carlo sampling

In each successive fit of the model, several parameters were fixed (i.e., not estimated) at values drawn at random from distributions described below.

3.25 Natural mortality

A vector of age-specific natural mortality was provided by the Life History Working Group. They used the Charnov et al. (2013) estimator scaled to the Then et al. (2014) max age asymptotic M, and then used the uncertainty around the determination of maximum age to provide an upper and lower bound to the M vector. The Assessment Panel thought the upper ($M = 0.14$) and lower ($M = 0.12$) bound were too similar to the base vector to represent the true uncertainty around M. Instead, the AW Panel wanted to carry the uncertainty forward in both maximum age and the parameters of the Then et al. (2014) estimator of asymptotic M:

$$M = aT^b_{max} \tag{3}$$

To estimate uncertainty in a and b, we acquired the data of Then et al. (2014) and conducted a bootstrap of $n = 10,000$ iterations, drawing from the original data set with replacement. For each MCB iterations, one of the 10,000 fits was drawn at random, thus maintaining any correlation structure between a and b. We then drew T_{max} from a uniform distribution and calculated asymptotic M. For the age-dependent vector, we started with the Charnov age-dependent curve, and scaled it to the M estimate we calculated in the previous steps. A new M value was drawn and a new age-dependent vector was calculated for each MCB trial.

3.26 Discard mortality

The discard mortality working group provided an upper and lower bound for each time block (pre- and post-regulation) and fishery (commercial and recreational). Commercial rates before 2007 ranged from 38% to 58%, and 2007 to present ranged from 28% to 48%. Recreational rates before 2011 ranged from 27% to 45%, and 2011 on ranged from 20% to 36%. The rates decreased in response to the implementation of circle hooks, which are meant to cause fewer fatal bycatch events. We drew the rate for the earlier time period for each fleet from a truncated normal distribution with mean equal to the point estimate and a standard deviation devised to provide a 95% confidence interval similar to what the working group provided above. For the later time period for each fleet we also drew from a truncated normal distribution created similarly as in the previous step but with the upper bound fixed at the random draw from the earlier time period. The last step is meant to ensure that the second value is not larger than the first, so as to maintain the feature that discard mortality has decreased due to the circle hook regulation.

3.27 Batch Fecundity

Prior to the MCB analysis, a bootstrap procedure was run on the data set used to estimate batch fecundity at age for the base run. For each of 10000 bootstrap runs, the 69 paired observations of batch fecundity and fish length were sampled 69 times with replacement, the regression model refit, and the bootstrap parameters estimates saved to a data matrix. Once all bootstraps were run, the parameter matrix was trimmed by removing runs where either parameter value was outside of its 95% confidence interval. The parameters were found to be highly correlated, so during the MCB analysis, pairs of parameters were randomly drawn, with replacement, from the trimmed bootstrap parameter matrix. For each MCB run, predicted batch fecundity at age was calculated using a set of bootstrap parameters and a vector of length at age.

3.28 Batch number

Prior to the MCB analysis, a similar but separate bootstrap procedure was run on the data set used to estimate batch number at age for the base run. For each of 10000 bootstrap runs, the 1472 paired observations of spawning indicator presence, fish length, and day of the year were sampled 1472 times with replacement and the regression model refit. Predicted batch number at age was then calculated from the bootstrap parameter estimates and a vector of length at age, and the vectors saved to a data matrix. Once all bootstraps were run, the batch number at age matrix was trimmed by first summing batch number at age for each run, yielding lifetime batch number; runs where lifetime batch number was outside of the 95% confidence interval were trimmed. During the MCB analysis, a vector of batch number at age was randomly drawn, with replacement, from the trimmed bootstrap batch number at age matrix for each MCB run.

3.29 Projections

Projections were run to predict stock status in years after the assessment, 2015–2044. The year 2044 is the last year of the current rebuilding plan.

The structure of the projection model was the same as that of the assessment model, and parameter estimates were those from the assessment. Any time-varying quantities, such as recreational selectivity, were fixed to the most recent values of the assessment period. A single selectivity curve was applied to calculate removals, averaged across fleets using geometric mean Fs from the last three years of the assessment period, similar to computation of $L_{\mathrm{F30\%}}$ benchmarks (§3.23).

Expected values of SSB (time of peak spawning), F, recruits, and removals were represented by deterministic projections using parameter estimates from the base run. These projections were built on the spawner-recruit relationship with steepness fixed ($h = 0.99$) and with bias correction, and were thus consistent with estimated benchmarks in the sense that long-term fishing at $F_{30\%}$ would yield $L_{\mathrm{F30\%}}$ from a stock size at $\mathrm{SSB}_{\mathrm{F30\%}}$. Uncertainty in future time series was quantified through stochastic projections that extended the Monte Carlo/Bootstrap (MCB) fits of the stock assessment model.

3.29.1 Initialization of projections

Initial age structure at the start of 2015 was computed by the assessment model.

Fishing rates that define the projections were assumed to start in 2017. Because the assessment period ended in 2014, the projections required an initialization period (2015–2016). For 2015, a moratorium year, the landings selectivity was set to 0 and the discard selectivity was rescaled to peak at 1. Then, an optimization routine solved for the F that matched the current dead discards (mean of 2012-2014) in numbers. In 2016, a similar routine soved for the F that matched current landings (mean of 2012-2014), assuming a mini-season would occur.

3.29.2 Uncertainty of projections

To characterize uncertainty in future stock dynamics, stochasticity was included in replicate projections, each an extension of a single MCB assessment model fit. Thus, projections carried forward uncertainties in natural mortality, reproduction, landings, discards, and discard mortalities, as well as in estimated quantities such as selectivity curves, and in initial (start of 2015) abundance at age.

Initial and subsequent recruitment values were generated with stochasticity using a Monte Carlo procedure, in which the estimated Beverton–Holt model (i.e. R_0, σ_R estimated, and $h = 0.99$) of each MCB fit was used to compute mean annual recruitment values ($\bar{R}_y$). Variability was added to the mean values by choosing multiplicative deviations at random from a lognormal distribution,

$$R_y = \bar{R}_y \exp(\epsilon_y). \tag{4}$$

Here ϵ_y was drawn from a normal distribution with mean 0 and standard deviation σ_R, where σ_R is the standard deviation from the relevant MCB fit.

The procedure generated 20,000 replicate projections of MCB model fits drawn at random (with replacement) from the MCB runs. In cases where the same MCB run was drawn, projections would still differ as a result of stochasticity in projected recruitment streams. Central tendencies were represented by the deterministic projections of the base run, as well as by medians of the stochastic projections. Precision of projections was represented graphically by the 10^{th} and 90^{th} percentiles of the replicate projections.

3.30 Rebuilding time frame

Based on results from the previous SEDAR24 benchmark assessment, Red Snapper is currently under a rebuilding plan. In this plan, the terminal year is 2044, and rebuilding is defined by the criterion that projection replicates achieve stock recovery (i.e., $\mathrm{SSB}_{2044} \geq \mathrm{SSB}_{\mathrm{F30\%}}$) with probability of at least 50%. Here, the probability of stock recovery in each year of the rebuilding plan was computed as the proportion of stochastic projections where $\mathrm{SSB} \geq \mathrm{SSB}_{\mathrm{F30\%}}$, with $\mathrm{SSB}_{\mathrm{F30\%}}$ taken to be iteration-specific (i.e., from that particular MCB run).

Projection scenarios Five projection scenarios were considered.

- Scenario 1: $F = 0$
- Scenario 2: $F = F_{\text{current}}$
- Scenario 3: $F = F_{30\%}$
- Scenario 4: $F_{target} = 98\% F_{30\%}$
- Scenario 5: $F = F_{\text{rebuild}}$, with rebuilding probability of 0.5 in 2044
- Scenario 6: Discards only

The F_{current} is represented by the geometric mean of fishing mortalities from 2012-2014. The F_{rebuild} is defined as the maximum F that achieves rebuilding in the allowable time frame. The discards only scenario treated the initialization year 2016 the same as 2015 (discards only), and then applied the mean F (from 2015-2016) forward starting in 2017.

3.31 Surplus Production Model

3.31.1 Overview

A logistic surplus production model, implemented in ASPIC (Version 7.03; Prager 2005), was used to estimate stock status of Red Snapper off the southeastern U.S. While primary assessment of the stock was performed using the age-structured BAM, the surplus production approach was intended as a complement, for additional comparison with the age-structured model's results. More specifically, this model focuses on the dynamics of the removals as they relate to the indices of abundance, while ignoring any age data or age-structure in the population.

3.31.2 Data Sources

Data sources supplied to a production model include a time series of removals (i.e. landings plus dead discards) and one or more indices of abundance (i.e. catch per unit of effort). These inputs should be in units of biomass (i.e. weight), therefore some of the data developed at the SEDAR41 DW required additional formatting. These changes are detailed below.

Removals

The available removals time series comprised commercial landings (1950-2014), recreational landings (1955-2014), commercial dead discards (1992-2014), and recreational dead discards (1981-2014), in pounds, summed by year.

Commercial Landings

The SEDAR41 DW reported commercial landings in pounds, thus these data did not need to be modified for the production model.

Recreational landings

During the SEDAR41 DW, recreational landings for the historical period (1955-1980) were estimated in numbers of individuals using the The National Survey of Fishing, Hunting, and Wildlife-Associated Recreation Survey (FHWAR) census method (see SEDAR41-DW17). For the contemporary period (1981-2014), the SEDAR-41 DW reported Southeast Region Headboat Survey (SRHS) and Marine Recreational Information Program (MRIP) recreational landings in numbers and weights. Recreational landings from this period did not need to be modified, but were used to convert historical landings to weight.

Following a similar approach used in SEDAR24, recreational landings in weight and numbers for all fleets were combined by year for the first three years of the contemporary period; dividing annual landings in weight by landings in numbers produced annual mean weight estimates. The average of these three mean weights (3.4 lb) was then multiplied by the historical landings in numbers to convert them to weight. The historical and combined contemporary recreational landings series were then joined to produce a single time series of recreational landings, in pounds.

Dead Discards

Discard estimates were generated in numbers at the SEDAR-41 DW. Since many discarded fish survive after release, discard mortality rates were applied to discards in numbers to calculate dead discards. For commercial discards, a discard mortality rate of 0.48 was applied prior to regulations in 2007, and a rate of 0.38 was applied from 2007 onward. For recreational discards, a discard mortality rate of 0.37 was applied prior to regulations in 2011, and a rate of 0.285 was applied from 2011 onward.

Mean weight of commercial discards was estimated by converting lengths of commercial discards to weights using data and a conversion equation supplied by the SEDAR-41 DW, and then calculating the average weight of these individuals. The data on lengths of commercial discards were divided into two time periods before (2007-2009) and after (2010-2013) the fishery was closed. The average estimated weights of commercial discards from each time period (before = 2.93 lb; after = 8.84 lb) were multiplied by discards in numbers, for years before and after the closure, respectively.

Mean weight of recreational discards was estimated by converting lengths of recreational headboat-at-sea observer discards to weights using data and a conversion equation supplied by the SEDAR-41 DW, and then calculating the average weight of these individuals. Year-specific mean weight estimates were multiplied by recreational discards in numbers for corresponding years when available (2005-2014). For years prior to 2005 where year-specific mean weights were not available, discards in numbers were multiplied by the average mean weight across the available years before the 2010 closure (1.96 lb).

Indices of Abundance

Five indices of abundance were produced by the SEDAR-41 DW for Red Snapper: commercial logbook handline index (hereafter commercial handline; units = lb kept per hook-hour), headboat (number of fish kept per angler), headboat-at-sea-observer (number of fish caught $<20''$ per angler), Southeast Reef Fish Survey (SERFS) chevron trap (number of fish caught per trap), and the SERFS video (number of fish observed per video). The commercial handline index was already in weight and did not need to be converted. The headboat index was converted to pounds by multiplying by year-specific mean weights, generated by dividing headboat landings in pounds by landings in numbers for each year. The headboat-at-sea-observer index was converted to pounds by multiplying by the same mean weights used to convert recreational discards to weight. The SERFS chevron trap and video indices were converted to weights by multiplying by year-specific mean weights calculated from combined recreational (headboat and MRIP) landings in weight divided by landings in numbers.

3.31.3 Model Configuration and Equations

Production modeling used the model formulation and ASPIC software (version 7.03) of Prager (1994; 2005). This is an observation-error estimator of the continuous-time form of the Schaefer (logistic) production model (Schaefer 1954; 1957). Estimation was conditioned on catch. The logistic model for population growth is the simplest form of a differential equation which satisfies a number of ecologically realistic constraints, such as a carrying capacity (a consequence of limited resources). When written in terms of stock biomass, this model specifies that

$$\frac{dB_t}{dt} = rB_t - \frac{r}{K}B_t^2 \quad (5)$$

where B_t is biomass in year t, r is the intrinsic rate of increase in absence of density dependence, and K is carrying capacity (Schaefer 1954; 1957). This equation may be rewritten to account for the effects of fishing by introducing an instantaneous fishing mortality term, F_t :

$$\frac{dB_t}{dt} = (r - F_t)B_t - \frac{r}{K}B_t^2 \quad (6)$$

By writing the term F_t as a function of catchability coefficients and effort expended by fishermen in different fisheries, Prager (1994) showed how to estimate model parameters from time series of yield and effort.

For Red Snapper, the model proved difficult to fit. It was configured using various combinations of removals, indices, starting dates, prior distributions and starting values, resulting in approximately 324 configurations. Many of these runs were completed during early model development but many others incorporated small changes to data inputs or model specifications suggested by AW panel members during the Assessment Workshop. As the BAM developed, most of these runs became obsolete and are not presented here. The run configured according to recommendations by the SEDAR41 AW panel is presented here. This model configuration (run 320) contained removals from 1950 to 2014 and the four indices used in the BAM (Comm, HB, HB-at-sea, CVID) from 1976 to 2014. Following the recommendations of the AW panel, the CVID index was upweighted by a factor of three (i.e. CVs divided by three), and the headboat-at-sea index was shifted forward by one year, since it indexes younger fish than the other indices.

Three other runs (318, 319, and 323) are also presented to relate the main run (320) to ASPIC results from the previous Red Snapper assessment (SEDAR 24). All three runs contain only the commercial and headboat indices, starting in 1993 and 1976 respectively, and removals starting in 1950. But in run 318 (the continuity run), the final year of removals and indices is 2009, as in SEDAR 24, while in run 319 (the updated continuity run) the final year of removals and indices is 2014, as in the BAM for the current assessment. Since both the commercial and headboat indices ended in 2009 the only difference between the continuity run and updated continuity run is the removals estimates from 2010-2014. Finally a run was completed (run 323; best configuration $\frac{B_1}{K}$ fixed) that is identical to the best configuration run, but with $\frac{B_1}{K}$ fixed at the estimate for the continuity run, for reasons described below.

To evaluate the uncertainty in the model fit and parameter estimates of the best configuration run, 1000 bootstrap runs were conducted. Percentile confidence intervals were also calculated for parameters.

4 Stock Assessment Results

4.1 Measures of Overall Model Fit

In general, the Beaufort assessment model (BAM) fit well to the available data. Predicted length compositions from the commercial handline and discards from the commercial and headboat fleets were reasonably close to observed data in most years, as were predicted age compositions (Figure 3). The model was configured to fit observed commercial and recreational removals closely (Figures 4–9). Fits to indices of abundance generally captured the observed trends but not all annual fluctuations (Figures 10–13).

4.2 Parameter Estimates

Estimates of all parameters from the catch-age model are shown in Appendix B. Estimates of management quantities and some key parameters are reported in sections below.

4.3 Stock Abundance and Recruitment

In general, estimated abundance at age showed truncation of the older ages through most of the assessment period, but with some signs of increase during the last decade (Figure 14; Table 7). Total estimated abundance was at its lowest value in the early 1990s, but near its highest levels at the end of the time series, comparable to those in the early 1970s, but with a more truncated age structure. The MCB results reflect the same patterns with their associated uncertainties for total abundance and abundance of age 2+ (Figure 18). Annual number of recruits is shown in Table 7 (age-1 column) and in Figure 15. The highest recruitment values were predicted to have occurred in the mid-1980s, 2006, and the terminal year of the model (2014).

4.4 Total and Spawning Biomass

Estimated biomass at age followed a similar pattern as abundance at age (Figure 16; Table 9). Total biomass and spawning biomass showed similar trends—general decline through to the early-1990s, and relatively stable or slowly increasing patterns since the mid-1990s (Figure 17; Table 10). Terminal year estimates are at levels not seen since the 1970s.

4.5 Selectivity

Selectivity of the SERFS index is shown in Figure 19, and selectivities of landings from commercial and recreational fleets are shown in Figures 20, 21, and 22. Selectivities of discards from commercial and recreational fleets are shown in Figures 23, 24, and 25. In the most recent years, full selection occurred near ages 2–4, depending on the fleet and time block.

Average selectivities of landings, dead discards, and the total weighted average of all selectivities were computed from F-weighted selectivities in the most recent three assessment years (Figure 26). This average selectivity was used in computation of point estimates of benchmarks, as well as in projections. All selectivities from each time block, including average selectivities, are tabulated in Tables 11, 12, and 13.

4.6 Fishing Mortality and Removals

Estimates of total F at age are shown in Table 15. In any given year, the maximum F at age (i.e., apical F) may be less than that year's sum of fully selected Fs across fleets. This inequality is due to the combination of two features of estimated selectivities: full selection occurs at different ages among gears and several sources of mortality have dome-shaped selectivity.

Estimated time series of landings and discards are shown in Tables 16, 17, 18, 19. Table 20 shows total landings at age in numbers, and Table 21 in weight. Table 22 shows total discards at age in numbers, and Table 23 in weight. Landings have been dominated by the general recreational and commercial handline fleet until recent years when the general recreational fleet became the dominant source of removals (Tables 16 and 17). Also since 2010, total landings remained below the level at $L_{\mathrm{F30\%}}$ (Figure 29).

Estimated discard mortalities occurred on a smaller scale than landings until the implementation of regulations and the use of mini-seasons, and have been above the $D_{F_{30\%}}$ level for most of the moratorium years (Tables 18 and 19, and Figure 30).

4.7 Spawner-Recruitment Parameters

The Beverton–Holt spawner-recruit curve is shown in Figure 31, along with the effect of density dependence on recruitment, depicted graphically by recruits per spawner as a function of spawning stock (1E8 Eggs). Values of recruitment-related parameters were as follows: steepness $h = 0.99$ (fixed), unfished age-1 recruitment $\widehat{R_0} = 330503$, and standard deviation of recruitment residuals in log space $\widehat{\sigma}_R = 0.79$ (which resulted in bias correction of $\varsigma = 1.37$). Uncertainty in these quantities was estimated through the MCB analysis (Figure 32).

4.8 Per Recruit and Equilibrium Analyses

Yield per recruit and spawning potential ratio were computed as functions of F. These computations applied the most recent selectivity patterns averaged across fleets, weighted by F from the last three years (2012–2014) (Figures 33 and 34).

As in per recruit analyses, equilibrium landings and spawning biomass were computed as functions of F (Figure 35). $F_{30\%}$ is used as a proxy for MSY, and the corresponding landings and spawning biomass are $L_{\mathrm{F30\%}}$ and $\mathrm{SSB}_{\mathrm{F30\%}}$.

4.9 Benchmarks / Reference Points

As described in §3.23, biological reference points (benchmarks) were derived analytically assuming equilibrium dynamics, corresponding to the spawner-recruit curve with fixed steepness $h = 0.99$ (Figure 31). Reference points estimated were $F_{30\%}$, $L_{\mathrm{F30\%}}$, $B_{\mathrm{F30\%}}$ and $\mathrm{SSB}_{\mathrm{F30\%}}$. Based on $F_{30\%}$, three possible values of F at optimum yield (OY) were considered—$F_{\mathrm{OY}} = 65\% F_{30\%}$, $F_{\mathrm{OY}} = 75\% F_{30\%}$, and $F_{\mathrm{OY}} = 85\% F_{30\%}$—and for each, the corresponding yield was computed. Standard errors of benchmarks were approximated as those from MCB analysis (§3.24).

Maximum likelihood estimates (base run) of benchmarks, as well as median values from MCB analysis, are summarized in Table 24. Point estimates of $L_{\mathrm{F30\%}}$-related quantities were $F_{30\%} = 0.15$ (y^{-1}), $L_{\mathrm{F30\%}} = 430$ (1000 lb), $B_{\mathrm{F30\%}} = 3647$ (mt), and $\mathrm{SSB}_{\mathrm{F30\%}} = 328552$ (1E8 Eggs). Median estimates were $F_{30\%} = 0.15$ (y^{-1}), $L_{\mathrm{F30\%}} = 419$ (1000 lb), $B_{\mathrm{F30\%}} = 3534$ (mt), and $\mathrm{SSB}_{\mathrm{F30\%}} = 294166$ (1E8 Eggs). Distributions of these benchmarks from the MCB analysis are shown in Figure 36.

4.10 Status of the Stock and Fishery

Estimated time series of stock status $SSB/SSB_{F30\%}$ showed general decline throughout the beginning of the assessment period, a leveling off, and then a modest increase since 2010 (Figure 37, Table 10). Base-run estimates of spawning biomass have remained below the threshold (MSST) since the early-1970s. Current stock status was estimated in the base run to be $SSB/SSB_{F30\%} = 0.16$ (Table 24), indicating that the stock has not yet recovered to $SSB_{F30\%}$. Median values from the MCB analysis indicated similar results $SSB/SSB_{F30\%}$ =0.17. The uncertainty analysis suggested that the terminal estimate of stock status is robust (Figures 38, 39). Of the MCB runs, 100% indicated that the stock was below $SSB_{F30\%}$ in 2014. Age structure estimated by the base run showed fewer older fish in the last few decades than the (equilibrium) age structure expected at $L_{F30\%}$ (Figure 40). However, there is improvement in the terminal year(2014), particularly for ages younger than ten.

The estimated time series of $F/F_{30\%}$ suggests that overfishing has occurred throughout most of the assessment period (Table 10, Figure 37). Current fishery status in the terminal year, with current F represented by the geometric mean from 2012–2014, was estimated by the base run to be $F/F_{30\%} = 2.52$ (Table 24). The fishery status was also robust (Figures 38, 39). Of the MCB runs, approximately 98.7% agreed with the base run that the stock is currently experiencing overfishing.

4.11 Sensitivity and Retrospective Analyses

Sensitivity runs, described in §3.3, were used for exploring data or model issues that arose during the assessment process, for evaluating implications of assumptions in the base assessment model, and for interpreting MCB results in terms of expected effects of input parameters. In some cases, sensitivity runs are simply a tool for better understanding model behavior, and therefore all runs are not considered equally plausible in the sense of alternative states of nature. Time series of $F/F_{30\%}$ and $SSB/SSB_{F30\%}$ are plotted to demonstrate sensitivity to the changing conditions in each run. The sensitivity of the base run to changes in natural mortality, steepness, dome-shaped selectivity for the commercial handline fleet, various index adjusts for both the fishery dependent indices and fishery independent index, the use of an ageing error matrix and high and low levels of landings and discards was explored (Figures 41–53). Sensitivity 24 is a version of a continuity run in that various assumptions made about parameters for SEDAR 24 were adopted for this sensitivity (e.g. higher discard mortalities, lower M, using gonad weight as a proxy for SSB, different female maturity and fecundity information, higher max age, lower steepness, different time of year for peak spawning, and fixed recruitment standard deviation). Time series of stock and fishery status estimated by this assessment are similar to those from the previous, SEDAR24 assessment (Figure 54). Trends in $F/F_{30\%}$ from the two assessments generally track each other, though the magnitude of the variations differ. Trends in $SSB/SSB_{F30\%}$ track each other, though there is divergence at the end of the time series where the current model estimates a more optimistic stock status.

None of the sensitivities show a recovered stock in 2014. A couple sensitivities suggest the stock is undergoing less overfishing than is estimated in the base. However, those runs eliminate the fishery independent index entirely, or upweight the fishery dependent indices to the point of swamping out any signal from the survey data. The vast majority of runs agree with the status indicated by the base run (Figure 55, Table 25). Results appeared to be most sensitive to natural mortality and steepness.

Retrospective analyses suggest a pattern of overestimating fishing mortality in the terminal year, however, the trend is less apparent for SSB (Figure 56).

4.12 Projections

Projections based on $F = 0$ allowed the spawning stock to grow such that the majority of replicate projections recovered to $\text{SSB}_{\text{F30\%}}$ by 2025 (Figure 57, Table 26), however the stock is already in a rebuilding plan so other projections were also requested in the TORs. This was not the case for projections based on $F = F_{\text{current}}$ (Figure 58, Table 27), or if the fishing rate were reduced to $F_{30\%}$ (Figure 59, Table 28) or F_{target} (Figure 60, Table 29). By design, projections based on $F = F_{\text{rebuild}}$ showed recovery with the desired probability in 2044 (Figure 61, Table 30). The projection with discard mortality only showed similar trajectories to the run assuming no other fishing mortality(Table 31 and Figure 62).

4.13 Surplus Production Model

4.13.1 Model Fit

For the best configuration run, model predictions underestimated observed values for the headboat index for the first ten years of the time series (1976-1985; Figure 63). They also underestimated the commercial index during the first five years of that series (1993-1997), while overestimating the headboat index for those same years. The model provided a very poor fit to the headboat-at-sea discard index (2006-2014) but produced a much better fit to the upweighted CVID index (2005-2014). The model did not fit high index values in 2008 and 2009 very closely, but predicted a slight decline from 2007-2009 followed by an increasing trend from 2010 to 2014.

4.13.2 Parameter Estimates and Uncertainty

The ASPIC model fits three main parameters ($\frac{B_1}{K}$, MSY, and F_{MSY}) as well as catchability coefficients (q_i) for each index i. Several other parameters can then be derived from these estimates: $r = 2F_{MSY}$, $K = \frac{2MSY}{F_{MSY}}$ and $B_{MSY} = \frac{K}{2}$. Recent status indicators $\frac{F}{F_{MSY}}$ and $\frac{B}{B_{MSY}}$ are calculated with the most recent estimates of F (2014) and B (2015). Estimates of the main parameters and recent status indicators for all four runs are presented in Table 32. Prior distributions and model estimates of the main parameters for the best configuration run are presented in Figure 64.

Across all runs, most of the main parameters varied very little (e.g. CV $MSY = 0.0027$; CV $F_{MSY} = 0.014$). By contrast $\frac{B_1}{K}$ varied widely (CV $\frac{B_1}{K} = 0.74$), due to variation in B_1 (CV $B_1 = 0.74$) rather than K (CV $K = 0.013$; Table 32). Among bootstrap runs based on the best configuration, distributions of $\frac{B_1}{K}$, MSY, and F_{MSY} were unimodal and relatively symmetrical (Figure 65).

4.13.3 Status of the Stock and Fishery

In the current best configuration run of the surplus production model, $\frac{B}{B_{MSY}}$ is greater than one, suggesting that the South Atlantic stock of Red Snapper is not overfished. The 95% bootstrap percentile confidence intervals for $\frac{B}{B_{MSY}}$ do not contain one (Figure 65). Since the surplus production model estimates that $\frac{F}{F_{MSY}}$ is less than one, the stock is considered to not be undergoing overfishing (Table 32; Figure 66). The 95% bootstrap percentile confidence intervals for $\frac{F}{F_{MSY}}$ do not contain one (Figure 65).

4.13.4 Interpretation

Status indicators in the continuity run (318), agree with the surplus production model from SEDAR 24 that South Atlantic Red Snapper were overfished and undergoing overfishing in 2009 (Table 32). However, in the updated continuity run (319), which is identical to the continuity run except for the 2010-2014 addition of landings data from 2010-2014, the surplus production model suggests that the stock is no longer overfished or undergoing overfishing. Despite several differences between the updated continuity run and the best configuration run (320), described above, most of the parameter estimates and status indicators are similar (Table 32). However the model estimate of $\frac{B_1}{K}$ is much lower in the best configuration run, driven by a lower estimate of B_1. After observing this difference, run 323 was configured by taking the best configuration run and fixing $\frac{B_1}{K}$ at the estimate from the continuity run to investigate potential influence. Fixing $\frac{B_1}{K}$ at this much lower value had little effect on status or most parameters, but caused the estimate of B_1 to go much lower.

As described above, the only data that go into a surplus production model are biomass of removals and abundance indices. Therefore such a model does not make use of many other sources of information such as sex, maturity, growth, fecundity, or population age and size structure. Because such data are available for Red Snapper, a model that uses them would be preferred for a detailed assessment on which to base management.

5 Discussion

5.1 Comments on the Assessment

Estimated benchmarks played a central role in this assessment. Values of $\mathrm{SSB}_{\mathrm{F30\%}}$ and $F_{30\%}$ were used to gauge the status of the stock and fishery to be consistent with established definitions of $MFMT$ and the existing rebuilding plan. The computation of the benchmarks was conditional on selectivity. If selectivity patterns change in the future, for example as a result of new size limits or different relative catch allocations among sectors, estimates of benchmarks would likely change as well.

The base run of the BAM indicated that the stock remains overfished $\mathrm{SSB}/\mathrm{SSB}_{\mathrm{F30\%}}$ =0.16, and that overfishing is occurring $F/F_{30\%}$ =2.52, though at a lower rate than in 2009 (F/F_{MSY} =4.12 for SEDAR 24). Median values from the MCB analyses were in qualitative agreement with those results. This assessment estimates that, since 2010, the stock has been increasing at a modest rate and is now at levels not seen since the 1970s.

In addition to including the more recent years of data, this benchmark assessment contained several modifications to the previous data of SEDAR24, such as the use of APAIS-adjusted MRIP estimates instead of MRFSS, a new method for the reconstruction of historic recreational catch, the inclusion of a new fishery-independent survey, and the corresponding age composition data. Furthermore, life-history information was updated, including female maturity, sex ratio, growth, natural mortality, fecundity, and meristics. The assessment model itself was also modernized to the current version of BAM. The sum of these improvements should result in a more robust assessment.

In general, fishery dependent indices of abundance may not track actual abundance well, because of factors such as hyperdepletion or hyperstability. Furthermore, this issue can be exacerbated by management measures. In this assessment, the commercial handline and headboat indices generated from logbook data, were not extended beyond 2009 because of the moratorium on Red Snapper. In general, management measures in the southeast U.S. have made the continued utility of fishery dependent indices will be questionable. This situation amplifies the importance of fishery independent sampling and sampling programs conducted by the states.

Many assessed stocks in the southeast U.S. have shown histories of heavy exploitation. High rates of fishing mortality can lead to adaptive responses in life-history characteristics, such as growth and maturity schedules. Such adaptations can affect expected yield and stock recovery, and thus resource managers might wish to consider possible evolutionary effects of fishing in their management plans (Dunlop et al. 2009; Enberg et al. 2009). Indeed, Red Snapper have a very young age at maturity relative to their maximum lifespan, and some have hypothesized that this may be an adaptive response to exploitation.

Because steepness could not be estimated reliably in this assessment, its value in the base run was fixed at 0.99. Fixing steepness at its upper bound was not meant to imply that the stock has perfect compensation at any exploitation or stock level. Rather, it was a computational convenience to use the stock recruitment curve with $h = 0.99$ in order to treat recruitment as an average through time while estimating deviations around that average. Thus MSY-based management quantities are not appropriate, and the AW Panel provided the proxy of $F_{30\%}$ as was used for management subsequent to the last assessment.

The assessment start year was 1950, so as to include the period of largest landings. To initialize the model in 1950, the initial age structure was assumed to be in equilibrium, based on natural mortality at age and F_{init}. Average recruitment was assumed until the recruitment deviations could be estimated at the onset of the composition data (1978). These assumptions are common in assessment models, and they were tested with sensitivity runs where the start was 1978 and with different values of F_{init}. The end results were qualitatively similar, which indicates that the base run is not sensitive to these assumptions.

A complementary analysis was conducted using a surplus production model (ASPIC). ASPIC treats the stock as a pooled biomass and ignores the age structure in the population and the landings. It is unable to take into account that different ages are differentially vulnerable to fishing and therefore was not able to incorporate the (time-varying) selectivities used in the BAM. ASPIC is also not able to take into account that the reproductive contribution of this species increases with age or that there is variability in recruitment through time. ASPIC is useful in examining the relationship between removals and the indices. However, for a long-lived species with age-based data available, the catch-age model (BAM) provides the best illustration of the stock and is a better indicator of stock status, because it can account for the age structure of the population and landings and for year-class strength.

5.2 Comments on the Projections

Projections should be interpreted in light of the model assumptions and key aspects of the data. Some major considerations are the following:

- In general, projections of fish stocks are highly uncertain, particularly in the long term (e.g., beyond 5–10 years).
- Although projections included many major sources of uncertainty, they did not include structural (model) uncertainty. That is, projection results are conditional on one set of functional forms used to describe population dynamics, selectivity, recruitment, etc.
- Fisheries were assumed to continue fishing at their estimated current proportions of total effort, using the estimated current selectivity patterns. New management regulations that alter those proportions or selectivities would likely affect projection results.
- The first five scenarios of projections assumed no change in the selectivity applied to discards. As stock increase generally begins with the smallest size classes, management action may be needed to meet that assumption.
- The projections assumed that the assumed spawner-recruit relationship applies in the future and that past deviations represent future uncertainty in recruitment. If future recruitment is characterized by runs of large or small year classes, possibly due to environmental or ecological conditions, stock projections may be affected.

- Projections apply the Baranov catch equation to relate F and landings using a one-year time step, as in the assessment. The catch equation implicitly assumes that mortality occurs throughout the year. This assumption is violated when seasonal closures or small intensive fishing seasons are in effect, introducing additional and unquantified uncertainty into the projection results.

5.3 Research Recommendations

- Increased fishery independent information, particularly maintaining reliable indices of abundance and composition data streams
- Red Snapper were modeled in this assessment as a unit stock off the southeastern U.S. For any stock, variation in exploitation and life-history characteristics might be expected at finer geographic scales. Modeling such sub-stock structure would require more data, such as information on the movements and migrations of adults and juveniles, as well as spatial patterns of larval dispersal and recruitment. In addition, it is unclear whether a spatial model would improve the assessment.
- More research to describe the juvenile life history of Red Snapper is needed, including more work to identify the location of juveniles before they recruit to the fishery.
- The effects of environmental variation on the changes in recruitment or survivorship.
- The Florida sampling program, during the miniseason in particular, provided invaluable data to this assessment. Programs such as these would be useful in all South Atlantic states, particularly if the management regulations continue to make established methods of index development or composition sampling from fleets less regular or possible.

Table 10. Estimated time series of status indicators, fishing mortality, and biomass. Fishing mortality rate is apical F. Total biomass (B, mt) is at the start of the year, and spawning biomass (SSB, 1E8 eggs) at the time of peak spawning (mid-year). The $MSST_{\mathrm{F30}}$ is defined by $\mathrm{MSST} = (1 - M)SSB_{\mathrm{F30}}$, with constant $M = 0.134$.

Year	F	F/F_{30}	B	B/B_{unfished}	SSB	$SSB/SSBB_{\mathrm{F30}}$	$SSB/MSST_{\mathrm{F30}}$

Table 14. Estimated time series of fully selected fishing mortality rates for commercial handlines (F.cH.L), headboat (F.HB.L), recreational (F.GR.L) landings (L) and discards (D). Also shown is Full F, the maximum F at age summed across fleets, which may not equal the sum of fully selected F's because of dome-shaped selectivities.

Year	F.cH.L	F.HB.L	F.GR.L	F.cH.D	F.HB.D	F.GR.D	Full F

Table 24. Estimated status indicators, benchmarks, and related quantities from the base run of the Beaufort catch-age model, conditional on estimated current selectivities averaged across fleets. Also presented are median values and measures of precision (standard errors, SE) from the Monte Carlo/Bootstrap analysis. Rate estimates (F) are in units of y^{-1}*; status indicators are dimensionless; and biomass estimates are in units of metric tons or pounds, as indicated. Spawning stock biomass (SSB) is measured as population fecundity (number of eggs)*

Quantity	Units	Estimate	Median	SE

Table 28. Projection results with fishing mortality rate fixed at $F = F_{30\%}$ starting in 2017. R = number of age-1 recruits (in 1000s), F = fishing mortality rate (per year), S = spawning stock (1E8 eggs), L = landings expressed in numbers (n, in 1000s) or whole weight (w, in 1000 lb*), and D = dead discards expressed in numbers (n, in 1000s) or whole weight (w, in 1000* lb*), pr.reb = proportion of stochastic projection replicates with* $\mathrm{SSB} \geq \mathrm{SSB}_{\mathrm{F30\%}}$. *The extension* b *indicates expected values (deterministic) from the base run; the extension* med *indicates median values from the stochastic projections.*

Table 32. Parameter estimates from selected ASPIC surplus production model runs 318 (continuity), 319 (updated continuity), 320 (best configuration), and 323 (best configuration with B_1/K fixed) All parameter values are rounded to 3 significant digits. MSY, B_1, and K are in units of 1000 pounds. Catchability parameters correspond to the commercial (q_1), headboat (q_2), headboat-at-sea (q_3), and CVID (q_4) indices.

Run	F/F_{MSY}	B/B_{MSY}	B_1/K	MSY	F_{MSY}	q_1	q_2	q_3	q_4	B_1	K
318	2.15	0.53	0.467	805	0.313	9.35e-07	7.14e-07			2400	5140
319	0.614	1.3	1.94	802	0.314	9.42e-07	7.14e-07			9930	5110

8 Figures

Figure 1. Indices of abundance used in fitting the assessment model. HB indicates the headboat logbook index; Handline indicated the the commercial handline logbook index; HB Disc indicated the headboat discard observer index, CVT indicates the SERFS chevron trap index; VID indicates the SERFS video index, and CVID indicates the combined chevron trap and video index. The CVT and VID indices were only used during sensitivity runs.

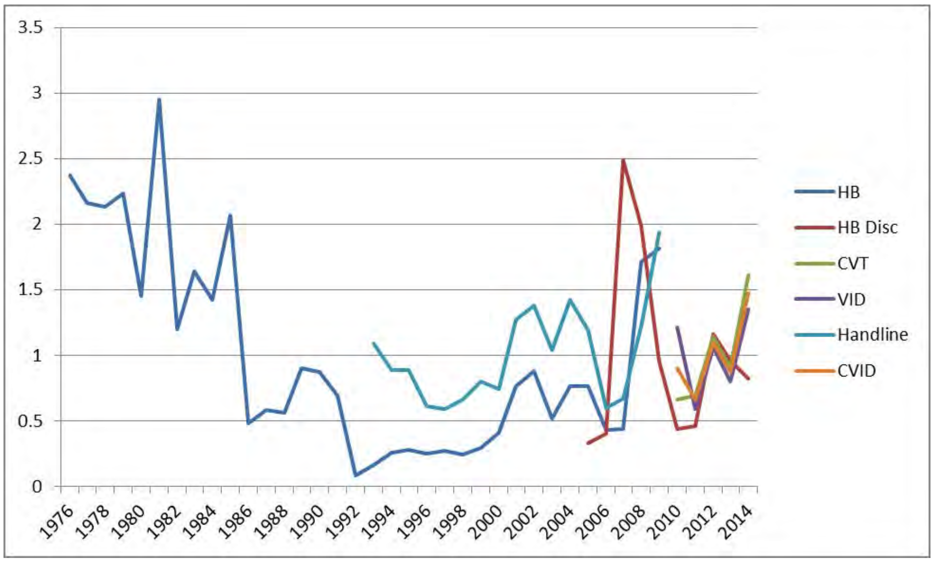

Figure 2. Mean total length at age (mm) and estimated upper and lower 95% confidence intervals of the population.

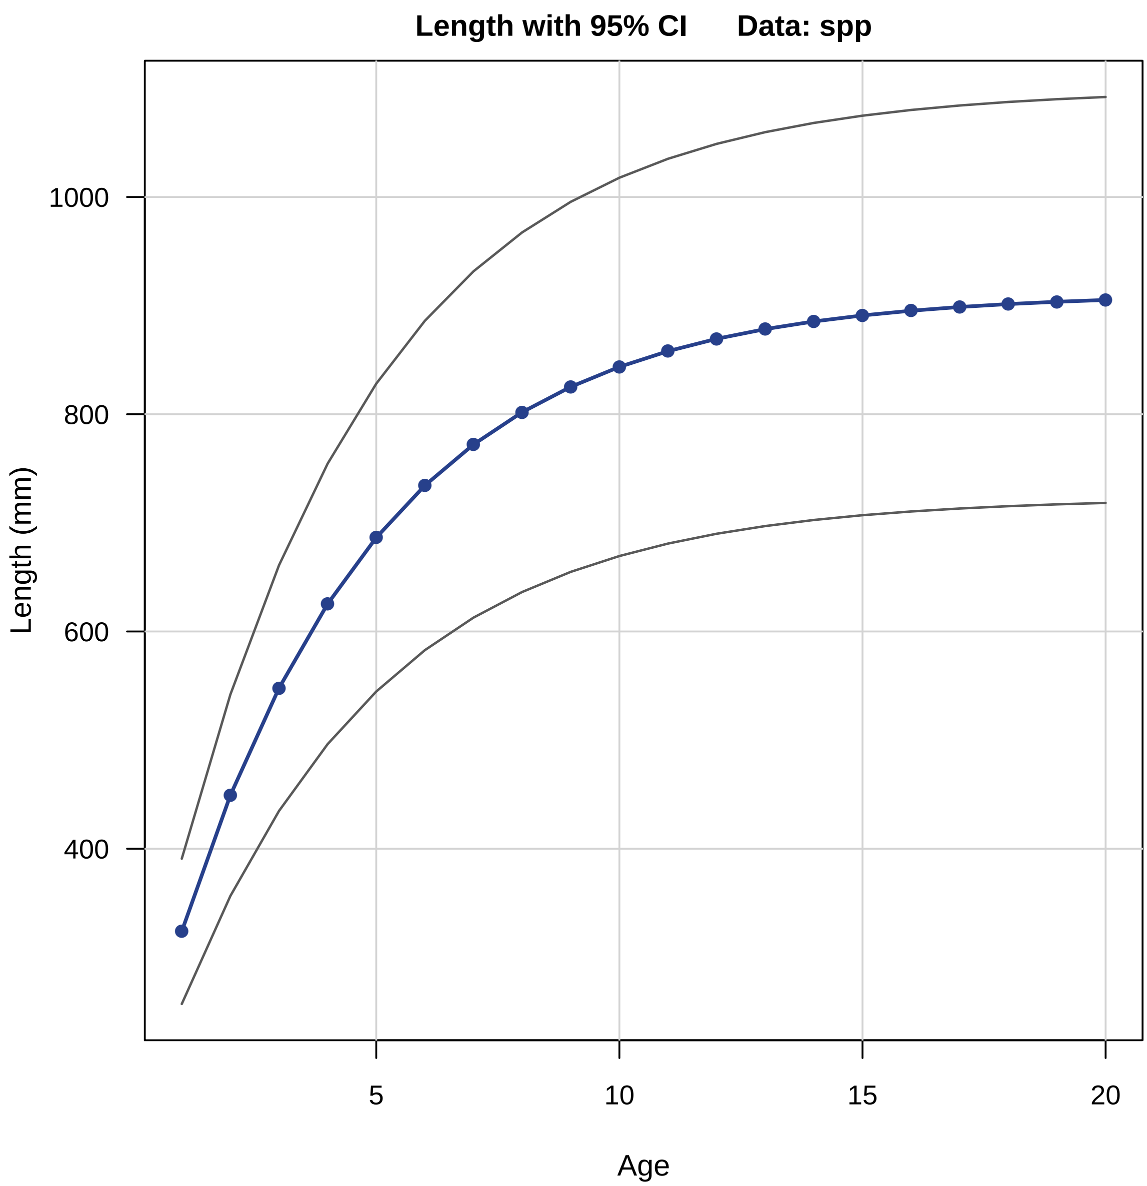

Figure 3. Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey. In panels indicating the data set, lcomp refers to length compositions, acomp to age compositions, CVT to MARMAP chevron trap, cH to commercial handline, HB to headboat and GR to general recreational.

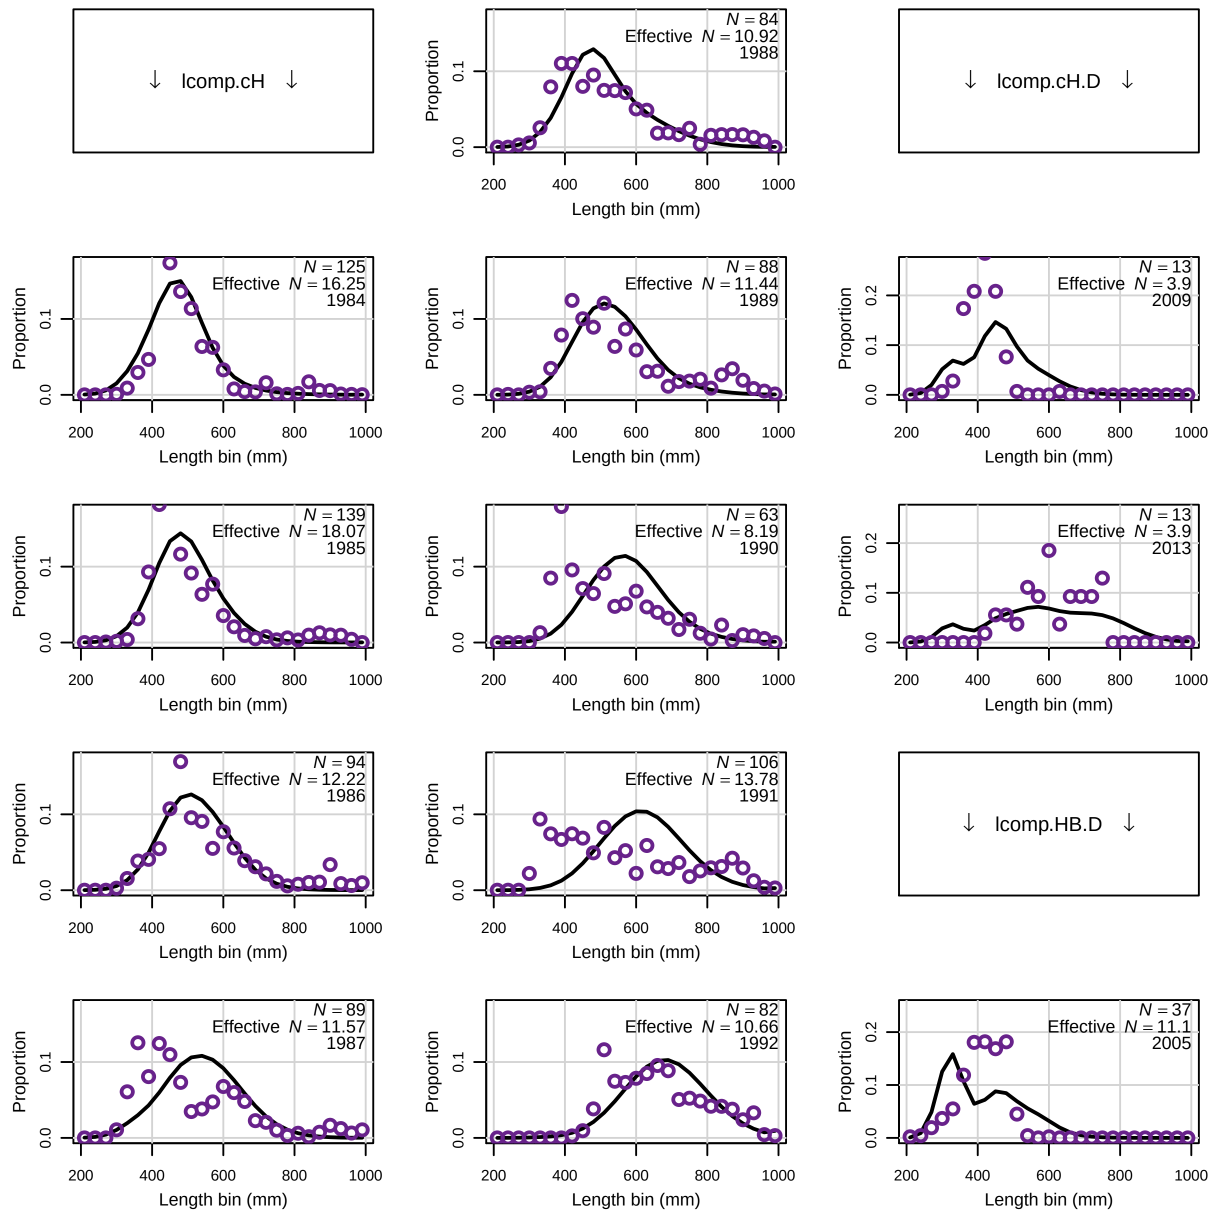

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey.

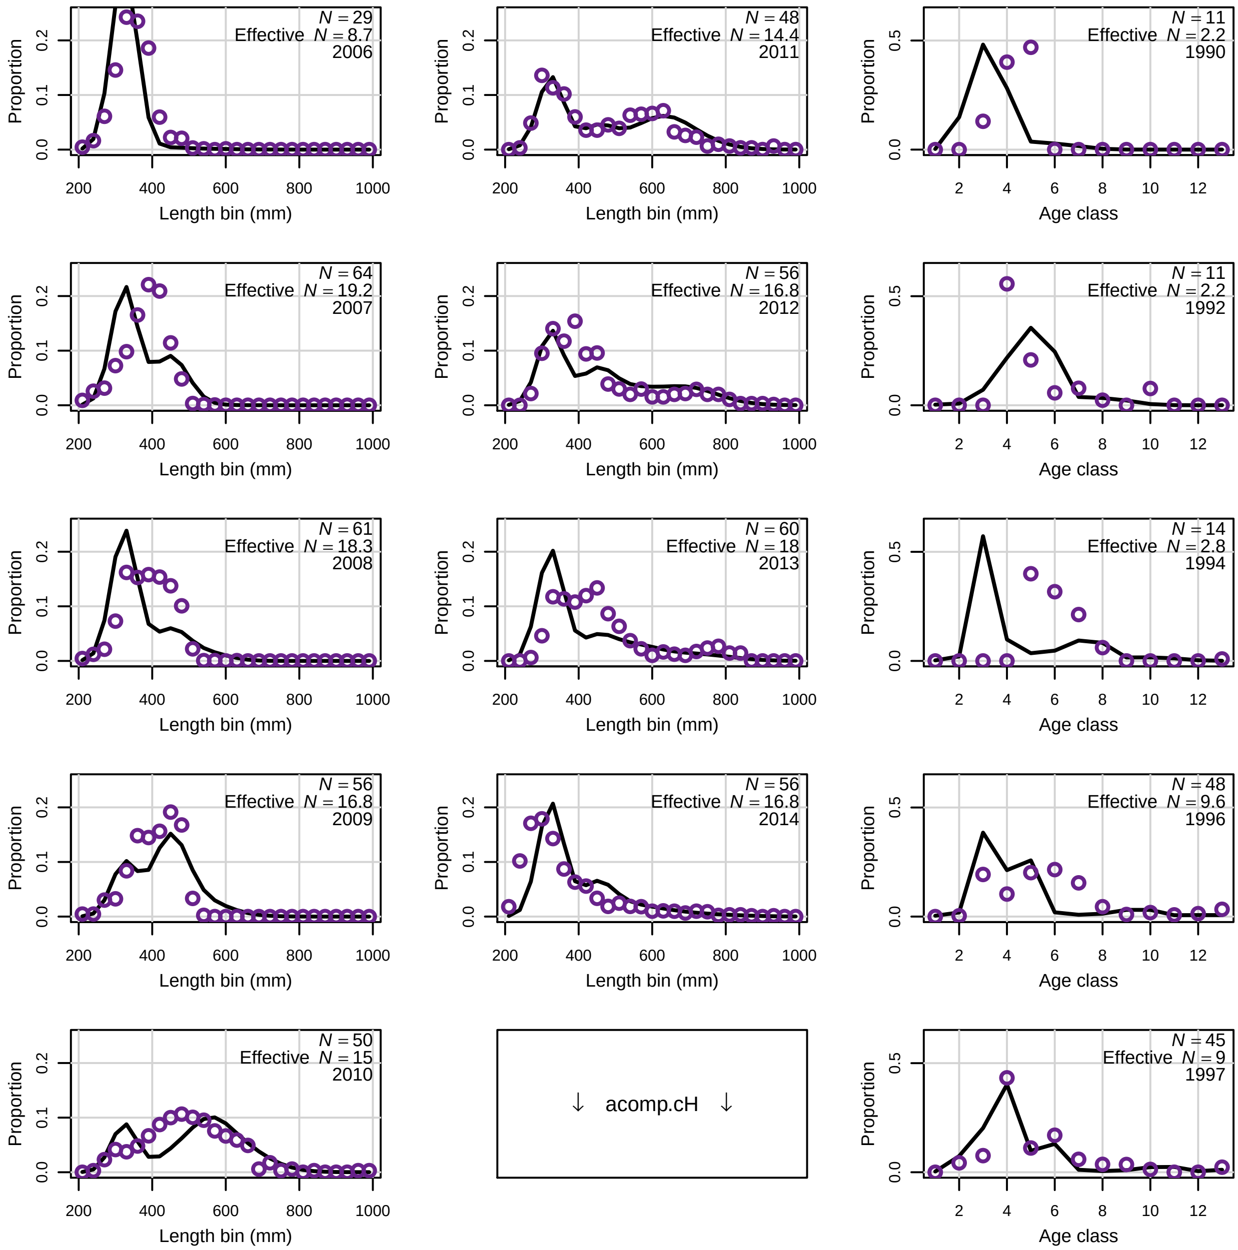

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey.

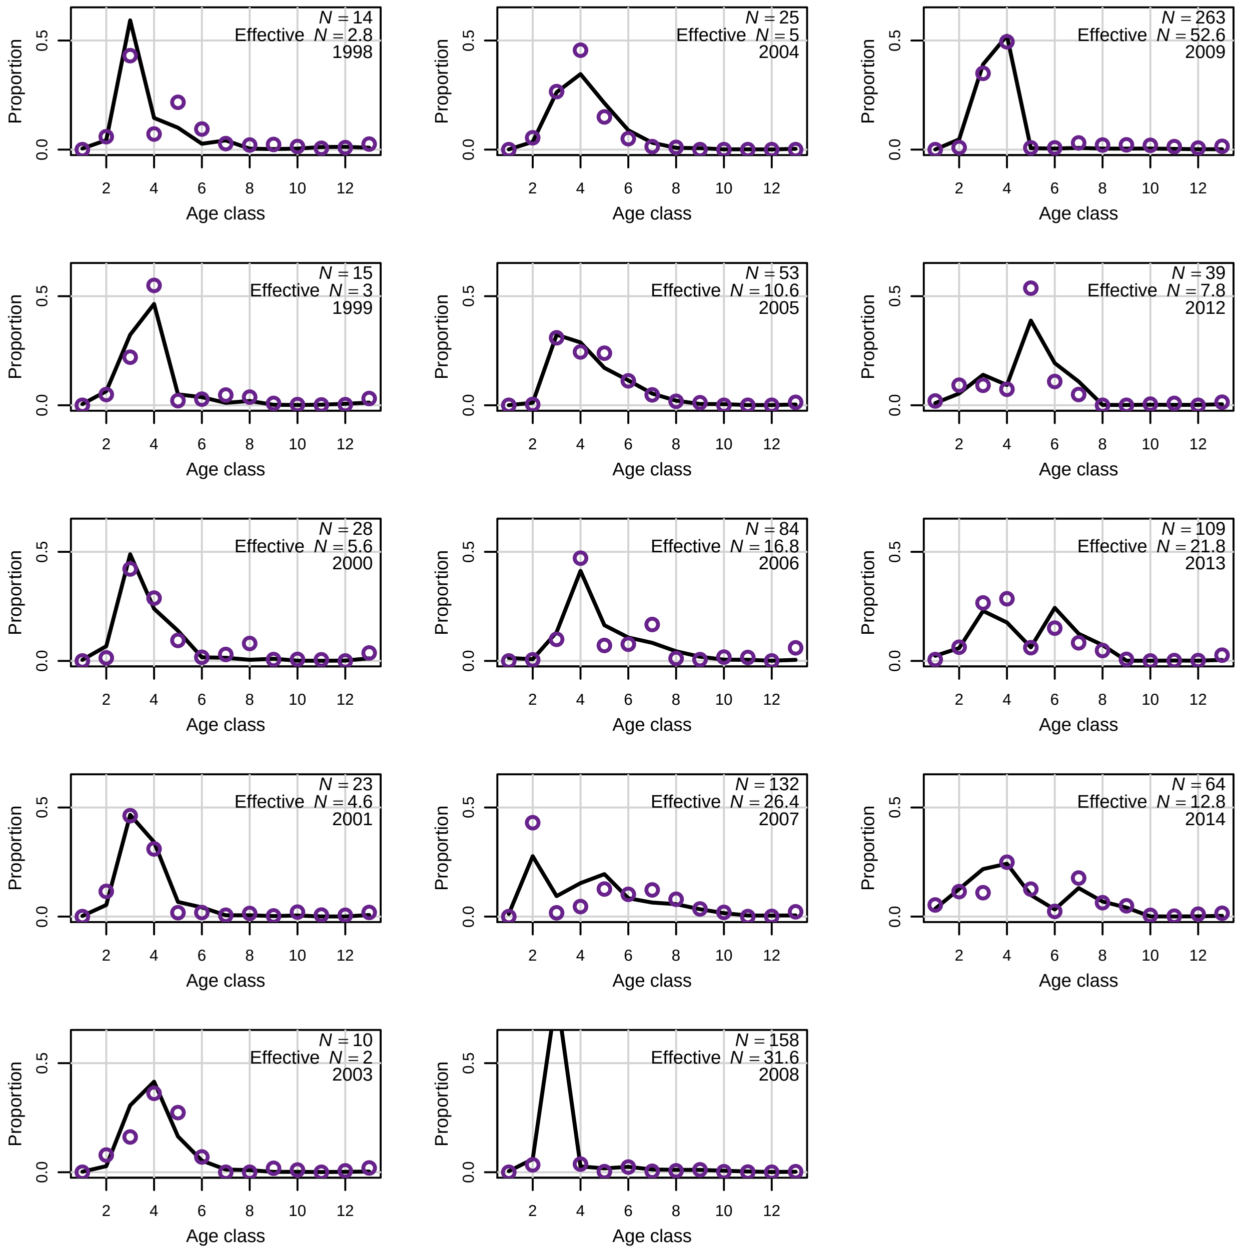

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey.

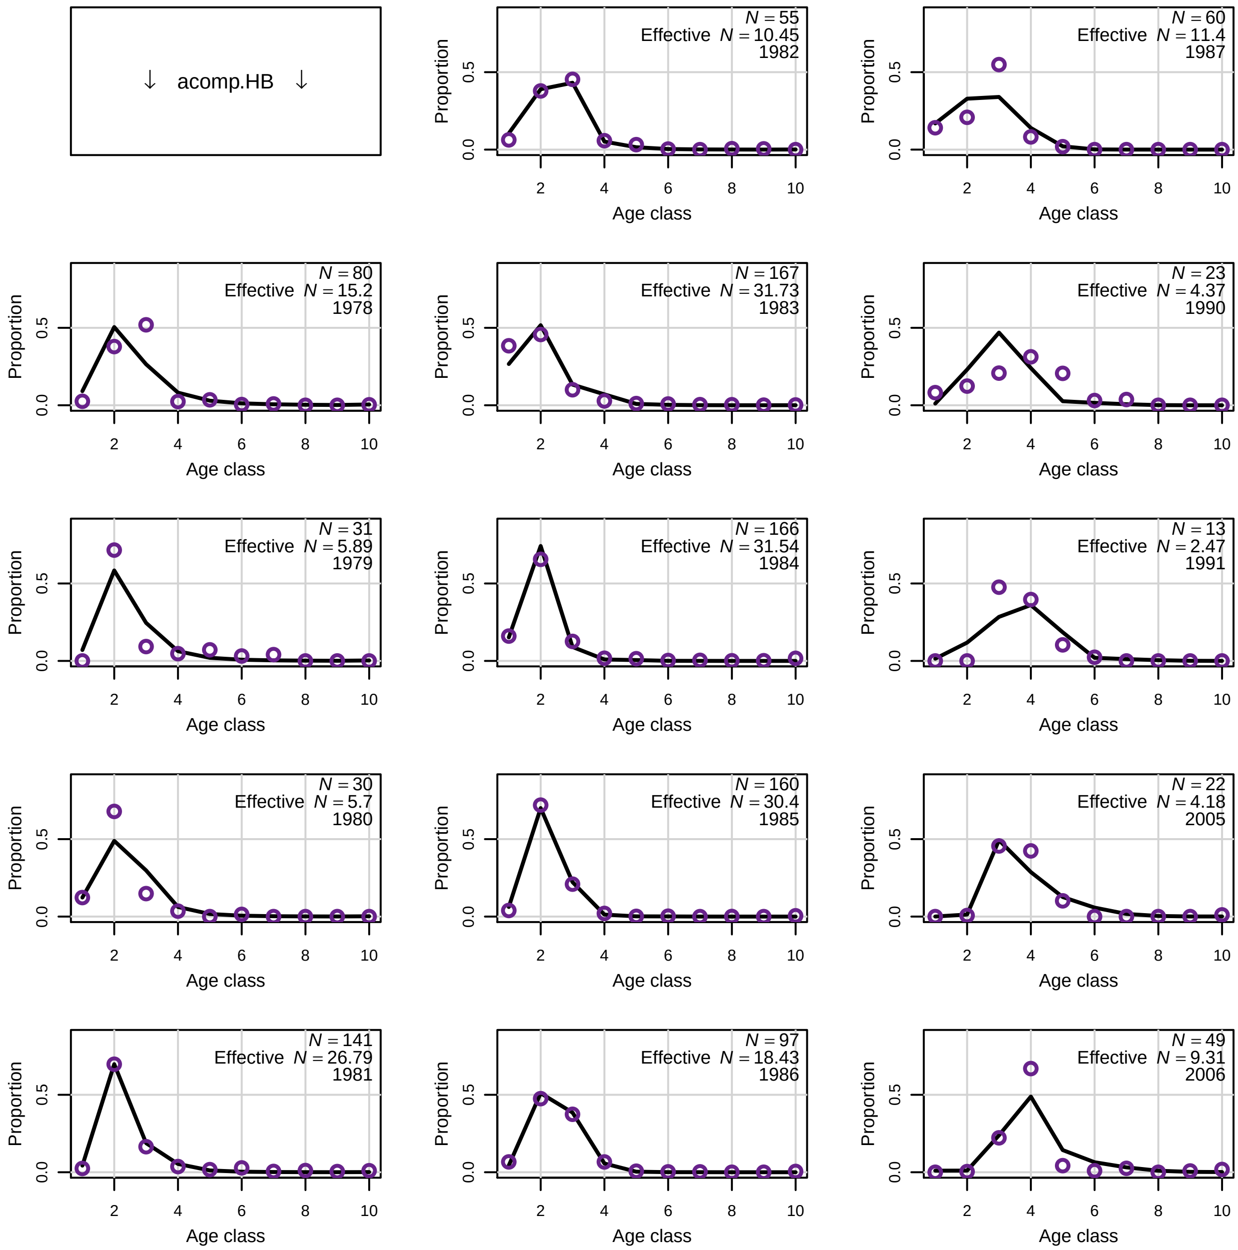

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey.

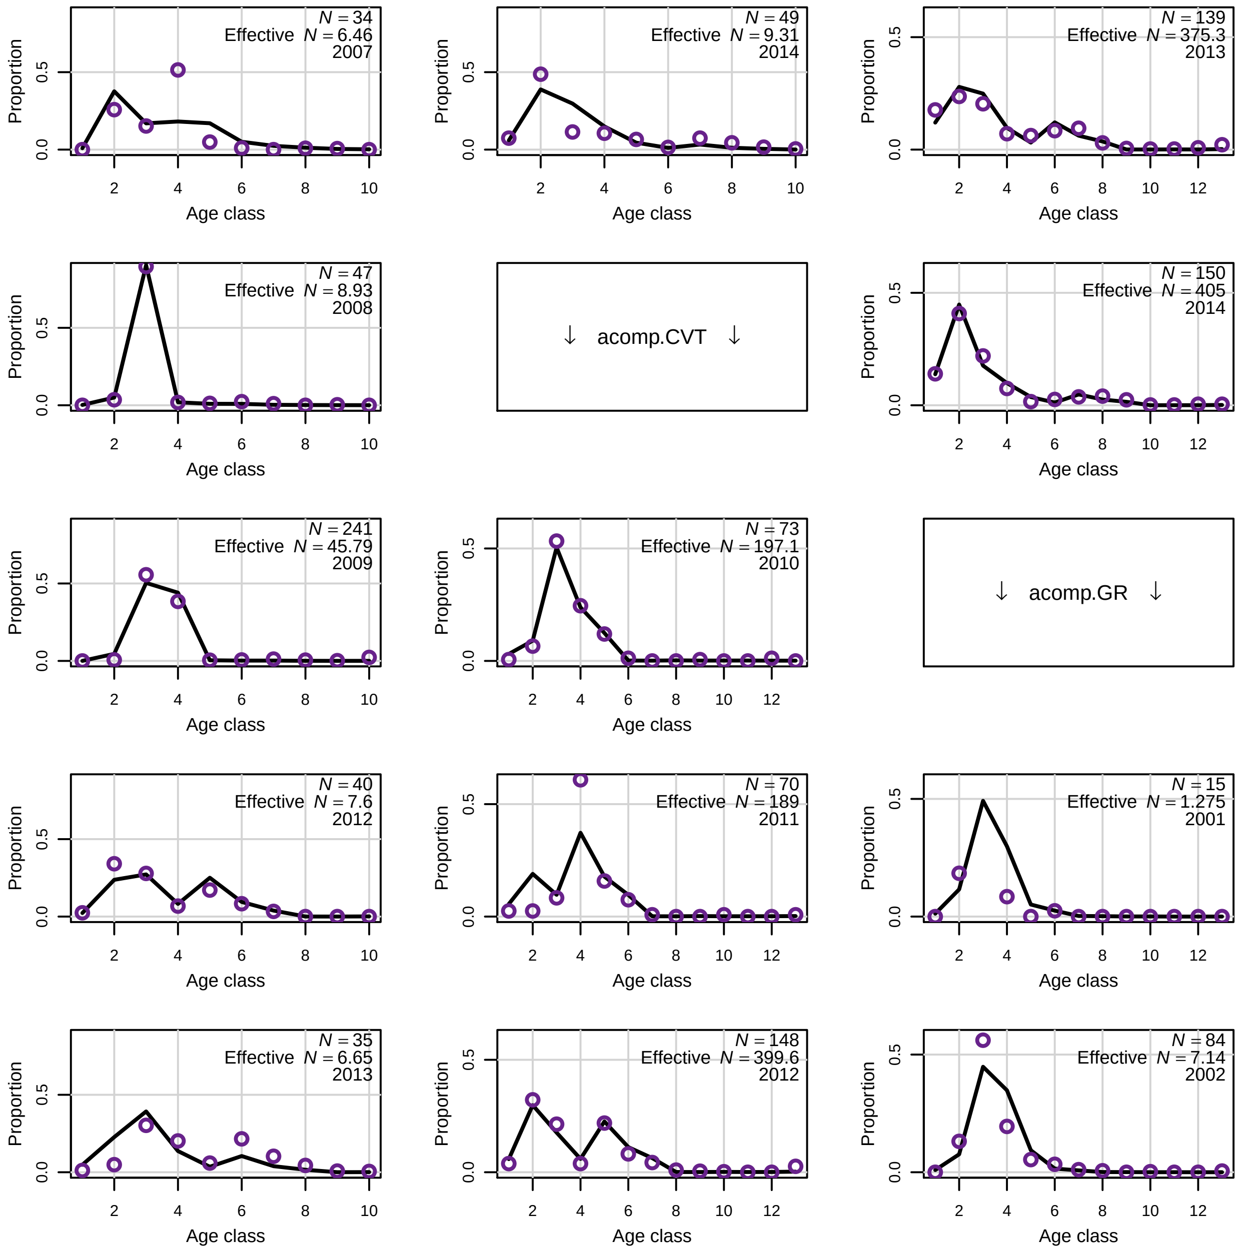

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey.

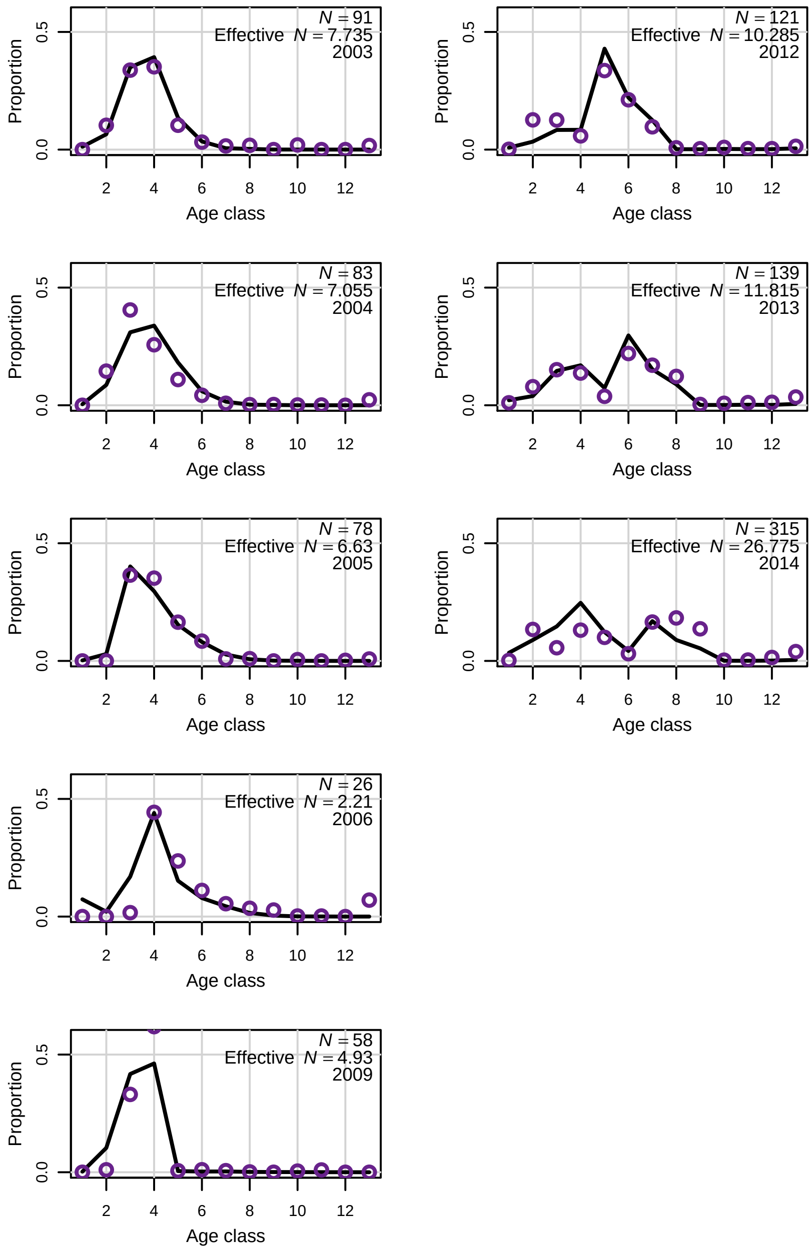

Figure 4. Observed (open circles) and estimated (solid line, circles) commercial handline landings in 1000 lb whole weight.

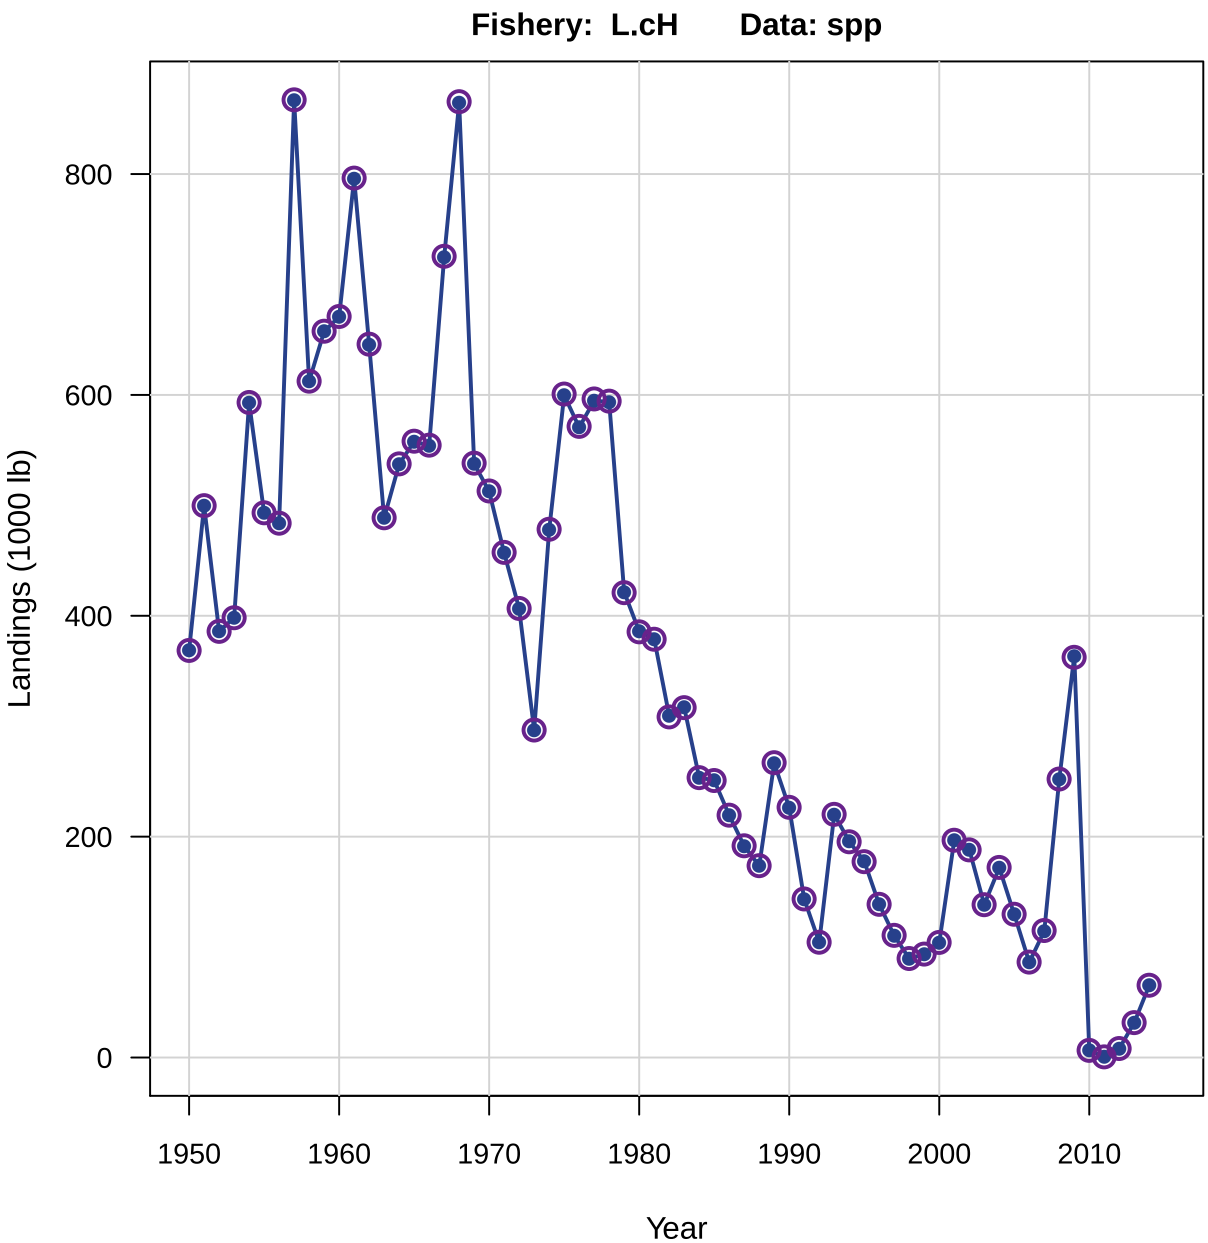

Figure 5. Observed (open circles) and estimated (solid line, circles) headboat landings in 1000s of fish.

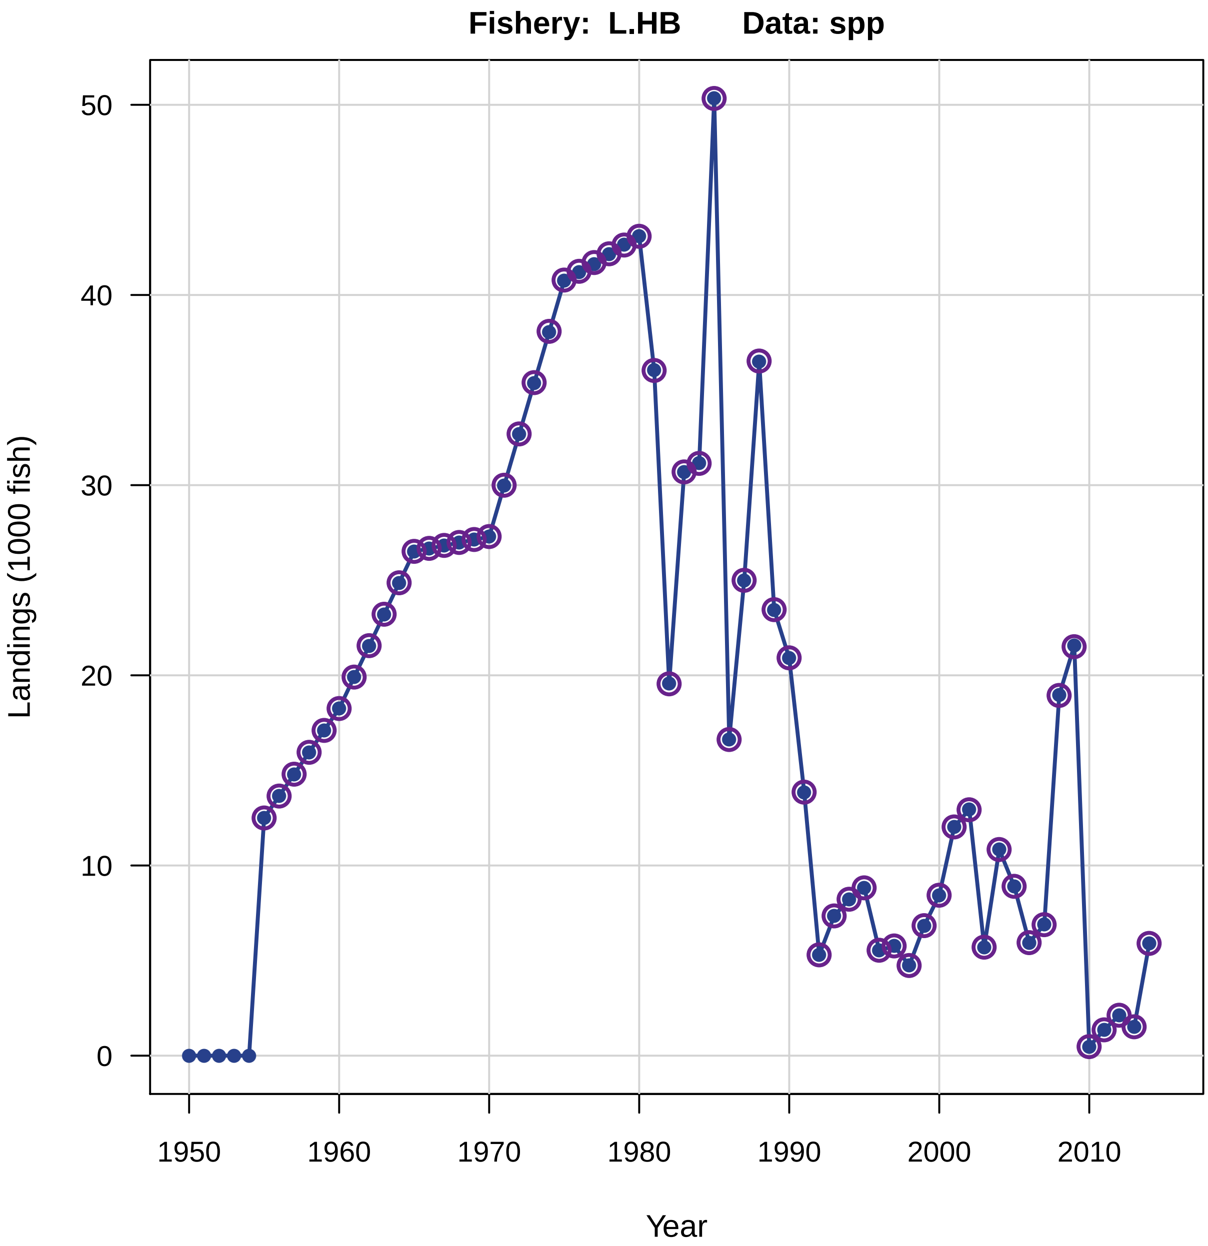

Figure 6. Observed (open circles) and estimated (solid line, circles) general recreational landings in 1000s of fish.

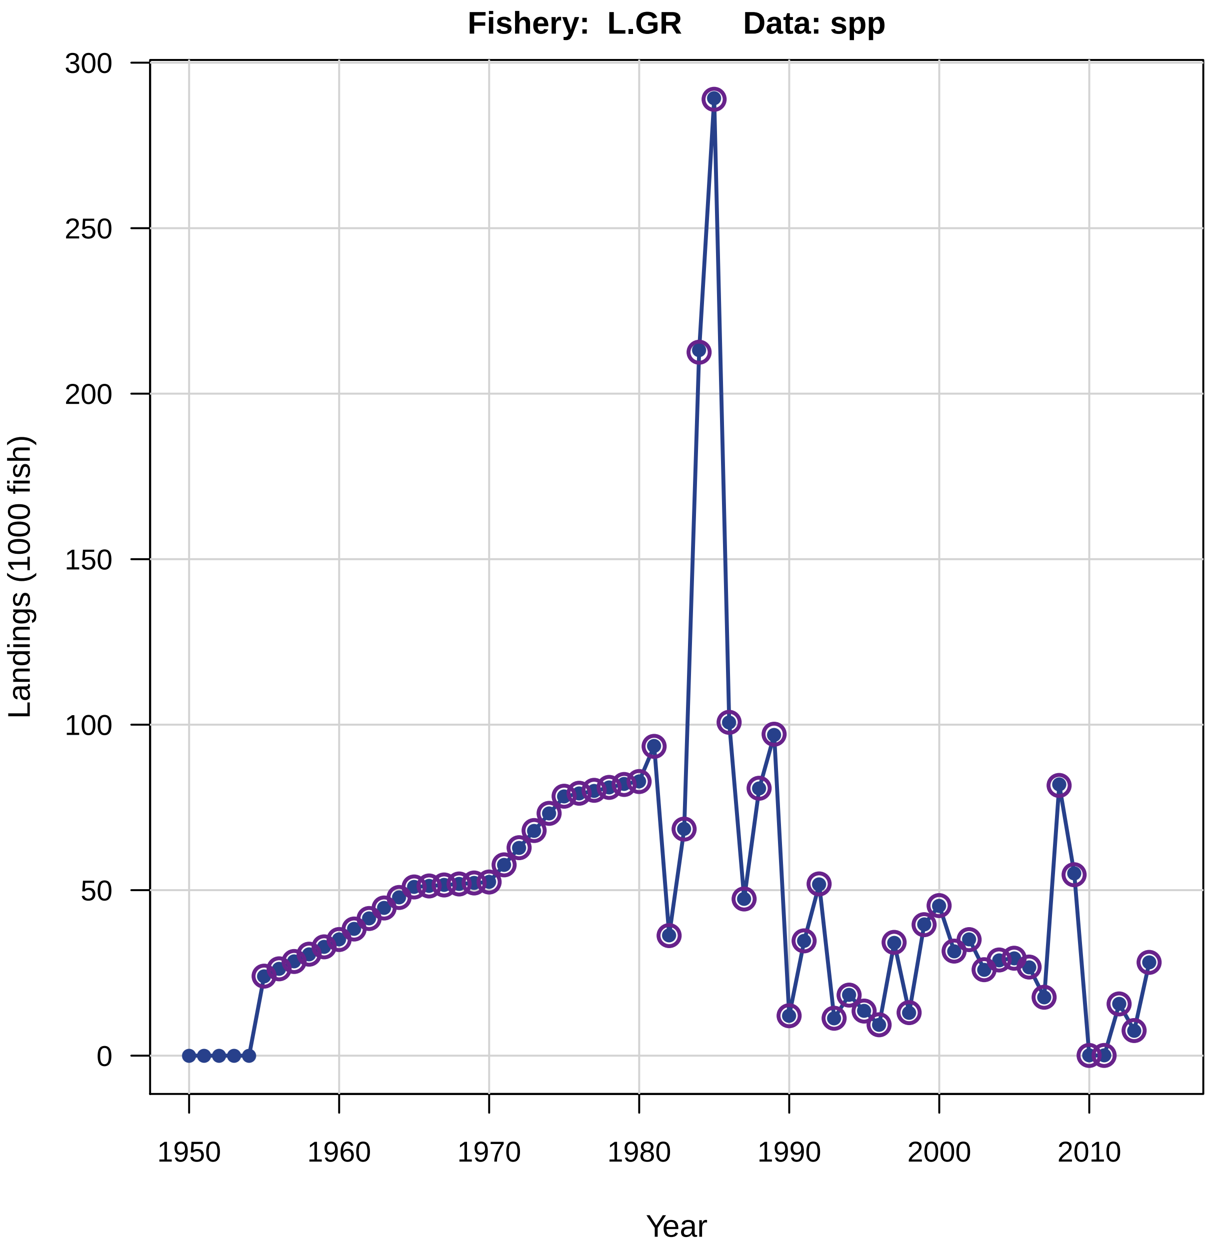

Figure 7. Observed (open circles) and estimated (solid line, circles) commercial handline discard mortalities.

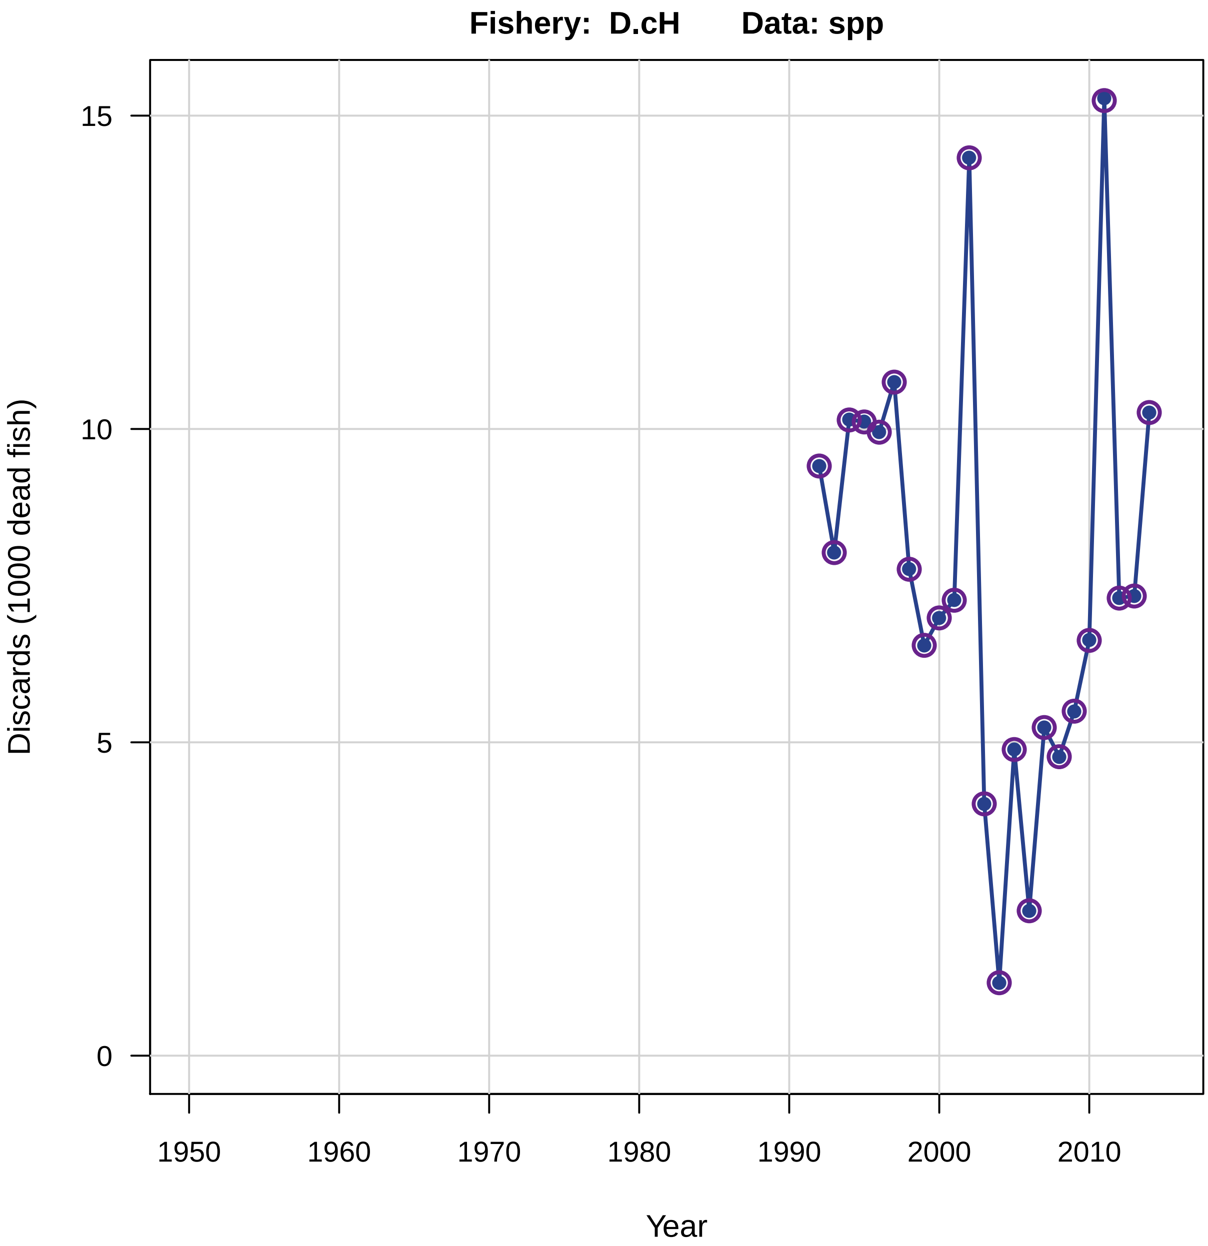

Figure 8. Observed (open circles) and estimated (solid line, circles) headboat discard mortalities.

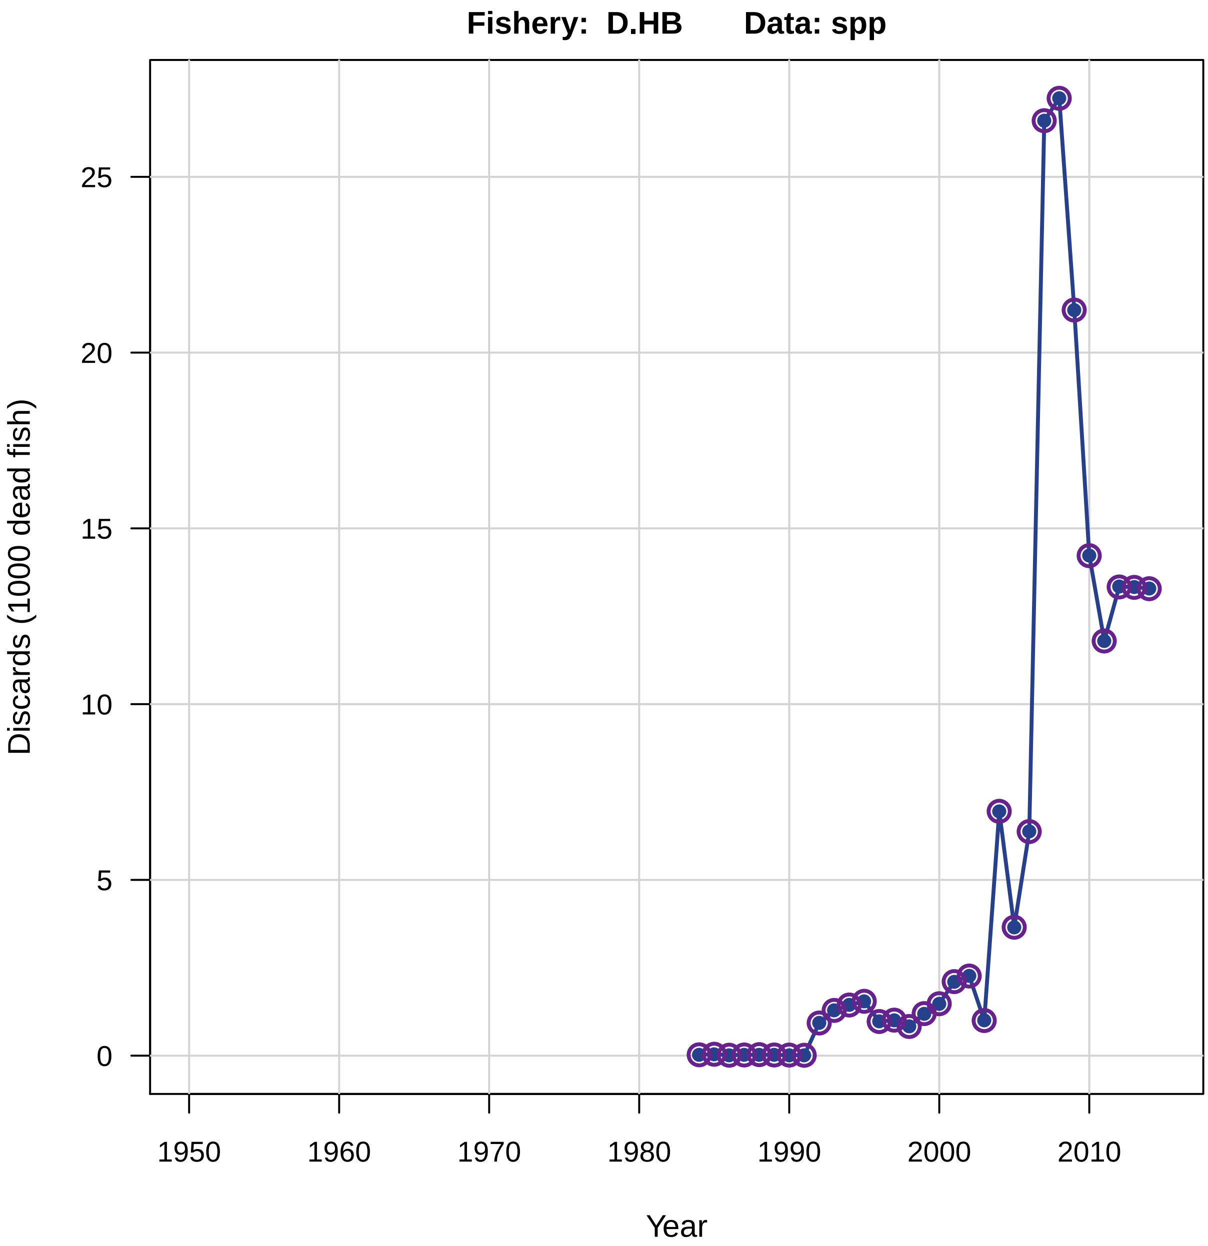

Figure 9. Observed (open circles) and estimated (solid line, circles) general recreational discard mortalities.

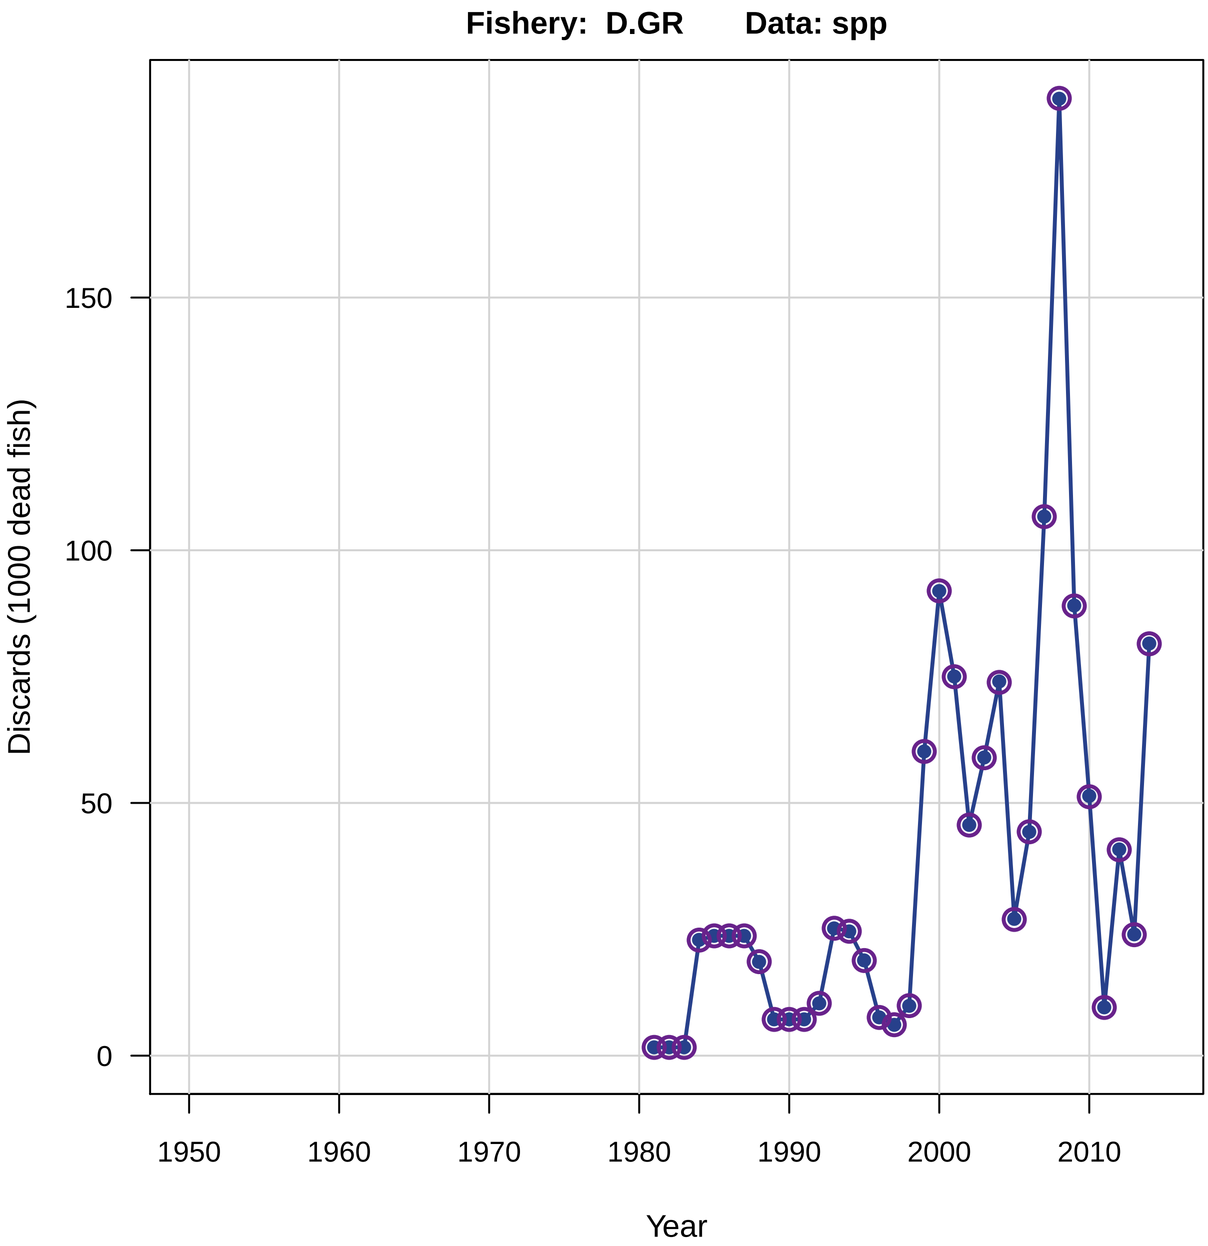

Figure 10. Observed (open circles) and estimated (solid line, circles) index of abundance from the SERFS combined trap and video index. The error bars represent the annual CV provided by the GLM standardization divided by the likelihood weight on the index.

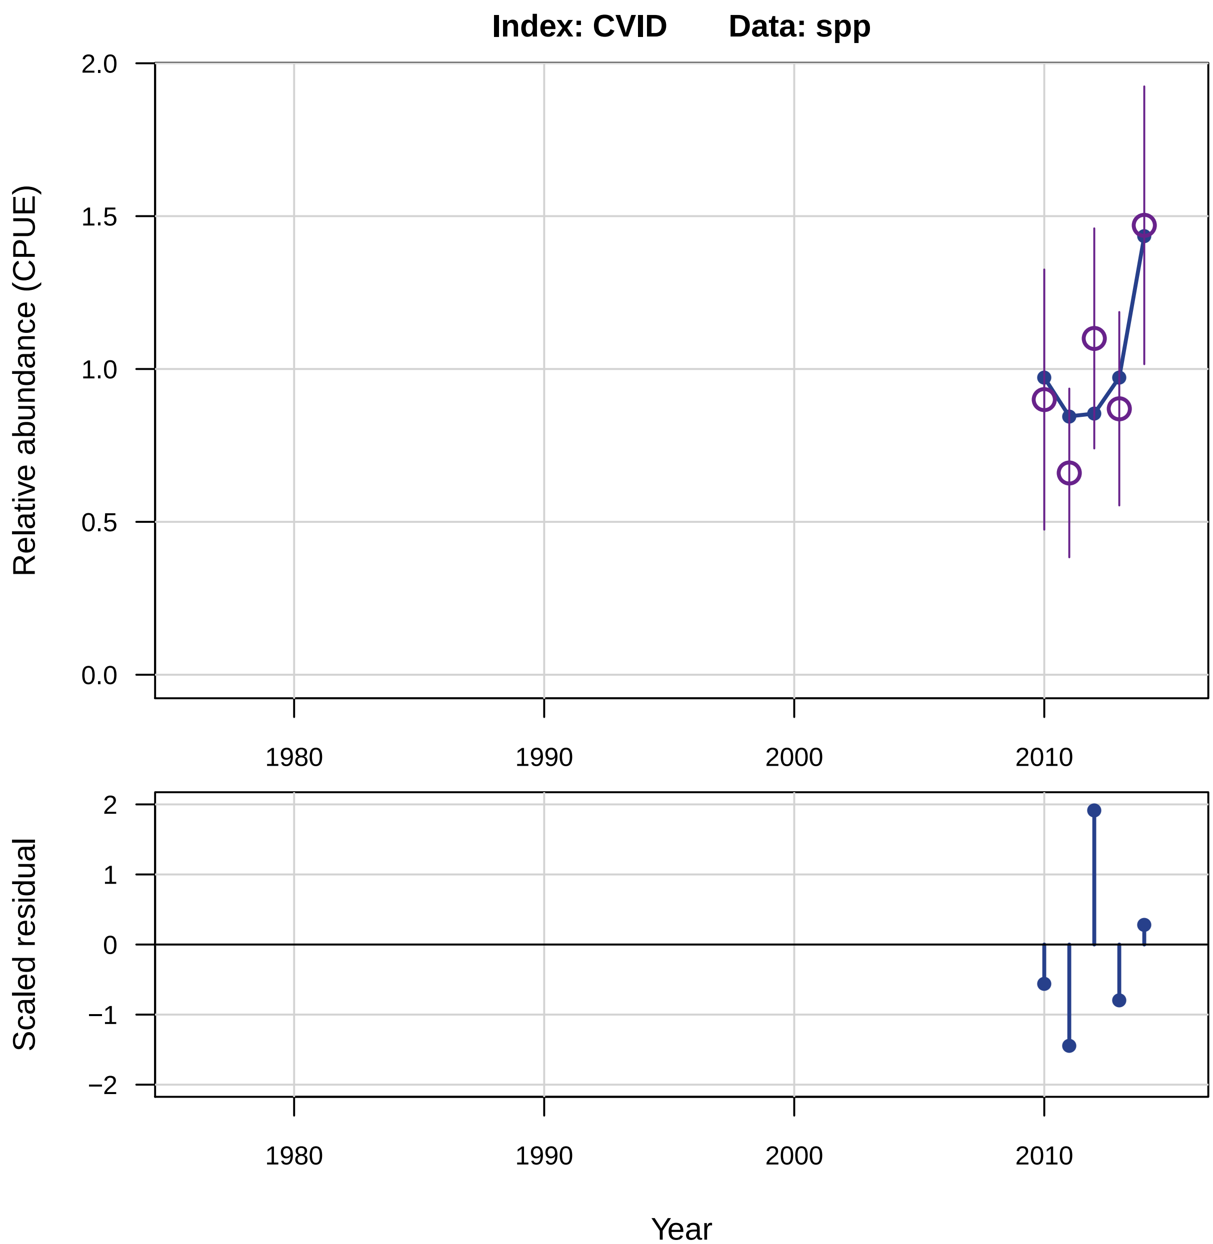

Figure 11. Observed (open circles) and estimated (solid line, circles) index of abundance from the commercial handline fleet. The error bars represent the annual CV of the index (0.2) divided by the likelihood weight on the index.

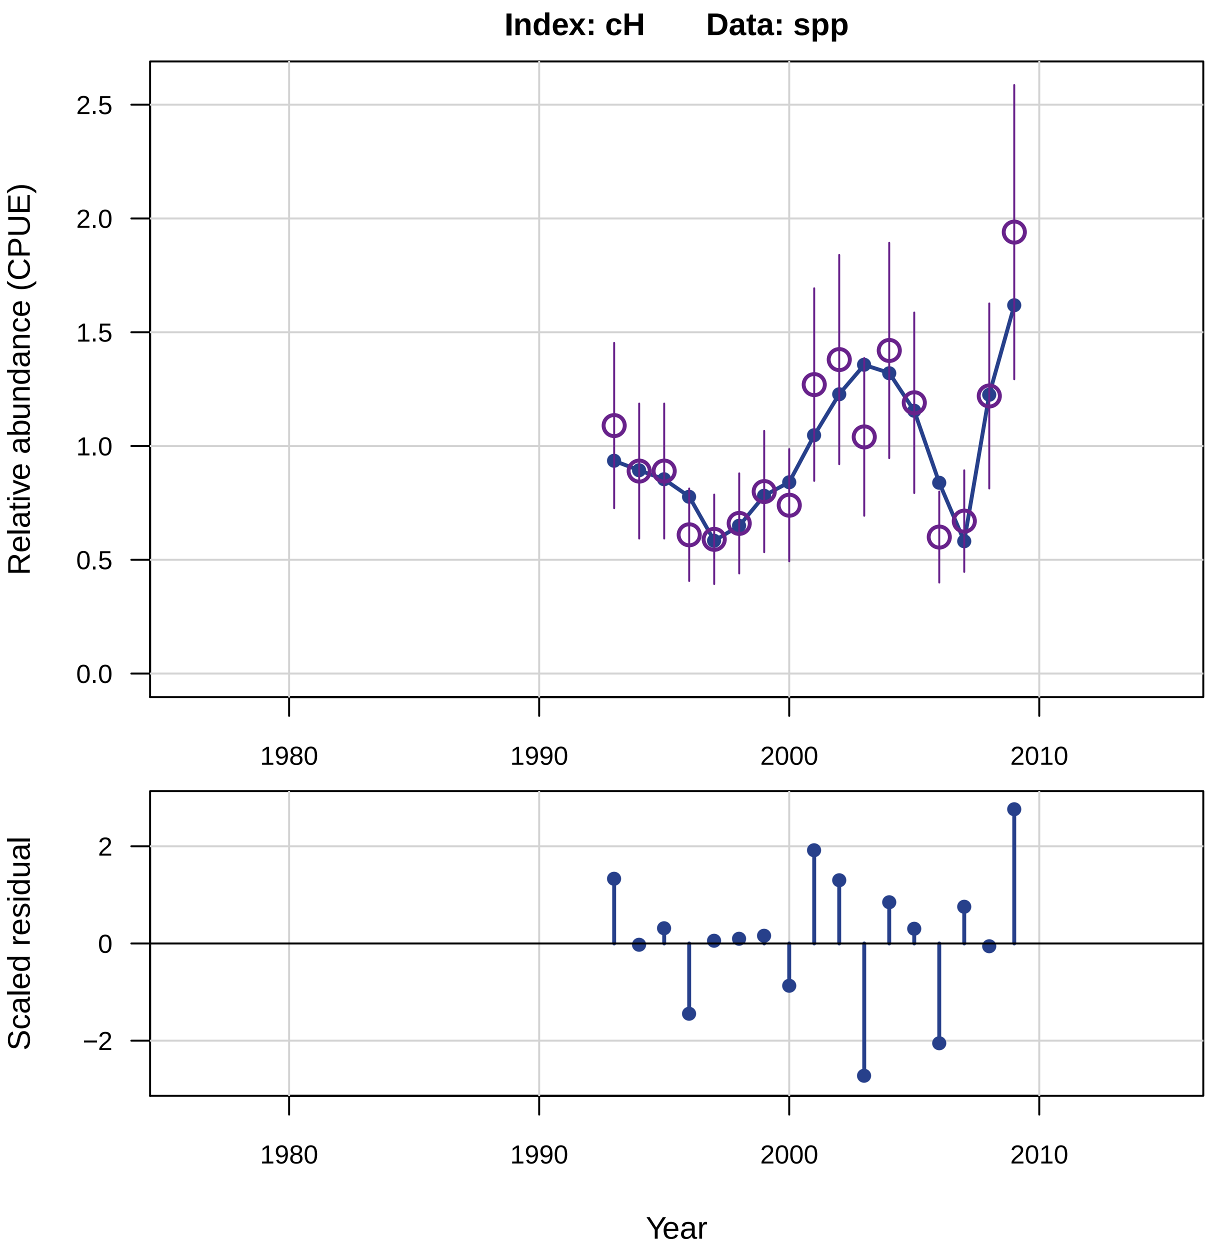

Figure 12. Observed (open circles) and estimated (solid line, circles) abundance from the headboat fleet. The error bars represent the annual CV of the index (0.2) divided by the likelihood weight on the index.

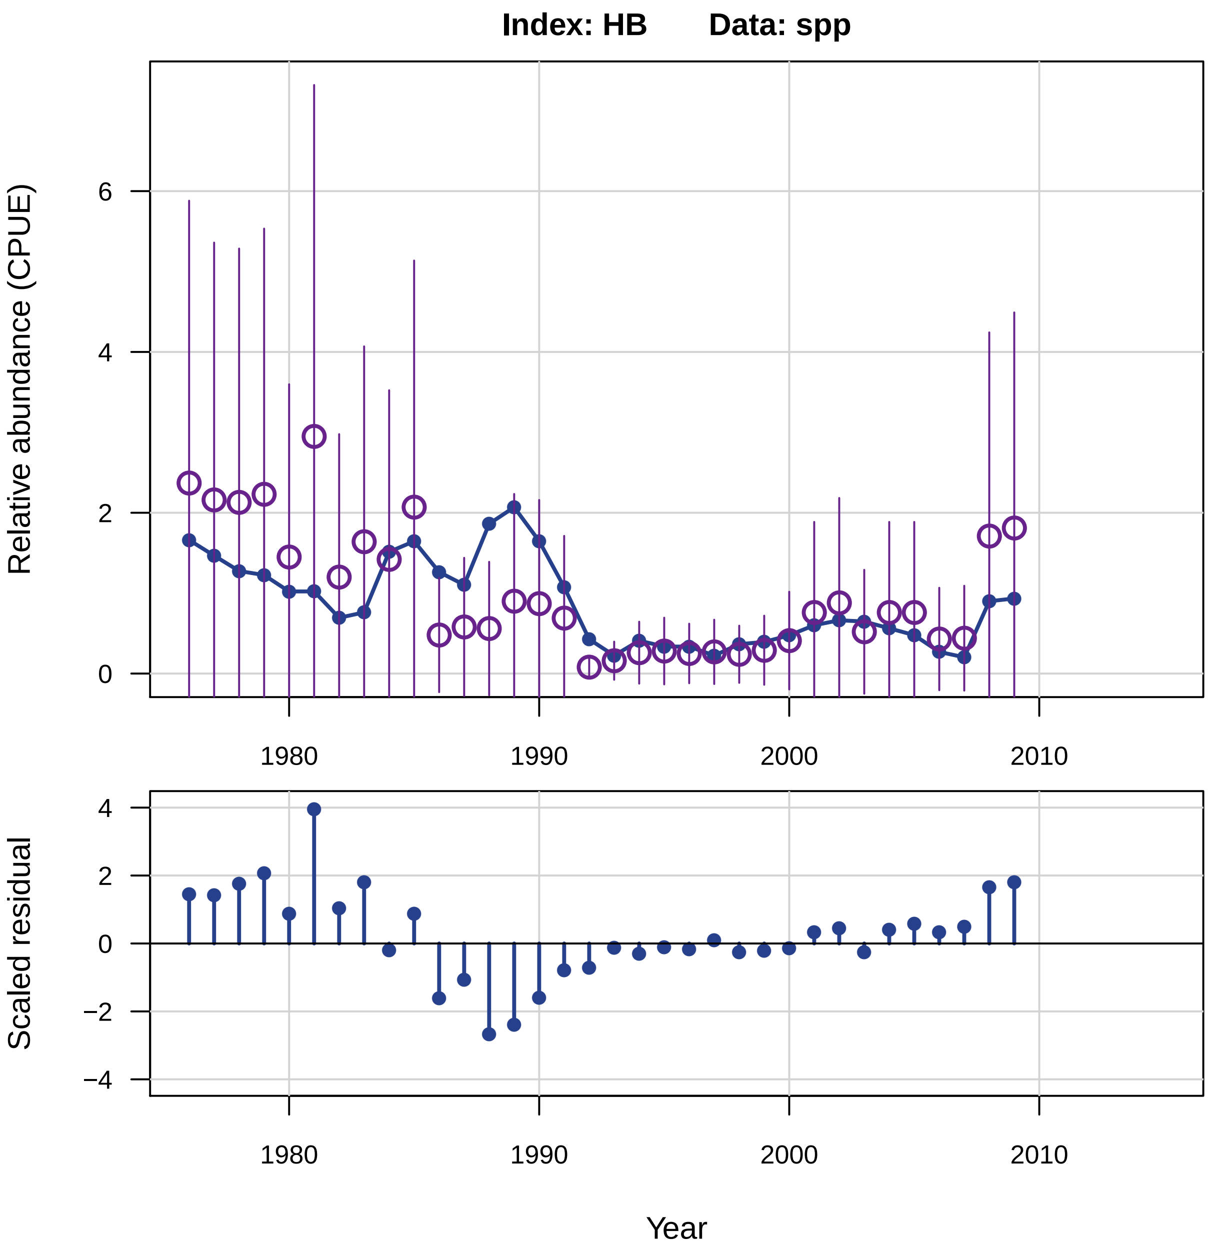

Figure 13. Observed (open circles) and estimated (solid line, circles) abundance from the headboat fleet (discards). The error bars represent the annual CV provided by the GLM standardization divided by the likelihood weight on the index.

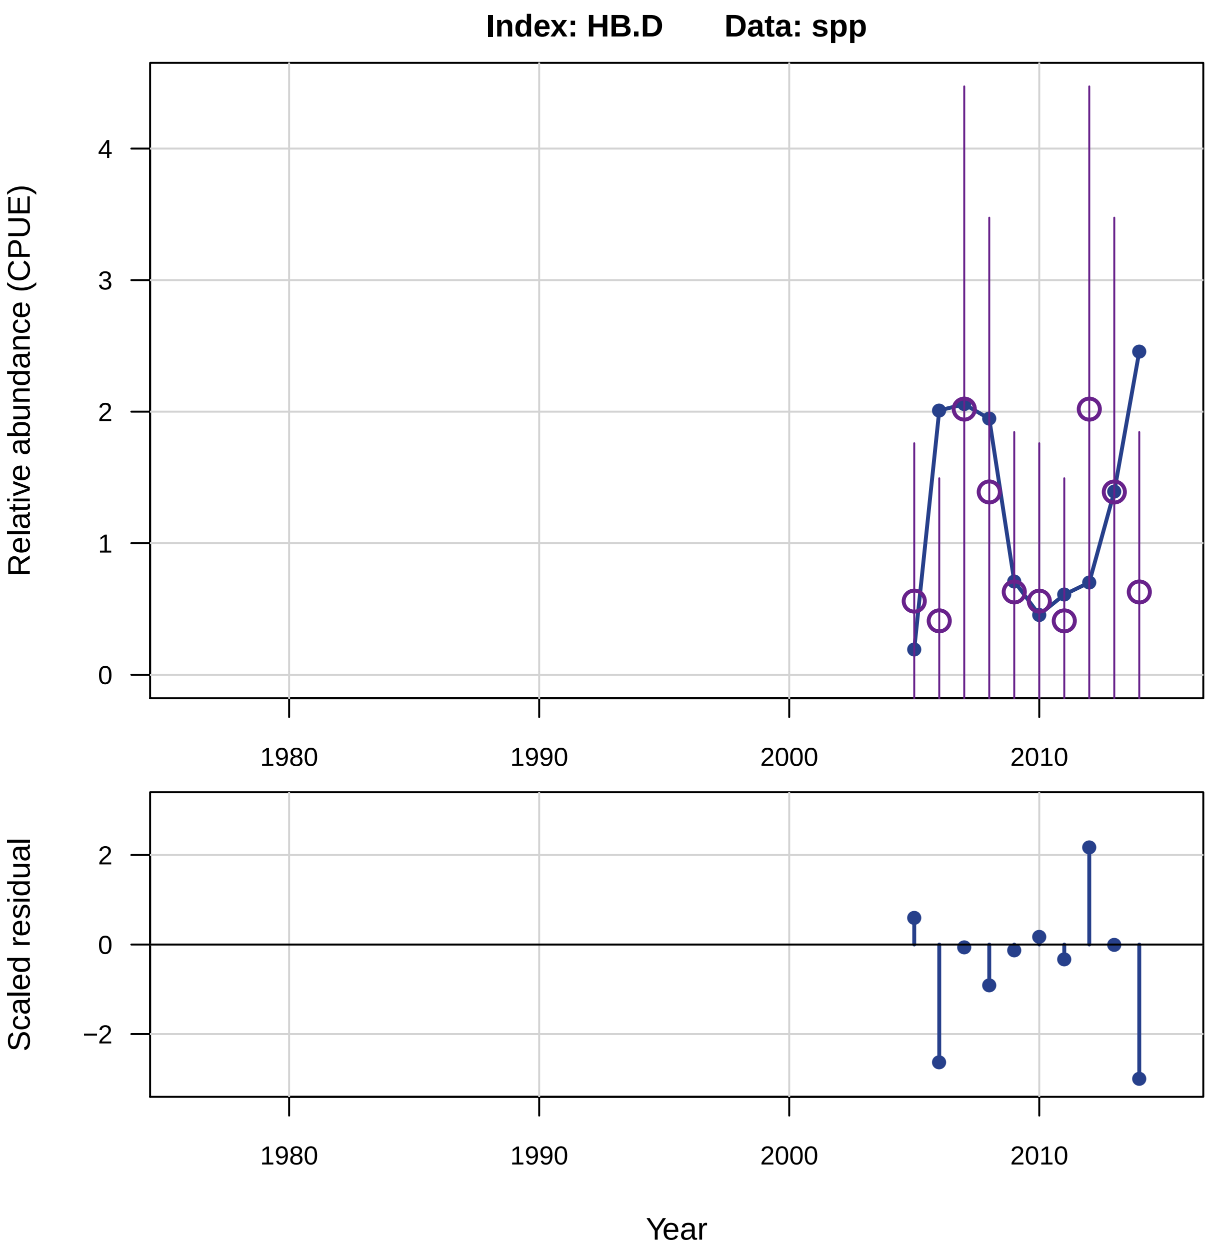

Figure 14. Estimated abundance at age at start of year.

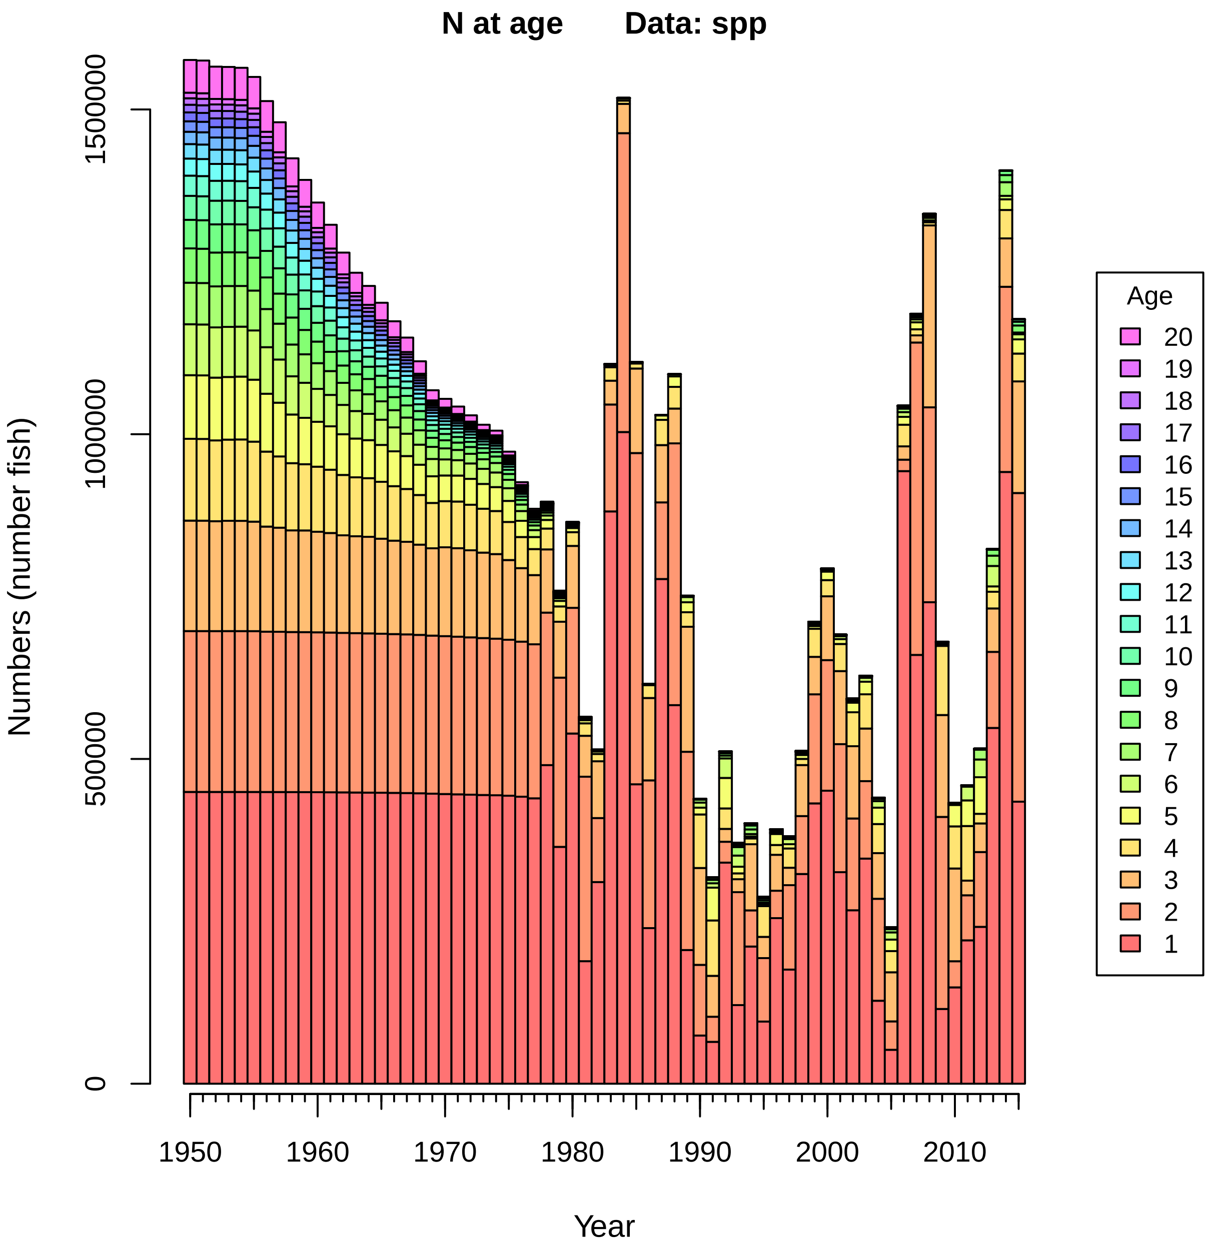

Figure 15. Top panel: Estimated recruitment of age-1 fish. Horizontal dashed line indicates $R_{F30\%}$. Bottom panel: log recruitment residuals.

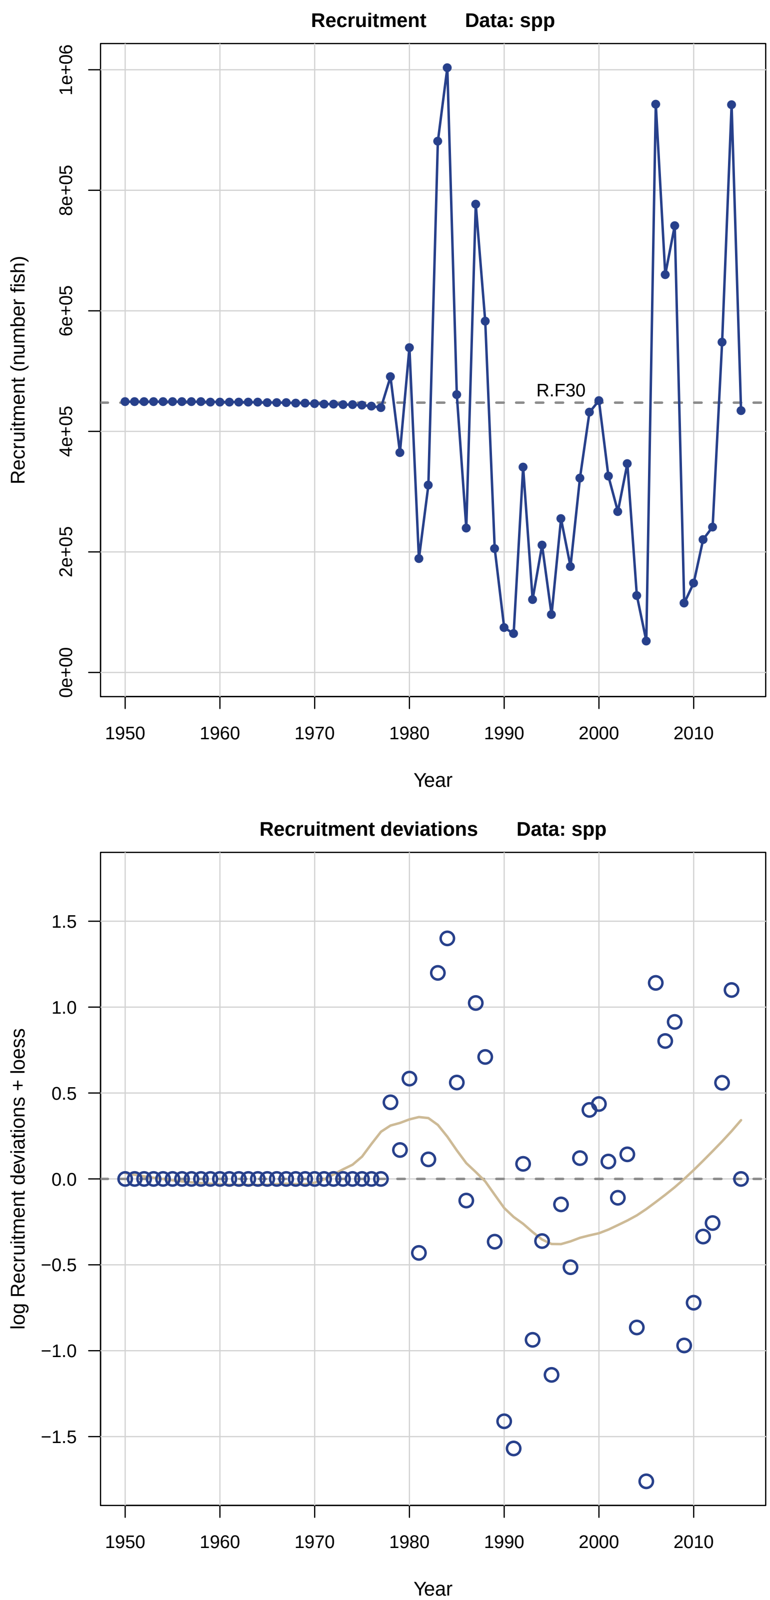

Figure 16. Estimated biomass at age at start of year.

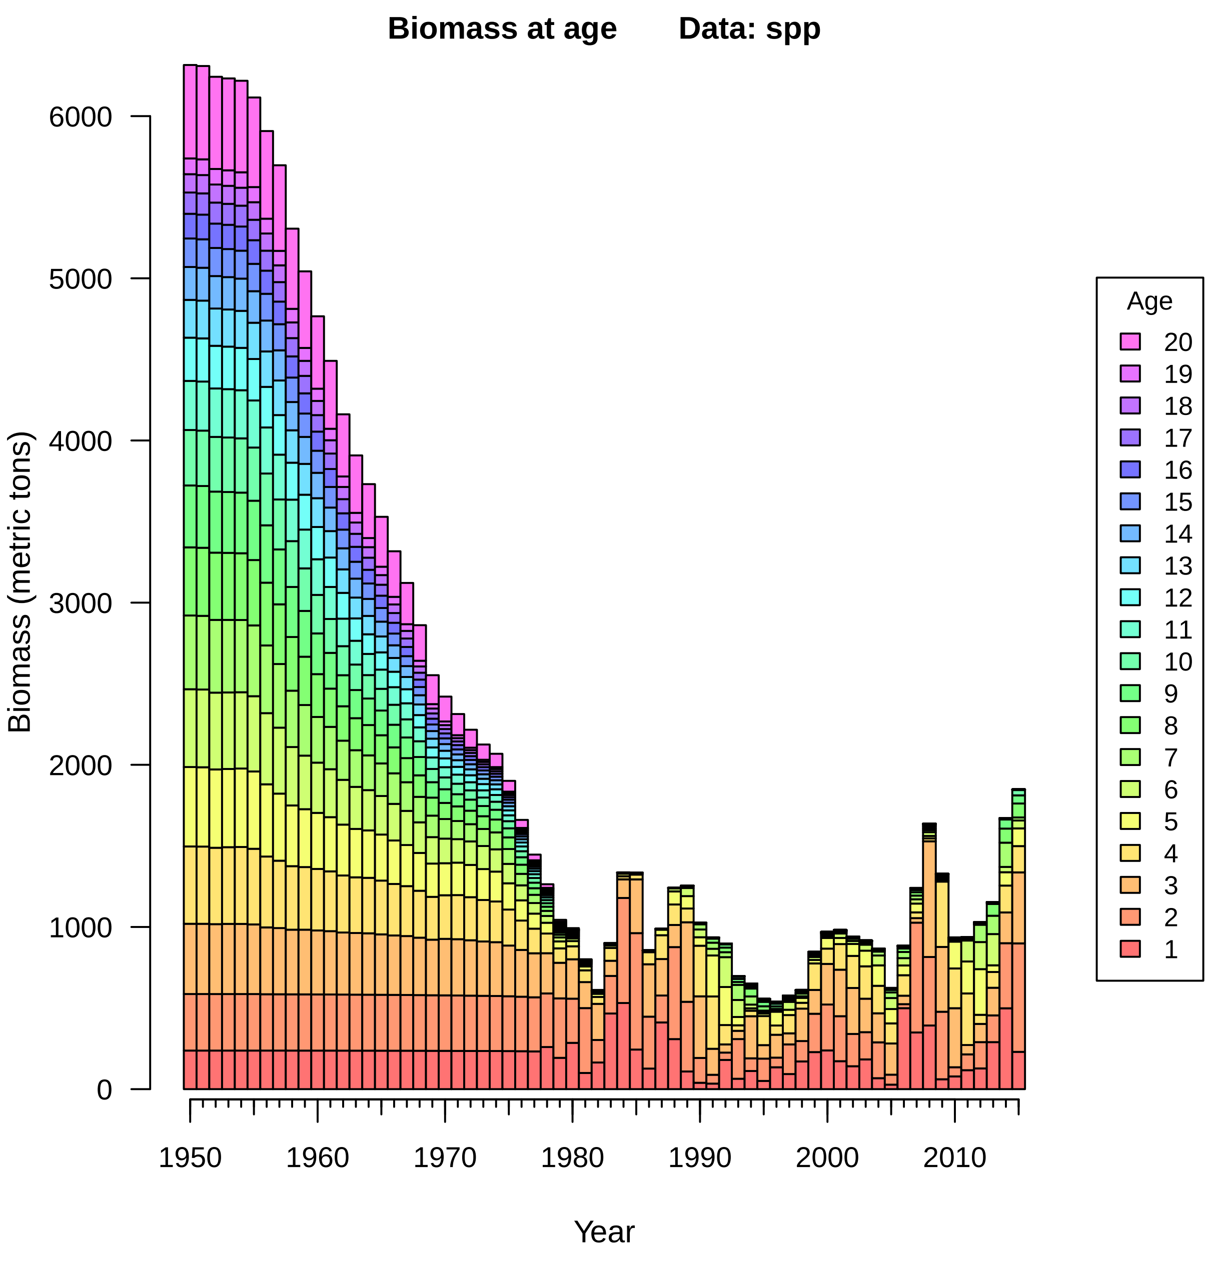

Figure 17. Top panel: Estimated total biomass (metric tons) at start of year. Horizontal dashed line indicates $B_{F30\%}$. *Bottom panel: Estimated spawning stock (population fecundity) at time of peak spawning.*

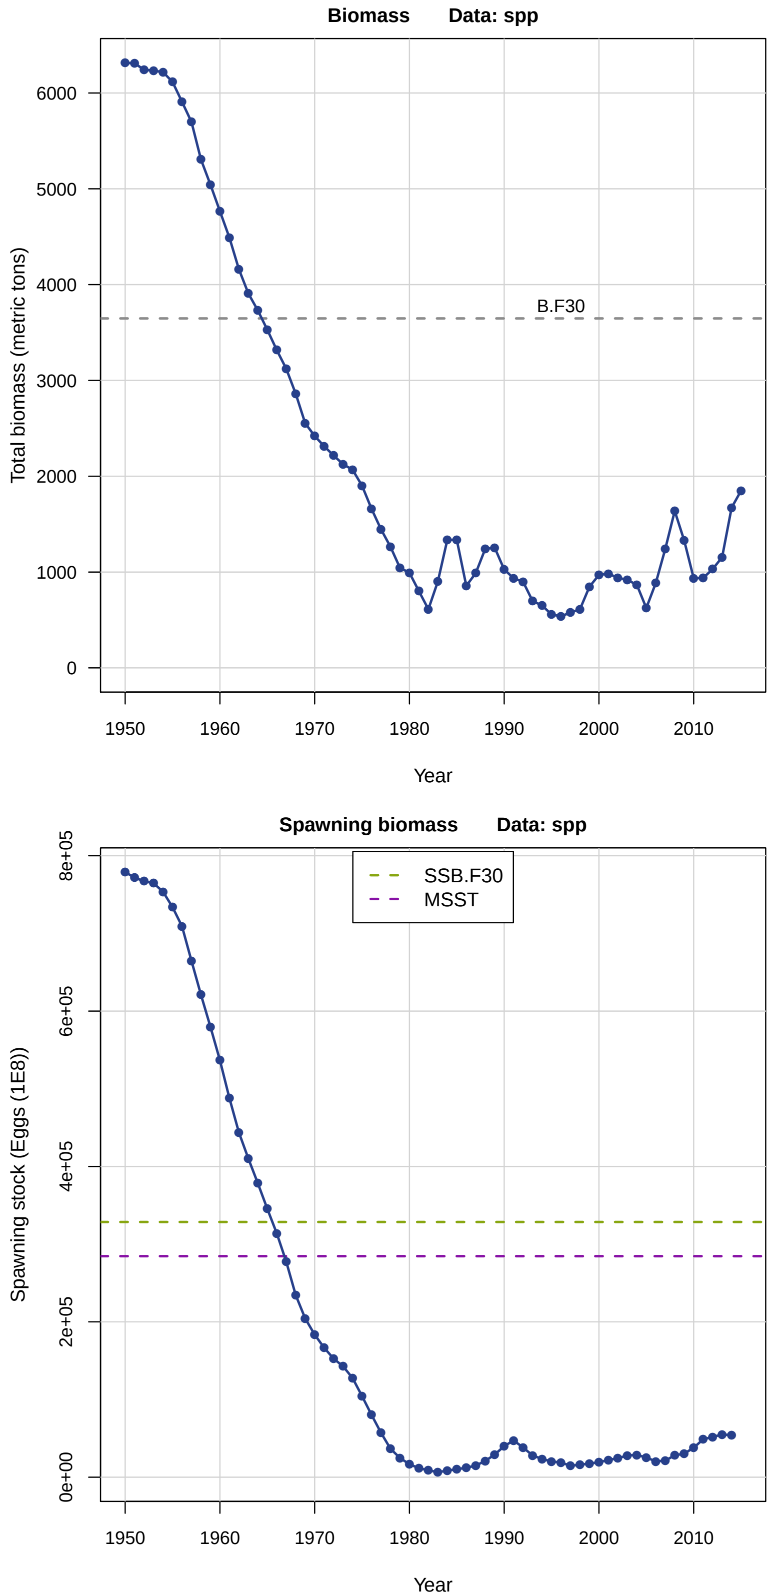

Figure 18. Monte Carlo Bootstrap estimates of population abundance. Top panel is all ages, and the bottom panel represents age 2+.

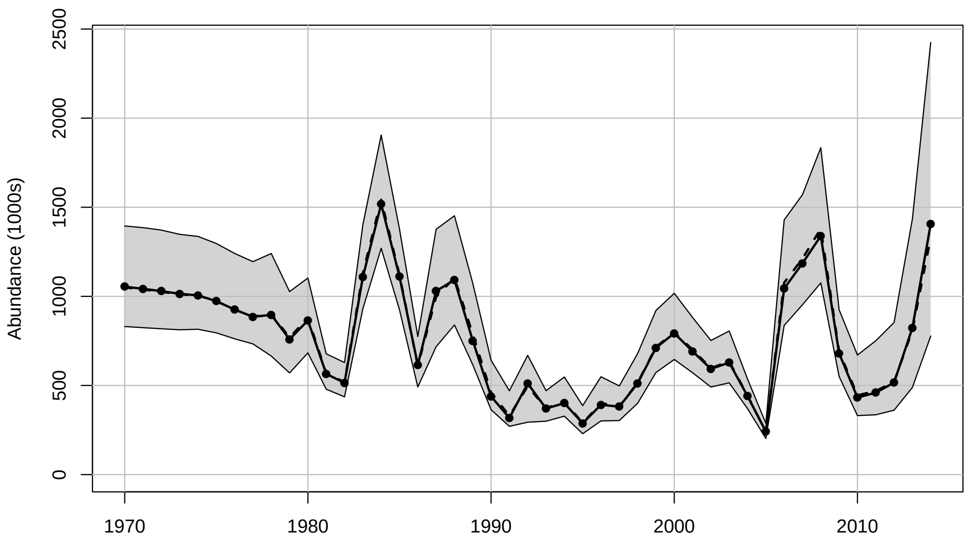

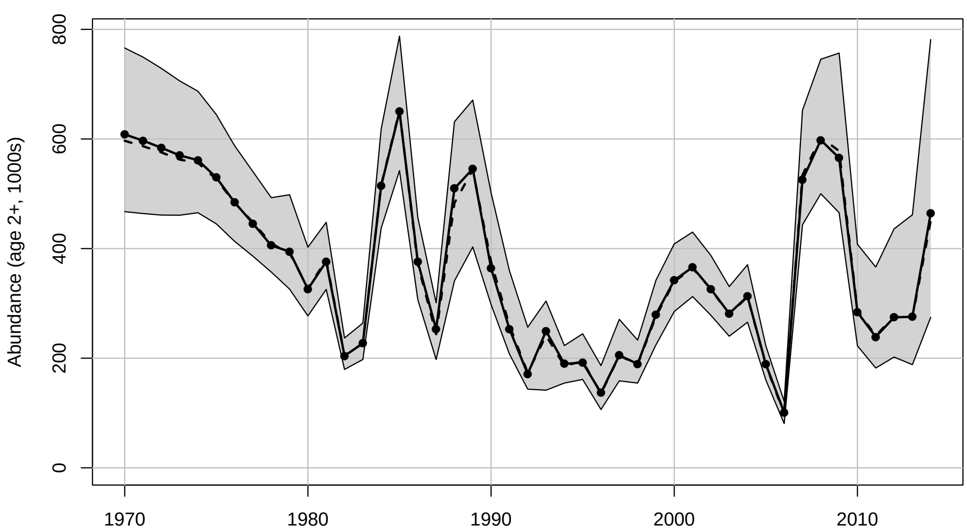

Figure 19. Selectivity of SERFS index.

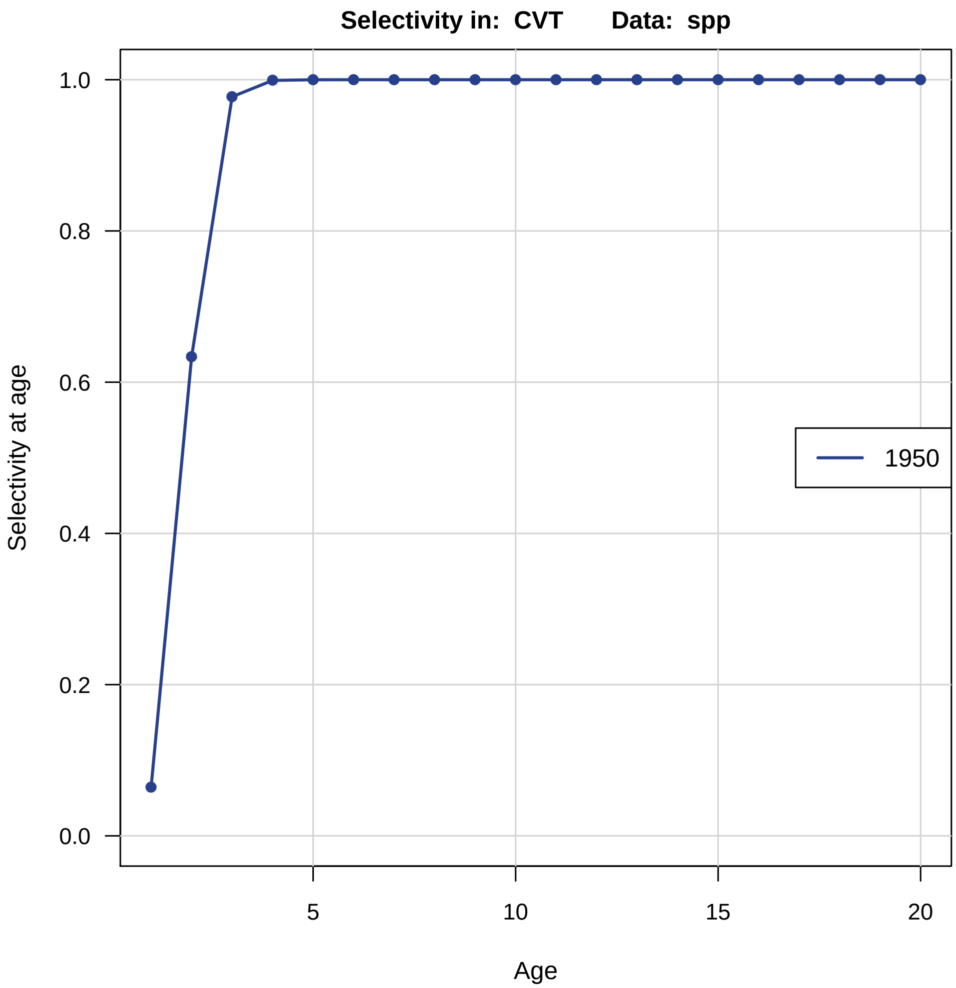

Figure 20. Selectivities of commercial handline landings. The legend indicates the first year each selectivity curve applies to the fleet.

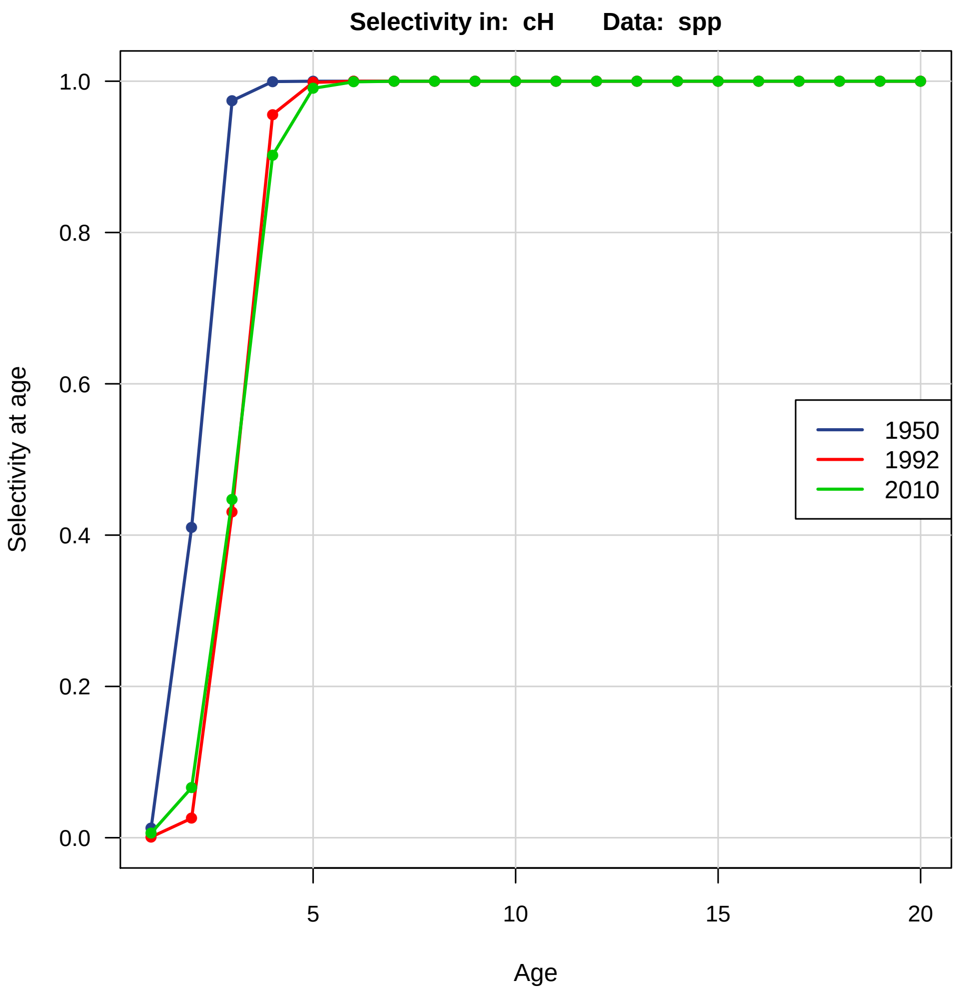

Figure 21. Selectivities of headboat landings. The legend indicates the first year each selectivity curve applies to the fleet.

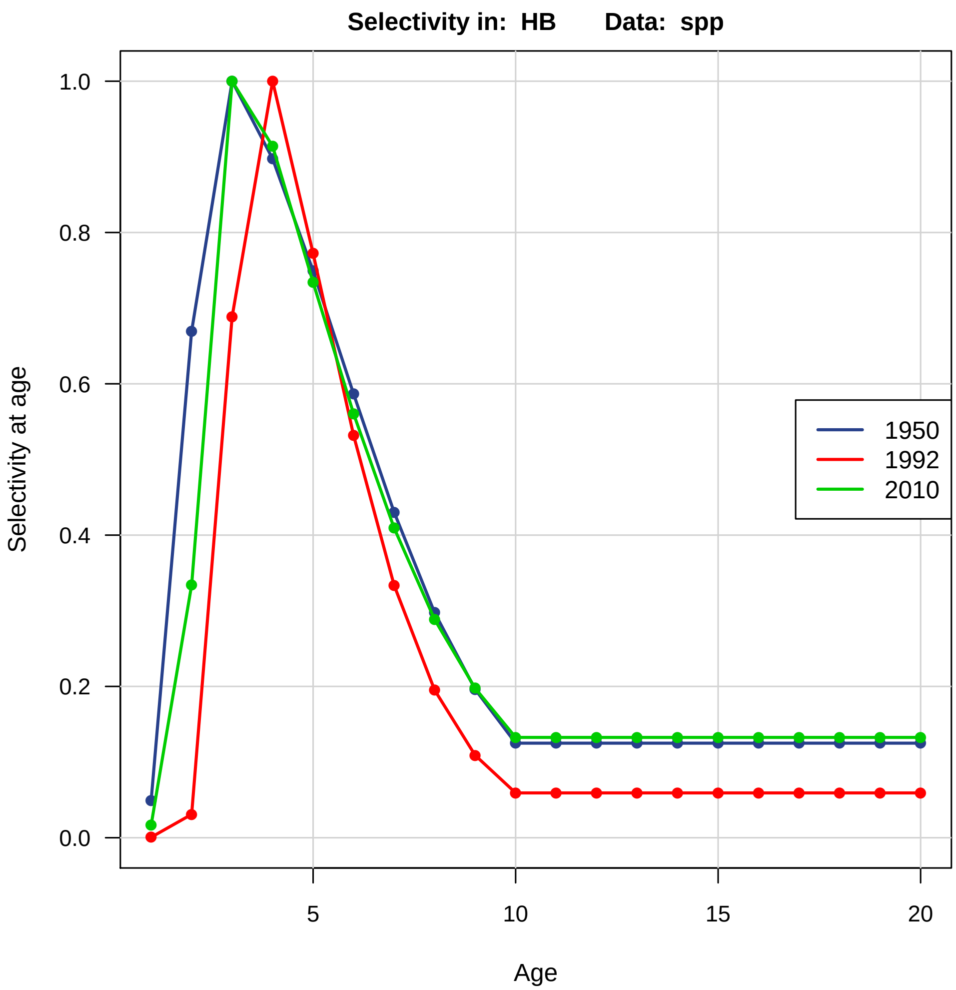

Figure 22. Selectivities of general recreational landings. The legend indicates the first year each selectivity curve applies to the fleet.

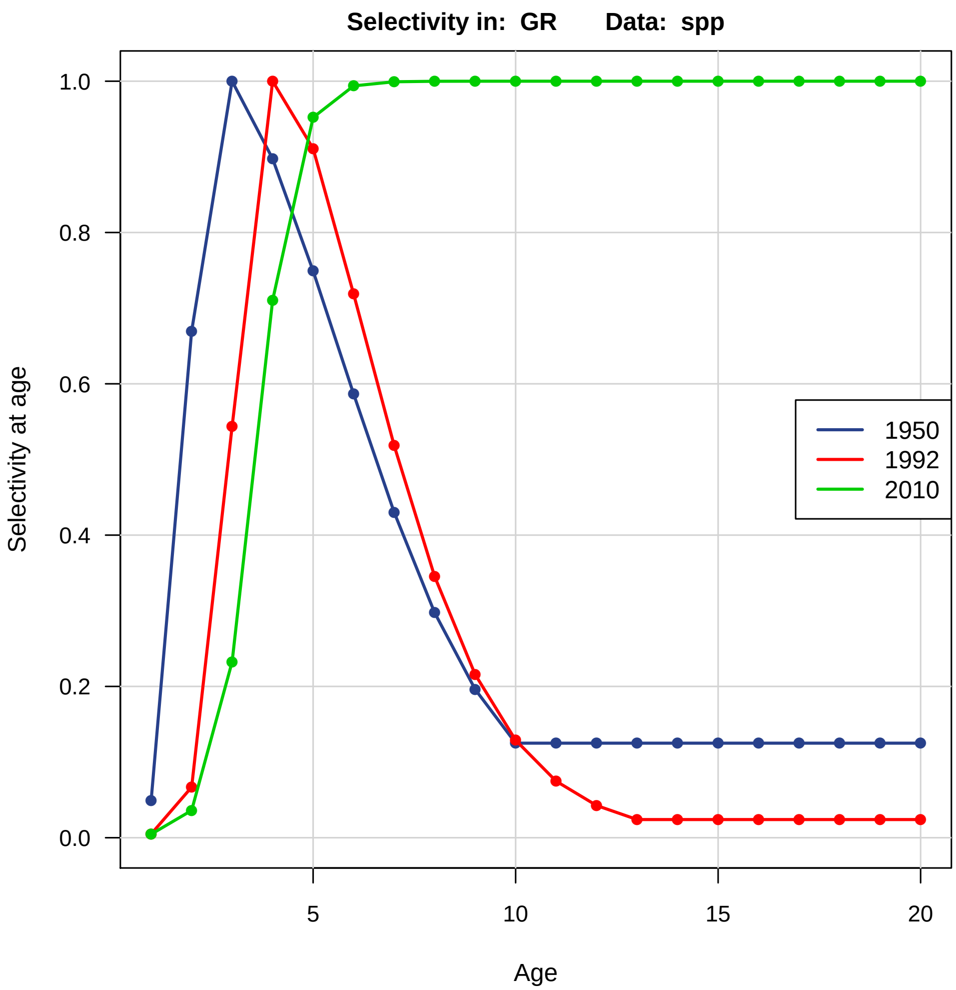

Figure 23. Selectivities of commercial handline discards. The legend indicates the first year each selectivity curve applies to the fleet.

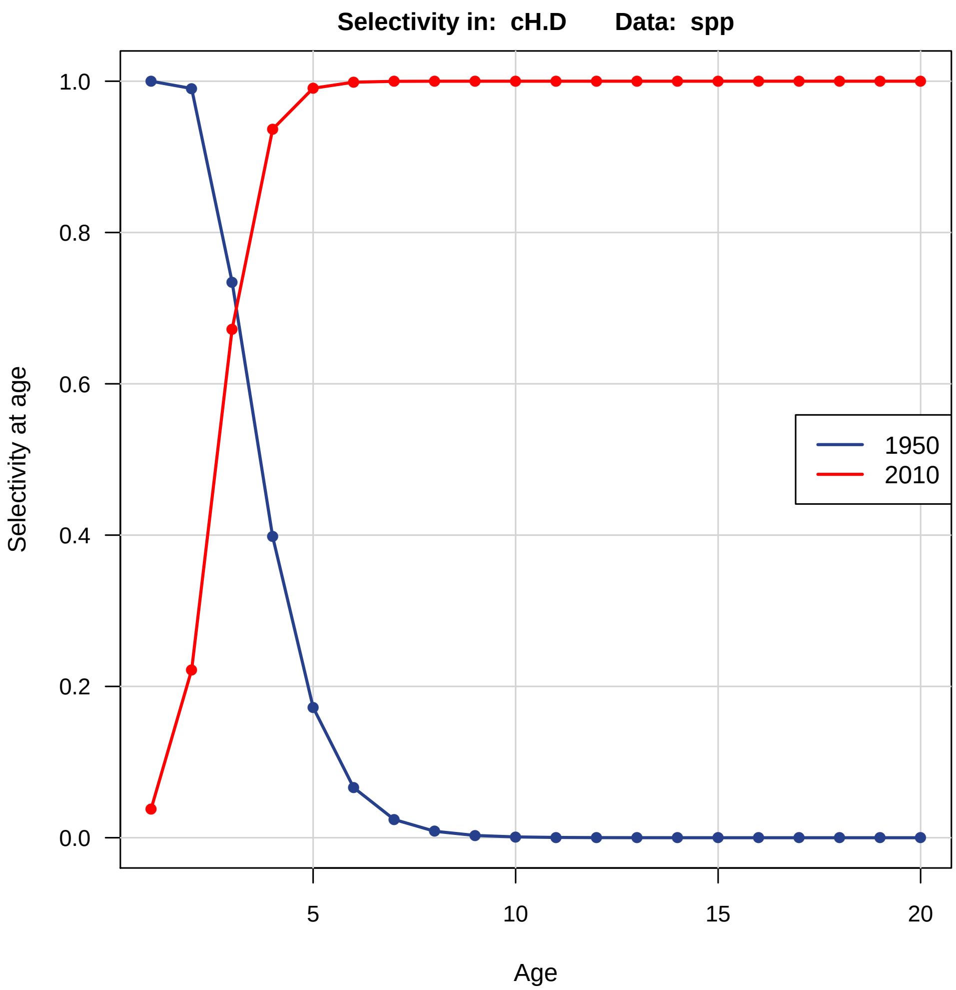

Figure 24. Selectivities of headboat discards. The legend indicates the first year each selectivity curve applies to the fleet.

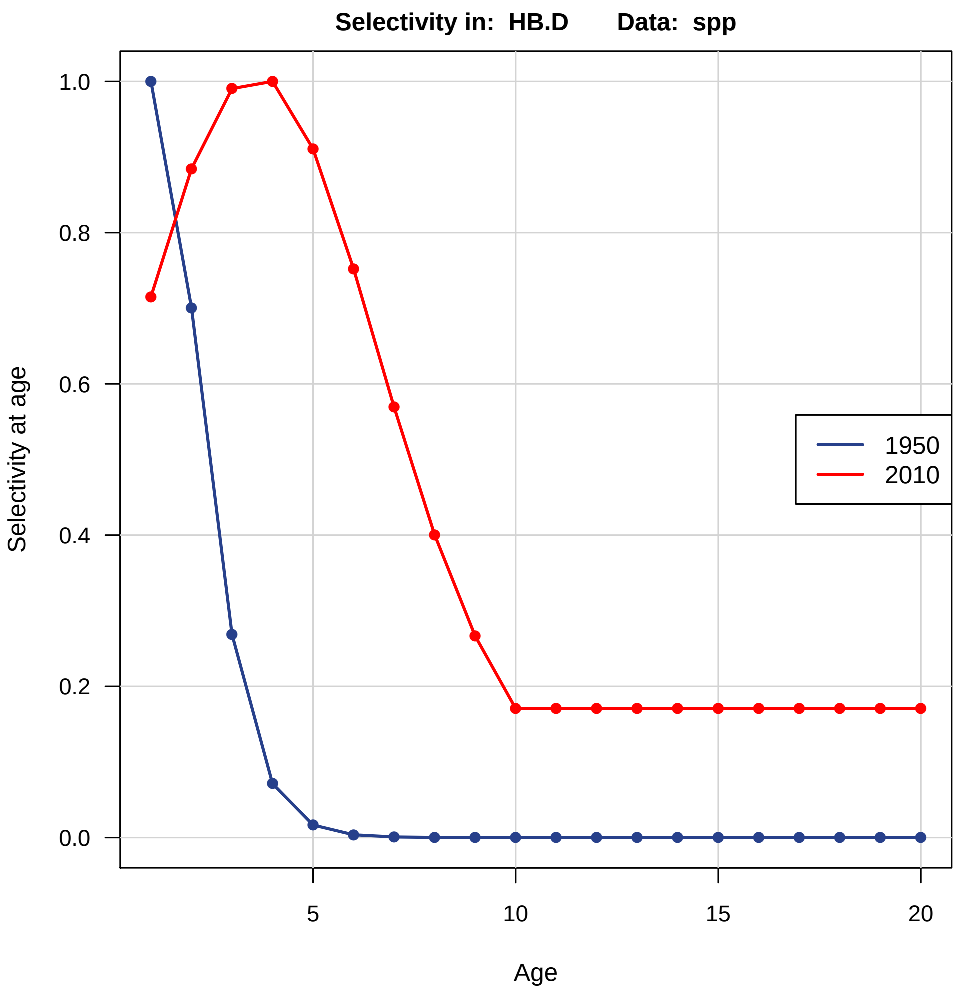

Figure 25. Selectivities of general recreational discards. The legend indicates the first year each selectivity curve applies to the fleet.

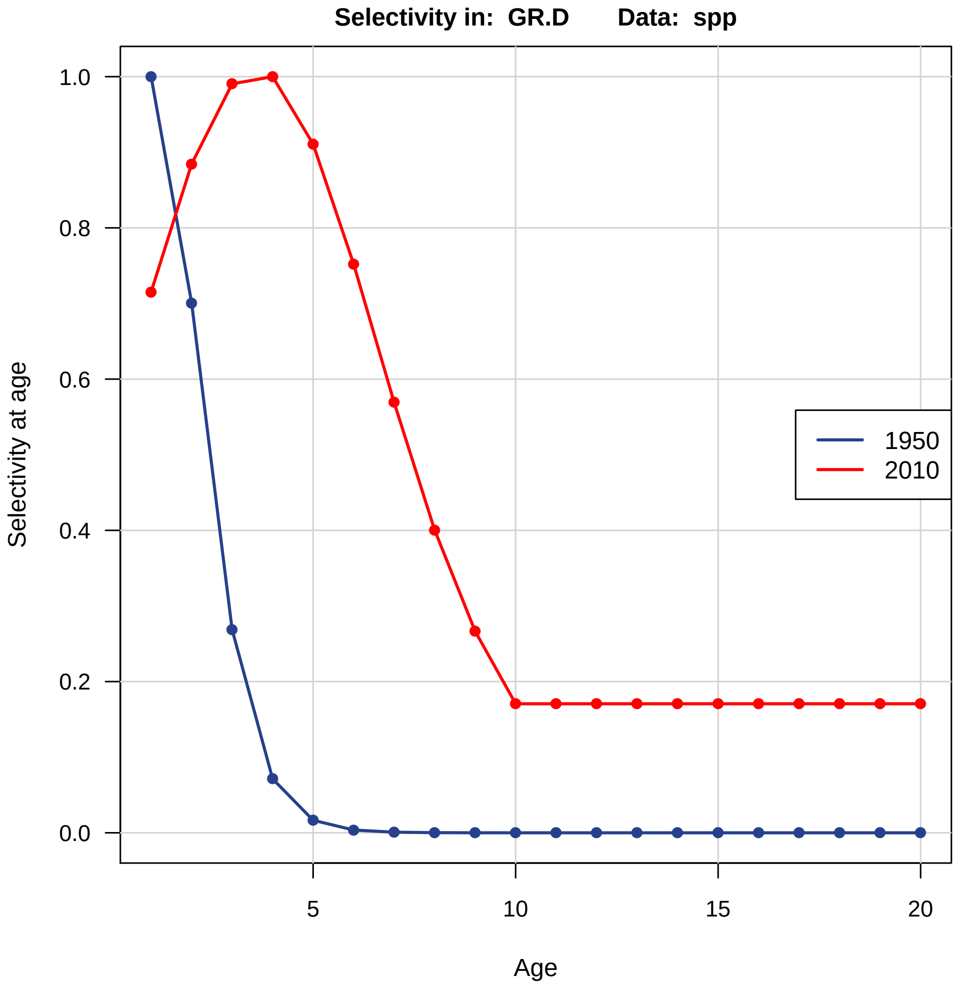

Figure 26. Average selectivity of discards(top left), landings (top right), and total weighted average (bottom) from the terminal assessment years, weighted by geometric mean F's from the last three assessment years, and used in computation of benchmarks and projections.

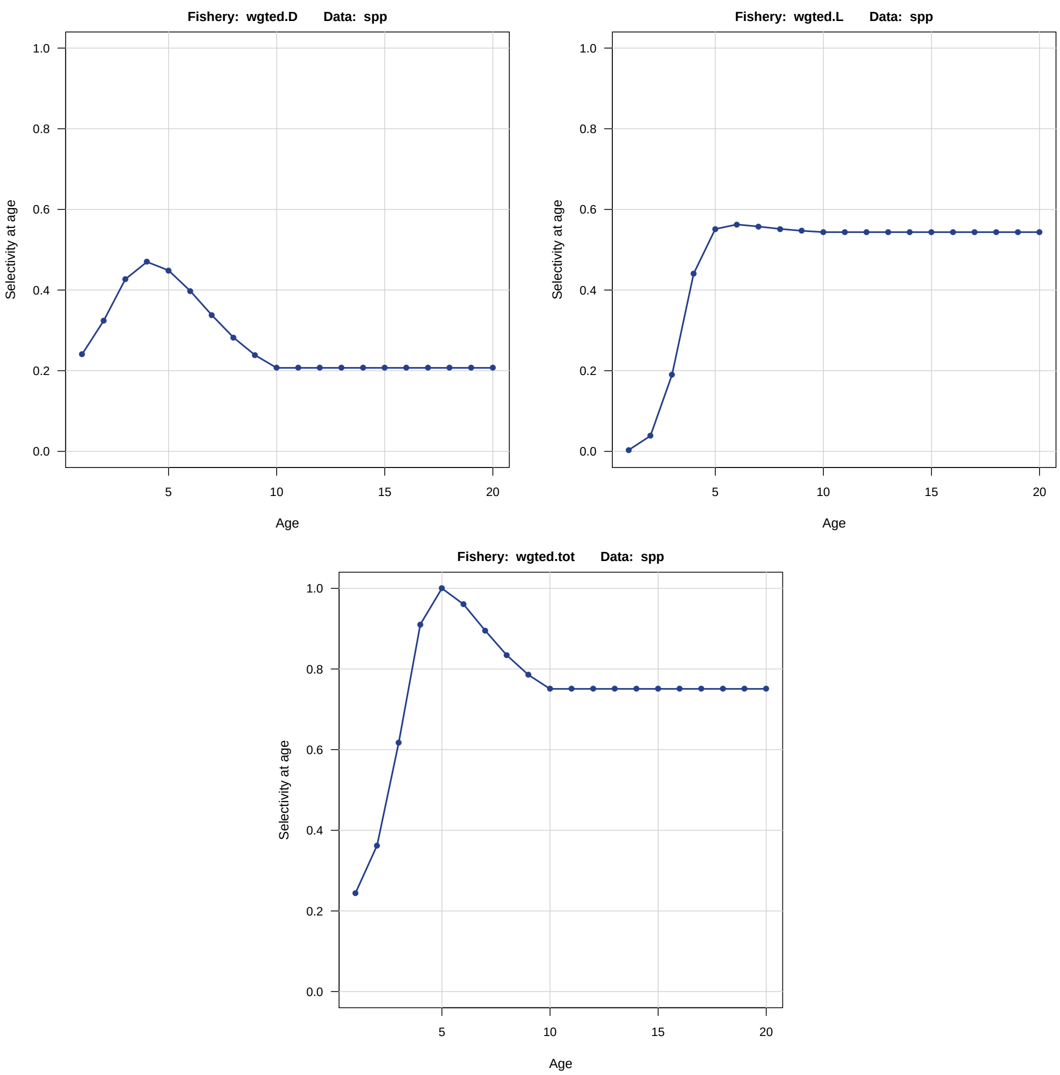

Figure 27. Estimated fully selected fishing mortality rate (per year) by fleet. cH refers to commercial handlines, HB to headboat, GR to general recreational, and D refers to discard mortality.

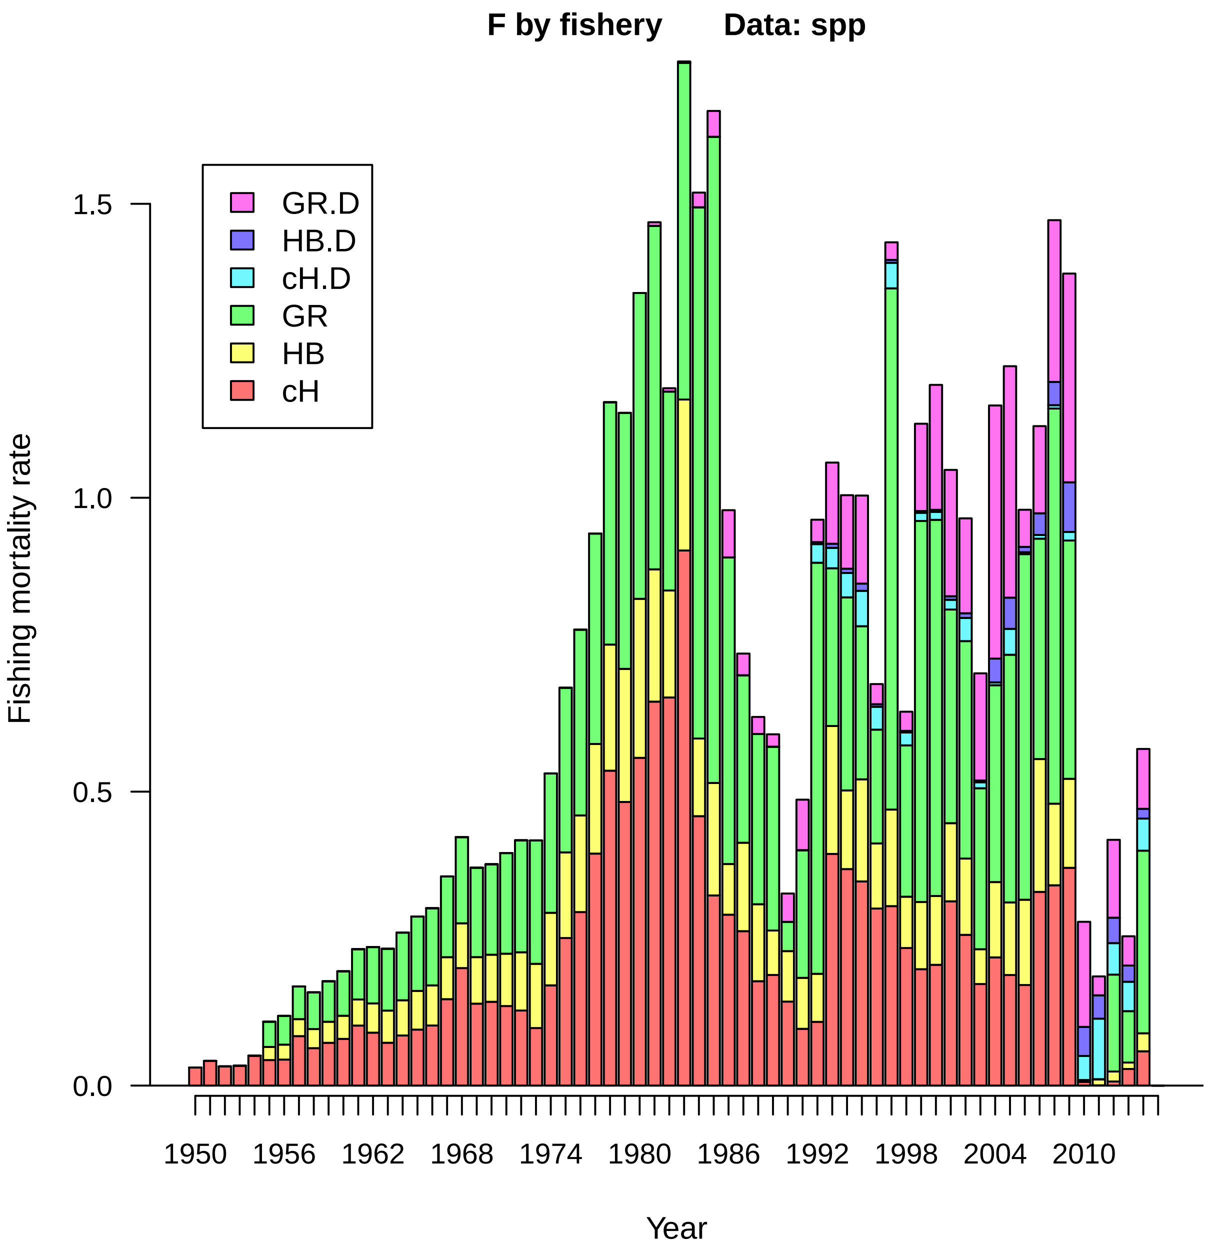

Figure 28. Estimated landings in numbers by fleet from the catch-age model. cH refers to commercial handlines, HB to headboat, and GR to general recreational. Horizontal dashed line in the top panel corresponds to the point estimate of $L_{\mathrm{F30\%}}$ in numbers.

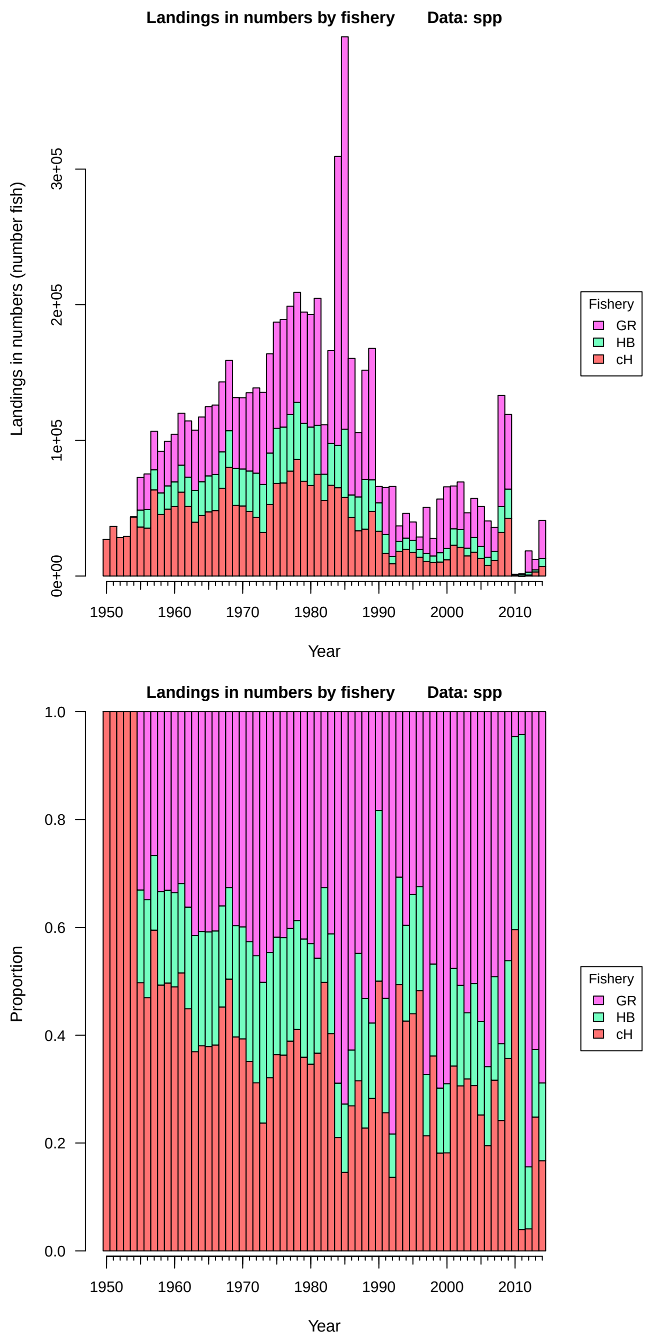

Figure 29. Estimated landings in whole weight by fleet from the catch-age model. cH refers to commercial handlines, HB to headboat, and GR to general recreational. Horizontal dashed line in the top panel corresponds to the point estimate of $L_{F30\%}$ in weight.

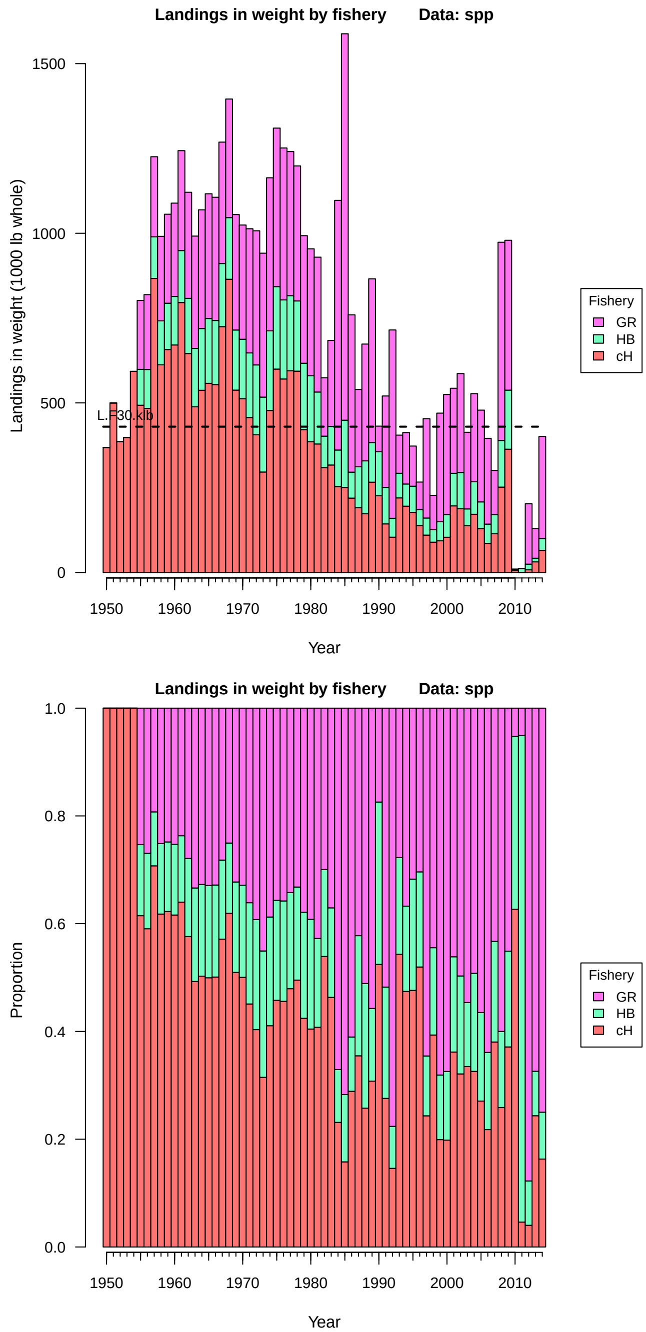

Figure 30. Estimated discard mortalities by fleet from the catch-age model. cH refers to commercial lines, hb to headboat, rec to general recreational. Horizontal dashed line in the top panel corresponds to the point estimate of $D_{F_{30\%}}$ in numbers.

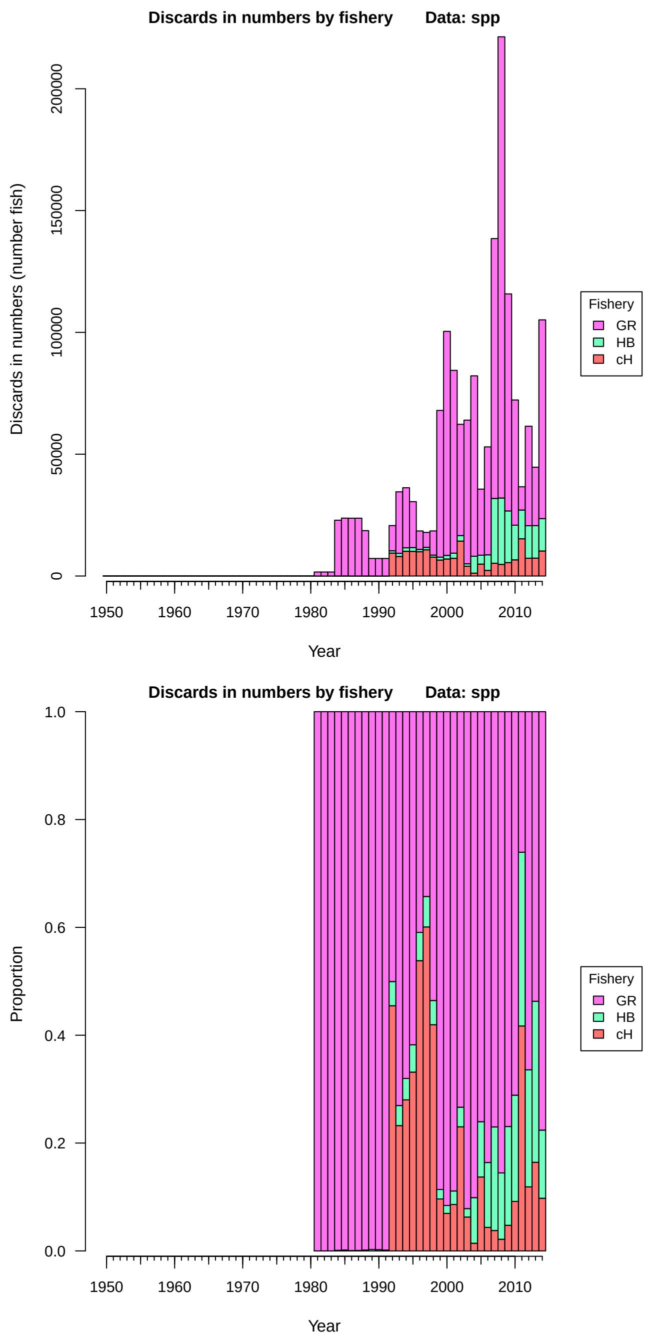

Figure 31. Top panel: Beverton–Holt spawner-recruit curves, with and without lognormal bias correction. The expected (upper) curve was used for computing management benchmarks. Bottom panel: log of recruits (number age-1 fish) per spawner as a function of spawners.

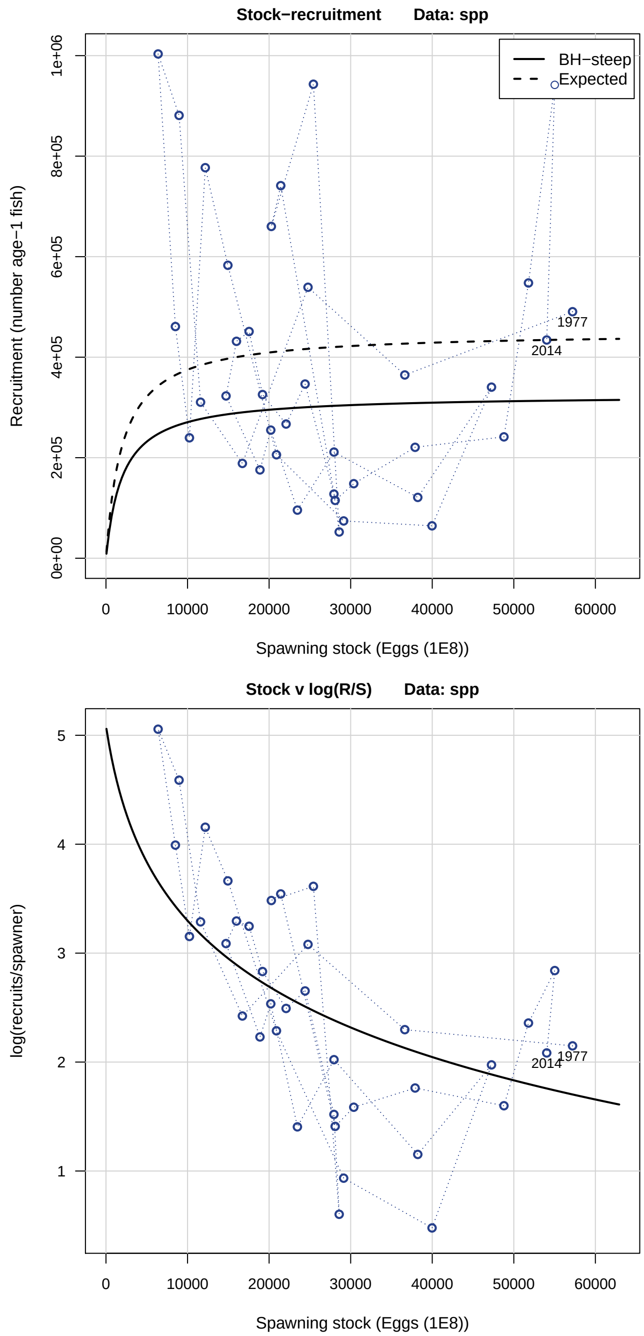

Figure 32. Probability densities of spawner-recruit quantities R0 (unfished recruitment of age-1 fish), steepness (fixed at 0.99), unfished spawners per recruit, and standard deviation of recruitment residuals in log space. Solid vertical lines represent point estimates or values from the base run of the Beaufort Assessment Model; dashed vertical lines represent medians from the MCB runs.

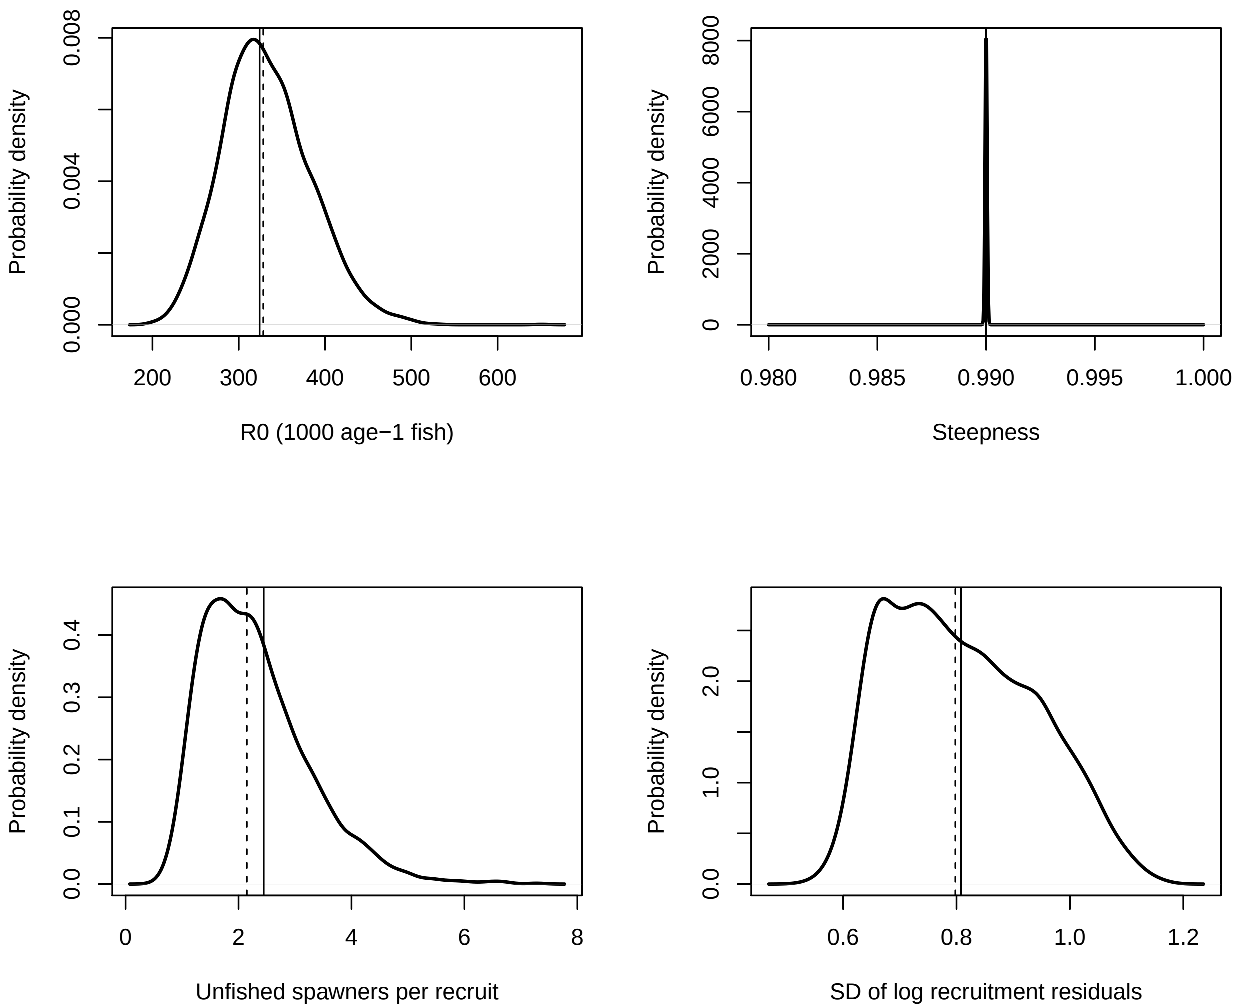

Figure 33. Yield per recruit based on average selectivity from the end of the assessment period.

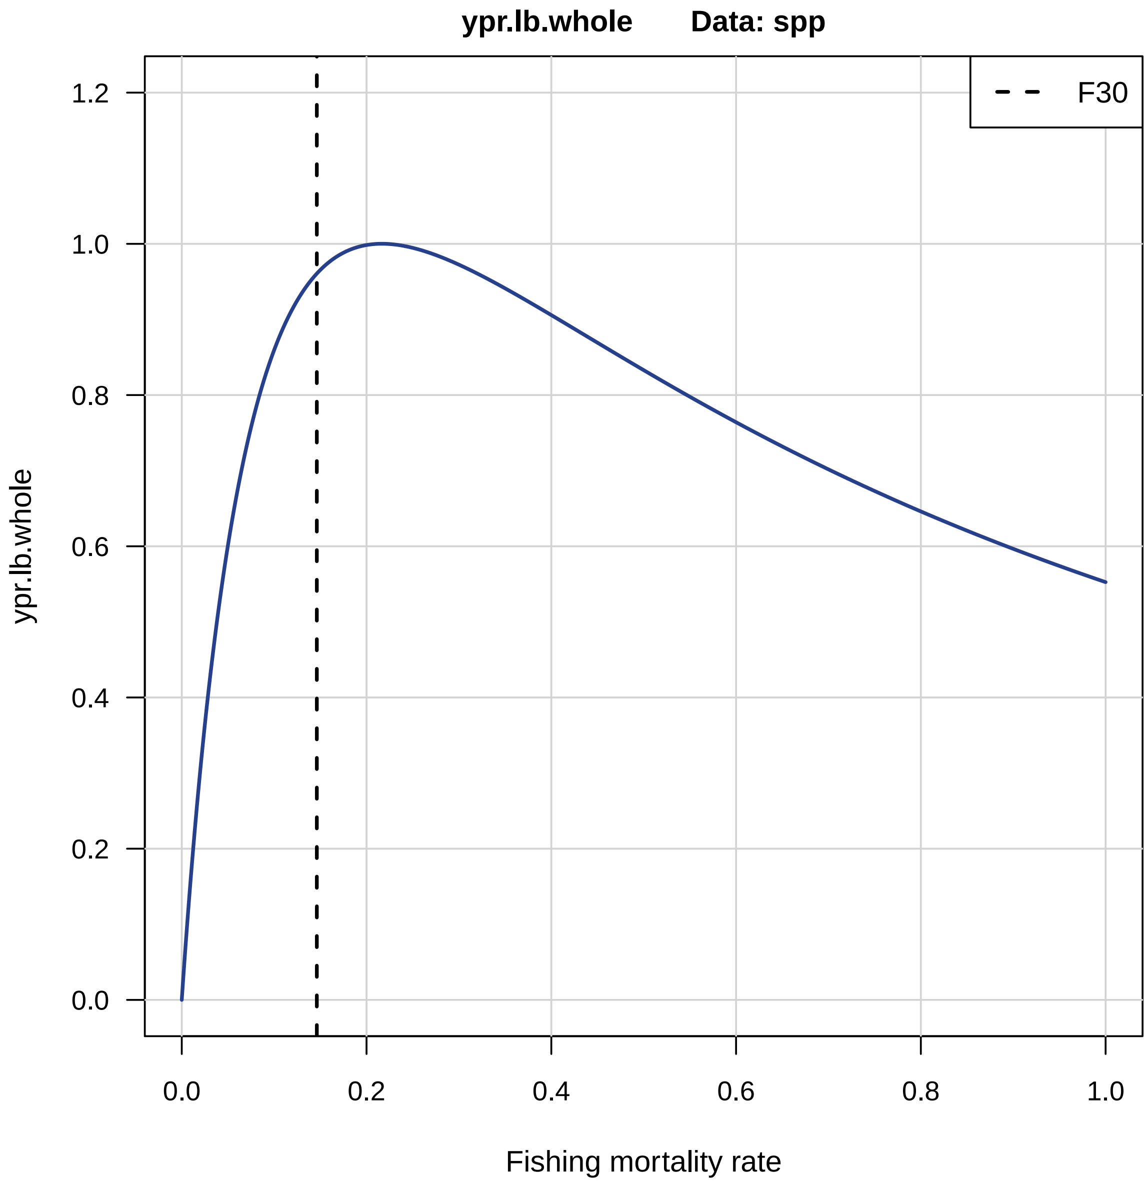

Figure 34. Spawning potential ratio (spawning biomass per recruit relative to that at the unfished level), from which the X% level of SPR provides $F_{X\%}$. SPR is based on average selectivity from the end of the assessment period.

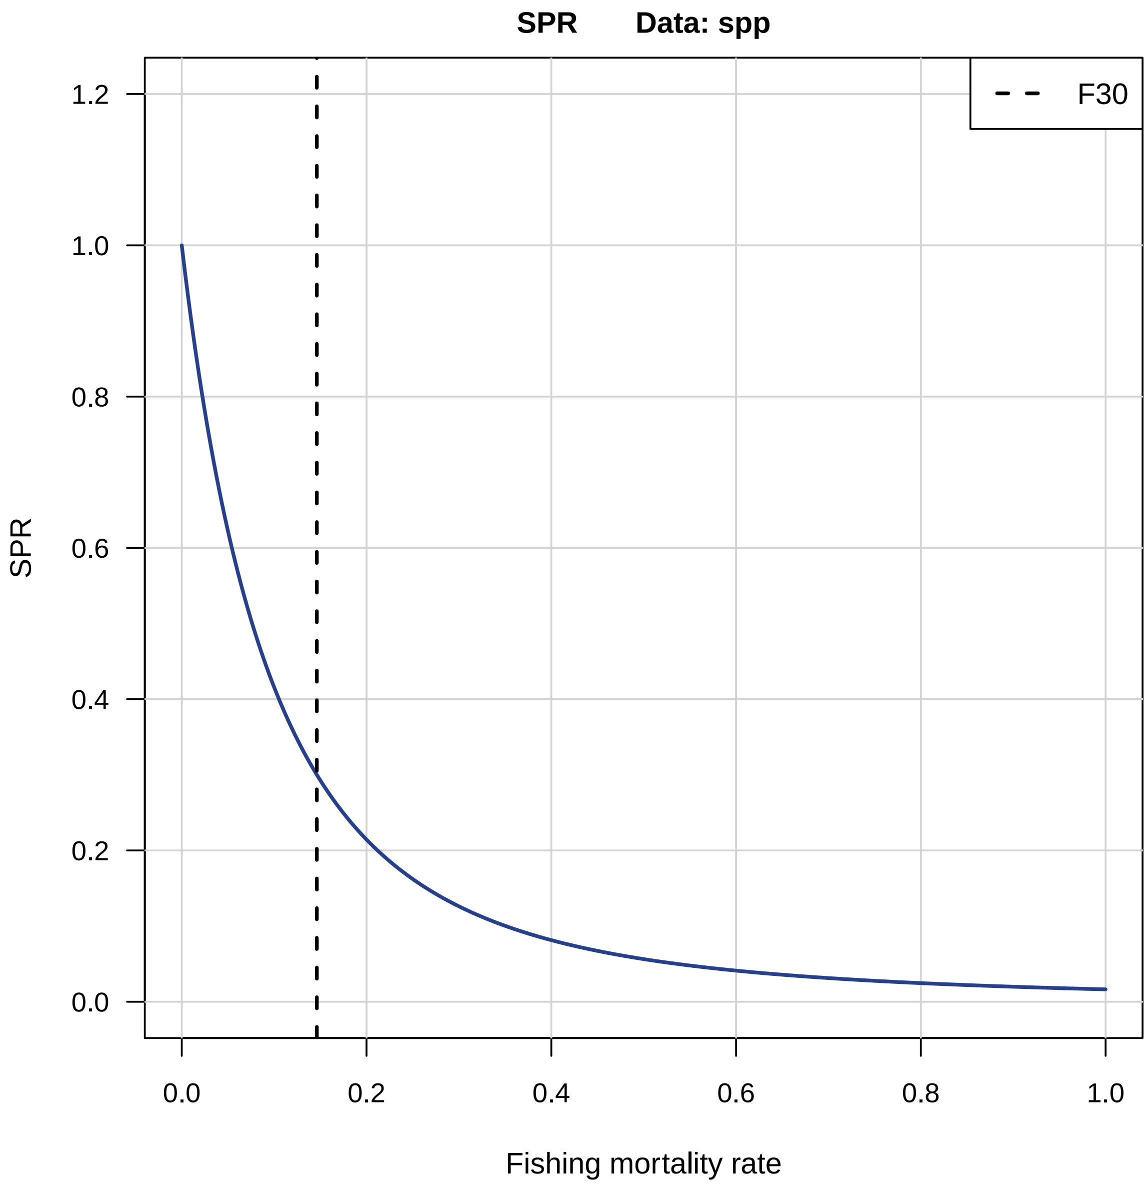

Figure 35. Equilibrium spawning biomass based on average selectivity from the end of the assessment period.

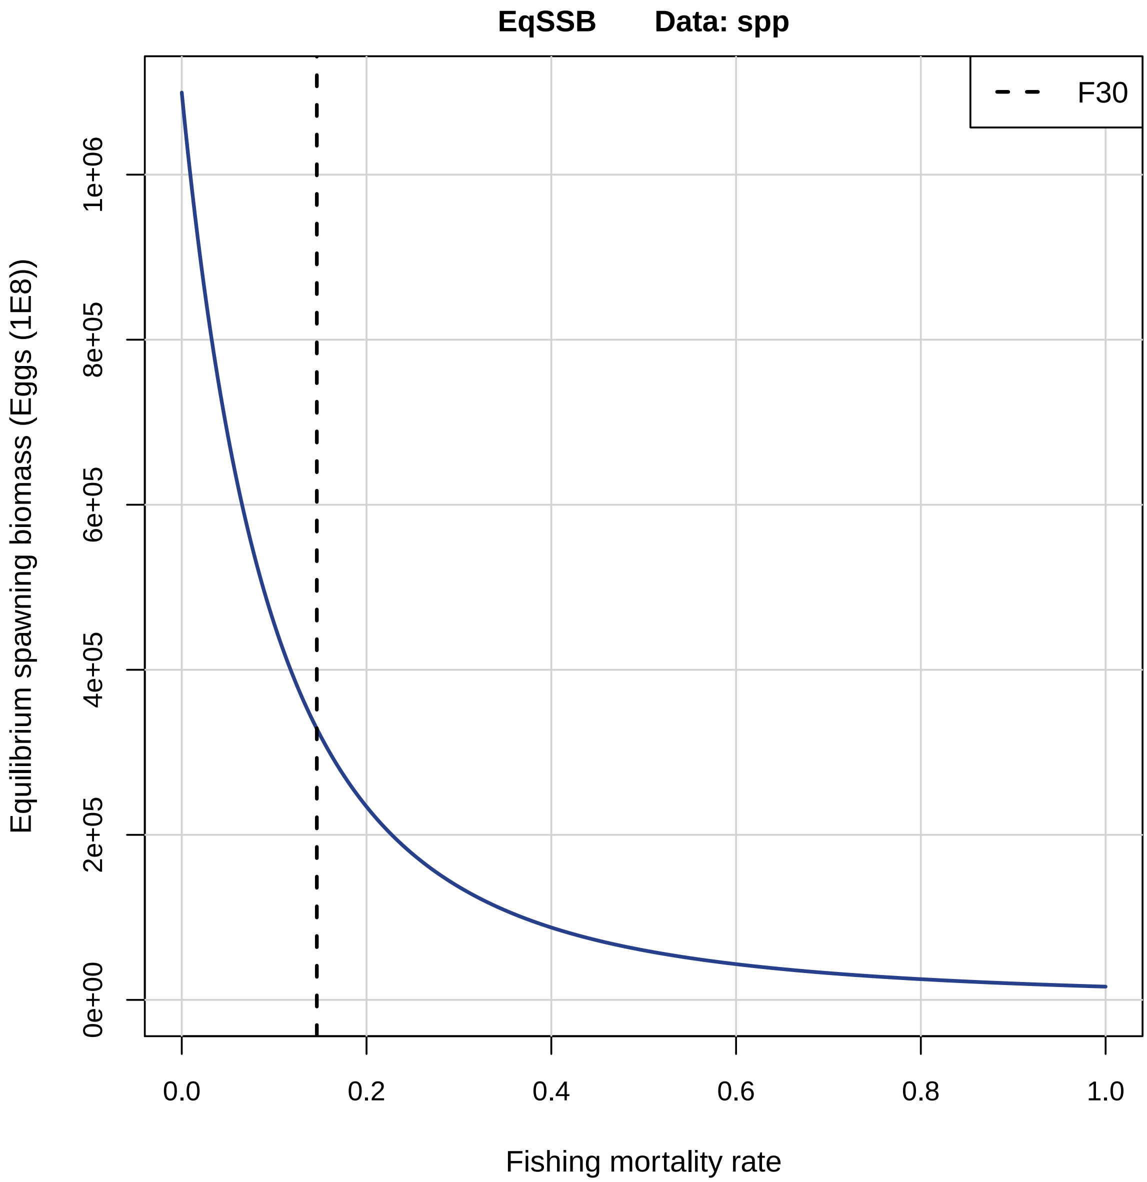

Figure 36. Probability densities of $F_{30\%}$-related benchmarks from MCB analysis of the Beaufort Assessment Model. Solid vertical lines represent point estimates from the base run; dashed vertical lines represent median values.

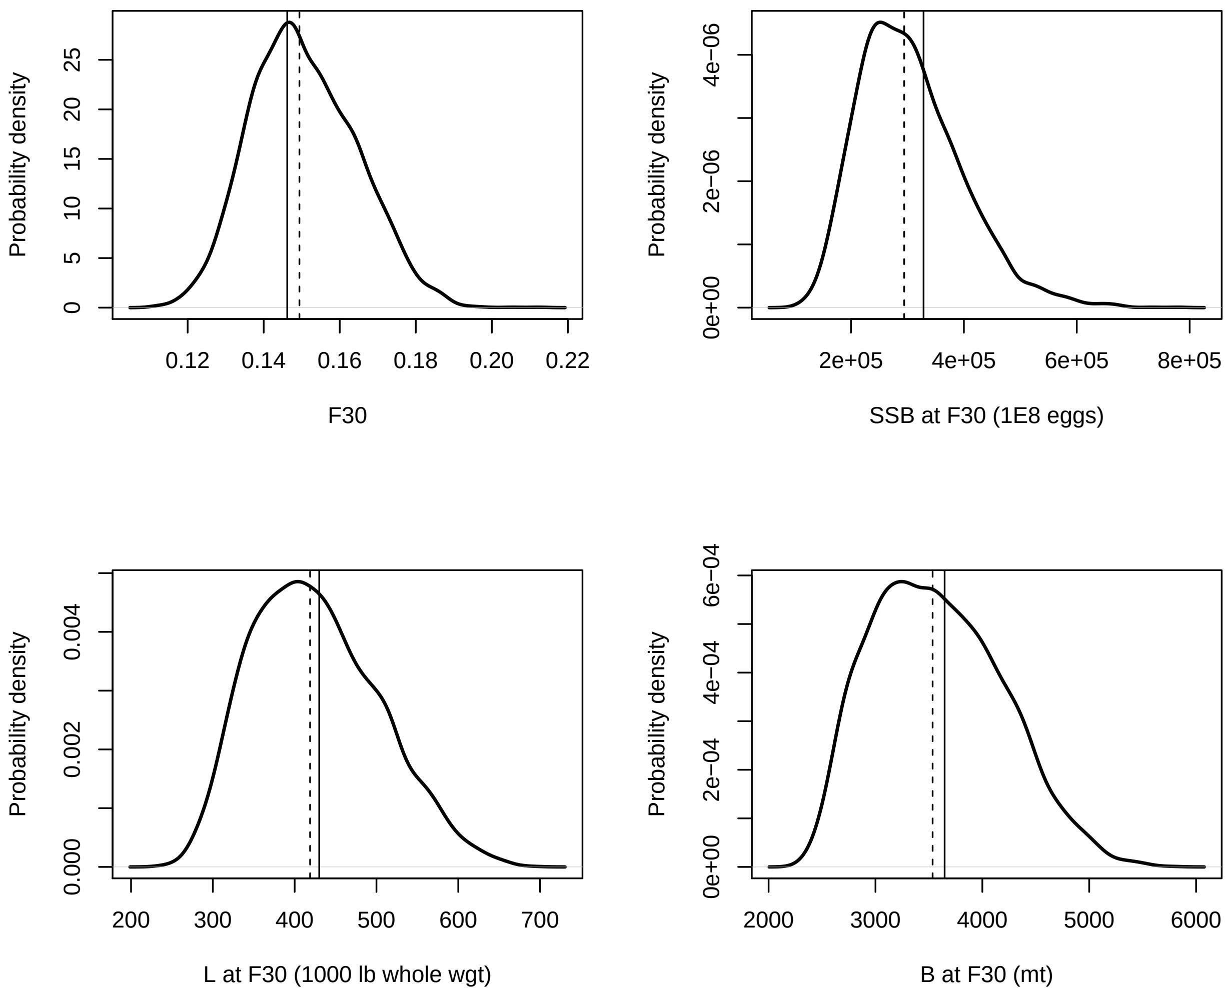

Figure 37. Estimated time series relative to benchmarks. Solid line indicates estimates from base run of the Beaufort Assessment Model; dashed lines represent median values; gray error bands indicate 5^{th} *and* 95^{th} *percentiles of the MCB trials. Top panel: spawning biomass relative to* $\mathrm{SSB}_{\mathrm{F30\%}}$*. Bottom panel: F relative to* $F_{30\%}$*.*

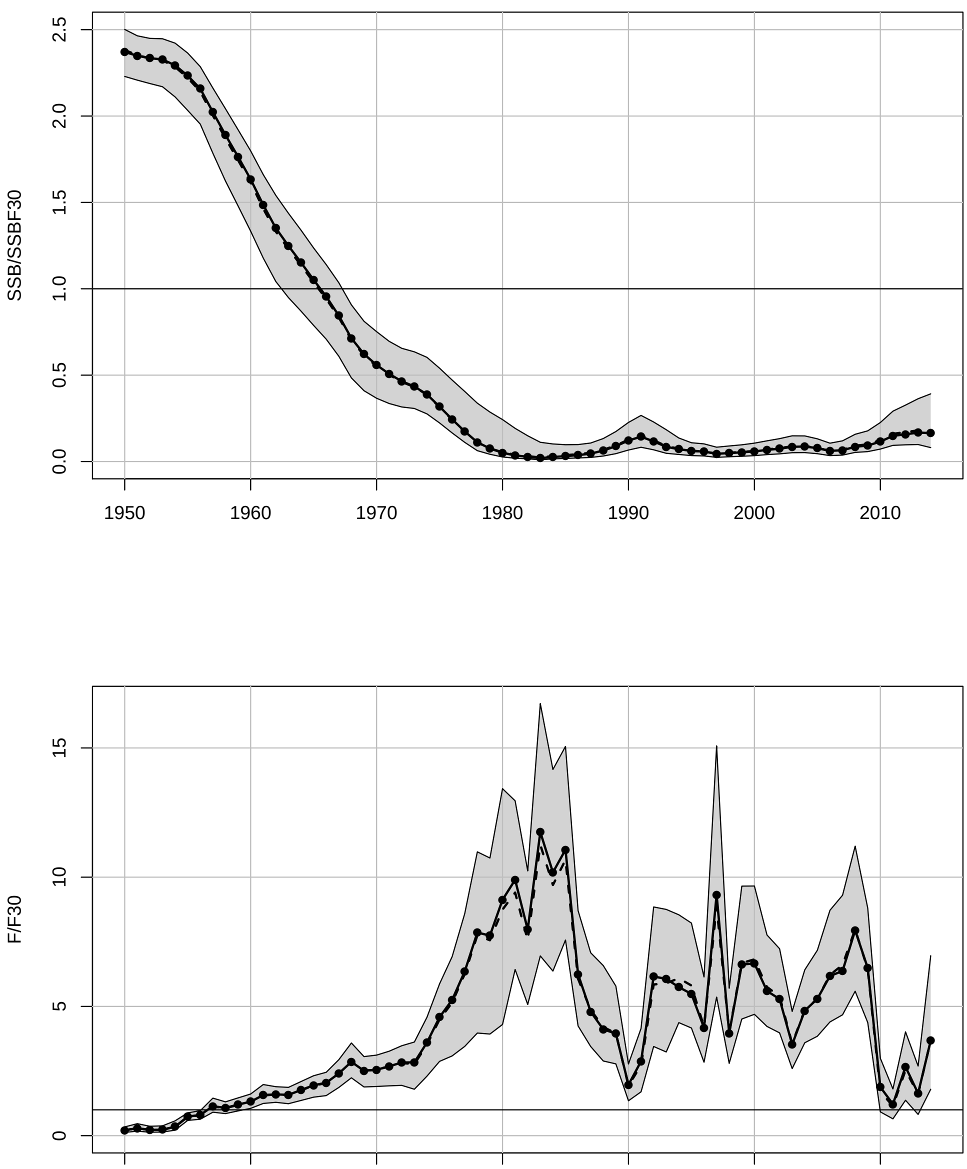

Figure 38. Probability densities of terminal status estimates from MCB analysis of the Beaufort Assessment Model. Solid vertical lines represent point estimates from the base run; dashed vertical lines represent median values.

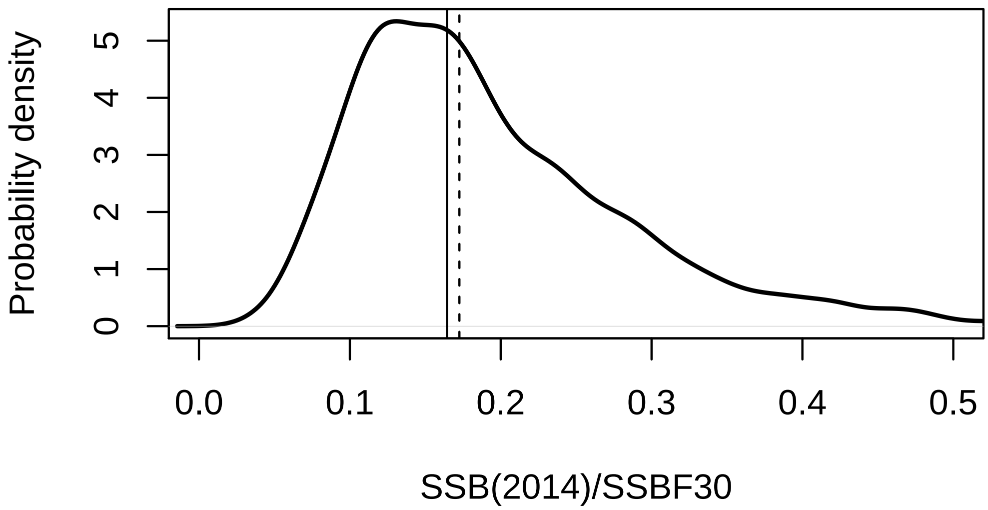

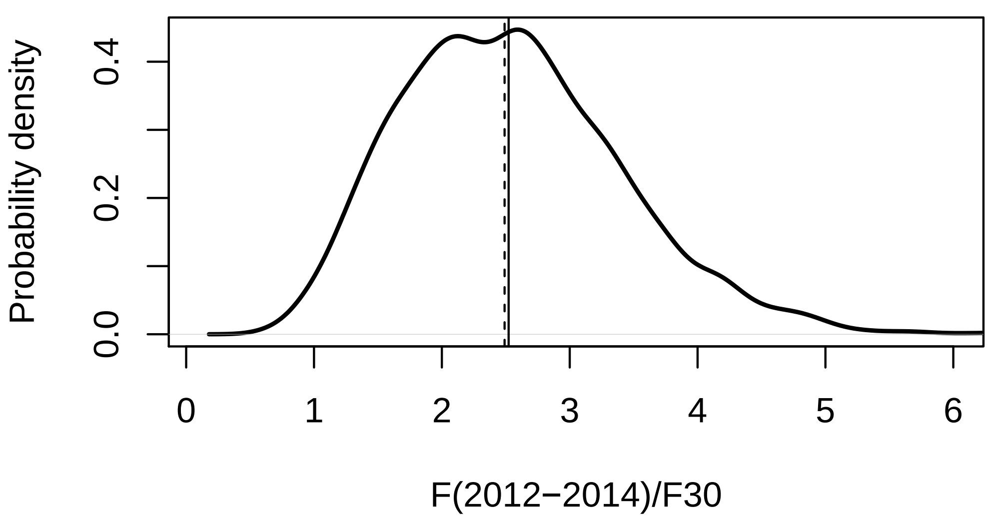

Figure 39. Phase plots of terminal status estimates from MCB analysis of the Beaufort Assessment Model. The intersection of crosshairs indicates estimates from the base run; lengths of crosshairs defined by 5^{th} and 95^{th} percentiles. Proportion of runs falling in each quadrant indicated.

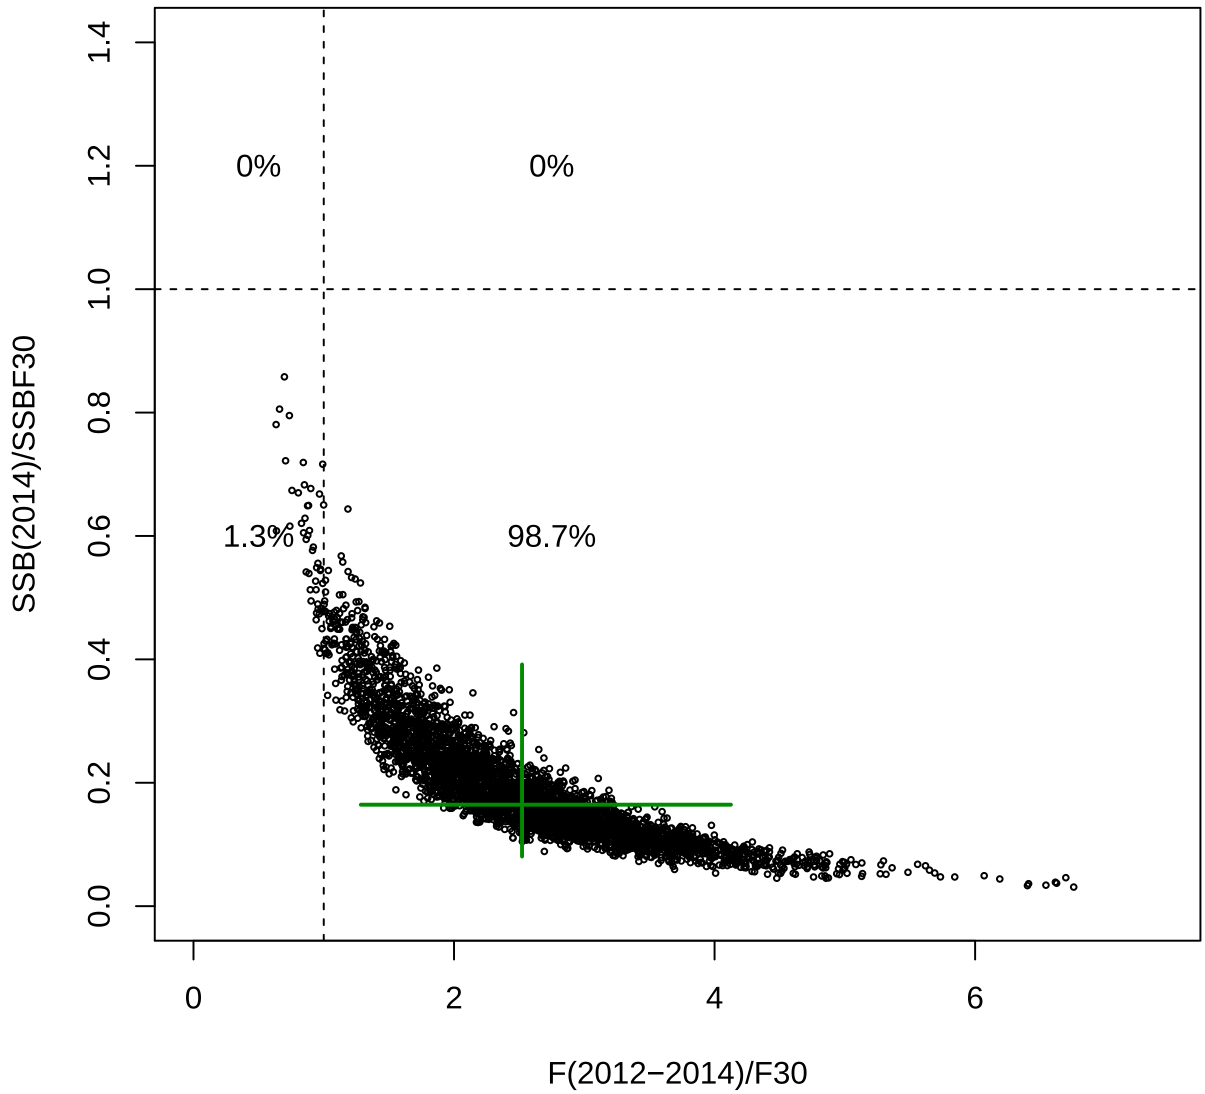

Figure 40. Age structure relative to the equilibrium expected at $F_{30\%}$.

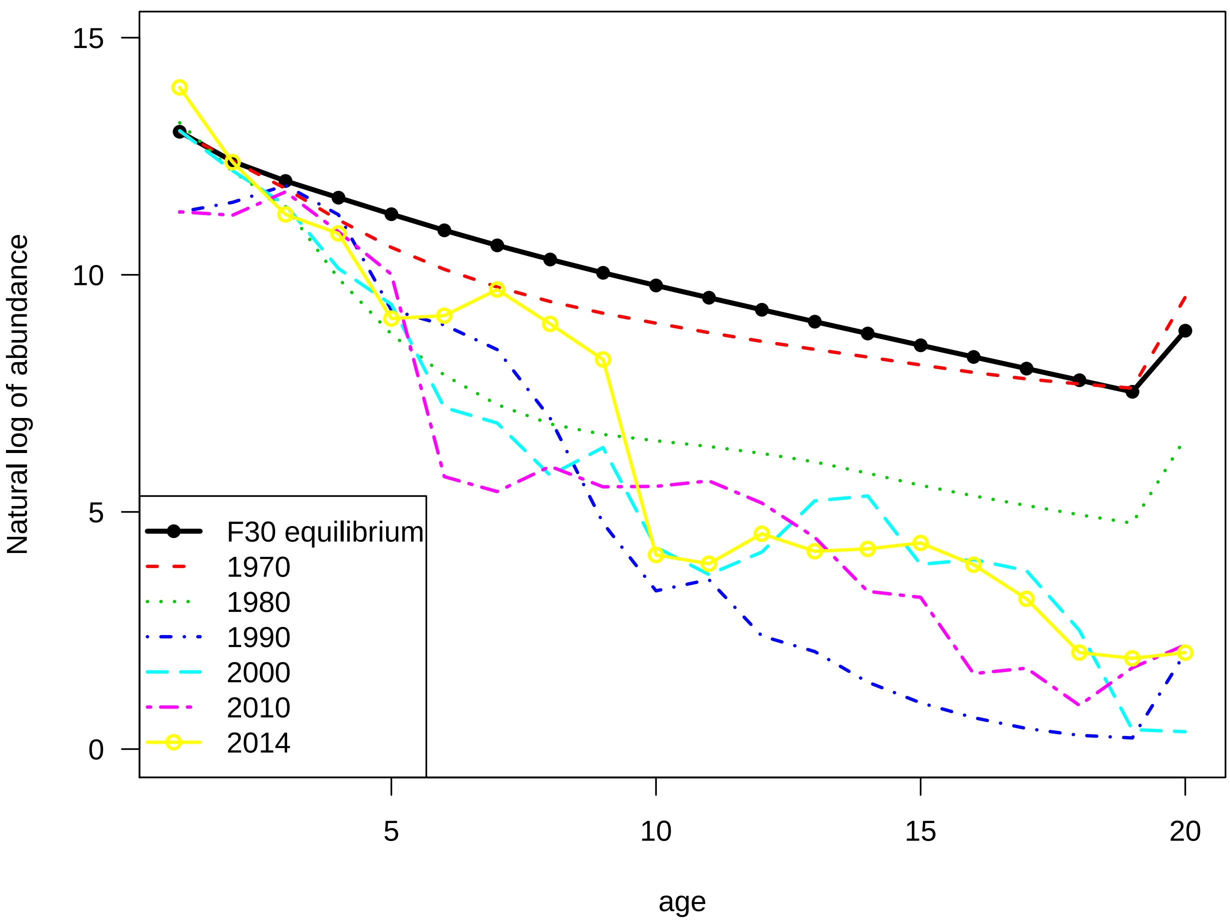

Figure 41. Sensitivity to changes in natural mortality (sensitivity runs S5 and S6). Top panel: Ratio of F to $F_{30\%}$. *Bottom panel: Ratio of* SSB *to* $SSB_{F30\%}$.

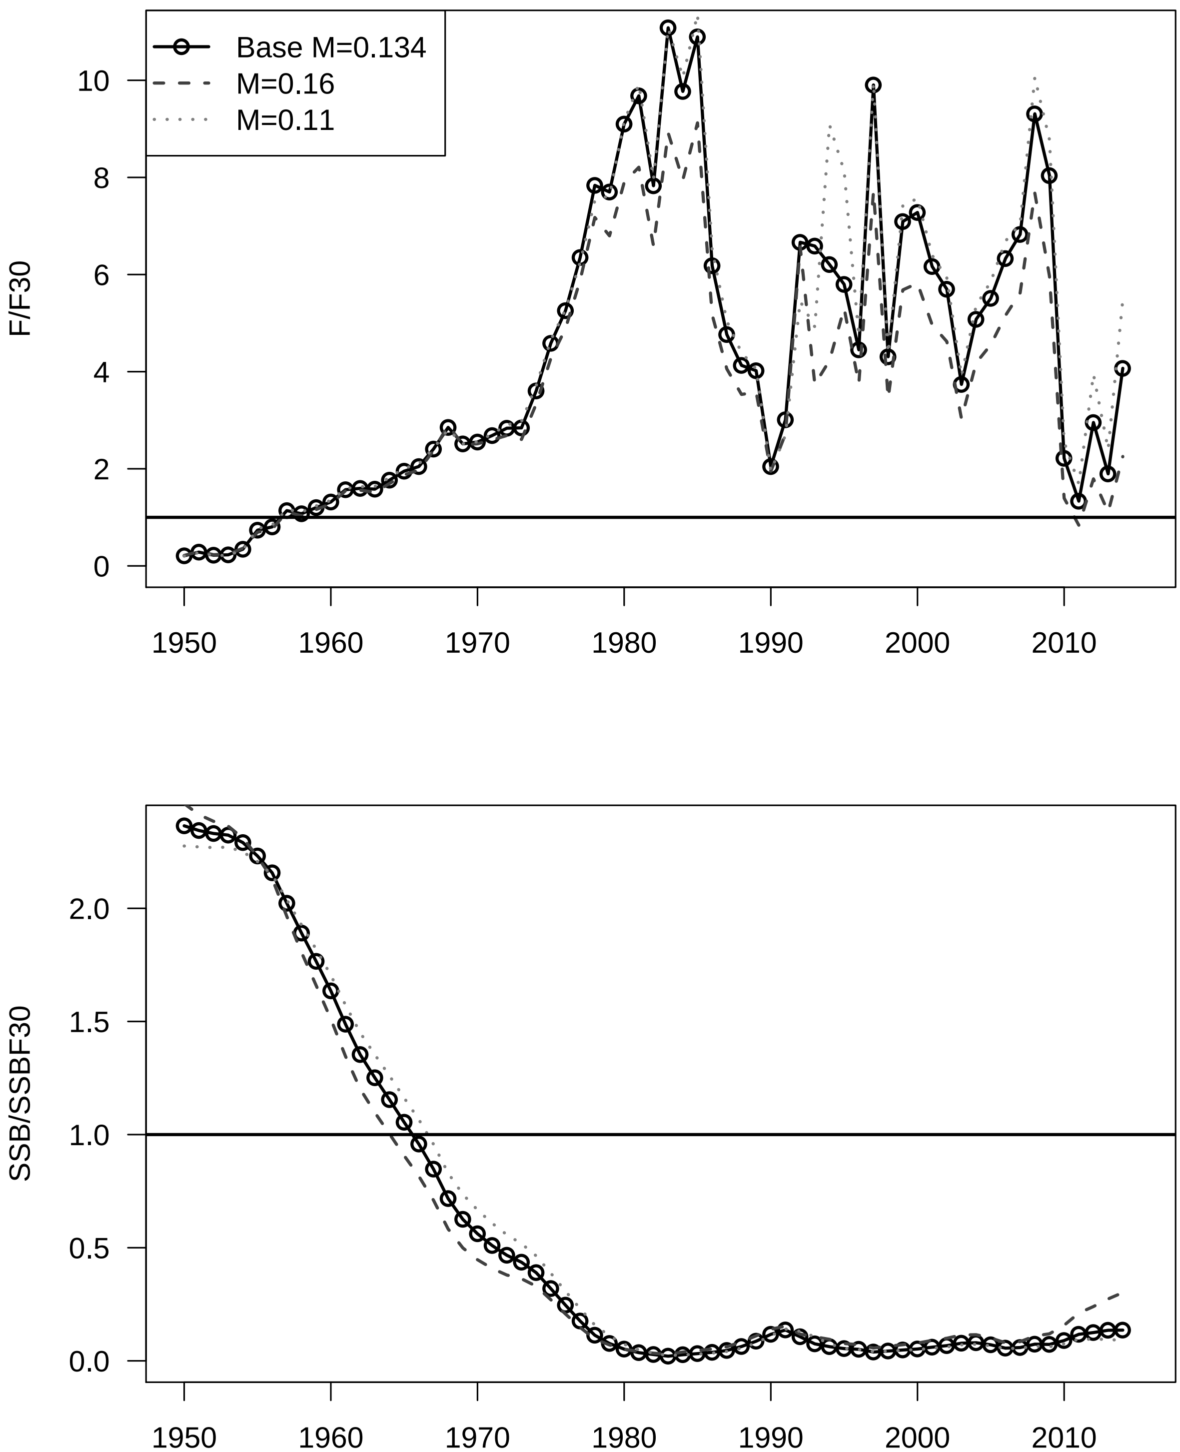

Figure 42. Sensitivity to steepness (sensitivity run S11). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $SSB_{F30\%}$.

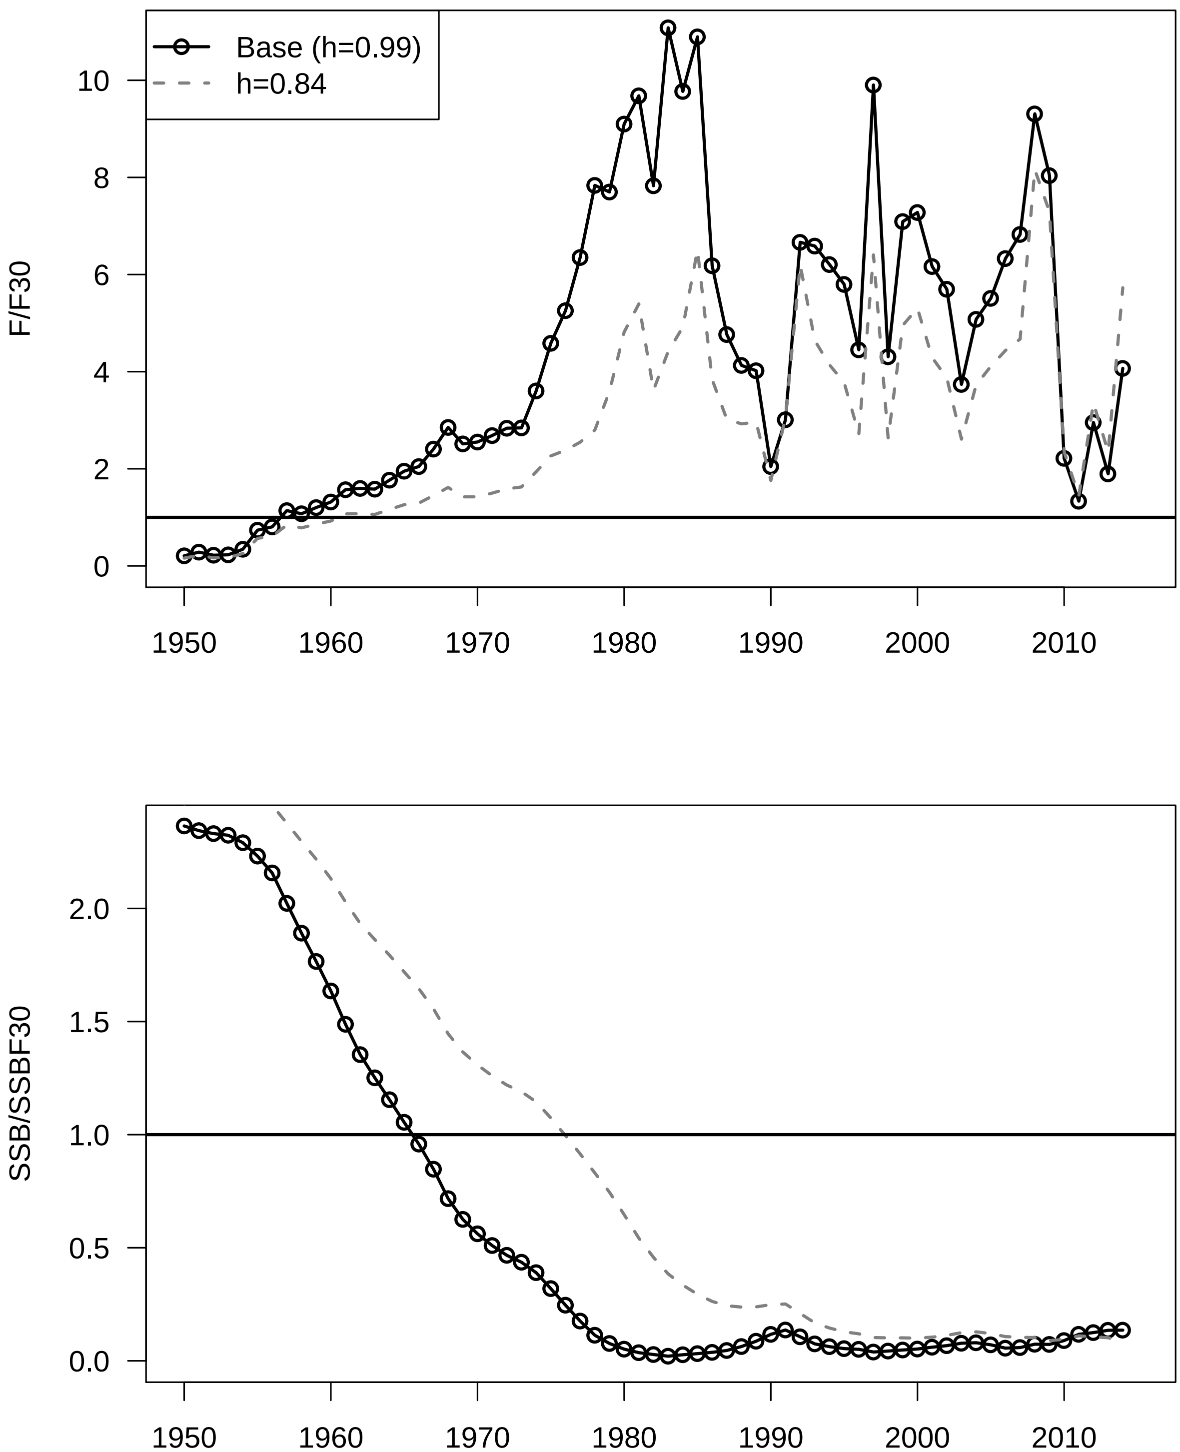

Figure 43. Sensitivity to start year (1978 compared to 1950) (sensitivity run S26). Top panel: Ratio of F to $F_{30\%}$. *Bottom panel: Ratio of* SSB *to* $\mathrm{SSB}_{F30\%}$.

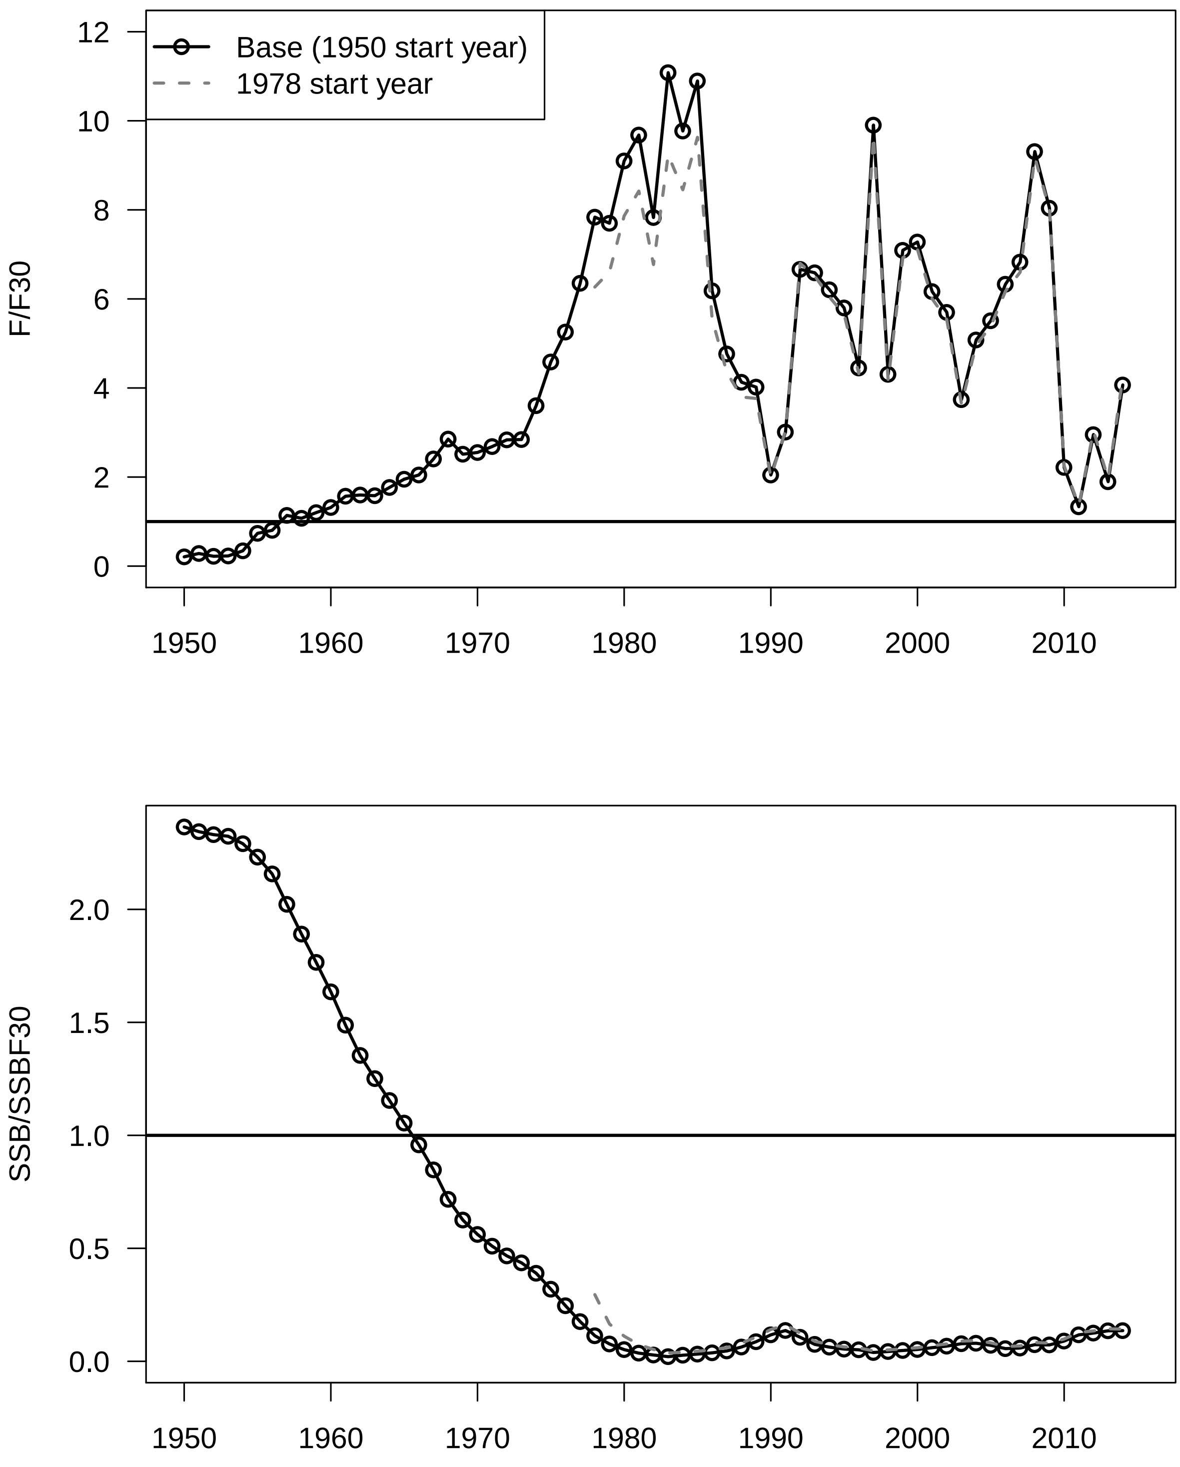

Figure 44. Sensitivity to aging error matrix (sensitivity run S13). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

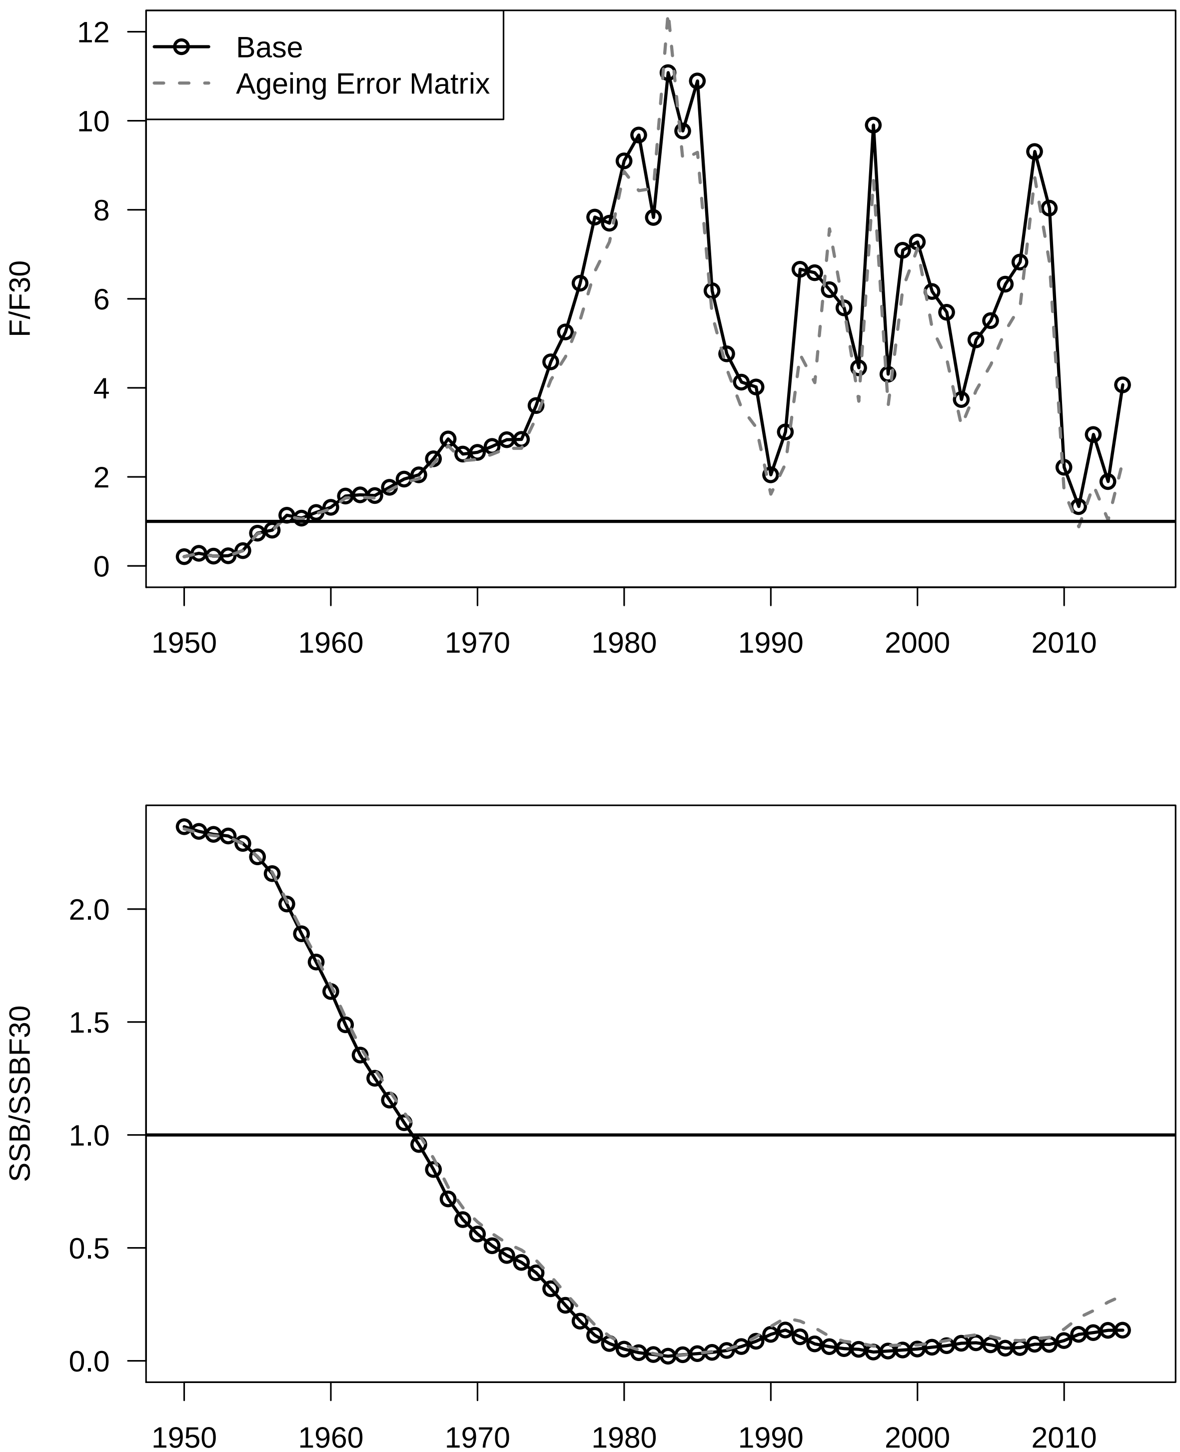

Figure 45. Sensitivity to batch number (sensitivity runs S14 and S15). Top panel: Ratio of F to $F_{30\%}$*. Bottom panel: Ratio of* SSB *to* $SSB_{F30\%}$.

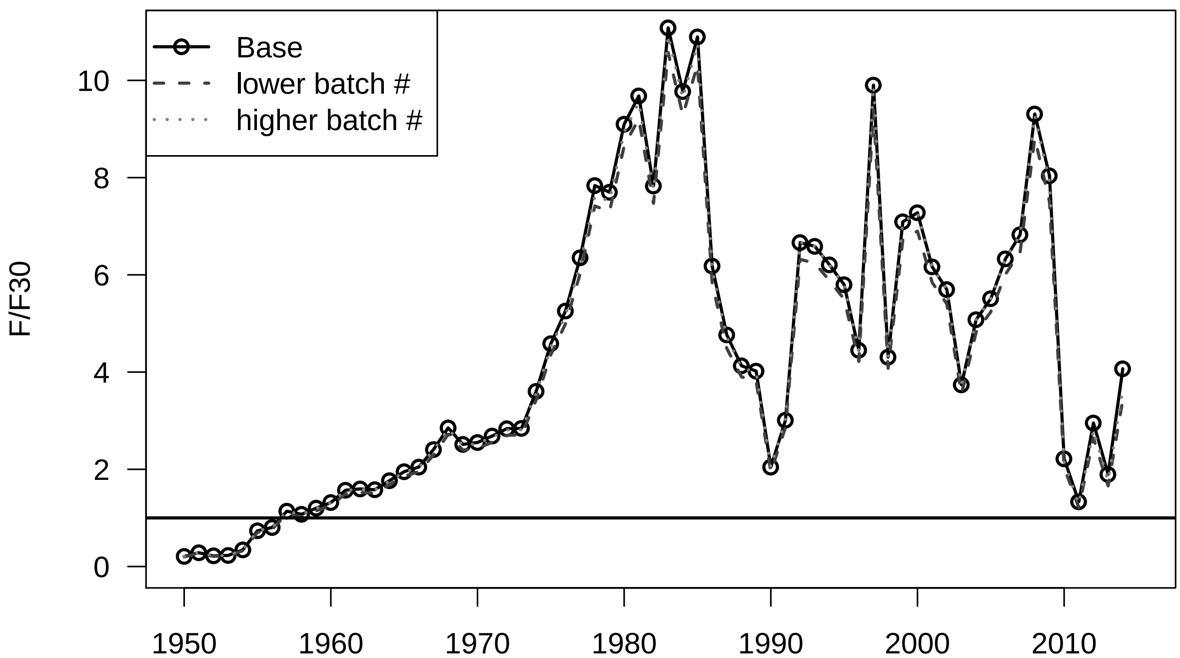

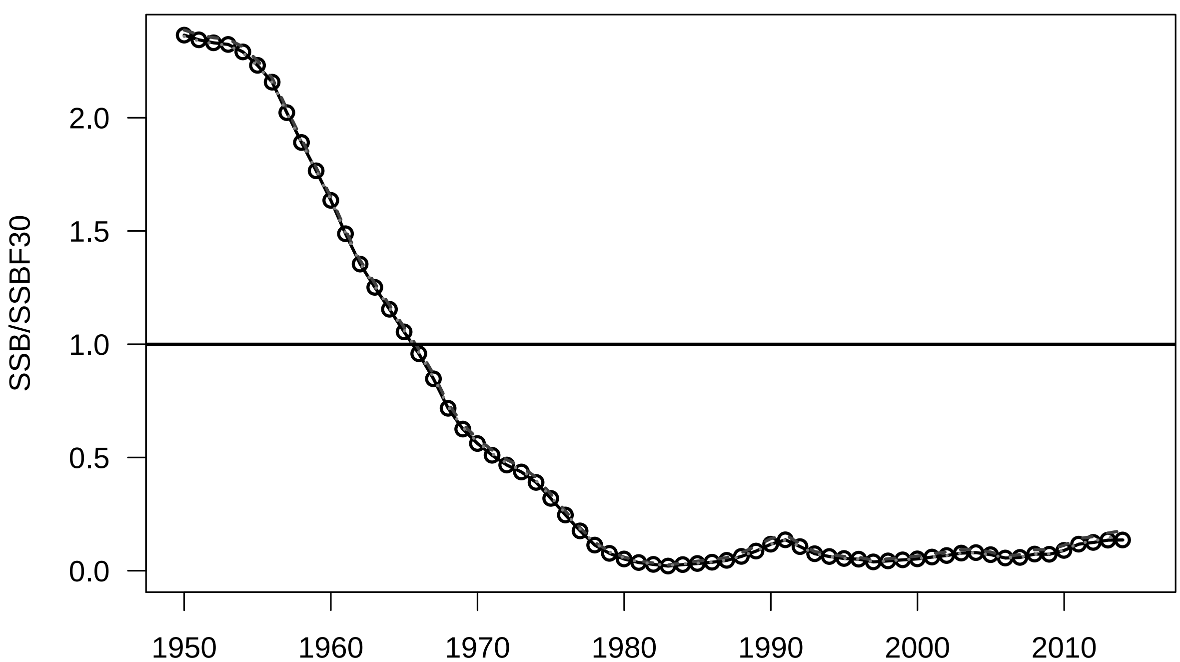

Figure 46. Sensitivity to various changes to SERFS video and trap indices (sensitivity runs S2, S9, S22 and S23). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

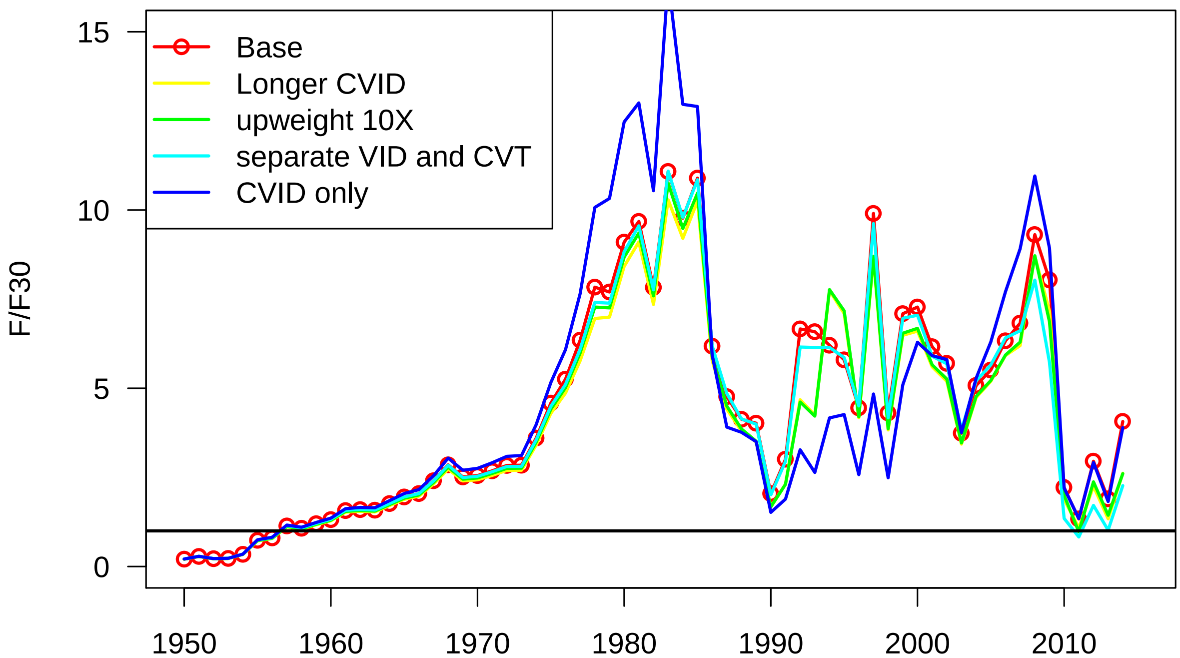

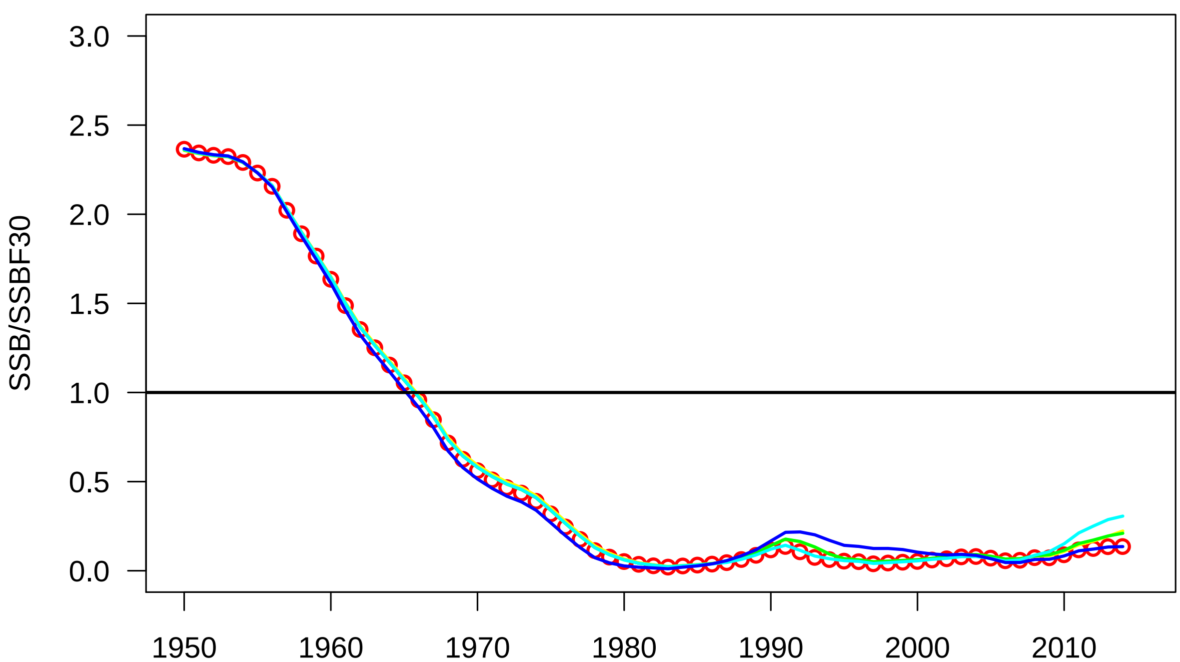

Figure 47. Sensitivity to discard mortality (sensitivity run S7 and S8). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $SSB_{F30\%}$.

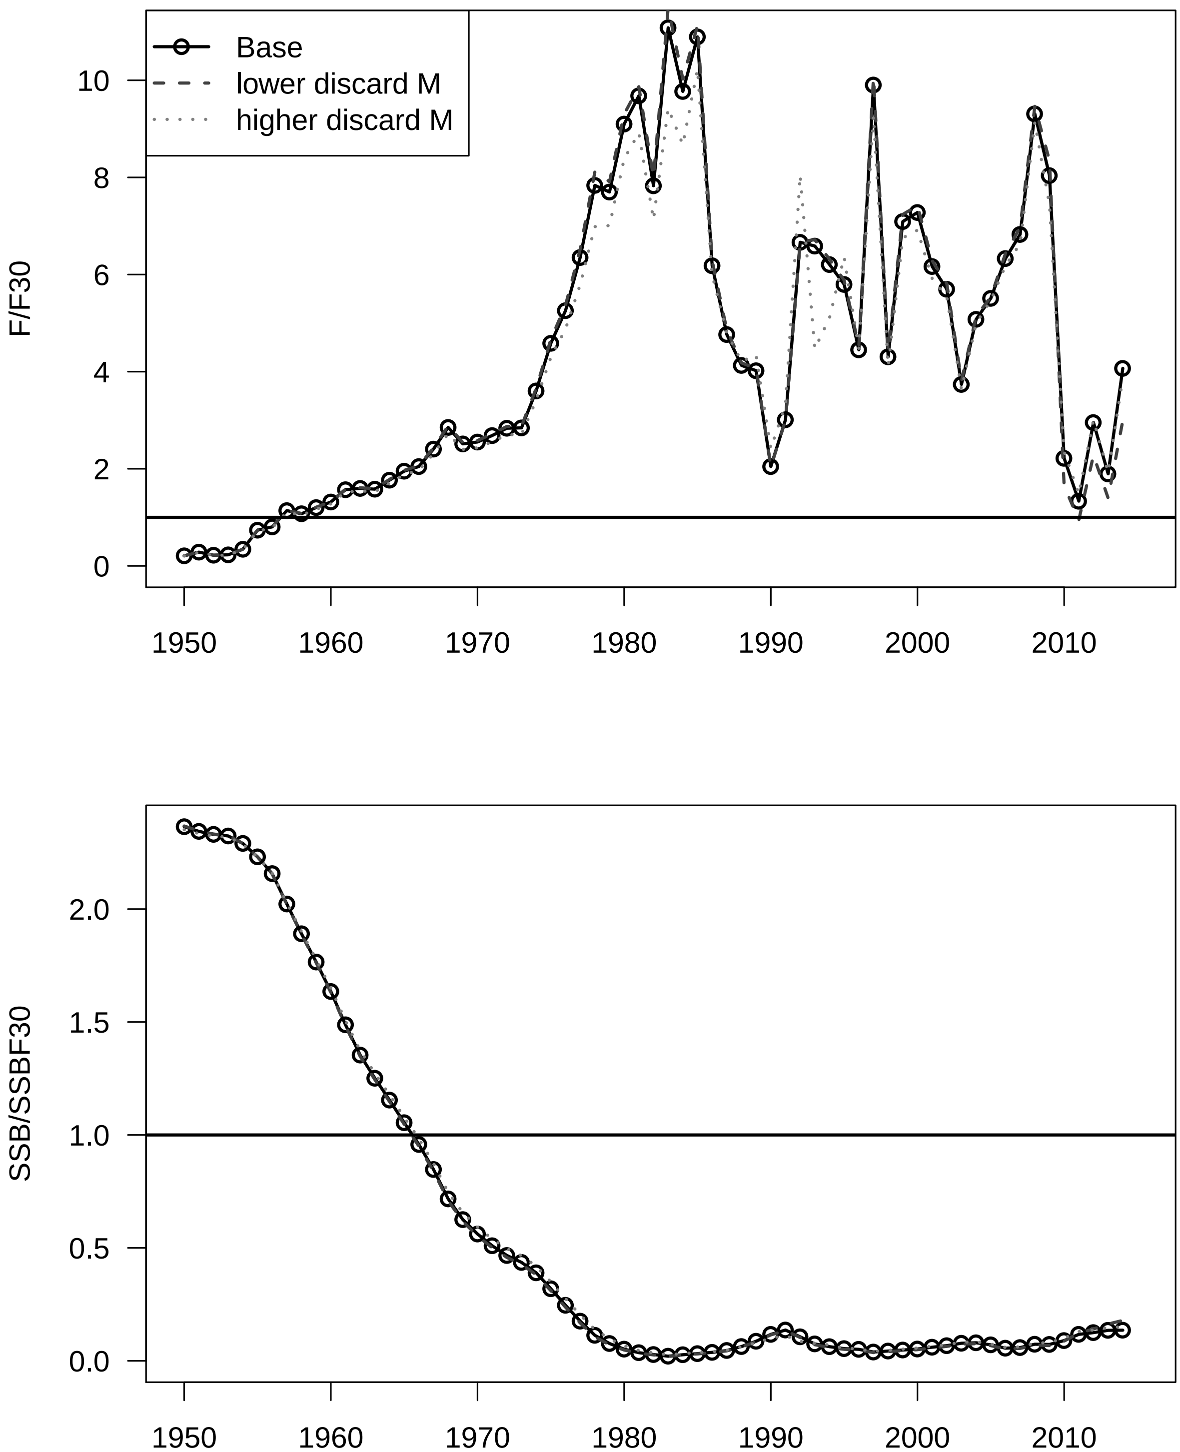

Figure 48. Sensitivity to dome-shaped selectivity for commercial handline (sensitivity run S21). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

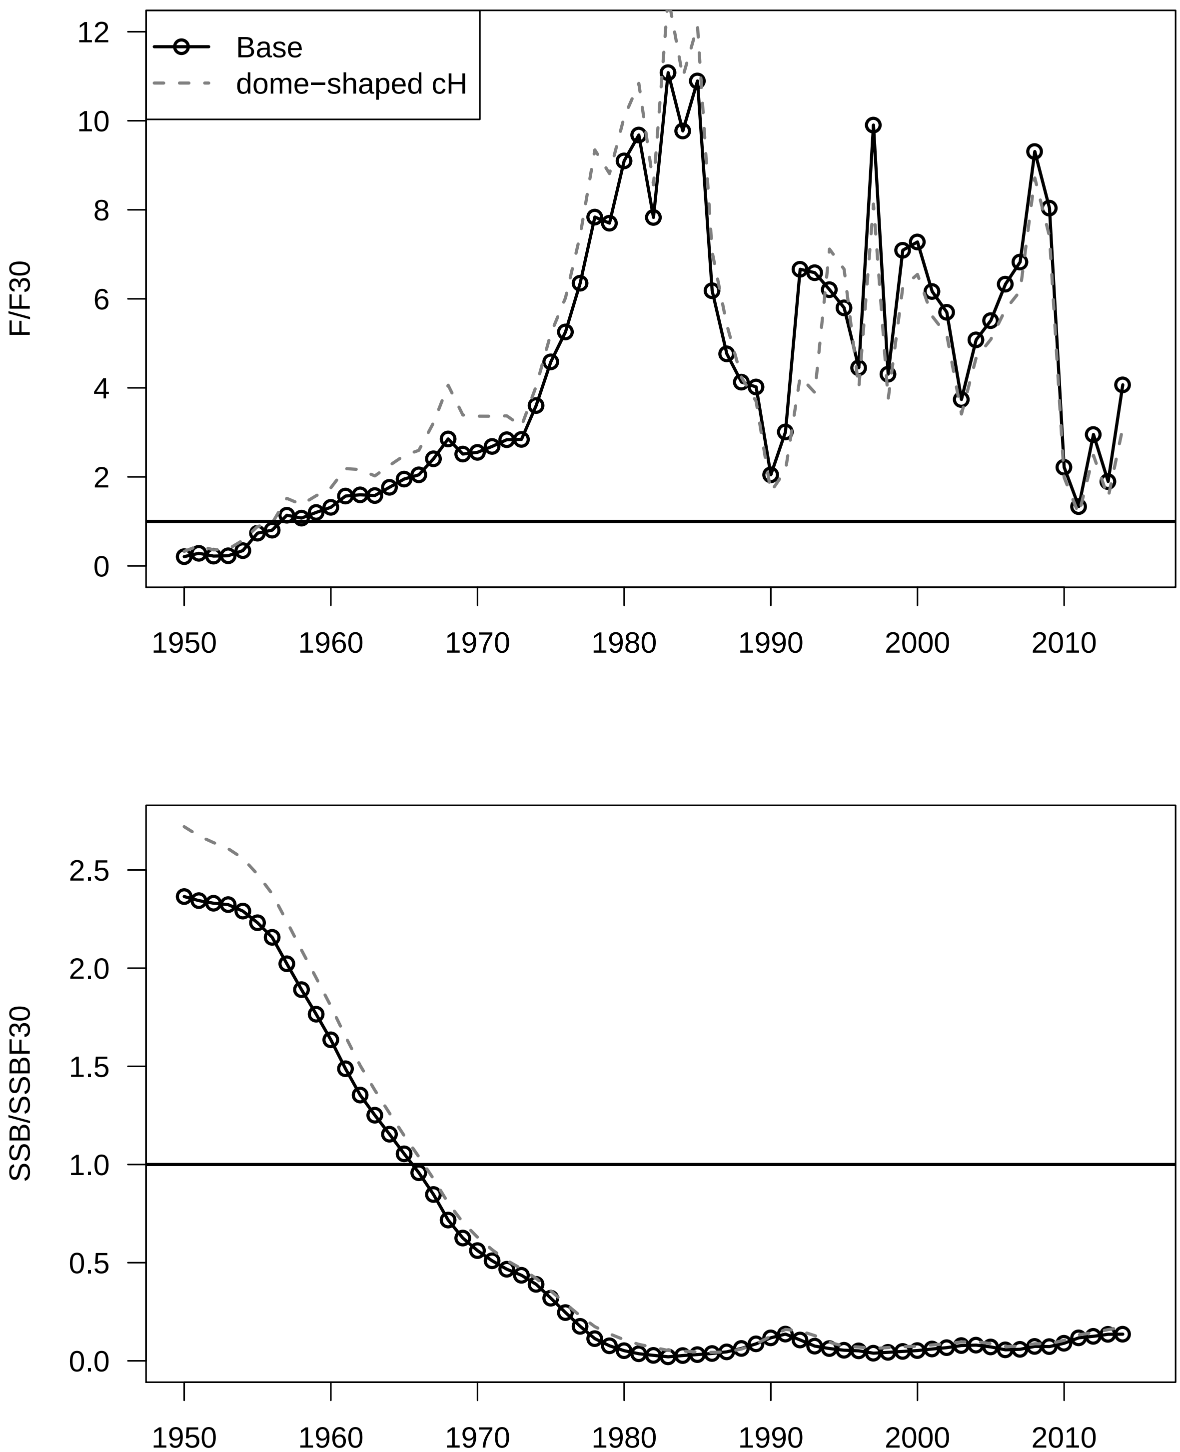

Figure 49. Sensitivity to various changes to fishery dependent indices (sensitivity runs S1, S3, S4, and S25). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

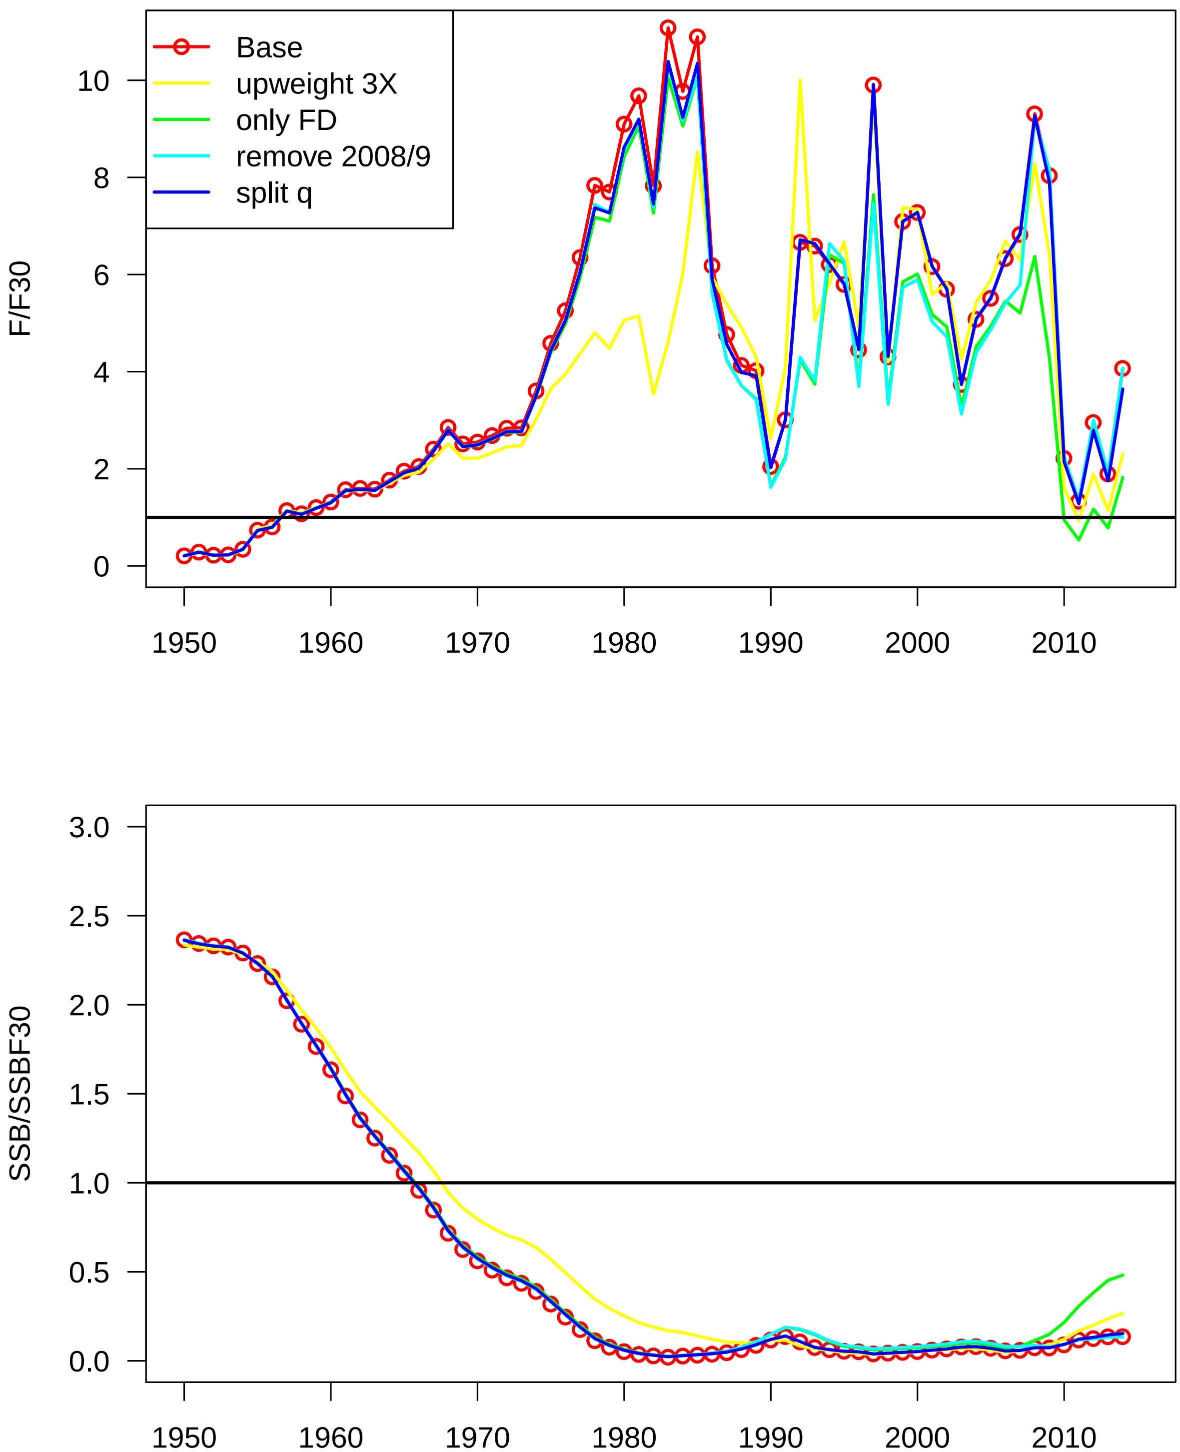

Figure 50. Sensitivity to not fixing selectivities (sensitivity run S27). Top panel: Ratio of F to $F_{30\%}$*. Bottom panel: Ratio of* SSB *to* $SSB_{F30\%}$.

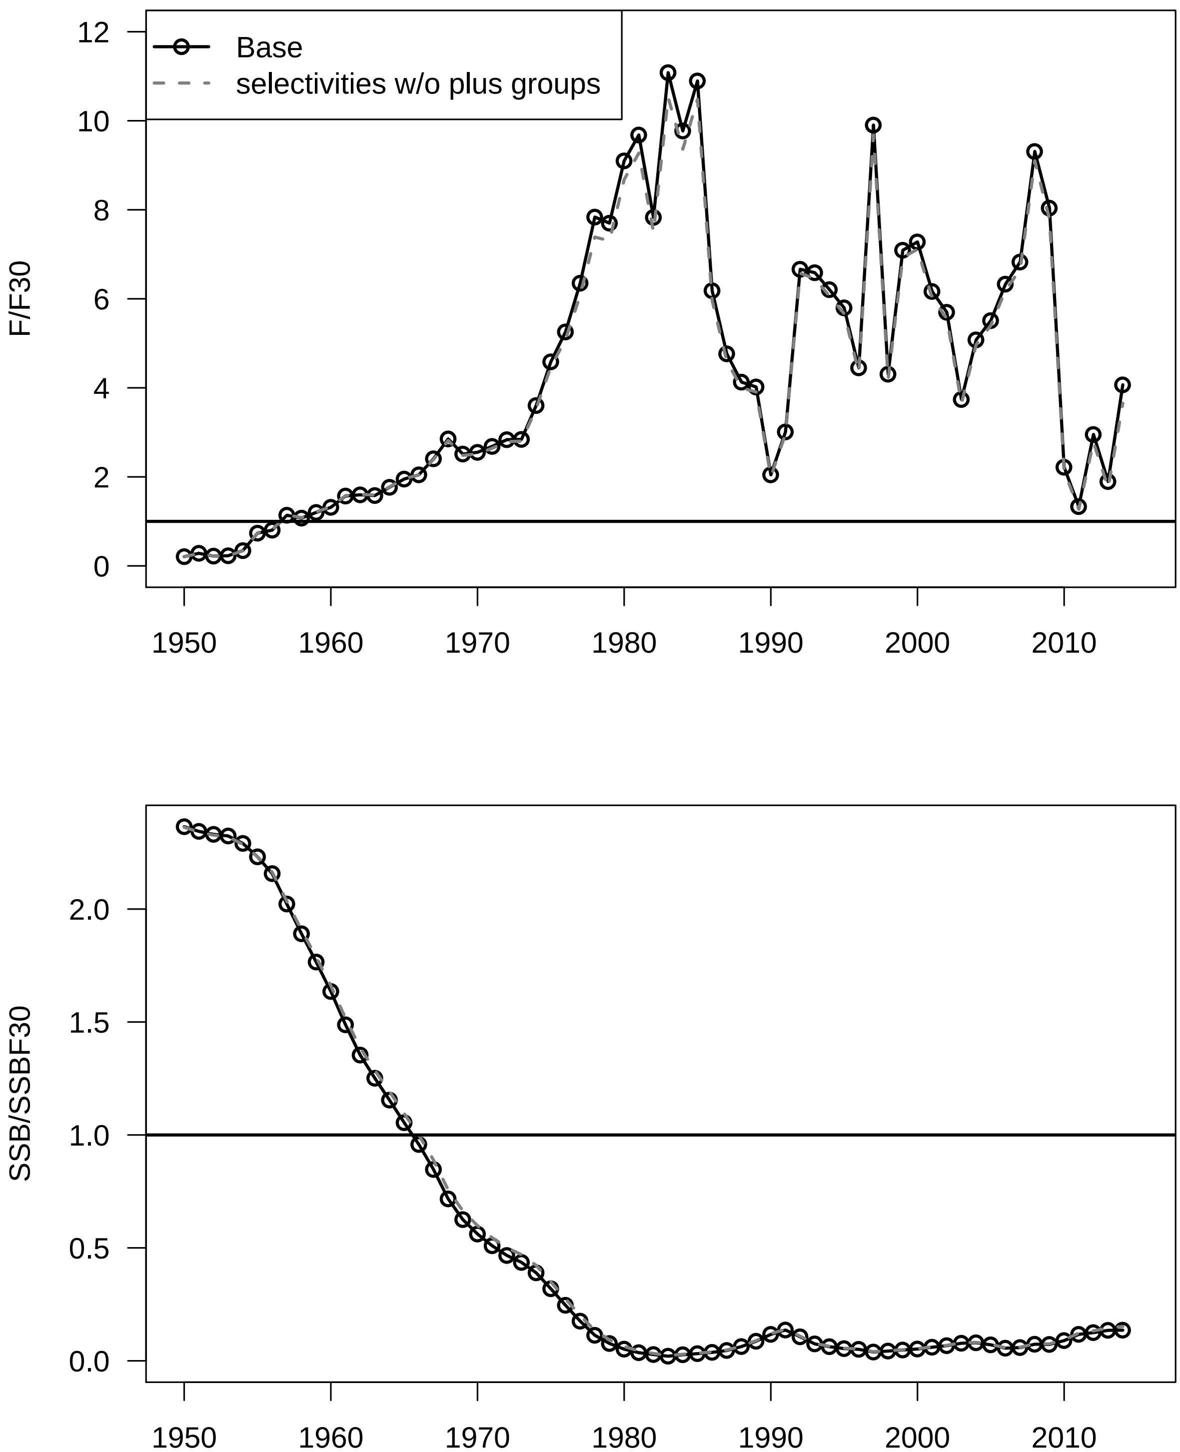

Figure 51. Sensitivity to dropping or truncating headboat discard index (sensitivity runs S12 and S16). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\mathrm{SSB_{F30\%}}$.

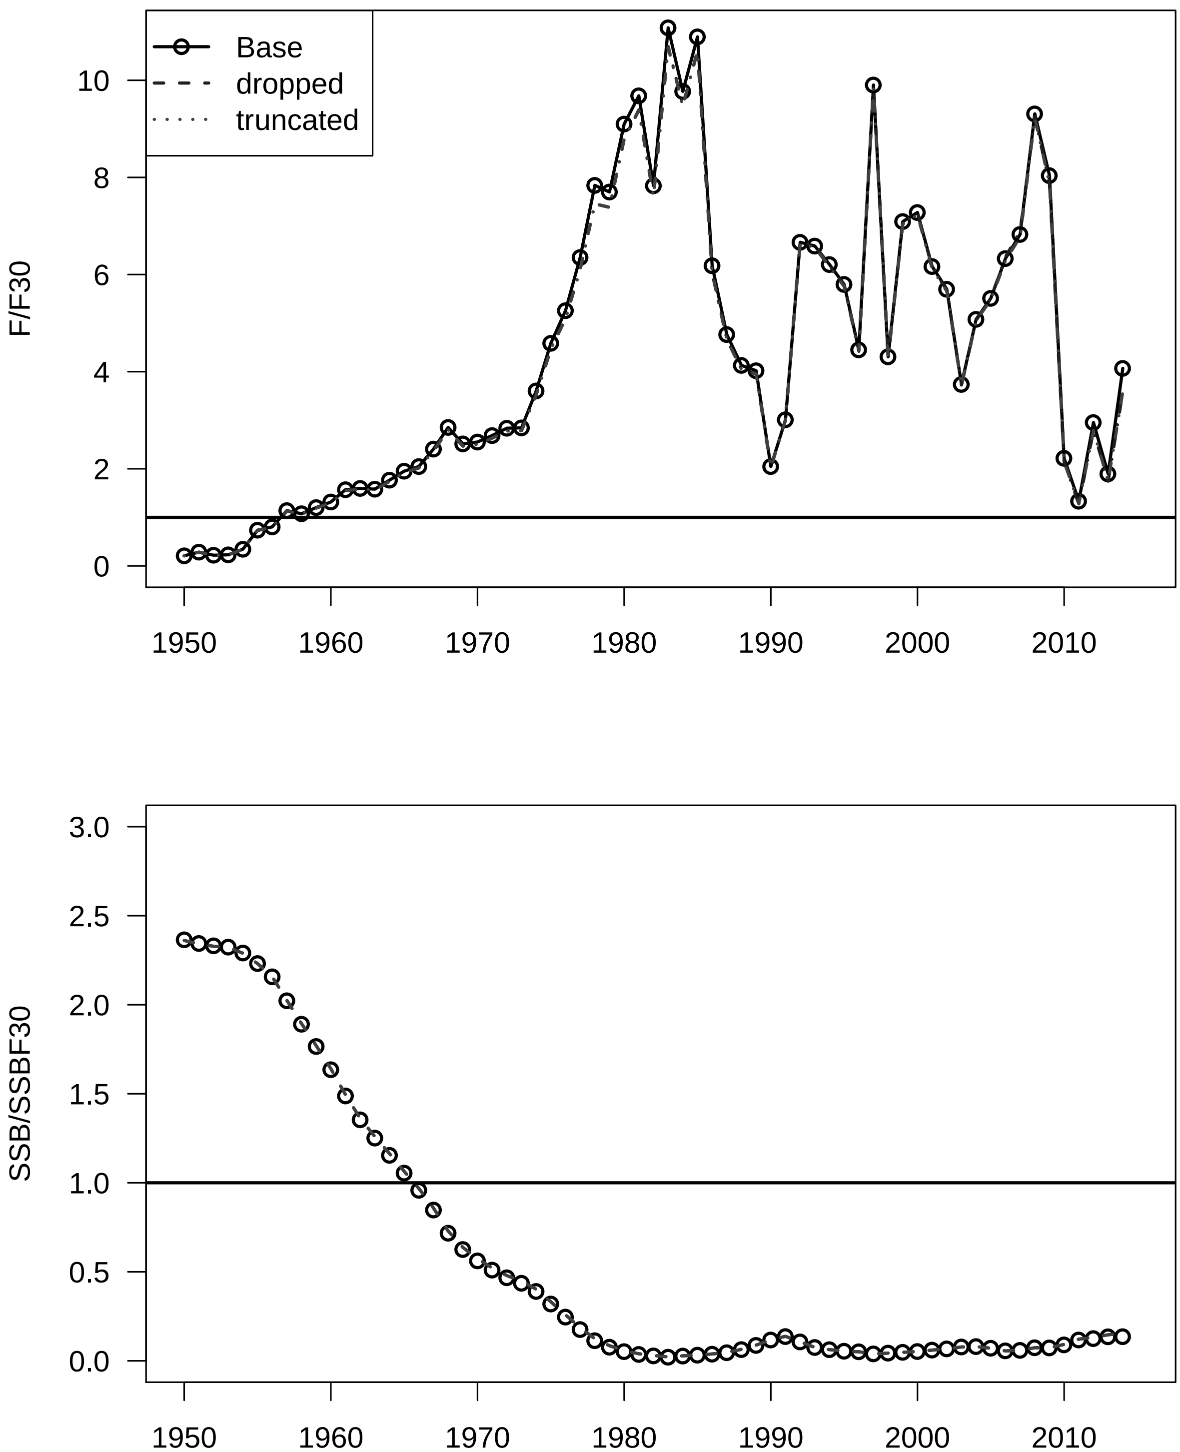

Figure 52. Sensitivity to higher or lower estimates of landings and discards (sensitivity runs S17–S20). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB to $SSB_{F30\%}$.

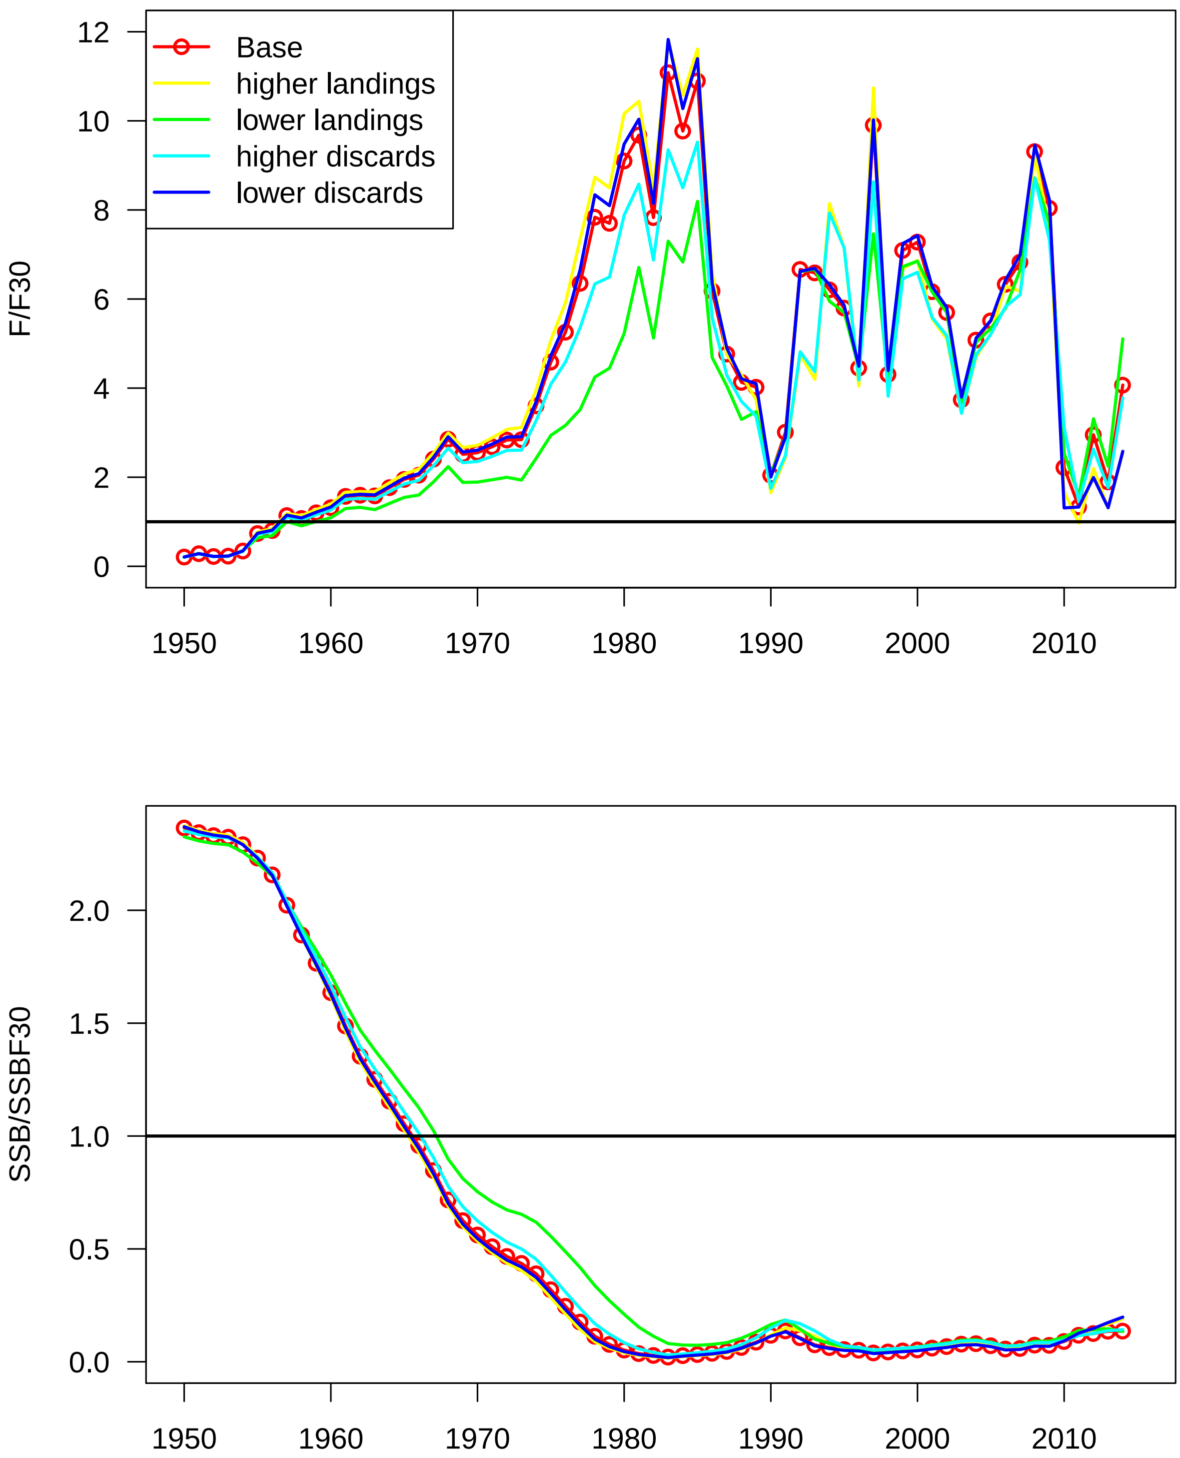

Figure 53. Sensitivity to smoothed 1984 and 1985 MRIP landings (sensitivity run S10). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

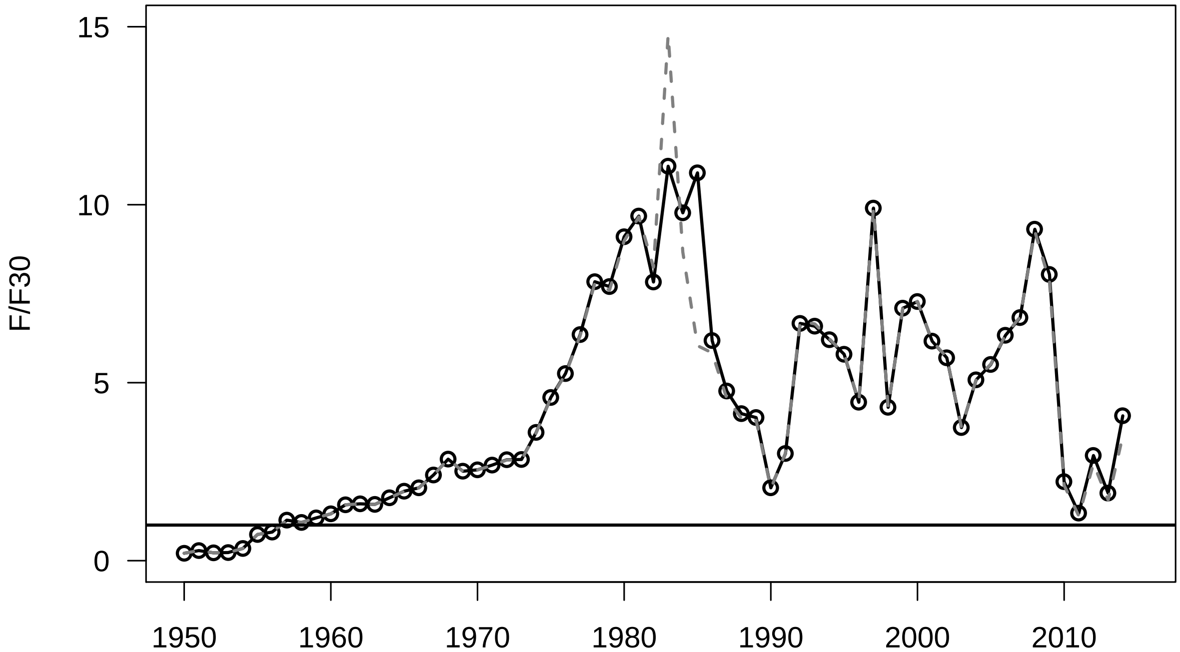

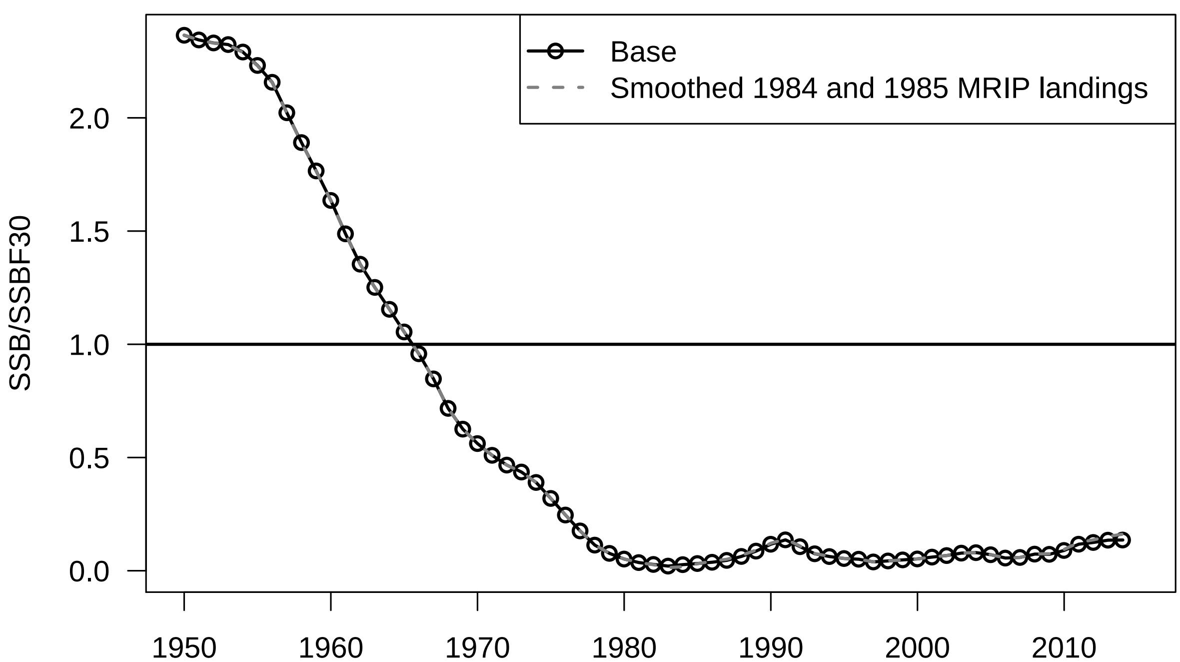

Figure 54. Sensitivity to continuity assumptions from SEDAR 24 (sensitivity run S24). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $SSB_{F30\%}$.

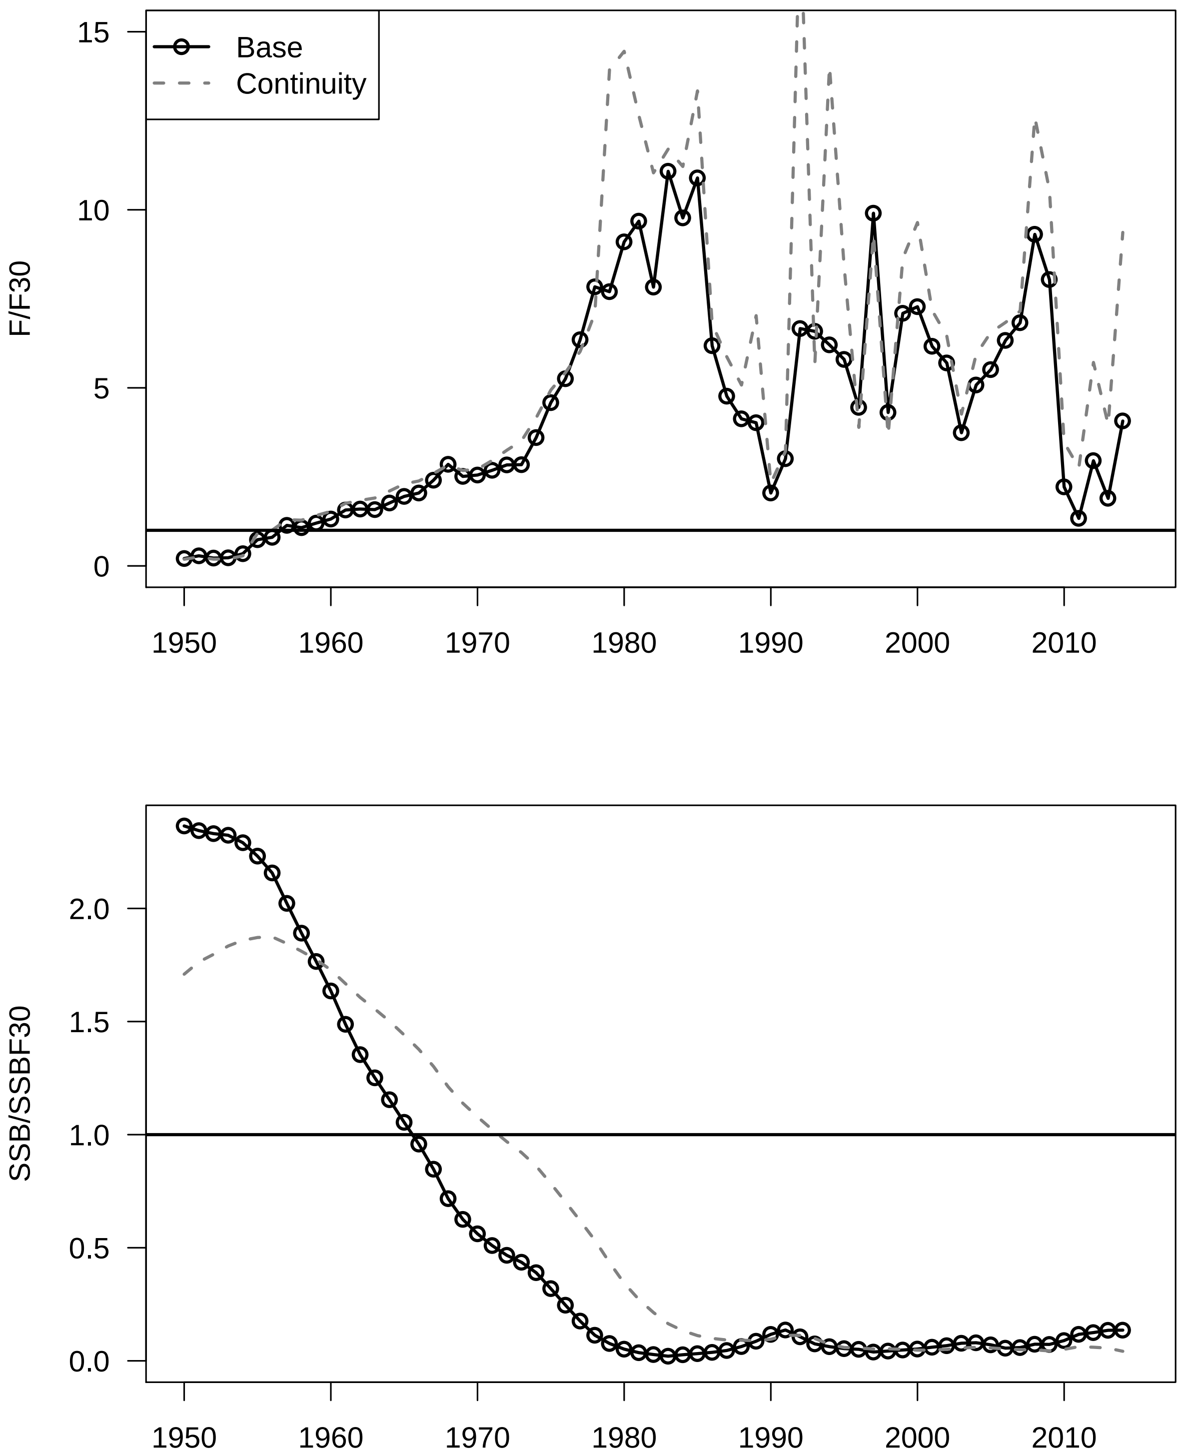

Figure 55. Phase plot of terminal status indicators from sensitivity runs of the Beaufort Assessment Model.

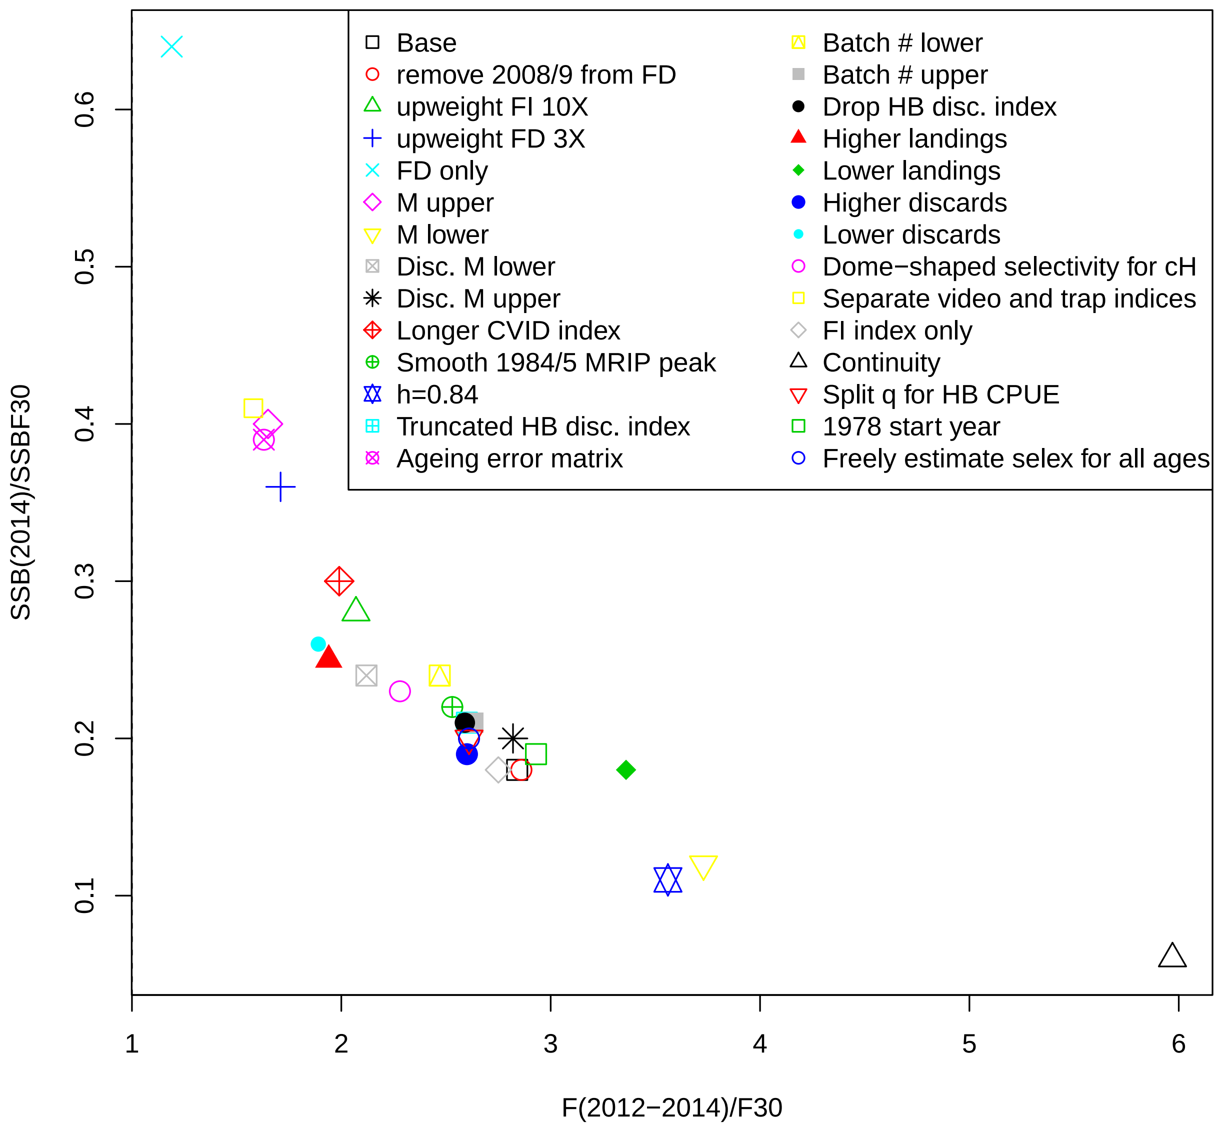

Figure 56. Retrospective analyses. Sensitivity to terminal year of data. Top panel: Fishing mortality rates. Middle panel: Recruits. Bottom panel: Spawning biomass. Closed circles show terminal-year estimates. Imperceptible lines overlap results of the base run.

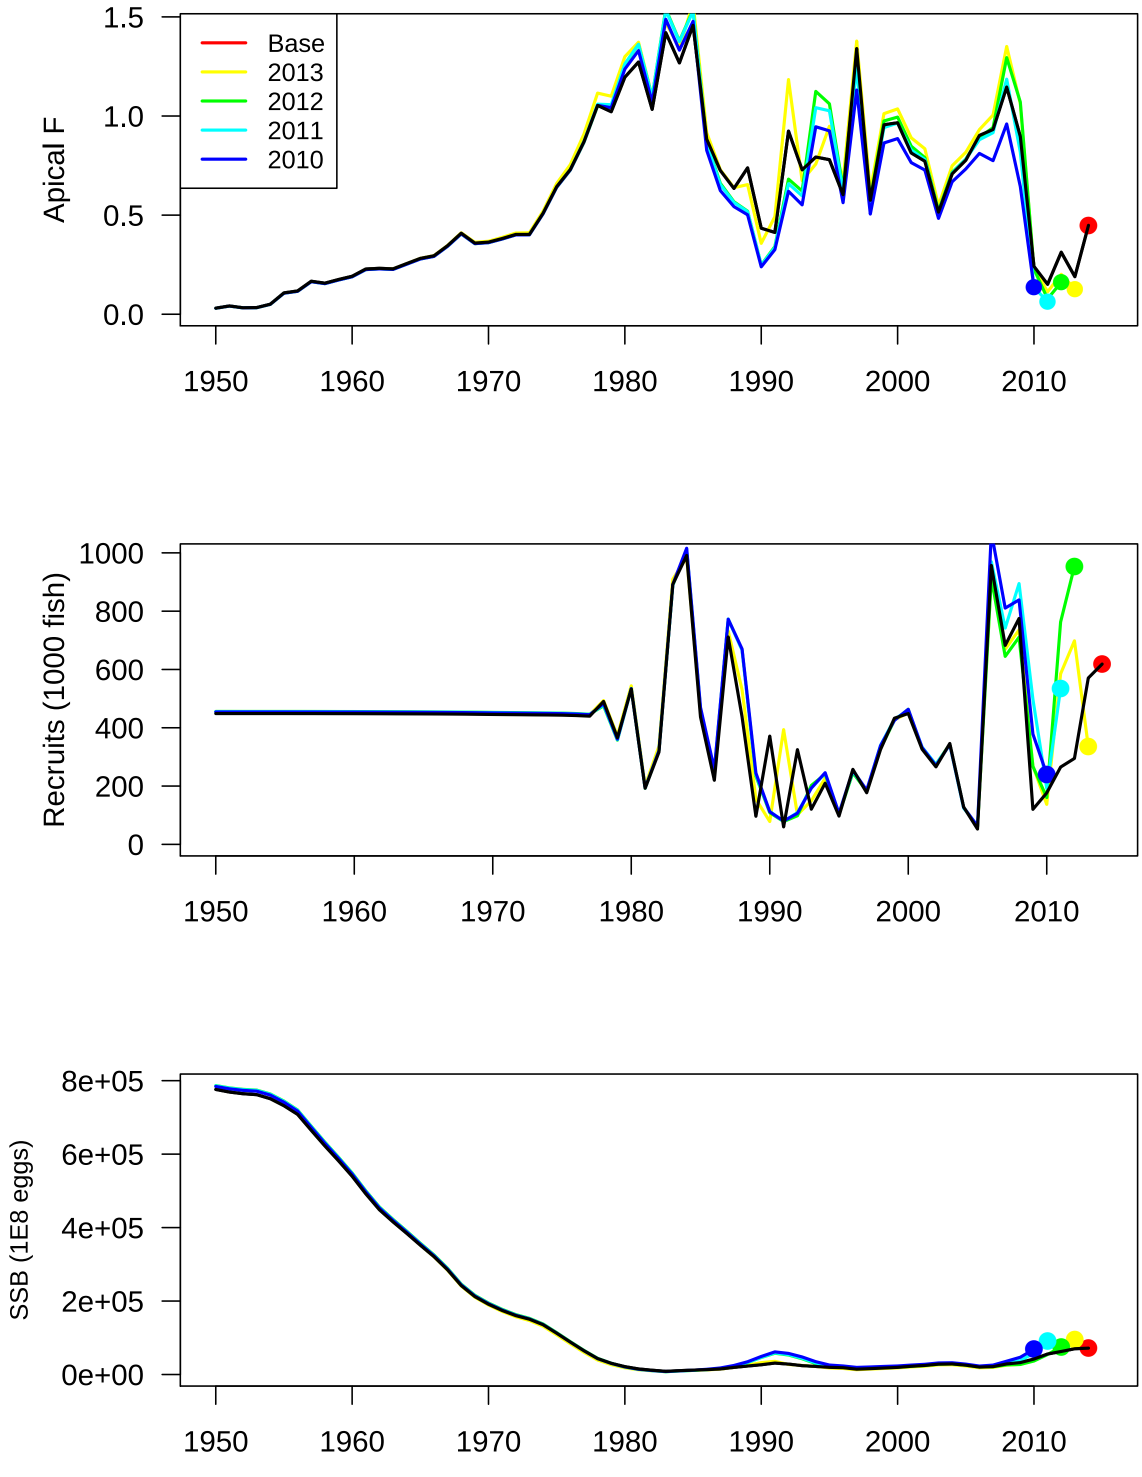

Figure 57. Projection results under scenario 1—fishing mortality rate at $F = 0$. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} and 95^{th} percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $\mathrm{SSB_{F30\%}}$.

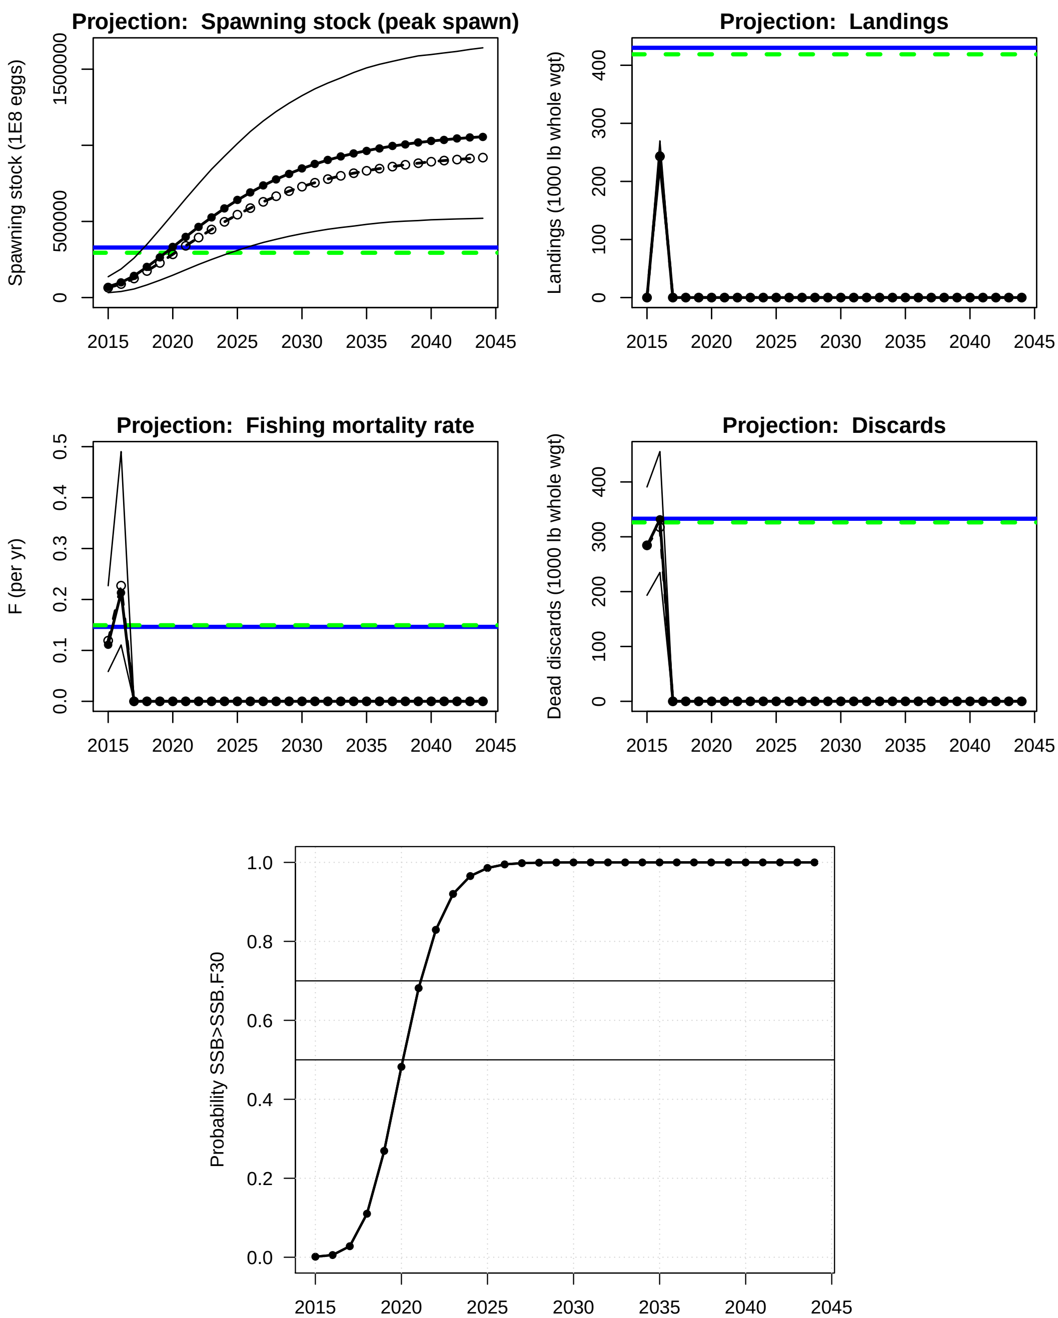

Figure 58. Projection results under scenario 2—fishing mortality rate at $F = F_{\text{current}}$. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} and 95^{th} percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $\text{SSB}_{\text{F30\%}}$.

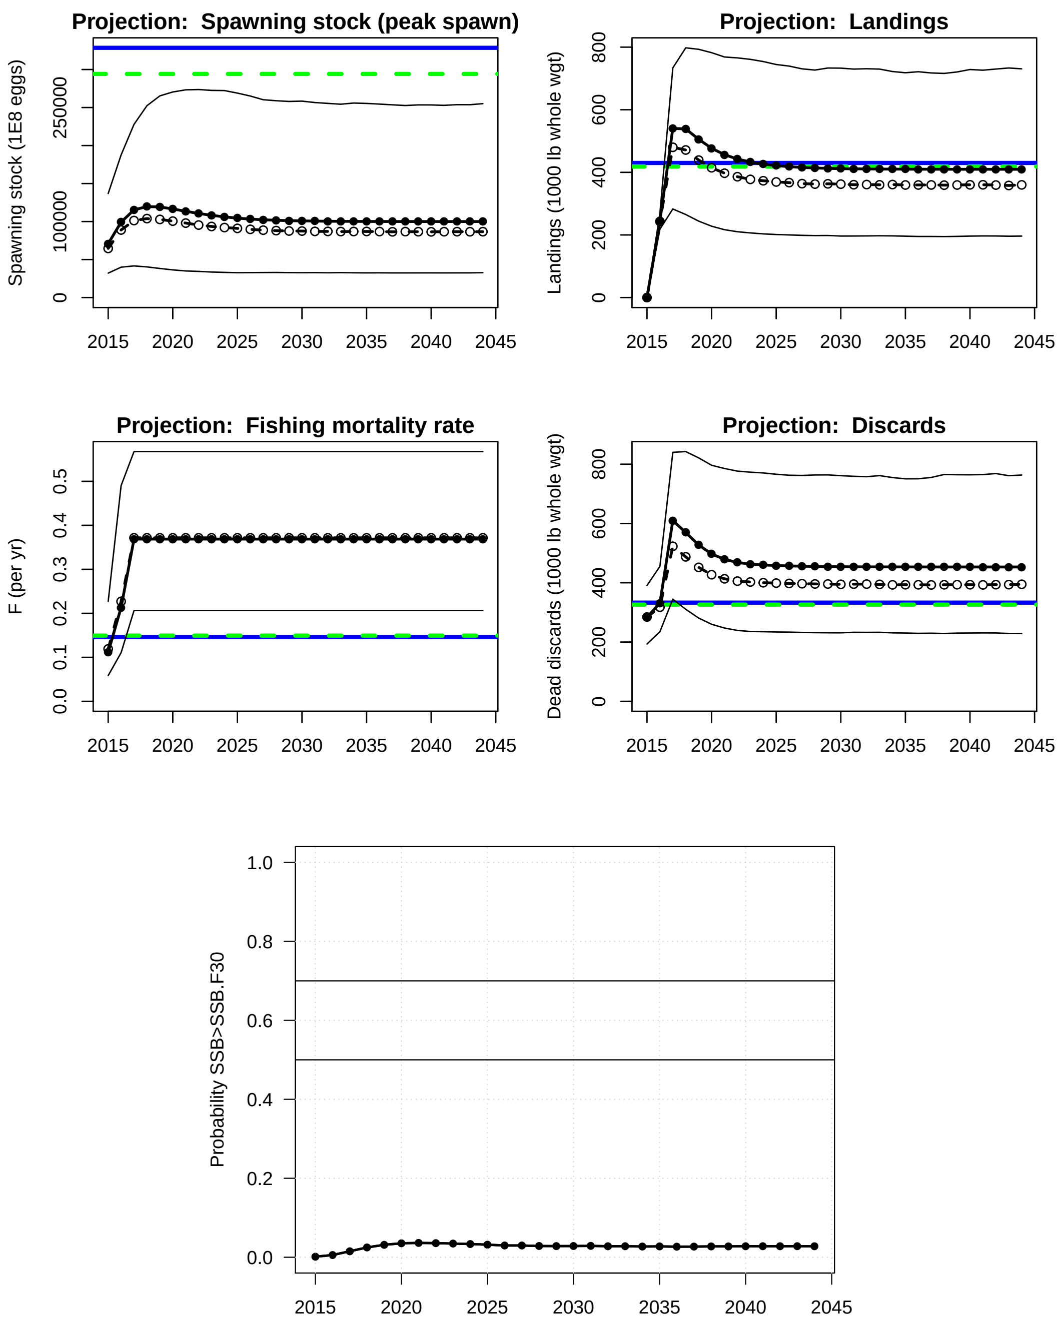

Figure 59. Projection results under scenario 3—fishing mortality rate at $F = F_{30\%}$. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} and 95^{th} percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $\mathrm{SSB_{F30\%}}$.

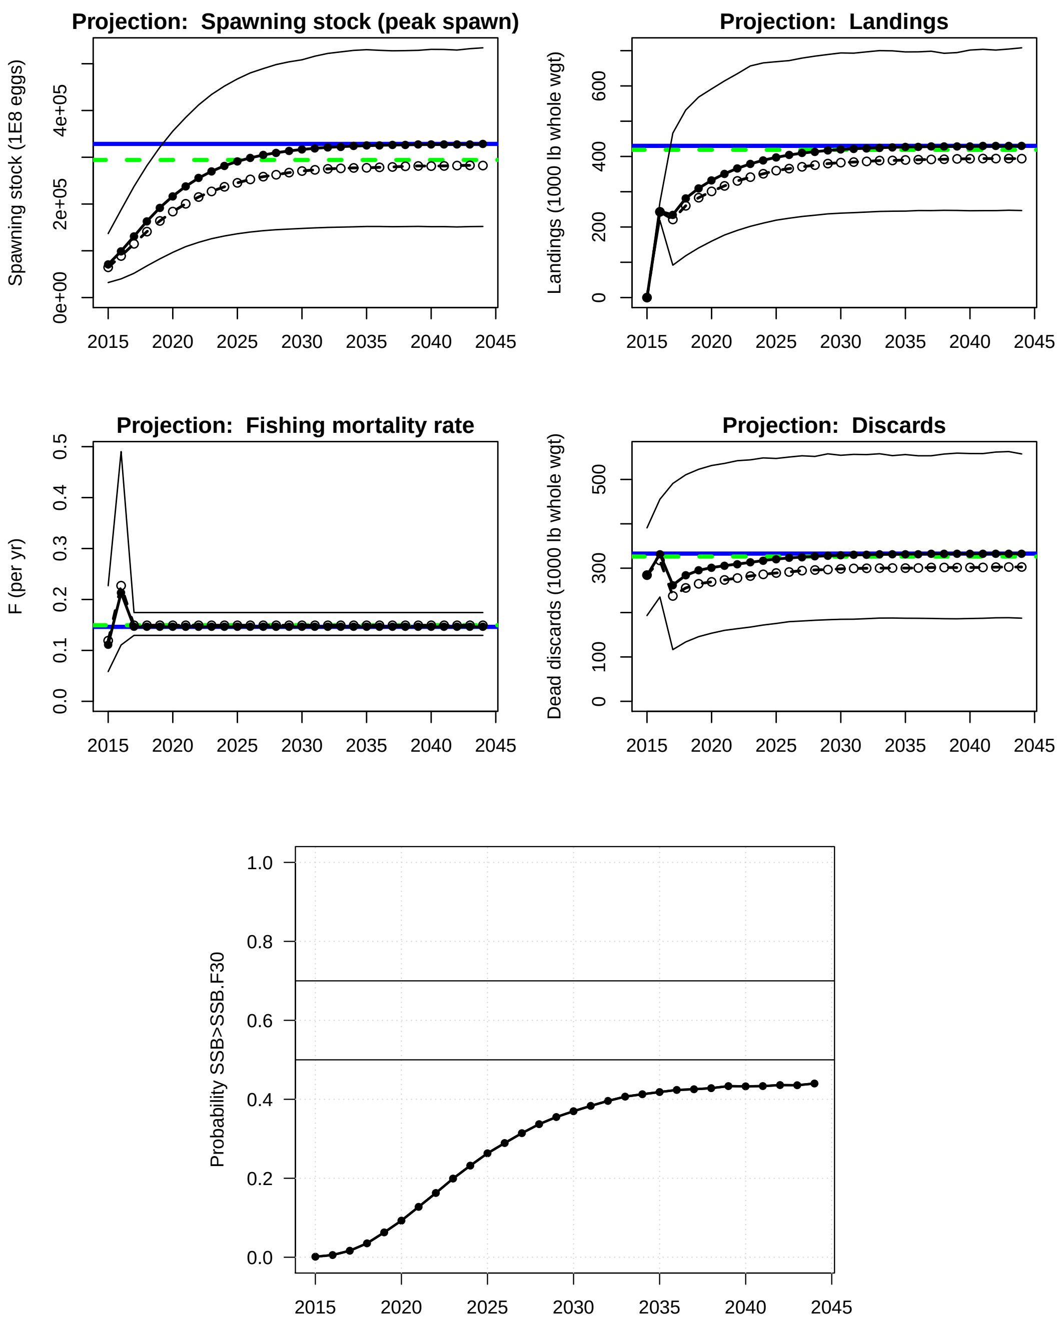

Figure 60. Projection results under scenario 4—fishing mortality rate at $F = 98\%F_{30\%}$. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} and 95^{th} percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $\mathrm{SSB}_{\mathrm{F30\%}}$.

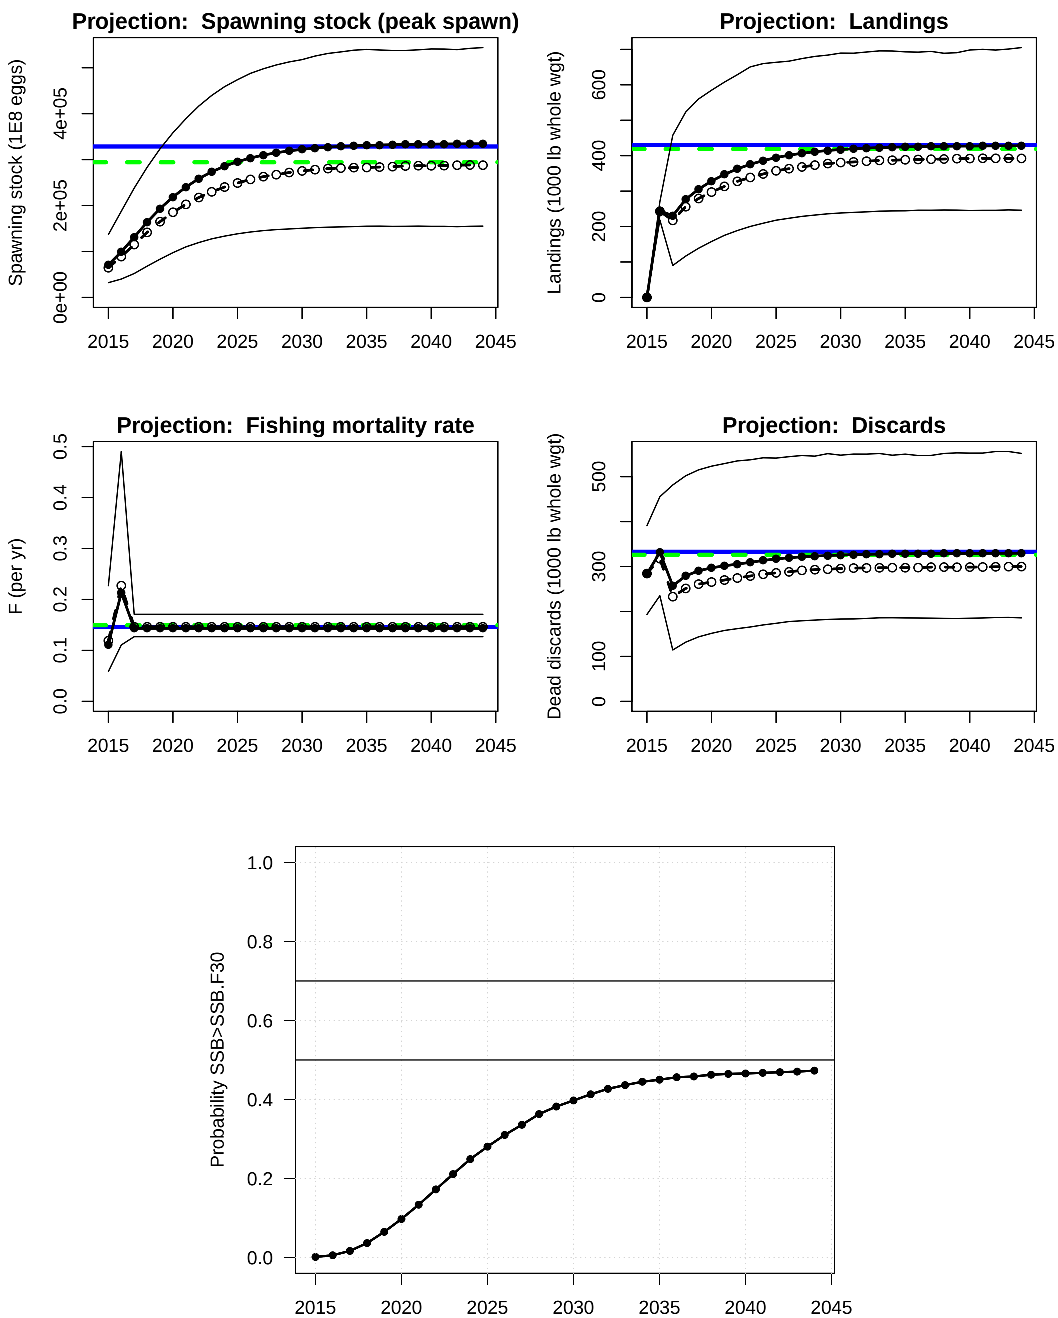

Figure 61. Projection results under scenario 5—fishing mortality rate at $F = F_{\text{rebuild}}$, with rebuilding probability of 0.5 in 2044. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} and 95^{th} percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $\text{SSB}_{\text{F30\%}}$.

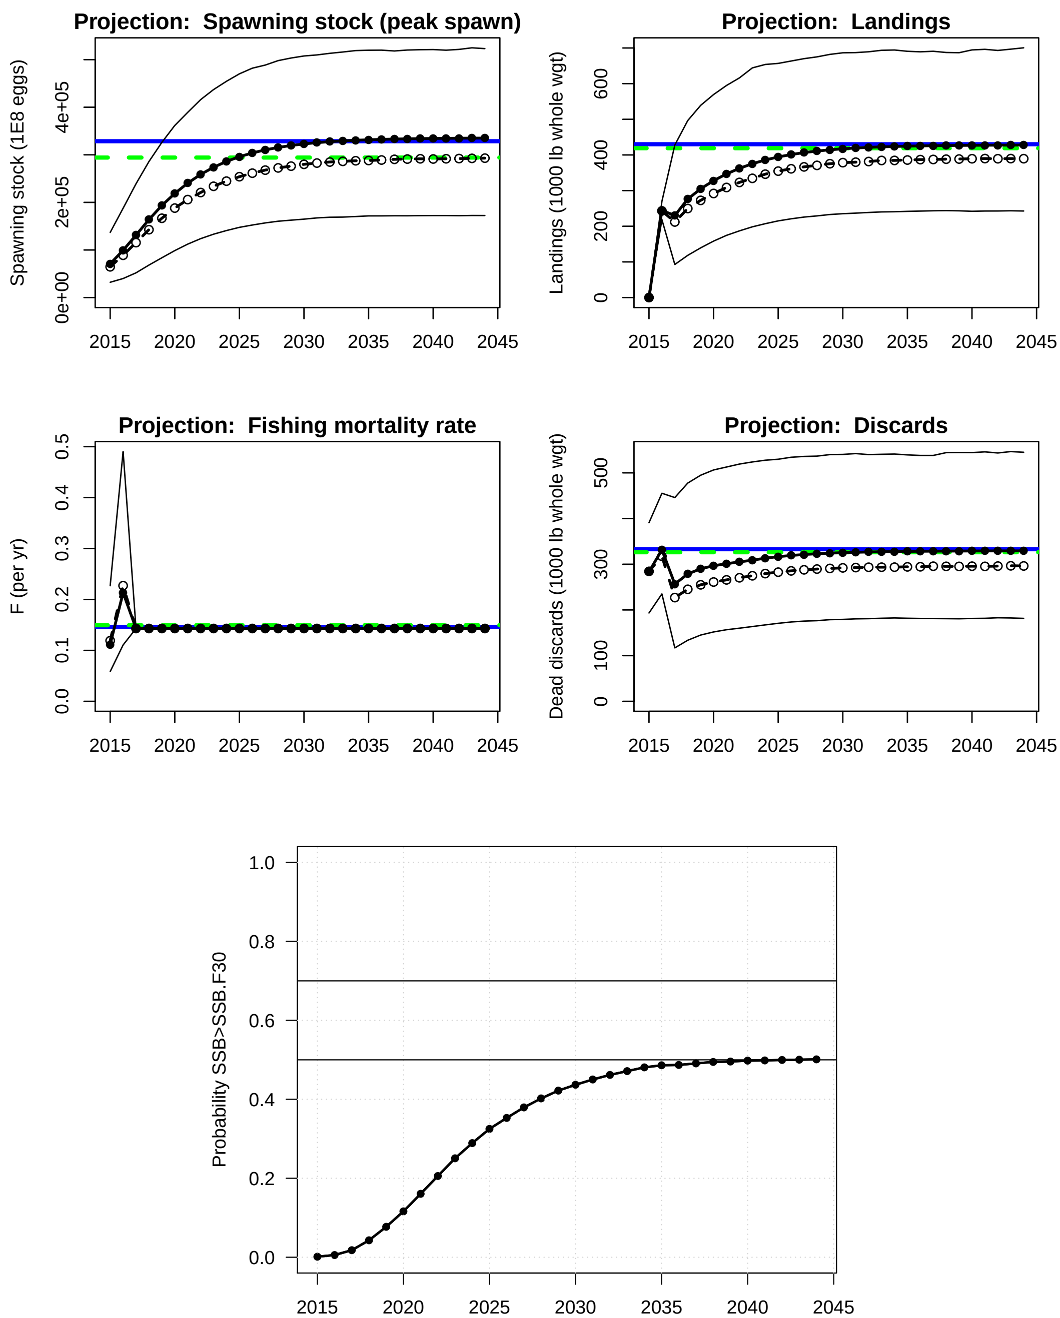

Figure 62. Projection results under scenario 6—fishing mortality rate set to average discard mortality rate only. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} and 95^{th} percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $\mathrm{SSB}_{\mathrm{F30\%}}$.

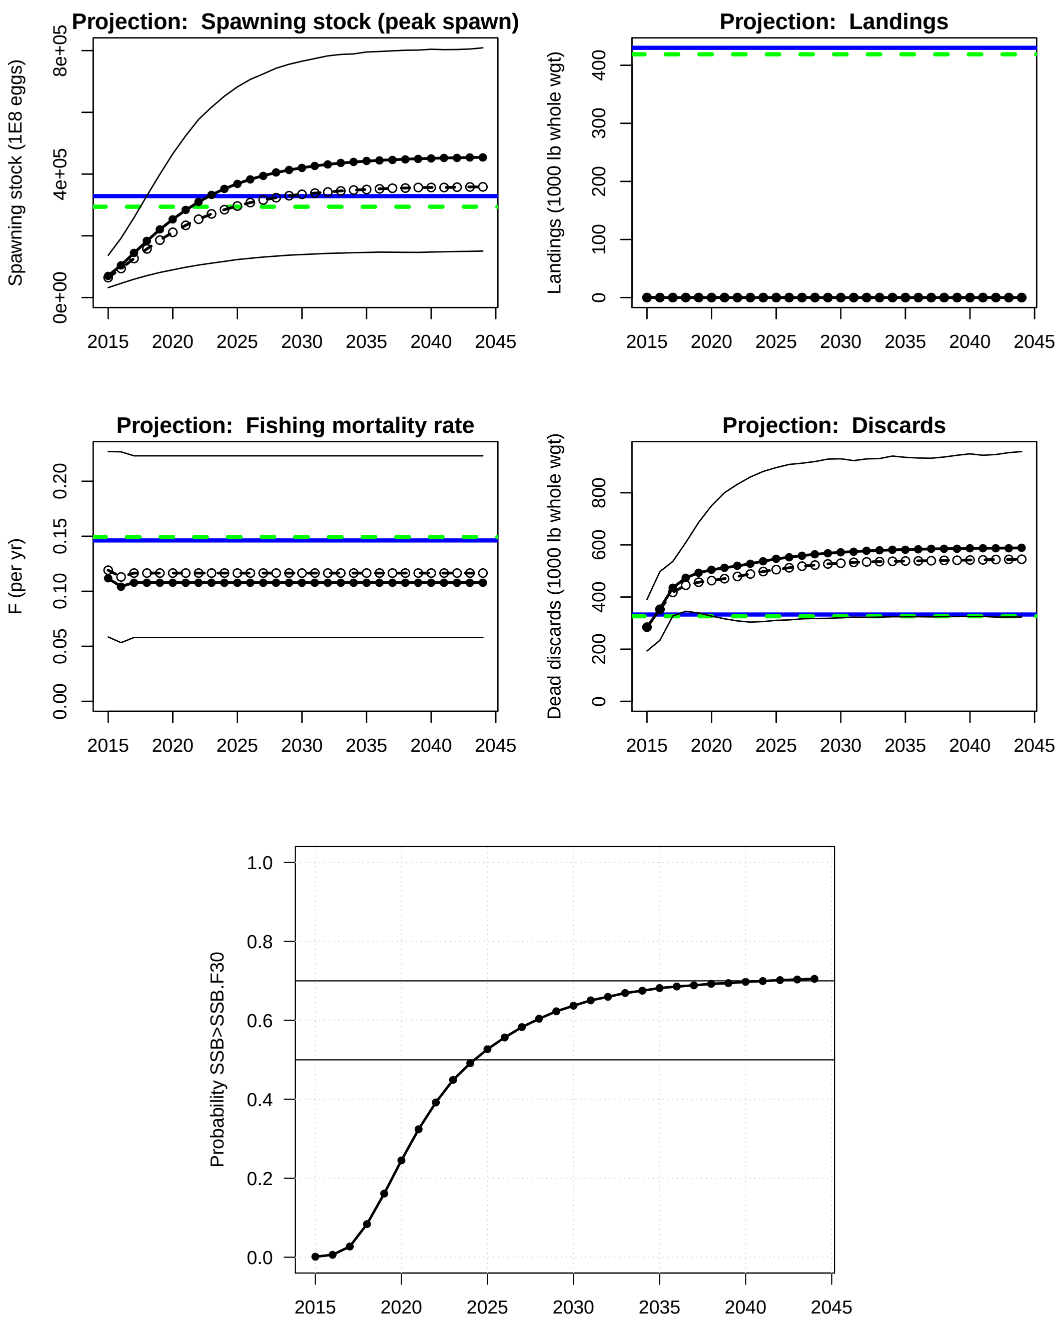

Figure 63. Abundance indices observed (obs.) and predicted (pred.) by the ASPIC surplus production model, and observed total removals (100,000 lbs) for South Atlantic red snapper. Comm = commercial, HB = headboat, HB.at.sea = headboat at sea discards, CVID = combined chevron trap-video index.

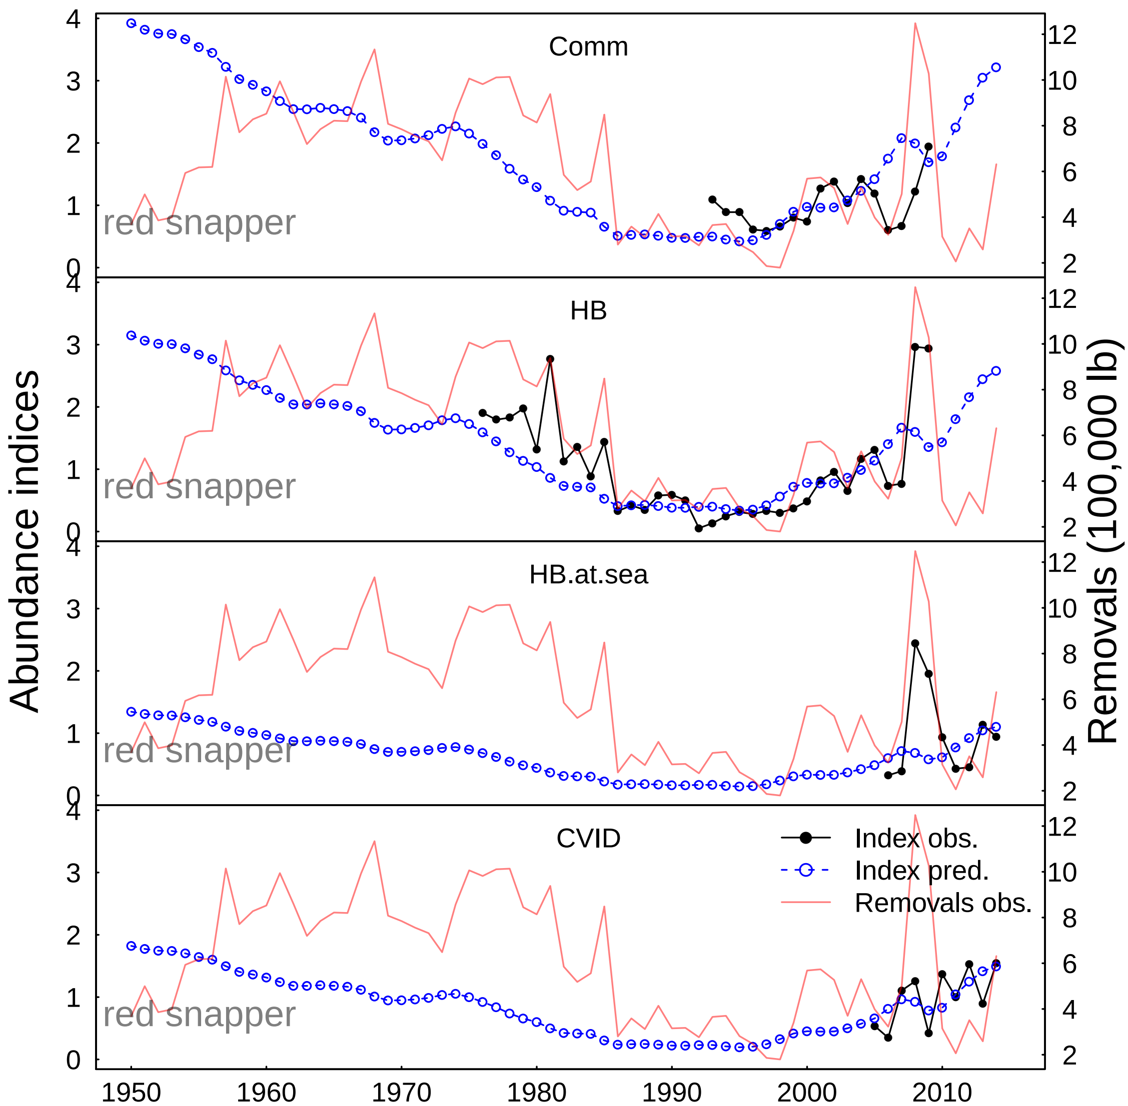

Figure 64. Prior distributions (blue shapes) and estimated parameter values (vertical black lines) for the South Atlantic red snapper ASPIC surplus production model.

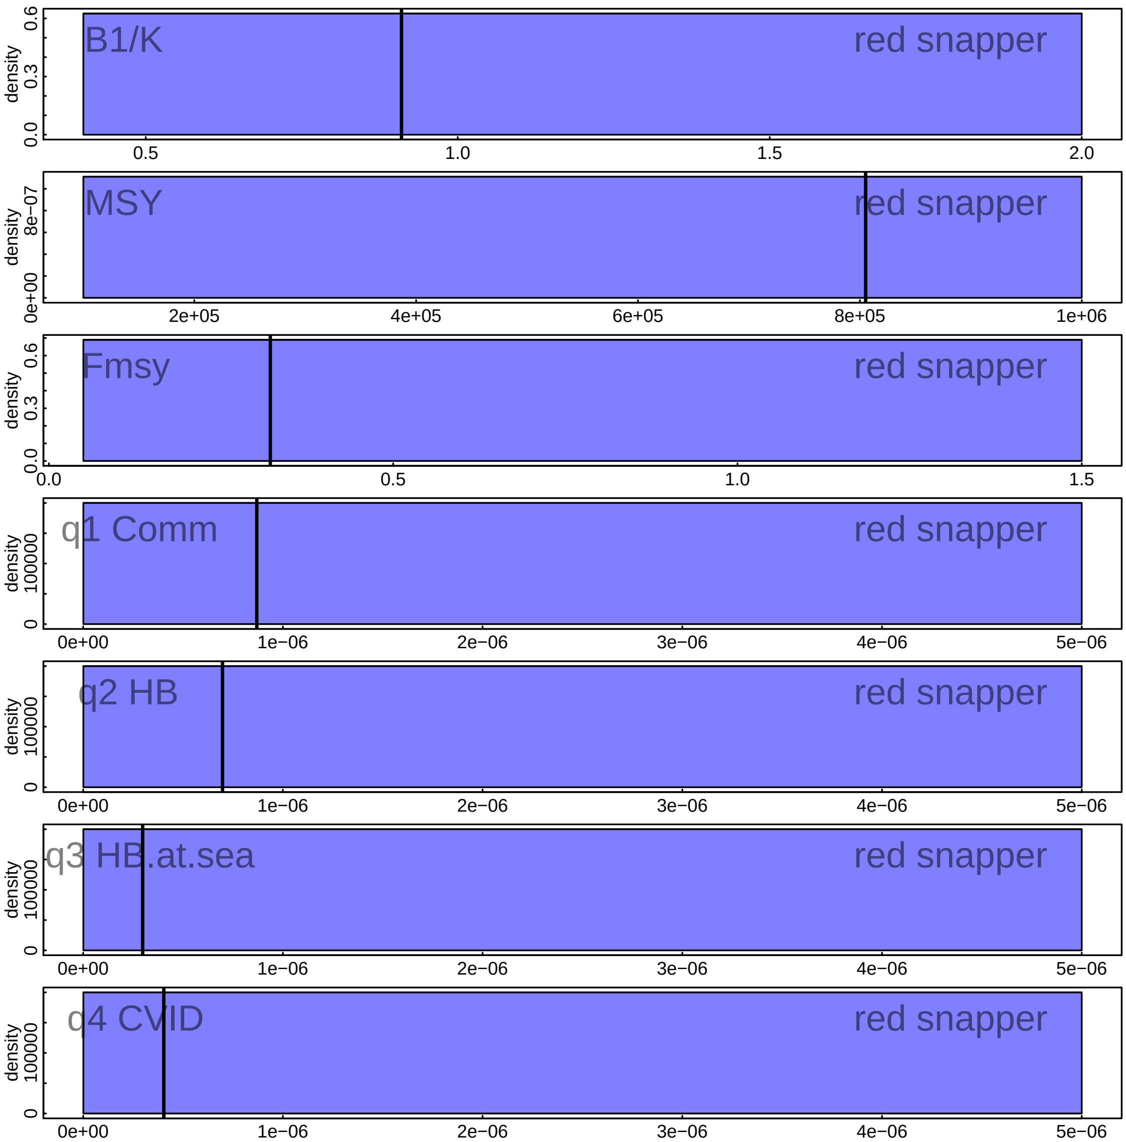

Figure 65. Bootstrap parameter values from ASPIC surplus production model run 320. Thick vertical lines represent ASPIC parameter estimates (solid) and 95% bootstrap percentile confidence intervals (dashed). Thin solid vertical lines are drawn at one in plots of F/F_{MSY} and B/B_{MSY} for reference.

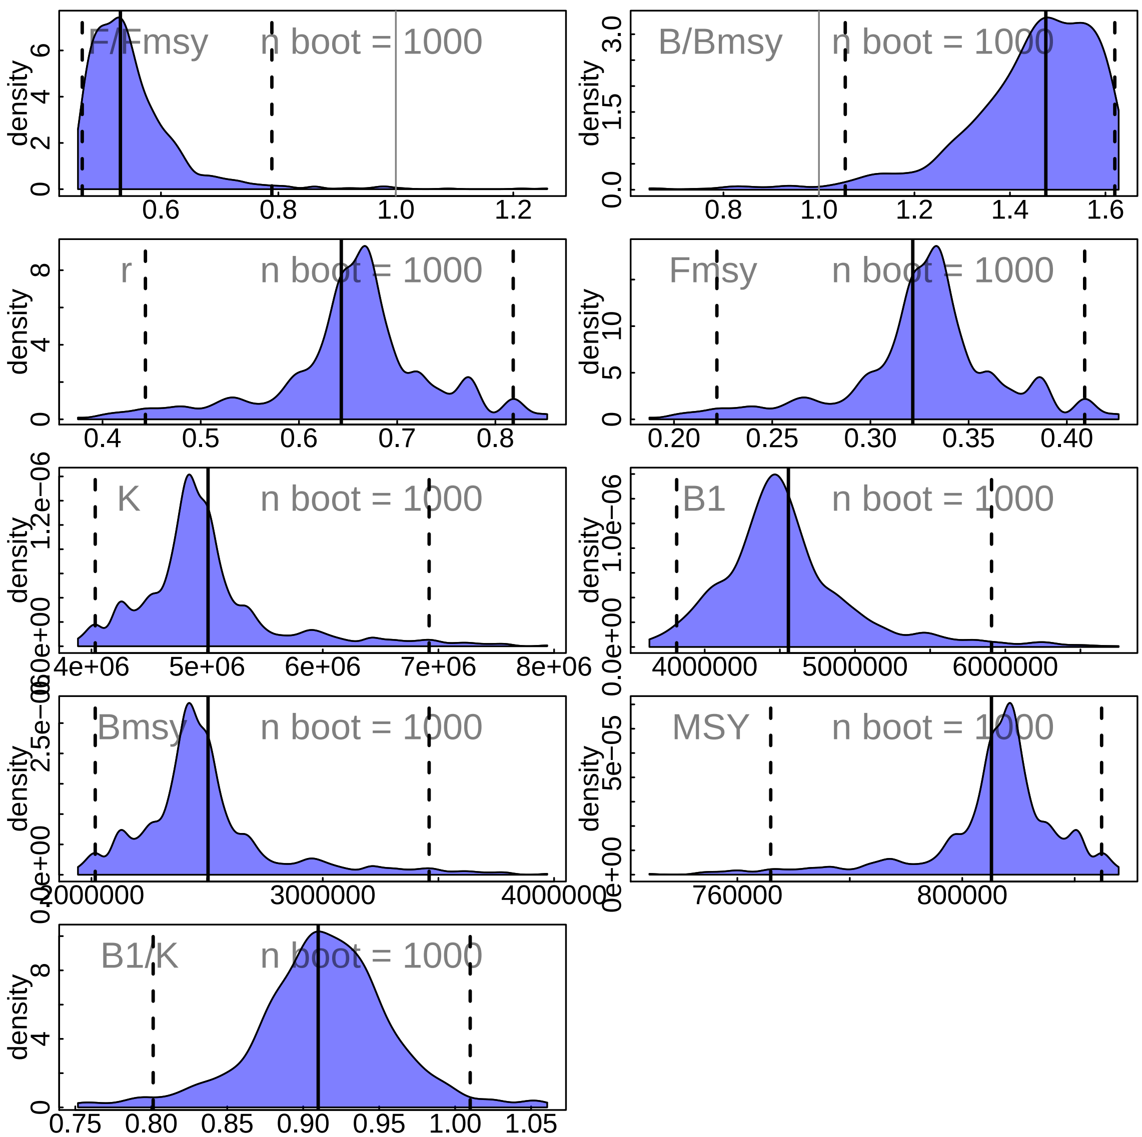

Figure 66. ASPIC surplus production model estimates of relative fishing rate (F/F_{MSY}) and biomass (B/B_{MSY}).

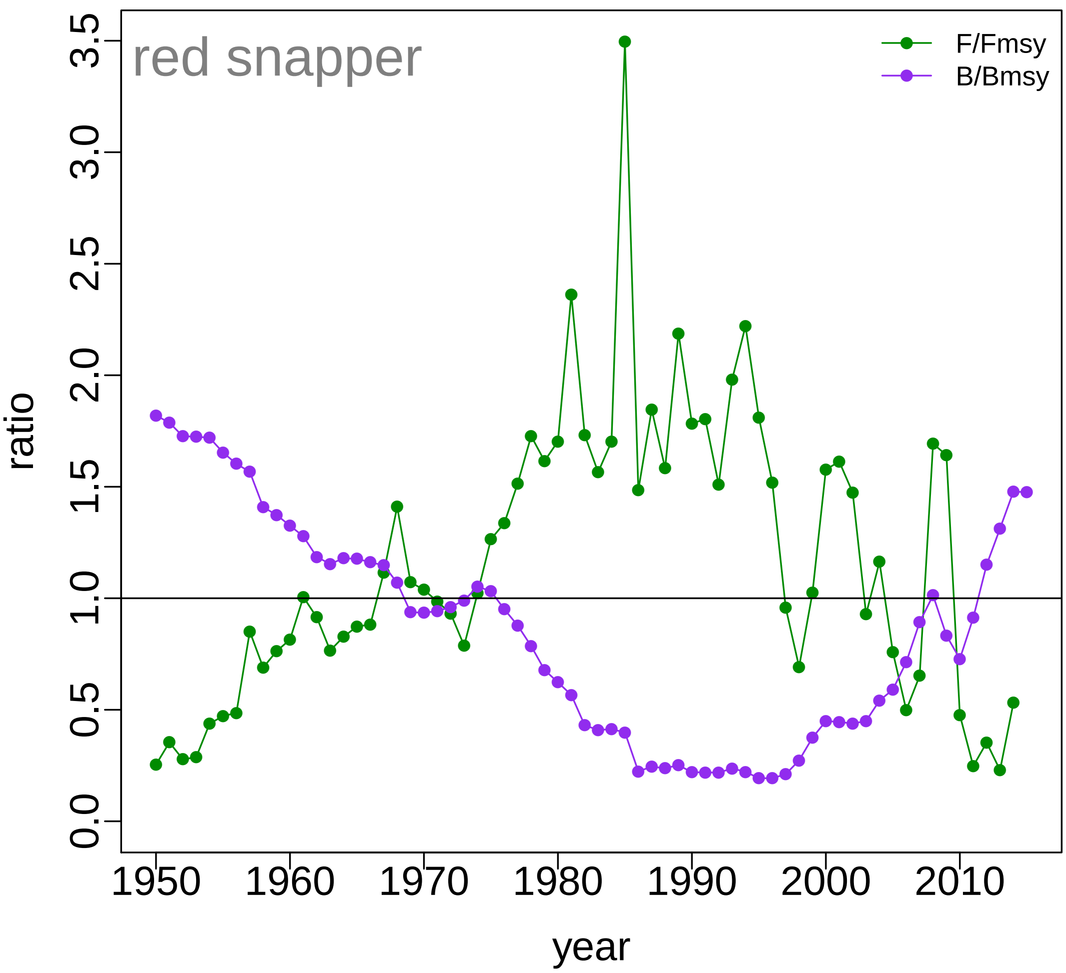

Appendix A Abbreviations and symbols

Table 33. Acronyms and abbreviations used in this report

Symbol	Meaning
ABC	Acceptable Biological Catch
AW	Assessment Workshop (here, for red snapper)
ASY	Average Sustainable Yield
B	Total biomass of stock, conventionally on January 1
BAM	Beaufort Assessment Model (a statistical catch-age formulation)
CPUE	Catch per unit effort; used after adjustment as an index of abundance
CV	Coefficient of variation
CVID	SERFS combined chevron trap and video survey
DW	Data Workshop (here, for red snapper)
F	Instantaneous rate of fishing mortality
$F_{30\%}$	Fishing mortality rate at which $F_{30\%}$ can be attained
F_{MSY}	Fishing mortality rate at which MSY can be attained
FL	State of Florida
FHWAR	The National Survey of Fishing, Hunting, and Wildlife-Associated Recreation Survey
GA	State of Georgia
GLM	Generalized linear model
K	Average size of stock when not exploited by man; carrying capacity
kg	Kilogram(s); 1 kg is about 2.2 lb.
klb	Thousand pounds; thousands of pounds
lb	Pound(s); 1 lb is about 0.454 kg
m	Meter(s); 1 m is about 3.28 feet.
M	Instantaneous rate of natural (non-fishing) mortality
MARMAP	Marine Resources Monitoring, Assessment, and Prediction Program, a fishery-independent data collection program of SCDNR
MCB	Monte Carlo/Bootstrap, an approach to quantifying uncertainty in model results
MFMT	Maximum fishing-mortality threshold; a limit reference point used in U.S. fishery management; often based on F_{MSY}
mm	Millimeter(s); 1 inch = 25.4 mm
MRFSS	Marine Recreational Fisheries Statistics Survey, a data-collection program of NMFS, predecessor of MRIP
MRIP	Marine Recreational Information Program, a data-collection program of NMFS, descended from MRFSS
MSST	Minimum stock-size threshold; a limit reference point used in U.S. fishery management. The SAFMC has defined MSST for red snapper as $(1 - M)\mathrm{SSB}_{\mathrm{MSY}} = 0.7\mathrm{SSB}_{\mathrm{MSY}}$.
MSY	Maximum sustainable yield (per year)
mt	Metric ton(s). One mt is 1000 kg, or about 2205 lb.
N	Number of fish in a stock, conventionally on January 1
NC	State of North Carolina
NMFS	National Marine Fisheries Service, same as "NOAA Fisheries Service"
NOAA	National Oceanic and Atmospheric Administration; parent agency of NMFS
OY	Optimum yield; SFA specifies that OY $\leq$ MSY.
PSE	Proportional standard error
R	Recruitment
SAFMC	South Atlantic Fishery Management Council (also, Council)
SC	State of South Carolina
SCDNR	Department of Natural Resources of SC
SDNR	Standard deviation of normalized residuals
SEDAR	SouthEast Data Assessment and Review process
SERFS	Southeast Regional Fishery-independent Sampling
SFA	Sustainable Fisheries Act; the Magnuson–Stevens Act, as amended
SL	Standard length (of a fish)
SRHS	Southeast Region Headboat Survey, conducted by NMFS-Beaufort laboratory
SPR	Spawning potential ratio
SSB	Spawning stock biomass; mature biomass of males and females
$\mathrm{SSB}_{\mathrm{MSY}}$	Level of SSB at which MSY can be attained
$\mathrm{SSB}_{\mathrm{F30\%}}$	Level of SSB at which $F_{30\%}$ can be attained
TIP	Trip Interview Program, a fishery-dependent biodata collection program of NMFS
TL	Total length (of a fish), as opposed to FL (fork length) or SL (standard length)
VPA	Virtual population analysis, an age-structured assessment
WW	Whole weight, as opposed to GW (gutted weight)
yr	Year(s)

Memorandum To: Gregg Waugh, Executive Director, SAFMC

From: Bonnie J. Ponwith, Ph.D BRAINERD.THEOPHILUS.R.DR.1365819285 Digitally signed by BRAINERD.THEOPHILUS.R.DR.1365819285 Date: 2017.04.19 13:02:33 -04'00'
Science and Research Director

Subject: Red Snapper Assessment Errata

Southeast Fisheries Science Center Analysis discovered an error in the Red Snapper Assessment in the Headboat Discard Index input to the model. The input data were corrected and the model was rerun. The difference between the original run and corrected run is negligible. Monte Carlo Bootstrap uncertainty analysis shows almost no change. The attached report contains the corrected base run.

This information will be discussed at the upcoming SSC meeting.

Stock Assessment of Red Snapper off the Southeastern United States

SEDAR Benchmark Assessment

Southeast Fisheries Science Center

National Marine Fisheries Service

Last revision: April, 2017

Document History

February, 2016 Original release.

March, 2016 This release incorporates some of the corrections made during the Review Workshop, including corrected age composition data from the MARMAP program.

April, 2016 This release incorporates all of the corrections made during the Review Workshop, including corrected chevron trap age composition data. The corrections resulted in a new base run, for which iterative reweighting of the likelihood components and the starting value analysis were re-run. The new base run results, including updated uncertainty analyses and projections are included. The sensitivities and retrospectives, however, are unchanged. The Reviewers did not request that sensitivities or retrospectives be re-run because the base run changes were relatively small.

April, 2017 This release corrects the data used for the Headboat at-sea discard index. The correction resulted in a new base run, for which iterative reweighting of the likelihood components was conducted. The new base run results, including updated uncertainty analyses and projections are included. The sensitivities and retrospectives, however, are unchanged.

2 Data Review and Update

The input data for this assessment are described below, with focus on modifications from the SEDAR41 DW.

2.1 Data Review

In this benchmark assessment, the Beaufort assessment model (BAM) was fitted to data sources developed during the SEDAR 41 DW with some modifications and additions.

Model input compiled during the DW

- Life history: Life history meristics, population growth, female maturity, proportion female, number of batches at age, size-dependent batch fecundity, and discard mortality
- Landings and discards: Commercial handline landings and discards, Headboat landings and discards, Recreational landings and discards
- Indices of abundance: Commercial handline, Headboat, Headboat discards, SERFS chevron trap, SERFS video

Model input modified or developed after the DW

- Life history: Fishery-dependent growth estimates, Growth estimates during the 20 inch size regulation, Age–specific natural mortality
- Landings and discards: changes to the recreational discards
- Indices of abundance: Fishery–independent indices combined (Chevron trap and Video)
- Length compositions: Commercial handline, Headboat, Recreational
- Age compositions: Commercial handline, Headboat, Recreational, Chevron trap

2.2 Data Update

2.2.1 Life History

Estimates of the von Bertalanffy growth parameters were provided by the DW for the population as a whole: (911.36mm, 0.24yr^{-1}, and -0.33yr). Two alternative von Bertalanffy curves were generated: one for all fisheries when no size limit was in place, and another to represent the fish captured by all fisheries under a 20 inch size limit regulation. Age-specific mortality was updated due to an error in the original calculation which forced the t_0 value to 0. Life-history information is summarized in Tables 1 and 2.

2.2.2 Landings and Discards

The fleet structure to be modeled was decided after the DW. The general recreational fleet comprises the charterboat and private boat fleets, while the headboat fleet stands alone. The decision was made to separate headboat from all other recreational fishing modes because length compositions diverge later in the time series. The general recreational fleet discards contained some zeros (years 1982, 1986, and 1990) that the panel considered unlikely to be accurate due to the magnitude of the surrounding years' values. The decision was made by the panel to fill in the zeros with the lowest observed discards in the regulatory time block of the zero value. Total removals as used in the assessment are in Table 3.

2.2.3 Indices of Abundance

The DW provided a SERFS chevron trap and video index separately. However, because the data are collected from the same sampling platforms (i.e. cameras mounted on the chevron traps), the two indices are not independent measures of abundance. Therefore, the panel decided to combine the two using the Conn (2010) method for combining indices. All indices and their corresponding CVs are shown in Table 4, and Figure 1 shows the indices as recommended by the data workshop plotted with the new CVID index for comparison. Fishery dependent indices of abundance were assumed to have CVs of 0.2, which is consistent with Francis (2003).

2.2.4 Length Compositions

Length compositions for all data sources were developed in 3-cm bins over the range 21–99 cm (labeled at bin center). All lengths below and above the minimum and maximum bins were pooled. The commercial handline, general recreational and headboat lengths were weighted by the region and landings (SEDAR41-AW05 2015). For inclusion, length compositions in any given year had to meet the sample size criteria of $nfish > 30$ and $ntrips \geq 10$ (Table 5). Furthermore, the AW panel decided to eliminate length comps where age comps were available. There were conflicts between the length compositions and age compositions, and the panel thought, given the relative ease of ageing this species and the fact the model is age-structured, the age compositions would provide more informative signals of year-class strength and better represent the catch in each fleet or survey.

2.2.5 Age Compositions

For age composition data, the upper range was pooled at 13 years old because a very small proportion of the data exist past age 13. The age compositions were weighted by the length compositions in attempt to address bias in selection of fish to be aged. For inclusion, age compositions in any given year had to meet the sample size criteria of $nfish > 10$ and $ntrips \geq 10$ (Table 5). Age composition was preferred over length composition when both were available from a given fleet in a given year. Age compositions were further corrected at the Review Workshop (SEDAR41-RW07 2016).

2.2.6 Additional Data Considerations

Size limits were in place beginning in 1983 (12 inch minimum size limit TL), and changed in 1992 (20 inch minimum size limit TL). A moratorium was put in place for Red Snapper in 2010, and three subsequent mini-seasons were allowed (2011-2014) with no size limit. The panel examined size composition data and determined that three time blocks should be used to account for size limits, or the lack thereof: 1950-1991, 1992-2009, and 2010-2014. Data available for this assessment are summarized in Tables 1–5.

3 Stock Assessment Methods

3.1 Overview

The primary model discussed during the Assessment Workshop (AW) was a statistical catch-age model implemented using the Beaufort Assessment Model (BAM) software (Williams and Shertzer 2015). BAM applies a statistical catch-age formulation, coded using AD Model Builder (Fournier et al. 2012). BAM is referred to as an integrated analysis because it uses all population dynamics-relevant data (e.g. removals, length and age compositions, and indices of abundance) in a single modeling framework. In contrast, production models (e.g. ASPIC or ASPM) or catch curve analyses only use subsets of the available data and often require simplifying assumptions. In essence, the catch-age model simulates a population forward in time while including fishing processes (Quinn and Deriso 1999; Shertzer et al. 2008). Quantities to be estimated are systematically varied until characteristics of the simulated population matches available data on the real population. The model is similar in structure to Stock Synthesis (Methot 1989; 2009). Versions of BAM have been used in previous SEDAR assessments of reef fishes in the U.S. South Atlantic, such as Red Porgy, Black Sea Bass, Tilefish, Blueline Tilefish, Gag, Greater Amberjack, Red Grouper, Snowy Grouper, and Vermilion Snapper, as well as in the previous SEDAR assessments of Red Snapper (SEDAR24 2010). In addition, a surplus production model implemented using ASPIC and a catch curve analysis (SEDAR41-AW08 2015) were used to provide supplementary information.

3.2 Data Sources

The catch-age model included data from three fleets that caught Red Snapper in southeastern U.S. waters: general recreational (charter and private boat), commercial handlines (hook-and-line), and recreational headboats. The model was fitted to data on annual landings (in numbers for the recreational fleets, in whole weight for commercial fleet); annual discards (in numbers for all fleets), annual length compositions of removals; annual age compositions of landings and surveys; three fishery dependent indices of abundance (commercial handlines, headboat, and headboat discards); and one fishery independent index of abundance (combined SERFS chevron trap and SERFS video index). Removals included landings and dead discards, assuming the mortality rates provided by the Data Workshop. Data used in the model are tabulated in §2 of this report.

3.3 Model Configuration

The assessment time period was 1950–2014. A general description of the assessment model follows.

3.4 Stock dynamics

In the assessment model, new biomass was acquired through growth and recruitment, while abundance of existing cohorts experienced exponential decay from fishing and natural mortality. The population was assumed closed to immigration and emigration. The model included age classes $1 - 20^+$, where the oldest age class 20^+ allowed for the accumulation of fish (i.e., plus group).

3.5 Initialization

Initial (1950) numbers at age assumed the stable age structure computed from expected recruitment and the initial, age-specific total mortality rate. That initial mortality was the sum of natural mortality and fishing mortality, where fishing mortality was the product of an initial fishing rate (F_{init}) and F-weighted average selectivity. The initial fishing rate was estimated using a prior centered around $F_{\text{init}} = 0.03$. The assumption matches what was used for SEDAR24 with the justification that the value should be small given the relatively low volume of landings prior to the assessment period. The initial recruitment in 1950 was assumed to be the expected value from the spawner-recruit curve. For the remainder of the initialization period (1950–1977), recruitment was assumed equal to expected values. Without sufficient age/length composition data prior to 1978, there is little information to estimate those historic recruitment deviations with accuracy.

3.6 Natural mortality rate

The natural mortality rate (M) was assumed constant over time, but decreasing with age. The form of M as a function of age was based on Charnov et al. (2013), a change from SEDAR24 which based natural mortality on the findings of Lorenzen (1996). The Charnov et al. (2013) approach inversely relates the natural mortality at age to somatic growth. As in previous SEDAR assessments, the age-dependent estimates of M_a were rescaled to provide the same fraction of fish surviving from age 4 through the oldest observed age (51 yr) as would occur with constant $M = 0.134$. This approach using cumulative mortality allows that fraction at the oldest age to be consistent with the findings of Then et al. (2014).

3.7 Growth

Mean size at age of the population, fishery removals under no size limit, and fishery removals under a 20 inch size limit (total length, TL) were modeled with the von Bertalanffy equation, and weight at age (whole weight, WW) was modeled as a function of total length (Figure 2, Table 2). Parameters of growth and conversions (TL-WW) were treated as input to the assessment model. For fitting length composition data, the distribution of size at age was assumed normal with a CV estimated by the assessment model for each growth curve.

3.8 Female maturity and sex ratio

Female maturity was modeled with a logistic function; parameters for this model and a vector of maturity at age were provided by the DW and treated as input to the assessment model (Table 2). The sex ratio was assumed to be 50:50, as recommended by the DW.

3.9 Spawning stock

Spawning biomass was modeled as population fecundity (number of eggs). For Red Snapper, peak spawning was considered to occur at the end of June. This included information on batch size as a function of age, as well as information on the number of annual batches as a function of age (SEDAR41-DW49 (2015) and Fitzhugh et al. (2012)).

3.10 Recruitment

Expected recruitment of age-1 fish was predicted from spawning biomass using the Beverton–Holt spawner-recruit model. Steepness, h, is a key parameter of this model, and unfortunately it is often difficult to estimate reliably (Conn et al. 2010). In this assessment, many initial attempts to estimate steepness resulted in a value near its upper bound of 1.0, indicating that the data were insufficient for estimation. Likelihood profiling showed that the value was likely above 0.92, and was unreliably estimated between 0.92 and 0.98. The AW Panel decided to assume an average annual recruitment while estimating lognormal deviations around that average. This was achieved by fixing steepness at $h = 0.99$.

3.11 Landings

Time series of landings from three fleets were modeled: commercial handline (1950–2014), general recreational (1955–2014), and headboat (1955–2014). Landings were modeled with the Baranov catch equation (Baranov 1918) and were fitted in either weight or numbers, depending on how the data were collected (1000 lb whole weight for commercial fleets, and 1000 fish for recreational). The DW provided observed landings back to the first assessment year (1950) for the commercial fleet and back to 1955 for the recreational fleets. However, sampling of headboats began in 1972 and other recreational sectors in 1981. Thus, historic landings of the recreational fleets were estimated indirectly by the DW using the FHWAR ratio method (SEDAR41-DW17). Historic landings were considered (and treated) in this assessment as a primary source of uncertainty.

3.12 Discards

As with landings, discard mortalities (in units of 1000 fish) were modeled with the Baranov catch equation (Baranov 1918), which required estimates of discard selectivities and release mortality probabilities. Discards were assumed to have fleet-specific, year-specific mortality probabilities, as suggested by the DW. Until 2007, the rate for commercial handlines was 0.48, and 0.38 thereafter. Until 2011, the general recreational and headboat rate was 0.37, with 0.285 thereafter. Annual discard mortalities, as fit by the model, were computed by multiplying total discards (tabulated in the DW report) by the fleet-specific and year-specific discard mortality rate. For general recreational and headboat fleets, discard time series were assumed to begin in 1981; for the commercial handlines fleet, discards were modeled starting in 1992 corresponding to the implementation of the 20-inch size limit.

3.13 Fishing

For each time series of removals (landings and discards), the assessment model estimated a separate full fishing mortality rate (F). Age-specific rates were then computed as the product of full F and selectivity at age. The across-fleet annual F was represented by apical F, computed as the maximum of F at age summed across fleets.

3.14 Selectivities

Selectivity curves applied to landings were estimated using a parametric approach. This approach applies plausible structure on the shape of the curves, and achieves greater parsimony than occurs with unique parameters for each age. Flat-topped selectivities were modeled as a two-parameter logistic function. Dome-shaped selectivities were modeled by combining two logistic functions: a two-parameter logistic function to describe the ascending limb of the curve, and a two-parameter logistic function to describe the descending limb. To model landings, the AW Panel recommended flat-topped selectivity for commercial handlines and dome-shaped selectivity for headboat and the general recreational fleets.

The assessment panel devoted substantial discussion and exploration to the pattern (flat-topped or dome-shaped) of selectivity at age. Several working papers and scientific literature (SEDAR24-AW05, SEDAR24-AW09, SEDAR24-AW12, SEDAR31-AW04, SEDAR31-AW12, SEDAR41-DW50, SEDAR41-DW08, Patterson et al. (2012), Wells et al. (2008), and Mitchell et al. (2014)) helped guide the panel's decisions by providing insight into selectivity based on length and age compositions, depth distributions of fishing effort, skill levels of fishermen, and how circumstances contrasted between the Atlantic and Gulf of Mexico. The choice of flat-topped selectivity for commercial handlines landings and dome-shaped for all others was based on several criteria. Two related considerations were the fleet-specific depths of fishing effort and the distribution of age at depth. In general, the commercial handlines fleet fish

in deeper water than other fleets, and although there was only weak correlation between depth and age of older fish (5^+), younger fish (1–5) were more readily caught in shallower depths (SEDAR24-AW05, and Mitchell et al. (2014)). It was also suggested that commercial gear and fishermen can better handle larger fish (SEDAR24-AW12). Catch curve data were consistent with the hypothesis that older fish are more vulnerable to the commercial handlines fleet than to recreational fleets (SEDAR41-AW08 2015).

Selectivity of each fleet was fixed within each block of size-limit regulations, but was permitted to vary among blocks where possible or reasonable. Fisheries experienced four blocks of size-limit regulations (no limit prior to 1983, 12-inch limit during 1983–1991, 20-inch limit during 1992–2009, and no size limit during the moratorium/miniseasons 2010–2014). However, the panel combined blocks one and two after seeing that the 12-inch size limit had a negligible effect on the selectivity pattern. Age and length composition data are critical for estimating selectivity parameters, and ideally, a model would have sufficient composition data from each fleet over time to estimate distinct selectivities in each period of regulations. That was not the case here, and thus additional assumptions were applied to define selectivities, as follows. Because the general recreational fleet had little age or length composition data prior to 1998, this fleet mirrored the headboat fleet until the final time block. All domed-shaped selectivities meant to characterize landings were configured so as not to allow a selectivity of 0 at older ages, which was considered implausible. Size and age composition data show larger, older fish are caught by all fleets. However, the selectivity functions would reach zero before the plus group age of 20. Therefore, the panel examined the age composition data and used the information they contained to create a plus group for the selectivities. Headboat selectivities were fixed as constant after age 10 at the value estimated for age 10. For the general recreational fleet, the constant age at which we fixed selectivity was 13. These plus groups were consistent with how the age composition data were fitted.

Selectivities of discards were estimated in a similar fashion to the landings in that the general recreational fleet discards mirrored the headboat fleet discards. Both the commercial handline discards and the headboat discards had sufficient length composition to estimate selectivities.

Selectivities of fishery dependent indices were the same as those of the relevant fleet. The fishery independent CVID index selectivity was assumed logistic and informed by the SERFS chevron trap age compositions.

3.15 Indices of abundance

The model was fit to three fishery dependent indices of relative abundance (headboat 1976–2009; headboat discards 2005–2014; and commercial handlines 1993–2009), and one fishery independent index of abundance (SERFS combined video and trap, CVID). Predicted indices were conditional on selectivity of the corresponding fleet or survey, and were computed from abundance at the midpoint of the year or, in the case of commercial handlines, biomass. The headboat discard index tracks small fish (less than 20 inches) and was included as a measure of recruitment strength.

3.16 Catchability

In the BAM, catchability scales indices of relative abundance to the estimated population at large. For the base model, the AW Panel recommended a time-invariant catchability.

A sensitivity run adopted a time-varying catchability for the headboat index. In this formulation, catchability was estimated in two stanzas, pre- and post-1992. Choice of the year 1992 was based on the implementation of a fishery management plan that may have changed fishing behavior.

3.17 Biological reference points

Biological reference points (benchmarks) were calculated based on the fishing rate that would allow a stock to attain 30% of the maximum spawning potential which would have been obtained in the absence of fishing mortality. Computed benchmarks included the MSY proxy, fishing mortality rate at $F_{30\%}$, total biomass at $F_{30\%}$, and spawning stock at $F_{30\%}$ (Gabriel and Mace 1999). In this assessment, spawning stock measures total eggs of the mature stock. These benchmarks are conditional on the estimated selectivity functions and the relative contributions of each fleet's fishing mortality. The selectivity pattern used here was the effort-weighted selectivities at age, with effort from each fleet estimated as the full F averaged over the last three years of the assessment.

3.18 Fitting criterion

The fitting criterion was a penalized likelihood approach in which observed removals (landings and discards) were fit closely, and observed composition data and abundance indices were fit to the degree that they were compatible. Removals and index data were fit using lognormal likelihoods. Length and age composition data were fit using robust multinomial likelihoods (Francis 2011), and only from years that met minimum sample size criteria ($nfish > 30$ and $ntrips \geq 10$) for length compositions and ($nfish > 10$ and $ntrips \geq 10$) for age compositions. Commercial and headboat discard length composition minimum sample size threshold was set lower ($nfish > 10$) due to the fact that the discard composition data were the only information available to estimate selectivity.

The model includes the capability for each component of the likelihood to be weighted by user-supplied values. For data components, these weights were applied by either adjusting CVs (lognormal components) or adjusting effective sample sizes (multinomial components). In this application to Red Snapper, CVs of landings and discards (in arithmetic space) were assumed equal to 0.05, to achieve a close fit to these time series yet allowing some imprecision. In practice, the small CVs are a matter of computational convenience, as they help achieve the desired result of close fits to the landings, while avoiding having to solve the Baranov equation iteratively (which is complex when there are multiple fisheries). Weights on other data components (indices, age/length compositions) were adjusted iteratively, starting from initial weights as follows. The CVs of indices were set equal to the values estimated by the GLMs used for standardization or at the fixed value of 0.2 for the headboat and commercial handline indices. Effective sample sizes of the multinomial components were assumed equal to the number of trips sampled annually, rather than the number of fish measured, reflecting the belief that the basic sampling unit occurs at the level of trip. These initial weights were then adjusted until standard deviations of normalized residuals were near 1.0 (Francis 2011). In sensitivity runs, weights on the fishery dependent indices were adjusted upward to explore their effects (not because up-weighted runs were considered equally plausible).

For parameters defining selectivities, CV of size at age, and σ_R, normal priors were applied to maintain parameter estimates near reasonable values, and to prevent the optimization routine from drifting into parameter space with negligible gradient in the likelihood. For σ_R, the prior mean (0.6) and standard deviation (0.25) were based on Beddington and Cooke (1983) and Mertz and Myers (1996).

3.19 Configuration of a base run

The base run was configured as described above. This configuration does not necessarily represent reality better than all other possible configurations, and thus this assessment attempted to portray uncertainty in point estimates through sensitivity analyses and through a Monte-Carlo/bootstrap approach (described below).

3.20 Sensitivity analyses

Sensitivity runs were chosen to investigate issues that arose specifically with this benchmark assessment. They were intended to demonstrate directionality of results with changes in inputs or simply to explore model behavior, and not all were considered equally plausible. These model runs vary from the base run as follows:

- S1: Remove the 2008 and 2009 years from the handline and headboat indices
- S2: Upweight fishery independent index further than was explored in the Assessment Workshop (10X likelihood weight after the iterative reweighting)
- S3: Upweight handline and headboat indices (3X likelihood weight after iterative reweighting)
- S4: Fishery dependent indices only
- S5: High value of M
- S6: Low value of M
- S7: Low discard mortality probabilities (commercial handlines rate set to 0.38 or 0.28, all recreational set to 0.27 or 0.20)
- S8: High discard mortality probabilities (commercial handlines rate set to 0.58 or 0.48, all recreational set 0.45 or 0.36)
- S9: Longer combined chevron trap and video (CVID) index (2005-2014)
- S10: Reduced general recreational landings in 1984 and 1985 by taking the geometric mean of surrounding years
- S11: Steepness $h = 0.84$
- S12: Headboat discard index excluded after 2009
- S13: Ageing error matrix included
- S14: Low value for age-specific number of batches
- S15: High value for age-specific number of batches
- S16: Headboat discard index dropped
- S17: High landings
- S18: Low landings
- S19: High discards
- S20: Low discards
- S21: Dome-shaped selectivity for commercial handline fleet
- S22: Separate video and trap index rather than a single CVID index
- S23: Fishery independent index only
- S24: Continuity run: changes include SEDAR24 values such as M, steepness, maturity, and SSB
- S25: Two time blocks for Headboat logbook index catchability (pre- and post-1992)
- S26: Retrospective - 1 year of data
- S27: Retrospective - 2 years of data
- S28: Retrospective - 3 years of data
- S29: Retrospective - 4 years of data

- S30: Use 1978 as the starting year, applied a loose prior to the estimation of F_{init} that corresponds to the geometric mean of the fishing mortality for 1950-1977
- S31: Estimate selectivities without fixing a plus group (for the selectivity estimation)

Sensitivities 5, 6, 14, 15, and 17-20 used the 10th and 90th quantiles (as the low and the high respectively) from the bootstraps of the observed data described in the uncertainty analysis methods (Section 3.24).

3.21 Parameters Estimated

The model estimated annual fishing mortality rates of each fleet, selectivity parameters, catchability coefficients associated with indices, parameters of the spawner-recruit model (except steepness), annual recruitment deviations, and CV of size at age for each age and growth relationship.

3.22 Per Recruit and Equilibrium Analyses

Yield per recruit and spawning potential ratio were computed as functions of F, as were equilibrium landings and spawning biomass. Equilibrium landings and discards were also computed as functions of biomass B, which itself is a function of F. As in the computation of benchmarks (described in §3.23), per recruit and equilibrium analyses applied the most recent selectivity patterns averaged across fleets, weighted by each fleet's F from the last three years of the assessment (2012–2014).

3.23 Benchmark/Reference Point Methods

In this assessment of Red Snapper, the quantities $F_{30\%}$, $\mathrm{SSB}_{\mathrm{F}30\%}$, $B_{\mathrm{F}30\%}$, and $L_{\mathrm{F}30\%}$ were estimated as proxies for MSY-based reference points. Steepness was not reliably estimable, so the stock-recruit relationship was not used to identify a maximum yield. Instead, steepness was fixed at 0.99 in order to assume an average level of recruitment while estimating deviations around the mean. $F_{30\%}$ was used in the rebuilding plan for Red Snapper, therefore, it was used here to generate fishing benchmarks. However, because the stock-recruitment relationship was not estimated, assumptions about recruitment are required to generate biomass benchmarks. Here, equilibrium recruitment was assumed equal to expected recruitment (arithmetic average). On average, expected recruitment is higher than that estimated directly from the spawner-recruit curve, because of lognormal deviation in recruitment. Thus, in this assessment, the method of benchmark estimation accounted for lognormal deviation by including a bias correction in equilibrium recruitment. The bias correction (ς) was computed from the variance (σ_R^2) of recruitment deviation in log space: $\varsigma = \exp(\sigma_R^2/2)$. Then, equilibrium recruitment (R_{eq}) associated with any F is,

$$R_{eq} = \frac{R_0 \left[\varsigma 0.8 h \Phi_F - 0.2(1-h)\right]}{(h-0.2)\Phi_F} \tag{1}$$

where R_0 is virgin recruitment, h is steepness which is fixed in this assessment, and $\Phi_F = \phi_F/\phi_0$ is spawning potential ratio given growth, maturity, and total mortality at age (including natural and fishing mortality rates). Because steepness is fixed at 0.99, R_{eq} as a function of F is approximately a straight line. The R_{eq} and mortality schedule imply an equilibrium age structure and an average sustainable yield (ASY). The estimate of $F_{30\%}$ is the F giving 30% of the SPR, and the estimate of $L_{\mathrm{F}30\%}$ is that ASY. The estimate of $\mathrm{SSB}_{\mathrm{F}30\%}$ follows from the corresponding equilibrium age structure, as does the estimate of discard mortalities $D_{F30\%\}}$, here separated from ASY (and consequently, $L_{\mathrm{F}30\%}$).

Estimates of $L_{\text{F30\%}}$ and related benchmarks are conditional on selectivity pattern. The selectivity pattern used here was an average of terminal-year selectivities from each fleet, where each fleet-specific selectivity was weighted in proportion to its corresponding estimate of F averaged over the last three years (2012–2014). If the selectivities or relative fishing mortalities among fleets were to change, so would the estimates of $L_{\text{F30\%}}$ and related benchmarks.

The maximum fishing mortality threshold (MFMT) is defined by the SAFMC as $F_{30\%}$, and the minimum stock size threshold (MSST) as 75%$\text{SSB}_{\text{F30\%}}$. Overfishing is defined as $F >$ MFMT and overfished as SSB < MSST. However, because this stock is currently under a rebuilding plan, increased emphasis is given to SSB relative to $\text{SSB}_{\text{F30\%}}$ (rather than MSST), as $\text{SSB}_{\text{F30\%}}$ is the rebuilding target. Current status of the stock is represented by SSB in the latest assessment year (2014), and current status of the fishery is represented by the geometric mean of F from the latest three years (2012–2014). Recent SEDAR assessments have considered the mean over the terminal three years to be a more robust metric.

3.24 Uncertainty and Measures of Precision

As in SEDAR24, this assessment used a mixed Monte Carlo and bootstrap (MCB) approach to characterize uncertainty in results of the base run. Monte Carlo and bootstrap methods (Efron and Tibshirani 1993; Manly 1997) are often used to characterize uncertainty in ecological studies, and the mixed approach has been applied successfully in stock assessment, including Restrepo et al. (1992), Legault et al. (2001), SEDAR4 (2004), and many South Atlantic SEDAR assessments since SEDAR19 (2009). The approach is among those recommended for use in SEDAR assessments (SEDAR Procedural Guidance 2010).

The approach translates uncertainty in model input into uncertainty in model output, by fitting the model many times with different values of "observed" data and key input parameters. A chief advantage of the approach is that the results describe a range of possible outcomes, so that uncertainty is characterized more thoroughly than it could be by any single fit or handful of sensitivity runs. A minor disadvantage of the approach is that computational demands are relatively high.

In this assessment, the BAM was successively re-fit in $n = 4000$ trials that differed from the original inputs by bootstrapping on data sources, and by Monte Carlo sampling of several key input parameters. The value of $n = 4000$ was chosen because a minimum of 3000 runs were desired, and it was anticipated that not all runs would converge or otherwise be valid. Of the 4000 trials, approximately 1.9% were discarded, because the model did not properly converge (in most cases, an estimated quantity was at its upper bound). This left $n = 3926$ MCB trials used to characterize uncertainty, which was sufficient for convergence of standard errors in management quantities.

The MCB analysis should be interpreted as providing an approximation to the uncertainty associated with each output. The results are approximate for two related reasons. First, not all combinations of Monte Carlo parameter inputs are equally likely, as biological parameters might be correlated. Second, all runs are given equal weight in the results, yet some might provide better fits to data than others.

3.24.1 Bootstrap of observed data

To include uncertainty in the indices of abundance, multiplicative lognormal errors were applied through a parametric bootstrap. To implement this approach in the MCB trials, random variables ($x_{s,y}$) were drawn for each year y of time series s from a normal distribution with mean 0 and variance $\sigma^2_{s,y}$ [that is, $x_{s,y} \sim N(0, \sigma^2_{s,y})$]. Annual observations were then perturbed from their original values ($\hat{O}_{s,y}$),

$$O_{s,y} = \hat{O}_{s,y}[\exp(x_{s,y} - \sigma^2_{s,y}/2)] \tag{2}$$

The term $\sigma^2_{s,y}/2$ is a bias correction that centers the multiplicative error on the value of 1.0. Standard deviations in log space were computed from CVs in arithmetic space, $\sigma_{s,y} = \sqrt{\log(1.0 + CV^2_{s,y})}$. As used for fitting the base run, CVs of indices of abundance were those provided by, or modified from, the data providers (tabulated in Table 4 of this assessment report).

Uncertainty was modeled for historical commercial landings similarly to the indices, and by the CVs provided by the commercial working group at the DW. No commercial discard CVs, headboat landings CVs, or headboat discard CVs by year were provided, therefore the panel had to make some assumptions. We assumed a value of $CV = 0.20$ for commercial discards and headboat discards. For headboat landings, we used information from the headboat program to assume a decreasing CV by time blocks (i.e. $CV = 0.15$ 1981-1995, $CV = 0.1$ for 1996-2007, and $CV = 0.05$ thereafter). General recreational landings and discards had complementary CVs, and those were used as provided except in a few instances. A CV greater than 1 was capped at 1, which was sufficiently large to represent high uncertainty but not so high that bootstrapped values caused implausible time series. The panel thought the resulting draws sufficiently represented uncertainty in spite of the dampening of a few years' CVs (Table 6).

Uncertainty in age and length compositions were included by drawing new distributions for each year of each data source, following a multinomial sampling process. Ages (or lengths) of individual fish were drawn at random with replacement using the cell probabilities of the original data. For each year of each data source, the number of fish sampled was the same as in the original data.

3.24.2 Monte Carlo sampling

In each successive fit of the model, several parameters were fixed (i.e., not estimated) at values drawn at random from distributions described below.

3.25 Natural mortality

A vector of age-specific natural mortality was provided by the Life History Working Group. They used the Charnov et al. (2013) estimator scaled to the Then et al. (2014) max age asymptotic M, and then used the uncertainty around the determination of maximum age to provide an upper and lower bound to the M vector. The Assessment Panel thought the upper ($M = 0.14$) and lower ($M = 0.12$) bound were too similar to the base vector to represent the true uncertainty around M. Instead, the AW Panel wanted to carry the uncertainty forward in both maximum age and the parameters of the Then et al. (2014) estimator of asymptotic M:

$$M = aT^b_{max} \tag{3}$$

To estimate uncertainty in a and b, we acquired the data of Then et al. (2014) and conducted a bootstrap of $n = 10,000$ iterations, drawing from the original data set with replacement. For each MCB iterations, one of the 10,000 fits was drawn at random, thus maintaining any correlation structure between a and b. We then drew T_{max} from a uniform distribution and calculated asymptotic M. For the age-dependent vector, we started with the Charnov age-dependent curve, and scaled it to the M estimate we calculated in the previous steps. A new M value was drawn and a new age-dependent vector was calculated for each MCB trial.

3.26 Discard mortality

The discard mortality working group provided an upper and lower bound for each time block (pre- and post-regulation) and fishery (commercial and recreational). Commercial rates before 2007 ranged from 38% to 58%, and 2007 to present ranged from 28% to 48%. Recreational rates before 2011 ranged from 27% to 45%, and 2011 on ranged from 20% to 36%. The rates decreased in response to the implementation of circle hooks, which are meant to cause fewer fatal bycatch events. We drew the rate for the earlier time period for each fleet from a truncated normal distribution with mean equal to the point estimate and a standard deviation devised to provide a 95% confidence interval similar to what the working group provided above. For the later time period for each fleet we also drew from a truncated normal distribution created similarly as in the previous step but with the upper bound fixed at the random draw from the earlier time period. The last step is meant to ensure that the second value is not larger than the first, so as to maintain the feature that discard mortality has decreased due to the circle hook regulation.

3.27 Batch Fecundity

Prior to the MCB analysis, a bootstrap procedure was run on the data set used to estimate batch fecundity at age for the base run. For each of 10000 bootstrap runs, the 69 paired observations of batch fecundity and fish length were sampled 69 times with replacement, the regression model refit, and the bootstrap parameters estimates saved to a data matrix. Once all bootstraps were run, the parameter matrix was trimmed by removing runs where either parameter value was outside of its 95% confidence interval. The parameters were found to be highly correlated, so during the MCB analysis, pairs of parameters were randomly drawn, with replacement, from the trimmed bootstrap parameter matrix. For each MCB run, predicted batch fecundity at age was calculated using a set of bootstrap parameters and a vector of length at age.

3.28 Batch number

Prior to the MCB analysis, a similar but separate bootstrap procedure was run on the data set used to estimate batch number at age for the base run. For each of 10000 bootstrap runs, the 1472 paired observations of spawning indicator presence, fish length, and day of the year were sampled 1472 times with replacement and the regression model refit. Predicted batch number at age was then calculated from the bootstrap parameter estimates and a vector of length at age, and the vectors saved to a data matrix. Once all bootstraps were run, the batch number at age matrix was trimmed by first summing batch number at age for each run, yielding lifetime batch number; runs where lifetime batch number was outside of the 95% confidence interval were trimmed. During the MCB analysis, a vector of batch number at age was randomly drawn, with replacement, from the trimmed bootstrap batch number at age matrix for each MCB run.

3.29 Projections

Projections were run to predict stock status in years after the assessment, 2015–2044. The year 2044 is the last year of the current rebuilding plan.

The structure of the projection model was the same as that of the assessment model, and parameter estimates were those from the assessment. Any time-varying quantities, such as recreational selectivity, were fixed to the most recent values of the assessment period. A single selectivity curve was applied to calculate removals, averaged across fleets using geometric mean Fs from the last three years of the assessment period, similar to computation of $L_{\mathrm{F30\%}}$ benchmarks (§3.23).

Expected values of SSB (time of peak spawning), F, recruits, and removals were represented by deterministic projections using parameter estimates from the base run. These projections were built on the spawner-recruit relationship with steepness fixed ($h = 0.99$) and with bias correction, and were thus consistent with estimated benchmarks in the sense that long-term fishing at $F_{30\%}$ would yield $L_{\text{F30\%}}$ from a stock size at $\text{SSB}_{\text{F30\%}}$. Uncertainty in future time series was quantified through stochastic projections that extended the Monte Carlo/Bootstrap (MCB) fits of the stock assessment model.

3.29.1 Initialization of projections

Initial age structure at the start of 2015 was computed by the assessment model.

Fishing rates that define the projections were assumed to start in 2017. Because the assessment period ended in 2014, the projections required an initialization period (2015–2016). For 2015, a moratorium year, the landings selectivity was set to 0 and the discard selectivity was rescaled to peak at 1. Then, an optimization routine solved for the F that matched the current dead discards (mean of 2012-2014) in numbers. In 2016, a similar routine soved for the F that matched current landings (mean of 2012-2014), assuming a mini-season would occur.

3.29.2 Uncertainty of projections

To characterize uncertainty in future stock dynamics, stochasticity was included in replicate projections, each an extension of a single MCB assessment model fit. Thus, projections carried forward uncertainties in natural mortality, reproduction, landings, discards, and discard mortalities, as well as in estimated quantities such as selectivity curves, and in initial (start of 2015) abundance at age.

Initial and subsequent recruitment values were generated with stochasticity using a Monte Carlo procedure, in which the estimated Beverton–Holt model (i.e. R_0, σ_R estimated, and $h = 0.99$) of each MCB fit was used to compute mean annual recruitment values ($\bar{R}_y$). Variability was added to the mean values by choosing multiplicative deviations at random from a lognormal distribution,

$$R_y = \bar{R}_y \exp(\epsilon_y). \tag{4}$$

Here ϵ_y was drawn from a normal distribution with mean 0 and standard deviation σ_R, where σ_R is the standard deviation from the relevant MCB fit.

The procedure generated 20,000 replicate projections of MCB model fits drawn at random (with replacement) from the MCB runs. In cases where the same MCB run was drawn, projections would still differ as a result of stochasticity in projected recruitment streams. Central tendencies were represented by the deterministic projections of the base run, as well as by medians of the stochastic projections. Precision of projections was represented graphically by the 10^{th} and 90^{th} percentiles of the replicate projections.

3.30 Rebuilding time frame

Based on results from the previous SEDAR24 benchmark assessment, Red Snapper is currently under a rebuilding plan. In this plan, the terminal year is 2044, and rebuilding is defined by the criterion that projection replicates achieve stock recovery (i.e., $\text{SSB}_{2044} \geq \text{SSB}_{\text{F30\%}}$) with probability of at least 50%. Here, the probability of stock recovery in each year of the rebuilding plan was computed as the proportion of stochastic projections where $\text{SSB} \geq \text{SSB}_{\text{F30\%}}$, with $\text{SSB}_{\text{F30\%}}$ taken to be iteration-specific (i.e., from that particular MCB run).

Projection scenarios Five projection scenarios were considered.

- Scenario 1: $F = 0$
- Scenario 2: $F = F_{\text{current}}$
- Scenario 3: $F = F_{30\%}$
- Scenario 4: $F_{target} = 98\% F_{30\%}$
- Scenario 5: $F = F_{\text{rebuild}}$, with rebuilding probability of 0.5 in 2044
- Scenario 6: Discards only

The F_{current} is represented by the geometric mean of fishing mortalities from 2012-2014. The F_{rebuild} is defined as the maximum F that achieves rebuilding in the allowable time frame. The discards only scenario treated the initialization year 2016 the same as 2015 (discards only), and then applied the mean F (from 2015-2016) forward starting in 2017.

3.31 Surplus Production Model

3.31.1 Overview

A logistic surplus production model, implemented in ASPIC (Version 7.03; Prager 2005), was used to estimate stock status of Red Snapper off the southeastern U.S. While primary assessment of the stock was performed using the age-structured BAM, the surplus production approach was intended as a complement, for additional comparison with the age-structured model's results. More specifically, this model focuses on the dynamics of the removals as they relate to the indices of abundance, while ignoring any age data or age-structure in the population.

3.31.2 Data Sources

Data sources supplied to a production model include a time series of removals (i.e. landings plus dead discards) and one or more indices of abundance (i.e. catch per unit of effort). These inputs should be in units of biomass (i.e. weight), therefore some of the data developed at the SEDAR41 DW required additional formatting. These changes are detailed below.

Removals

The available removals time series comprised commercial landings (1950-2014), recreational landings (1955-2014), commercial dead discards (1992-2014), and recreational dead discards (1981-2014), in pounds, summed by year.

Commercial Landings

The SEDAR41 DW reported commercial landings in pounds, thus these data did not need to be modified for the production model.

Recreational landings

During the SEDAR41 DW, recreational landings for the historical period (1955-1980) were estimated in numbers of individuals using the The National Survey of Fishing, Hunting, and Wildlife-Associated Recreation Survey (FHWAR) census method (see SEDAR41-DW17). For the contemporary period (1981-2014), the SEDAR-41 DW reported Southeast Region Headboat Survey (SRHS) and Marine Recreational Information Program (MRIP) recreational landings in numbers and weights. Recreational landings from this period did not need to be modified, but were used to convert historical landings to weight.

Following a similar approach used in SEDAR24, recreational landings in weight and numbers for all fleets were combined by year for the first three years of the contemporary period; dividing annual landings in weight by landings in numbers produced annual mean weight estimates. The average of these three mean weights (3.4 lb) was then multiplied by the historical landings in numbers to convert them to weight. The historical and combined contemporary recreational landings series were then joined to produce a single time series of recreational landings, in pounds.

Dead Discards

Discard estimates were generated in numbers at the SEDAR-41 DW. Since many discarded fish survive after release, discard mortality rates were applied to discards in numbers to calculate dead discards. For commercial discards, a discard mortality rate of 0.48 was applied prior to regulations in 2007, and a rate of 0.38 was applied from 2007 onward. For recreational discards, a discard mortality rate of 0.37 was applied prior to regulations in 2011, and a rate of 0.285 was applied from 2011 onward.

Mean weight of commercial discards was estimated by converting lengths of commercial discards to weights using data and a conversion equation supplied by the SEDAR-41 DW, and then calculating the average weight of these individuals. The data on lengths of commercial discards were divided into two time periods before (2007-2009) and after (2010-2013) the fishery was closed. The average estimated weights of commercial discards from each time period (before = 2.93 lb; after = 8.84 lb) were multiplied by discards in numbers, for years before and after the closure, respectively.

Mean weight of recreational discards was estimated by converting lengths of recreational headboat-at-sea observer discards to weights using data and a conversion equation supplied by the SEDAR-41 DW, and then calculating the average weight of these individuals. Year-specific mean weight estimates were multiplied by recreational discards in numbers for corresponding years when available (2005-2014). For years prior to 2005 where year-specific mean weights were not available, discards in numbers were multiplied by the average mean weight across the available years before the 2010 closure (1.96 lb).

Indices of Abundance

Five indices of abundance were produced by the SEDAR-41 DW for Red Snapper: commercial logbook handline index (hereafter commercial handline; units = lb kept per hook-hour), headboat (number of fish kept per angler), headboat-at-sea-observer (number of fish caught $<20''$ per angler), Southeast Reef Fish Survey (SERFS) chevron trap (number of fish caught per trap), and the SERFS video (number of fish observed per video). The commercial handline index was already in weight and did not need to be converted. The headboat index was converted to pounds by multiplying by year-specific mean weights, generated by dividing headboat landings in pounds by landings in numbers for each year. The headboat-at-sea-observer index was converted to pounds by multiplying by the same mean weights used to convert recreational discards to weight. The SERFS chevron trap and video indices were converted to weights by multiplying by year-specific mean weights calculated from combined recreational (headboat and MRIP) landings in weight divided by landings in numbers.

3.31.3 Model Configuration and Equations

Production modeling used the model formulation and ASPIC software (version 7.03) of Prager (1994; 2005). This is an observation-error estimator of the continuous-time form of the Schaefer (logistic) production model (Schaefer 1954; 1957). Estimation was conditioned on catch. The logistic model for population growth is the simplest form of a differential equation which satisfies a number of ecologically realistic constraints, such as a carrying capacity (a consequence of limited resources). When written in terms of stock biomass, this model specifies that

$$\frac{dB_t}{dt} = rB_t - \frac{r}{K}B_t^2 \quad (5)$$

where B_t is biomass in year t, r is the intrinsic rate of increase in absence of density dependence, and K is carrying capacity (Schaefer 1954; 1957). This equation may be rewritten to account for the effects of fishing by introducing an instantaneous fishing mortality term, F_t :

$$\frac{dB_t}{dt} = (r - F_t)B_t - \frac{r}{K}B_t^2 \quad (6)$$

By writing the term F_t as a function of catchability coefficients and effort expended by fishermen in different fisheries, Prager (1994) showed how to estimate model parameters from time series of yield and effort.

For Red Snapper, the model proved difficult to fit. It was configured using various combinations of removals, indices, starting dates, prior distributions and starting values, resulting in approximately 324 configurations. Many of these runs were completed during early model development but many others incorporated small changes to data inputs or model specifications suggested by AW panel members during the Assessment Workshop. As the BAM developed, most of these runs became obsolete and are not presented here. The run configured according to recommendations by the SEDAR41 AW panel is presented here. This model configuration (run 320) contained removals from 1950 to 2014 and the four indices used in the BAM (Comm, HB, HB-at-sea, CVID) from 1976 to 2014. Following the recommendations of the AW panel, the CVID index was upweighted by a factor of three (i.e. CVs divided by three), and the headboat-at-sea index was shifted forward by one year, since it indexes younger fish than the other indices.

Three other runs (318, 319, and 323) are also presented to relate the main run (320) to ASPIC results from the previous Red Snapper assessment (SEDAR 24). All three runs contain only the commercial and headboat indices, starting in 1993 and 1976 respectively, and removals starting in 1950. But in run 318 (the continuity run), the final year of removals and indices is 2009, as in SEDAR 24, while in run 319 (the updated continuity run) the final year of removals and indices is 2014, as in the BAM for the current assessment. Since both the commercial and headboat indices ended in 2009 the only difference between the continuity run and updated continuity run is the removals estimates from 2010-2014. Finally a run was completed (run 323; best configuration $\frac{B_1}{K}$ fixed) that is identical to the best configuration run, but with $\frac{B_1}{K}$ fixed at the estimate for the continuity run, for reasons described below.

To evaluate the uncertainty in the model fit and parameter estimates of the best configuration run, 1000 bootstrap runs were conducted. Percentile confidence intervals were also calculated for parameters.

4 Stock Assessment Results

4.1 Measures of Overall Model Fit

In general, the Beaufort assessment model (BAM) fit well to the available data. Predicted length compositions from the commercial handline and discards from the commercial and headboat fleets were reasonably close to observed data in most years, as were predicted age compositions (Figure 3). The model was configured to fit observed commercial and recreational removals closely (Figures 4–9). Fits to indices of abundance generally captured the observed trends but not all annual fluctuations (Figures 10–13).

4.2 Parameter Estimates

Estimates of all parameters from the catch-age model are shown in Appendix B. Estimates of management quantities and some key parameters are reported in sections below.

4.3 Stock Abundance and Recruitment

In general, estimated abundance at age showed truncation of the older ages through most of the assessment period, but with some signs of increase during the last decade (Figure 14; Table 7). Total estimated abundance was at its lowest value in the early 1990s, but near its highest levels at the end of the time series, comparable to those in the early 1970s, but with a more truncated age structure. The MCB results reflect the same patterns with their associated uncertainties for total abundance and abundance of age 2+ (Figure 18). Annual number of recruits is shown in Table 7 (age-1 column) and in Figure 15. The highest recruitment values were predicted to have occurred in the mid-1980s, 2006, and the terminal year of the model (2014).

4.4 Total and Spawning Biomass

Estimated biomass at age followed a similar pattern as abundance at age (Figure 16; Table 9). Total biomass and spawning biomass showed similar trends—general decline through to the early-1990s, and relatively stable or slowly increasing patterns since the mid-1990s (Figure 17; Table 10). Terminal year estimates are at levels not seen since the 1970s.

4.5 Selectivity

Selectivity of the SERFS index is shown in Figure 19, and selectivities of landings from commercial and recreational fleets are shown in Figures 20, 21, and 22. Selectivities of discards from commercial and recreational fleets are shown in Figures 23, 24, and 25. In the most recent years, full selection occurred near ages 2–4, depending on the fleet and time block.

Average selectivities of landings, dead discards, and the total weighted average of all selectivities were computed from F-weighted selectivities in the most recent three assessment years (Figure 26). This average selectivity was used in computation of point estimates of benchmarks, as well as in projections. All selectivities from each time block, including average selectivities, are tabulated in Tables 11, 12, and 13.

4.6 Fishing Mortality and Removals

Estimates of total F at age are shown in Table 15. In any given year, the maximum F at age (i.e., apical F) may be less than that year's sum of fully selected Fs across fleets. This inequality is due to the combination of two features of estimated selectivities: full selection occurs at different ages among gears and several sources of mortality have dome-shaped selectivity.

Estimated time series of landings and discards are shown in Tables 16, 17, 18, 19. Table 20 shows total landings at age in numbers, and Table 21 in weight. Table 22 shows total discards at age in numbers, and Table 23 in weight. Landings have been dominated by the general recreational and commercial handline fleet until recent years when the general recreational fleet became the dominant source of removals (Tables 16 and 17). Also since 2010, total landings remained below the level at $L_{\mathrm{F30\%}}$ (Figure 29).

Estimated discard mortalities occurred on a smaller scale than landings until the implementation of regulations and the use of mini-seasons, and have been above the $D_{F_{30\%}}$ level for most of the moratorium years (Tables 18 and 19, and Figure 30).

4.7 Spawner-Recruitment Parameters

The Beverton–Holt spawner-recruit curve is shown in Figure 31, along with the effect of density dependence on recruitment, depicted graphically by recruits per spawner as a function of spawning stock (1E8 Eggs). Values of recruitment-related parameters were as follows: steepness $h = 0.99$ (fixed), unfished age-1 recruitment $\widehat{R_0} = 320738$, and standard deviation of recruitment residuals in log space $\widehat{\sigma}_R = 0.81$ (which resulted in bias correction of $\varsigma = 1.40$). Uncertainty in these quantities was estimated through the MCB analysis (Figure 32).

4.8 Per Recruit and Equilibrium Analyses

Yield per recruit and spawning potential ratio were computed as functions of F. These computations applied the most recent selectivity patterns averaged across fleets, weighted by F from the last three years (2012–2014) (Figures 33 and 34).

As in per recruit analyses, equilibrium landings and spawning biomass were computed as functions of F (Figure 35). $F_{30\%}$ is used as a proxy for MSY, and the corresponding landings and spawning biomass are $L_{\mathrm{F30\%}}$ and $\mathrm{SSB}_{\mathrm{F30\%}}$.

4.9 Benchmarks / Reference Points

As described in §3.23, biological reference points (benchmarks) were derived analytically assuming equilibrium dynamics, corresponding to the spawner-recruit curve with fixed steepness $h = 0.99$ (Figure 31). Reference points estimated were $F_{30\%}$, $L_{\mathrm{F30\%}}$, $B_{\mathrm{F30\%}}$ and $\mathrm{SSB}_{\mathrm{F30\%}}$. Based on $F_{30\%}$, three possible values of F at optimum yield (OY) were considered—$F_{\mathrm{OY}} = 65\%F_{30\%}$, $F_{\mathrm{OY}} = 75\%F_{30\%}$, and $F_{\mathrm{OY}} = 85\%F_{30\%}$—and for each, the corresponding yield was computed. Standard errors of benchmarks were approximated as those from MCB analysis (§3.24).

Maximum likelihood estimates (base run) of benchmarks, as well as median values from MCB analysis, are summarized in Table 24. Point estimates of $L_{\mathrm{F30\%}}$-related quantities were $F_{30\%} = 0.15$ (y^{-1}), $L_{\mathrm{F30\%}} = 427.01$ (1000 lb), $B_{\mathrm{F30\%}} = 3637.2$ (mt), and $\mathrm{SSB}_{\mathrm{F30\%}} = 327705.9$ (1E8 Eggs). Median estimates were $F_{30\%} = 0.15$ (y^{-1}), $L_{\mathrm{F30\%}} = 415.17$ (1000 lb), $B_{\mathrm{F30\%}} = 3524.9$ (mt), and $\mathrm{SSB}_{\mathrm{F30\%}} = 293943.5$ (1E8 Eggs). Distributions of these benchmarks from the MCB analysis are shown in Figure 36.

4.10 Status of the Stock and Fishery

Estimated time series of stock status SSB/$SSB_{F30\%}$ showed general decline throughout the beginning of the assessment period, a leveling off, and then a modest increase since 2010 (Figure 37, Table 10). Base-run estimates of spawning biomass have remained below the threshold (MSST) since the early-1970s. Current stock status was estimated in the base run to be SSB/$SSB_{F30\%}$ = 0.15 (Table 24), indicating that the stock has not yet recovered to $SSB_{F30\%}$. Median values from the MCB analysis indicated similar results SSB/$SSB_{F30\%}$ =0.16. The uncertainty analysis suggested that the terminal estimate of stock status is robust (Figures 38, 39). Of the MCB runs, 100% indicated that the stock was below $SSB_{F30\%}$ in 2014. Age structure estimated by the base run showed fewer older fish in the last few decades than the (equilibrium) age structure expected at $L_{F30\%}$ (Figure 40). However, there is improvement in the terminal year(2014), particularly for ages younger than ten.

The estimated time series of $F/F_{30\%}$ suggests that overfishing has occurred throughout most of the assessment period (Table 10, Figure 37). Current fishery status in the terminal year, with current F represented by the geometric mean from 2012–2014, was estimated by the base run to be $F/F_{30\%}$ = 2.7 (Table 24). The fishery status was also robust (Figures 38, 39). Of the MCB runs, approximately 99.1% agreed with the base run that the stock is currently experiencing overfishing.

4.11 Sensitivity and Retrospective Analyses

Sensitivity runs, described in §3.3, were used for exploring data or model issues that arose during the assessment process, for evaluating implications of assumptions in the base assessment model, and for interpreting MCB results in terms of expected effects of input parameters. In some cases, sensitivity runs are simply a tool for better understanding model behavior, and therefore all runs are not considered equally plausible in the sense of alternative states of nature. Time series of $F/F_{30\%}$ and SSB/$SSB_{F30\%}$ are plotted to demonstrate sensitivity to the changing conditions in each run. The sensitivity of the base run to changes in natural mortality, steepness, dome-shaped selectivity for the commercial handline fleet, various index adjusts for both the fishery dependent indices and fishery independent index, the use of an ageing error matrix and high and low levels of landings and discards was explored (Figures 41–53). Sensitivity 24 is a version of a continuity run in that various assumptions made about parameters for SEDAR 24 were adopted for this sensitivity (e.g. higher discard mortalities, lower M, using gonad weight as a proxy for SSB, different female maturity and fecundity information, higher max age, lower steepness, different time of year for peak spawning, and fixed recruitment standard deviation). Time series of stock and fishery status estimated by this assessment are similar to those from the previous, SEDAR24 assessment (Figure 54). Trends in $F/F_{30\%}$ from the two assessments generally track each other, though the magnitude of the variations differ. Trends in SSB/$SSB_{F30\%}$ track each other, though there is divergence at the end of the time series where the current model estimates a more optimistic stock status.

None of the sensitivities show a recovered stock in 2014. A couple sensitivities suggest the stock is undergoing less overfishing than is estimated in the base. However, those runs eliminate the fishery independent index entirely, or upweight the fishery dependent indices to the point of swamping out any signal from the survey data. The vast majority of runs agree with the status indicated by the base run (Figure 55, Table 25). Results appeared to be most sensitive to natural mortality and steepness.

Retrospective analyses suggest a pattern of overestimating fishing mortality in the terminal year, however, the trend is less apparent for SSB (Figure 56).

4.12 Projections

Projections based on $F = 0$ allowed the spawning stock to grow such that the majority of replicate projections recovered to $\mathrm{SSB}_{\mathrm{F30\%}}$ by 2025 (Figure 57, Table 26), however the stock is already in a rebuilding plan so other projections were also requested in the TORs. This was not the case for projections based on $F = F_{\mathrm{current}}$ (Figure 58, Table 27), or if the fishing rate were reduced to $F_{30\%}$ (Figure 59, Table 28) or F_{target} (Figure 60, Table 29). By design, projections based on $F = F_{\mathrm{rebuild}}$ showed recovery with the desired probability in 2044 (Figure 61, Table 30). The projection with discard mortality only showed similar trajectories to the run assuming no other fishing mortality(Table 31 and Figure 62).

4.13 Surplus Production Model

4.13.1 Model Fit

For the best configuration run, model predictions underestimated observed values for the headboat index for the first ten years of the time series (1976-1985; Figure 63). They also underestimated the commercial index during the first five years of that series (1993-1997), while overestimating the headboat index for those same years. The model provided a very poor fit to the headboat-at-sea discard index (2006-2014) but produced a much better fit to the upweighted CVID index (2005-2014). The model did not fit high index values in 2008 and 2009 very closely, but predicted a slight decline from 2007-2009 followed by an increasing trend from 2010 to 2014.

4.13.2 Parameter Estimates and Uncertainty

The ASPIC model fits three main parameters ($\frac{B_1}{K}$, MSY, and F_{MSY}) as well as catchability coefficients (q_i) for each index i. Several other parameters can then be derived from these estimates: $r = 2F_{MSY}$, $K = \frac{2MSY}{F_{MSY}}$ and $B_{MSY} = \frac{K}{2}$. Recent status indicators $\frac{F}{F_{MSY}}$ and $\frac{B}{B_{MSY}}$ are calculated with the most recent estimates of F (2014) and B (2015). Estimates of the main parameters and recent status indicators for all four runs are presented in Table 32. Prior distributions and model estimates of the main parameters for the best configuration run are presented in Figure 64.

Across all runs, most of the main parameters varied very little (e.g. CV $MSY = 0.0027$; CV $F_{MSY} = 0.014$). By contrast $\frac{B_1}{K}$ varied widely (CV $\frac{B_1}{K} = 0.74$), due to variation in B_1 (CV $B_1 = 0.74$) rather than K (CV $K = 0.013$; Table 32). Among bootstrap runs based on the best configuration, distributions of $\frac{B_1}{K}$, MSY, and F_{MSY} were unimodal and relatively symmetrical (Figure 65).

4.13.3 Status of the Stock and Fishery

In the current best configuration run of the surplus production model, $\frac{B}{B_{MSY}}$ is greater than one, suggesting that the South Atlantic stock of Red Snapper is not overfished. The 95% bootstrap percentile confidence intervals for $\frac{B}{B_{MSY}}$ do not contain one (Figure 65). Since the surplus production model estimates that $\frac{F}{F_{MSY}}$ is less than one, the stock is considered to not be undergoing overfishing (Table 32; Figure 66). The 95% bootstrap percentile confidence intervals for $\frac{F}{F_{MSY}}$ do not contain one (Figure 65).

4.13.4 Interpretation

Status indicators in the continuity run (318), agree with the surplus production model from SEDAR 24 that South Atlantic Red Snapper were overfished and undergoing overfishing in 2009 (Table 32). However, in the updated continuity run (319), which is identical to the continuity run except for the 2010-2014 addition of landings data from 2010-2014, the surplus production model suggests that the stock is no longer overfished or undergoing overfishing. Despite several differences between the updated continuity run and the best configuration run (320), described above, most of the parameter estimates and status indicators are similar (Table 32). However the model estimate of $\frac{B_1}{K}$ is much lower in the best configuration run, driven by a lower estimate of B_1. After observing this difference, run 323 was configured by taking the best configuration run and fixing $\frac{B_1}{K}$ at the estimate from the continuity run to investigate potential influence. Fixing $\frac{B_1}{K}$ at this much lower value had little effect on status or most parameters, but caused the estimate of B_1 to go much lower.

As described above, the only data that go into a surplus production model are biomass of removals and abundance indices. Therefore such a model does not make use of many other sources of information such as sex, maturity, growth, fecundity, or population age and size structure. Because such data are available for Red Snapper, a model that uses them would be preferred for a detailed assessment on which to base management.

5 Discussion

5.1 Comments on the Assessment

Estimated benchmarks played a central role in this assessment. Values of $\mathrm{SSB}_{\mathrm{F30\%}}$ and $F_{30\%}$ were used to gauge the status of the stock and fishery to be consistent with established definitions of $MFMT$ and the existing rebuilding plan. The computation of the benchmarks was conditional on selectivity. If selectivity patterns change in the future, for example as a result of new size limits or different relative catch allocations among sectors, estimates of benchmarks would likely change as well.

The base run of the BAM indicated that the stock remains overfished $\mathrm{SSB}/\mathrm{SSB}_{\mathrm{F30\%}}=0.15$, and that overfishing is occurring $F/F_{30\%}=2.7$, though at a lower rate than in 2009 ($F/F_{\mathrm{MSY}}=4.12$ for SEDAR 24). Median values from the MCB analyses were in qualitative agreement with those results. This assessment estimates that, since 2010, the stock has been increasing at a modest rate and is now at levels not seen since the 1970s.

In addition to including the more recent years of data, this benchmark assessment contained several modifications to the previous data of SEDAR24, such as the use of APAIS-adjusted MRIP estimates instead of MRFSS, a new method for the reconstruction of historic recreational catch, the inclusion of a new fishery-independent survey, and the corresponding age composition data. Furthermore, life-history information was updated, including female maturity, sex ratio, growth, natural mortality, fecundity, and meristics. The assessment model itself was also modernized to the current version of BAM. The sum of these improvements should result in a more robust assessment.

In general, fishery dependent indices of abundance may not track actual abundance well, because of factors such as hyperdepletion or hyperstability. Furthermore, this issue can be exacerbated by management measures. In this assessment, the commercial handline and headboat indices generated from logbook data, were not extended beyond 2009 because of the moratorium on Red Snapper. In general, management measures in the southeast U.S. have made the continued utility of fishery dependent indices will be questionable. This situation amplifies the importance of fishery independent sampling and sampling programs conducted by the states.

Many assessed stocks in the southeast U.S. have shown histories of heavy exploitation. High rates of fishing mortality can lead to adaptive responses in life-history characteristics, such as growth and maturity schedules. Such adaptations can affect expected yield and stock recovery, and thus resource managers might wish to consider possible evolutionary effects of fishing in their management plans (Dunlop et al. 2009; Enberg et al. 2009). Indeed, Red Snapper have a very young age at maturity relative to their maximum lifespan, and some have hypothesized that this may be an adaptive response to exploitation.

Because steepness could not be estimated reliably in this assessment, its value in the base run was fixed at 0.99. Fixing steepness at its upper bound was not meant to imply that the stock has perfect compensation at any exploitation or stock level. Rather, it was a computational convenience to use the stock recruitment curve with $h = 0.99$ in order to treat recruitment as an average through time while estimating deviations around that average. Thus MSY-based management quantities are not appropriate, and the AW Panel provided the proxy of $F_{30\%}$ as was used for management subsequent to the last assessment.

The assessment start year was 1950, so as to include the period of largest landings. To initialize the model in 1950, the initial age structure was assumed to be in equilibrium, based on natural mortality at age and F_{init}. Average recruitment was assumed until the recruitment deviations could be estimated at the onset of the composition data (1978). These assumptions are common in assessment models, and they were tested with sensitivity runs where the start was 1978 and with different values of F_{init}. The end results were qualitatively similar, which indicates that the base run is not sensitive to these assumptions.

A complementary analysis was conducted using a surplus production model (ASPIC). ASPIC treats the stock as a pooled biomass and ignores the age structure in the population and the landings. It is unable to take into account that different ages are differentially vulnerable to fishing and therefore was not able to incorporate the (time-varying) selectivities used in the BAM. ASPIC is also not able to take into account that the reproductive contribution of this species increases with age or that there is variability in recruitment through time. ASPIC is useful in examining the relationship between removals and the indices. However, for a long-lived species with age-based data available, the catch-age model (BAM) provides the best illustration of the stock and is a better indicator of stock status, because it can account for the age structure of the population and landings and for year-class strength.

5.2 Comments on the Projections

Projections should be interpreted in light of the model assumptions and key aspects of the data. Some major considerations are the following:

- In general, projections of fish stocks are highly uncertain, particularly in the long term (e.g., beyond 5–10 years).
- Although projections included many major sources of uncertainty, they did not include structural (model) uncertainty. That is, projection results are conditional on one set of functional forms used to describe population dynamics, selectivity, recruitment, etc.
- Fisheries were assumed to continue fishing at their estimated current proportions of total effort, using the estimated current selectivity patterns. New management regulations that alter those proportions or selectivities would likely affect projection results.
- The first five scenarios of projections assumed no change in the selectivity applied to discards. As stock increase generally begins with the smallest size classes, management action may be needed to meet that assumption.
- The projections assumed that the assumed spawner-recruit relationship applies in the future and that past deviations represent future uncertainty in recruitment. If future recruitment is characterized by runs of large or small year classes, possibly due to environmental or ecological conditions, stock projections may be affected.

- Projections apply the Baranov catch equation to relate F and landings using a one-year time step, as in the assessment. The catch equation implicitly assumes that mortality occurs throughout the year. This assumption is violated when seasonal closures or small intensive fishing seasons are in effect, introducing additional and unquantified uncertainty into the projection results.

5.3 Research Recommendations

- Increased fishery independent information, particularly maintaining reliable indices of abundance and composition data streams
- Red Snapper were modeled in this assessment as a unit stock off the southeastern U.S. For any stock, variation in exploitation and life-history characteristics might be expected at finer geographic scales. Modeling such sub-stock structure would require more data, such as information on the movements and migrations of adults and juveniles, as well as spatial patterns of larval dispersal and recruitment. In addition, it is unclear whether a spatial model would improve the assessment.
- More research to describe the juvenile life history of Red Snapper is needed, including more work to identify the location of juveniles before they recruit to the fishery.
- The effects of environmental variation on the changes in recruitment or survivorship.
- The Florida sampling program, during the miniseason in particular, provided invaluable data to this assessment. Programs such as these would be useful in all South Atlantic states, particularly if the management regulations continue to make established methods of index development or composition sampling from fleets less regular or possible.

Table 10. Estimated time series of status indicators, fishing mortality, and biomass. Fishing mortality rate is apical F. Total biomass (B, mt) is at the start of the year, and spawning biomass (SSB, 1E8 eggs) at the time of peak spawning (mid-year). The $MSST_{F30}$ is defined by $\mathrm{MSST} = (1 - M)SSB_{F30}$*, with constant* $M = 0.134$.

Year	F	F/F_{30}	B	$B/B_{unfished}$	SSB	$SSB/SSBB_{F30}$	$SSB/MSST_{F30}$

Table 14. Estimated time series of fully selected fishing mortality rates for commercial handlines (F.cH.L), headboat (F.HB.L), recreational (F.GR.L) landings (L) and discards (D). Also shown is Full F, the maximum F at age summed across fleets, which may not equal the sum of fully selected F's because of dome-shaped selectivities.

Year	F.cH.L	F.HB.L	F.GR.L	F.cH.D	F.HB.D	F.GR.D	Full F

Table 24. Estimated status indicators, benchmarks, and related quantities from the base run of the Beaufort catch-age model, conditional on estimated current selectivities averaged across fleets. Also presented are median values and measures of precision (standard errors, SE) from the Monte Carlo/Bootstrap analysis. Rate estimates (F) are in units of y^{-1}*; status indicators are dimensionless; and biomass estimates are in units of metric tons or pounds, as indicated. Spawning stock biomass (SSB) is measured as population fecundity (number of eggs)*

Quantity	Units	Estimate	Median	SE
$F_{30\%}$	y^{-1}	0.15	0.15	0.01

Table 26. Projection results with fishing mortality rate fixed at $F = 0$ starting in 2017. R = number of age-1 recruits (in 1000s), F = fishing mortality rate (per year), S = spawning stock (1E8 eggs), L = landings expressed in numbers (n, in 1000s) or whole weight (w, in 1000 lb), and D = dead discards expressed in numbers (n, in 1000s) or whole weight (w, in 1000 lb), pr.reb = proportion of stochastic projection replicates with $\mathrm{SSB} \geq \mathrm{SSB}_{\mathrm{F}30\%}$. The extension b *indicates expected values (deterministic) from the base run; the extension* med *indicates median values from the stochastic projections.*

Table 28. Projection results with fishing mortality rate fixed at $F = F_{30\%}$ starting in 2017. R = number of age-1 recruits (in 1000s), F = fishing mortality rate (per year), S = spawning stock (1E8 eggs), L = landings expressed in numbers (n, in 1000s) or whole weight (w, in 1000 lb), and D = dead discards expressed in numbers (n, in 1000s) or whole weight (w, in 1000 lb), pr.reb = proportion of stochastic projection replicates with $\mathrm{SSB} \geq \mathrm{SSB}_{\mathrm{F30\%}}$. *The extension* b *indicates expected values (deterministic) from the base run; the extension* med *indicates median values from the stochastic projections.*

Table 31. Projection results with fishing mortality rate applied only to discards. R = number of age-1 recruits (in 1000s), F = fishing mortality rate (per year), S = spawning stock (1E8 eggs), L = landings expressed in numbers (n, in 1000s) or whole weight (w, in 1000 lb*), and D = dead discards expressed in numbers (n, in 1000s) or whole weight (w, in 1000* lb*), pr.reb = proportion of stochastic projection replicates with* $\mathrm{SSB} \geq \mathrm{SSB}_{\mathrm{F30\%}}$*. The extension* b *indicates expected values (deterministic) from the base run; the extension* med *indicates median values from the stochastic projections.*

Table 32. Parameter estimates from selected ASPIC surplus production model runs 318 (continuity), 319 (updated continuity), 320 (best configuration), and 323 (best configuration with B_1/K fixed) All parameter values are rounded to 3 significant digits. MSY, B_1, and K are in units of 1000 pounds. Catchability parameters correspond to the commercial (q_1), headboat (q_2), headboat-at-sea (q_3), and CVID (q_4) indices.

Run	F/F_{MSY}	B/B_{MSY}	B_1/K	MSY	F_{MSY}	q_1	q_2	q_3	q_4	B_1	K

8 Figures

Figure 1. Indices of abundance used in fitting the assessment model. HB indicates the headboat logbook index; Handline indicated the the commercial handline logbook index; HB Disc indicated the headboat discard observer index, CVT indicates the SERFS chevron trap index; VID indicates the SERFS video index, and CVID indicates the combined chevron trap and video index. The CVT and VID indices were only used during sensitivity runs.

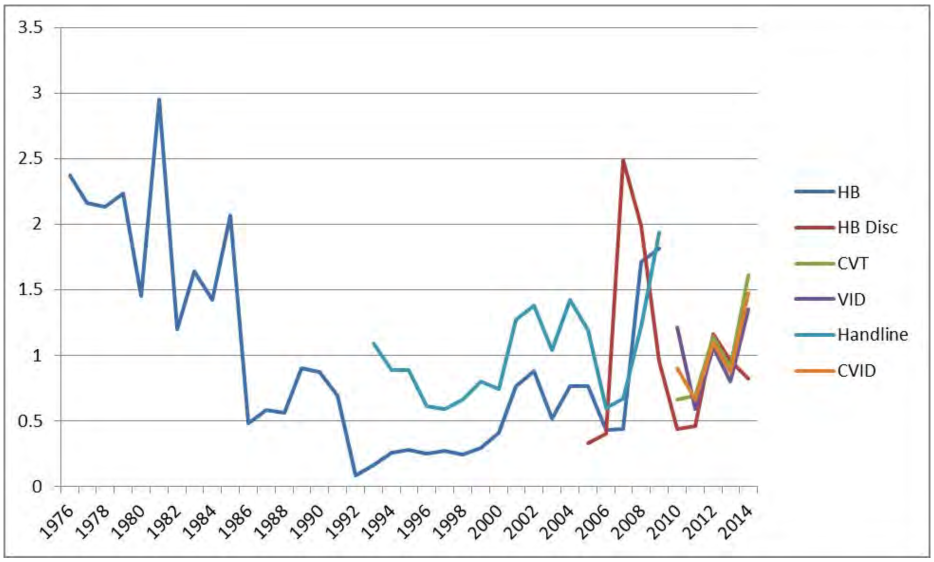

Figure 2. Mean total length at age (mm) and estimated upper and lower 95% confidence intervals of the population.

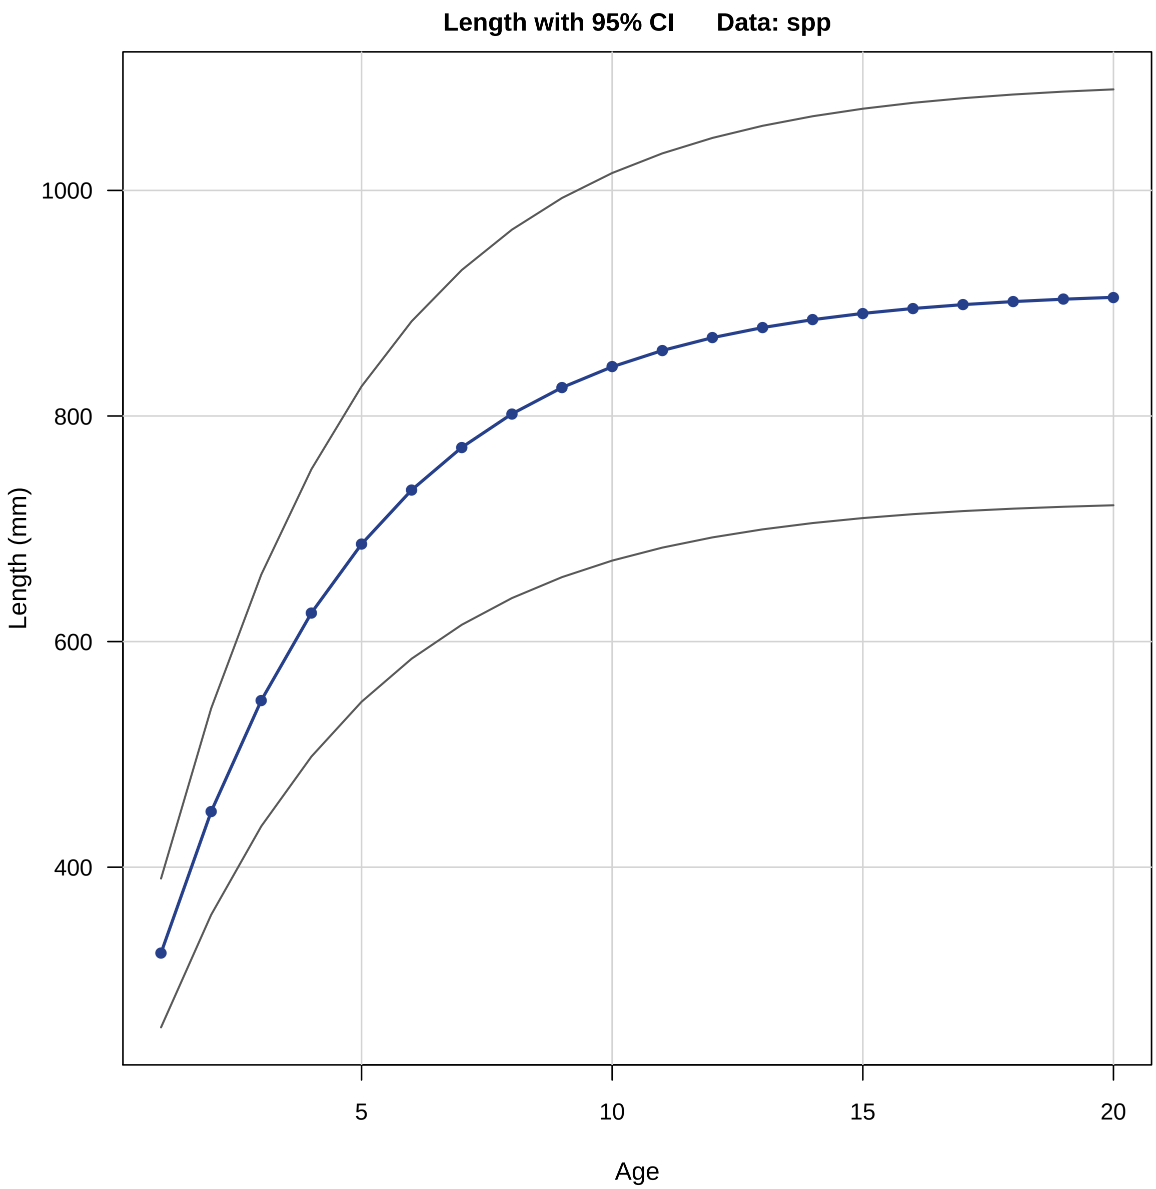

Figure 3. Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey. In panels indicating the data set, lcomp refers to length compositions, acomp to age compositions, CVT to MARMAP chevron trap, cH to commercial handline, HB to headboat and GR to general recreational.

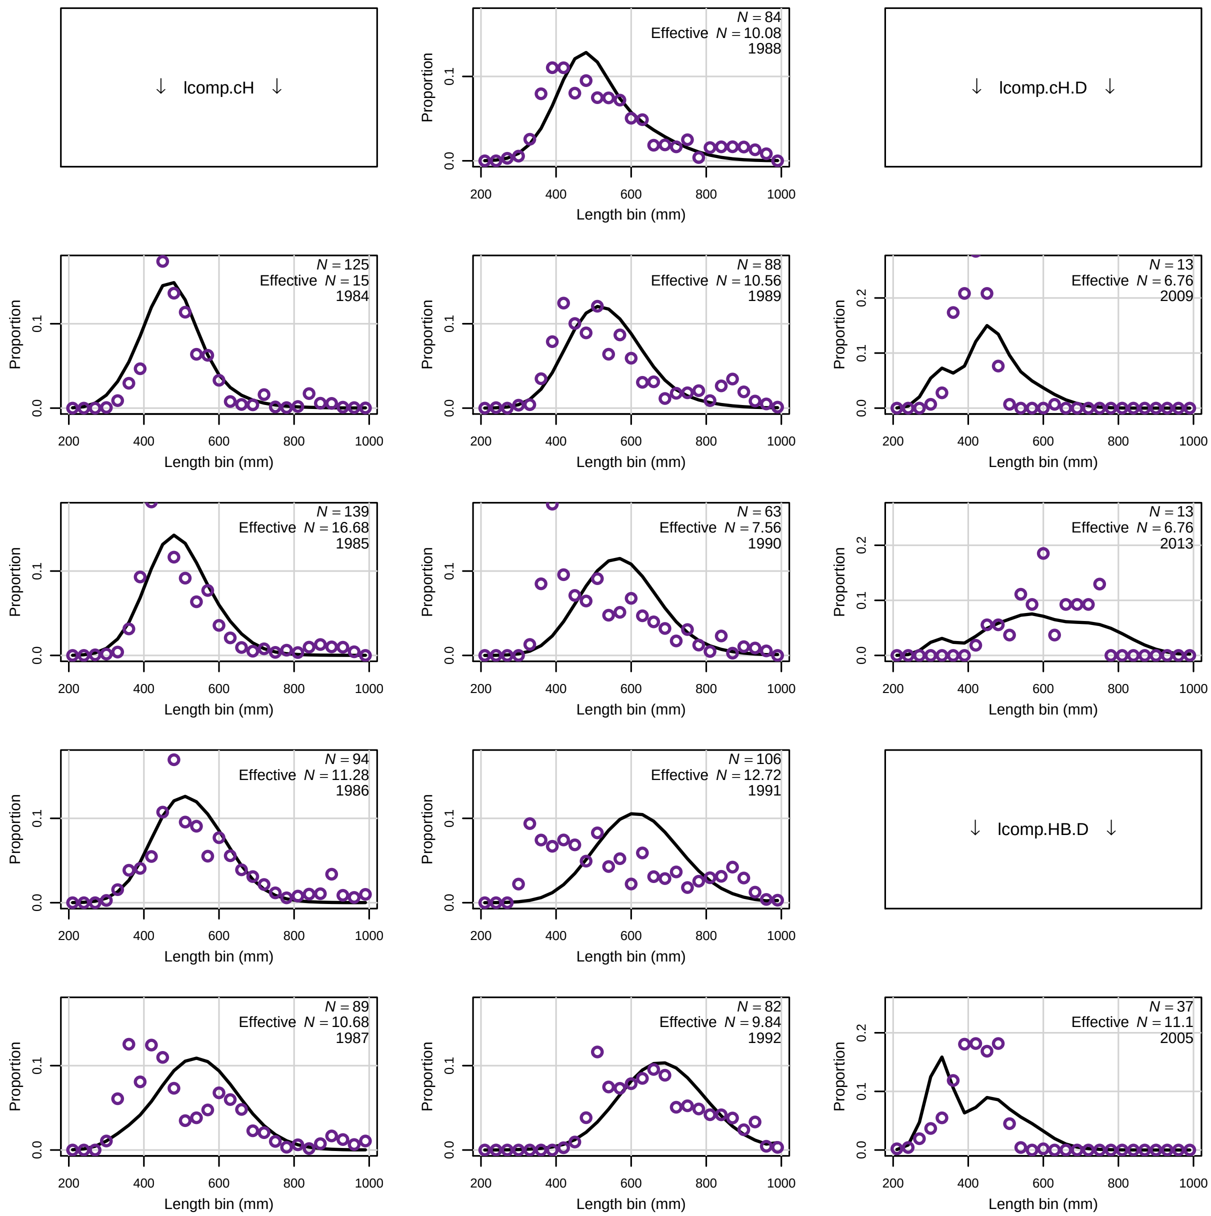

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey.

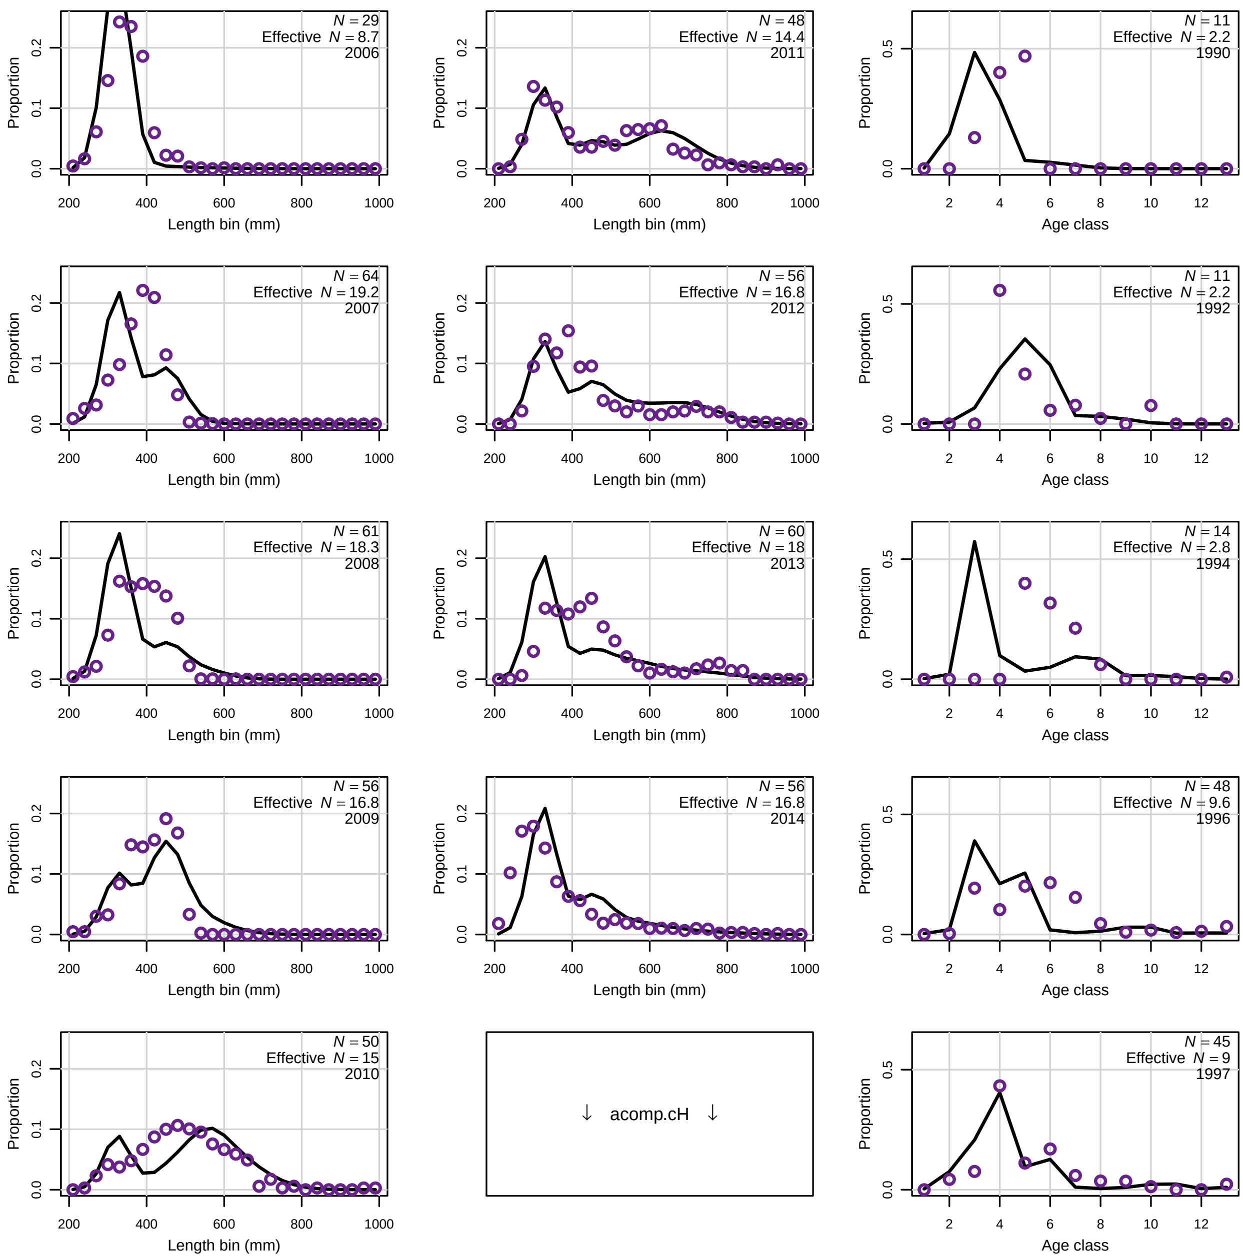

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey.

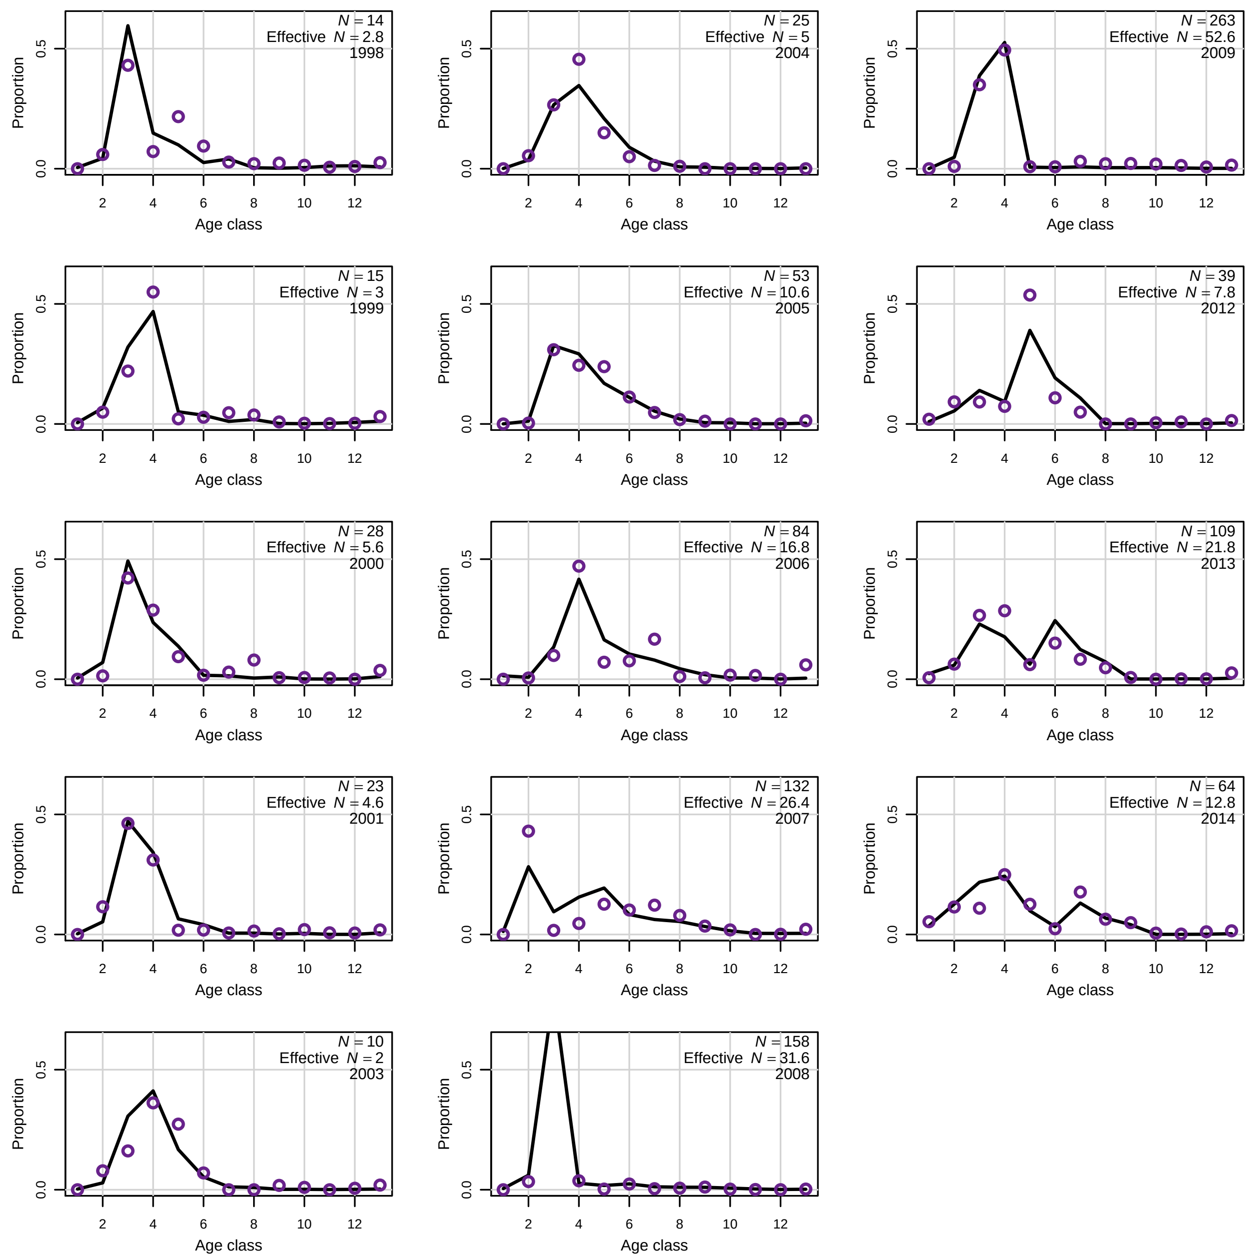

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey.

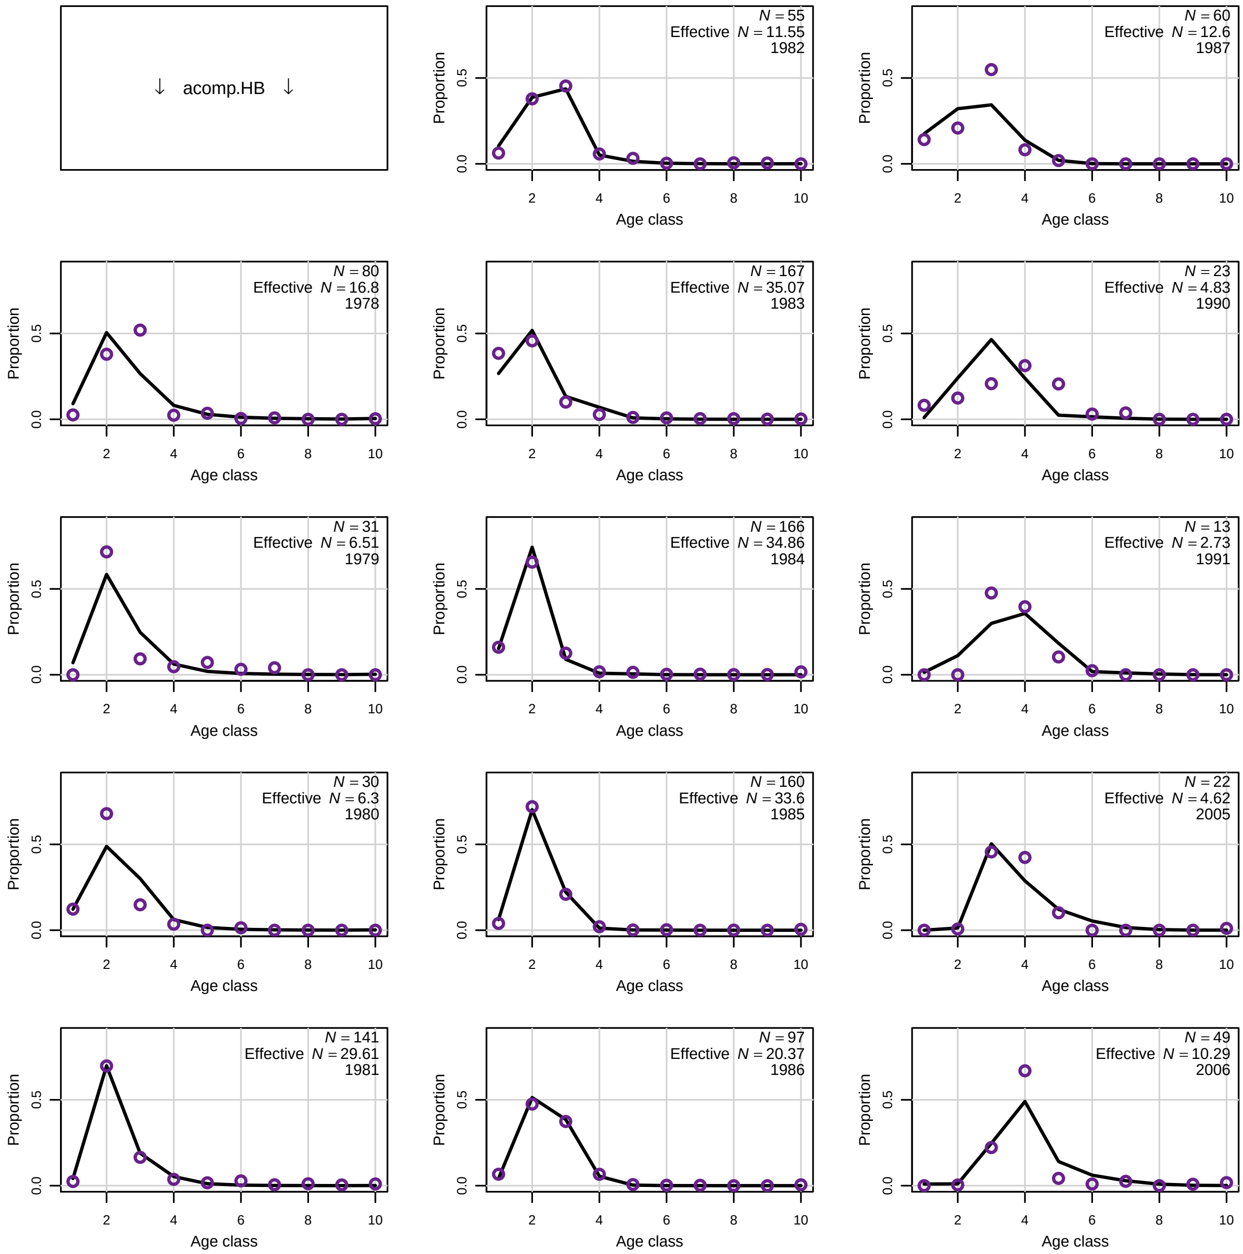

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey.

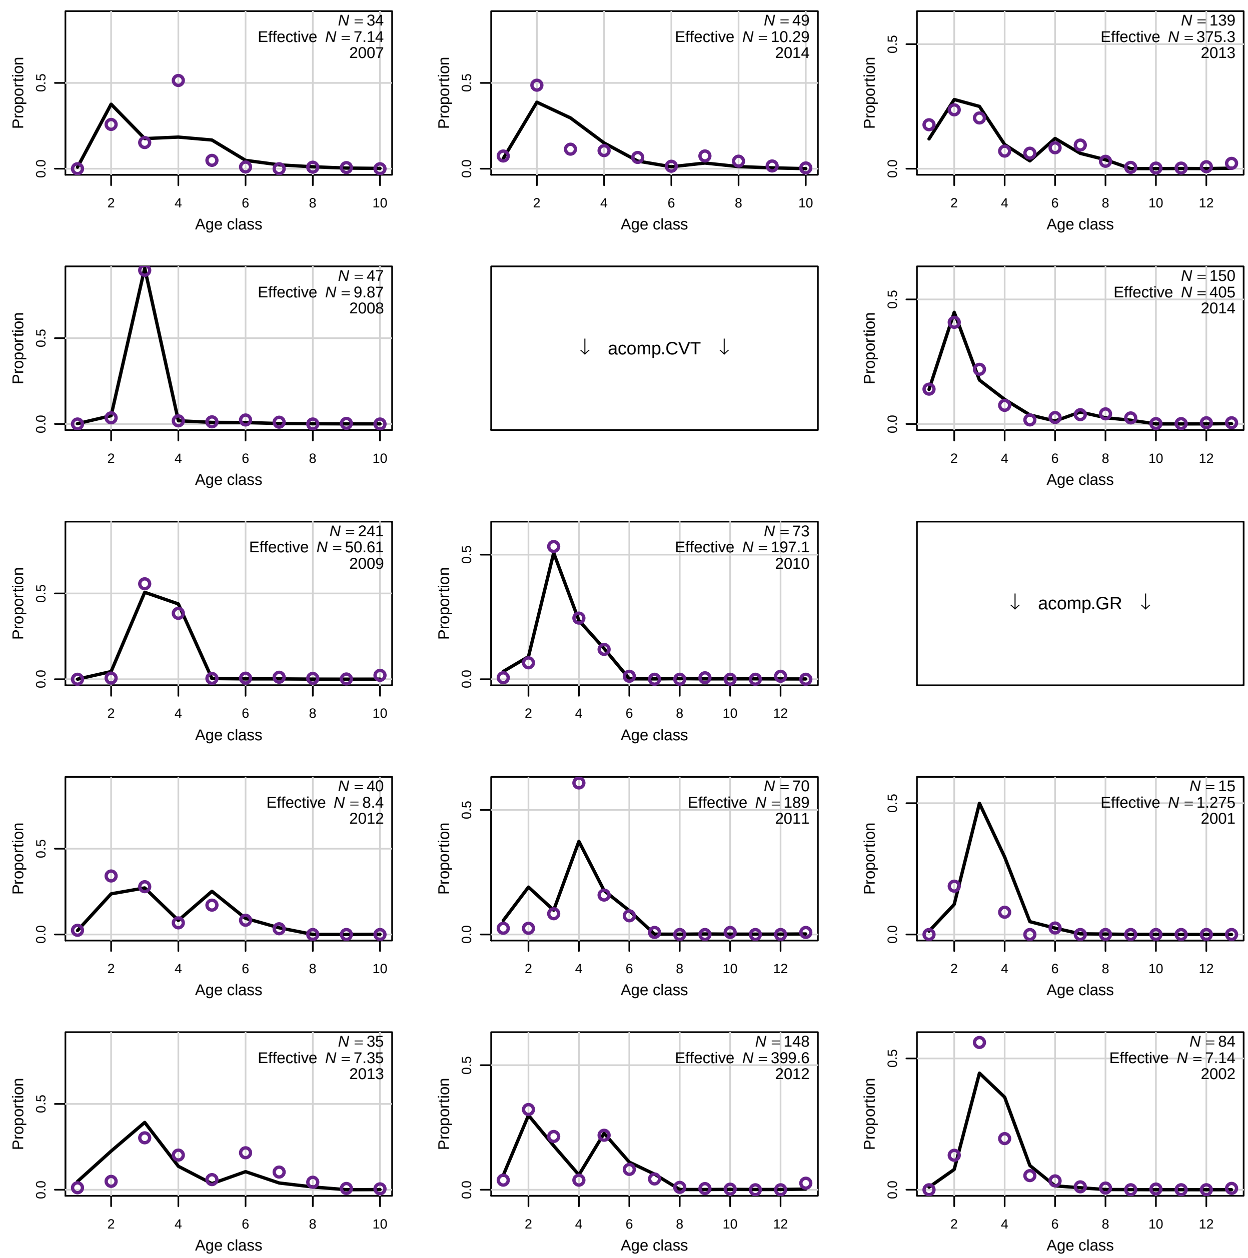

Figure 3. (cont.) Observed (open circles) and estimated (solid line) annual length and age compositions by fleet or survey.

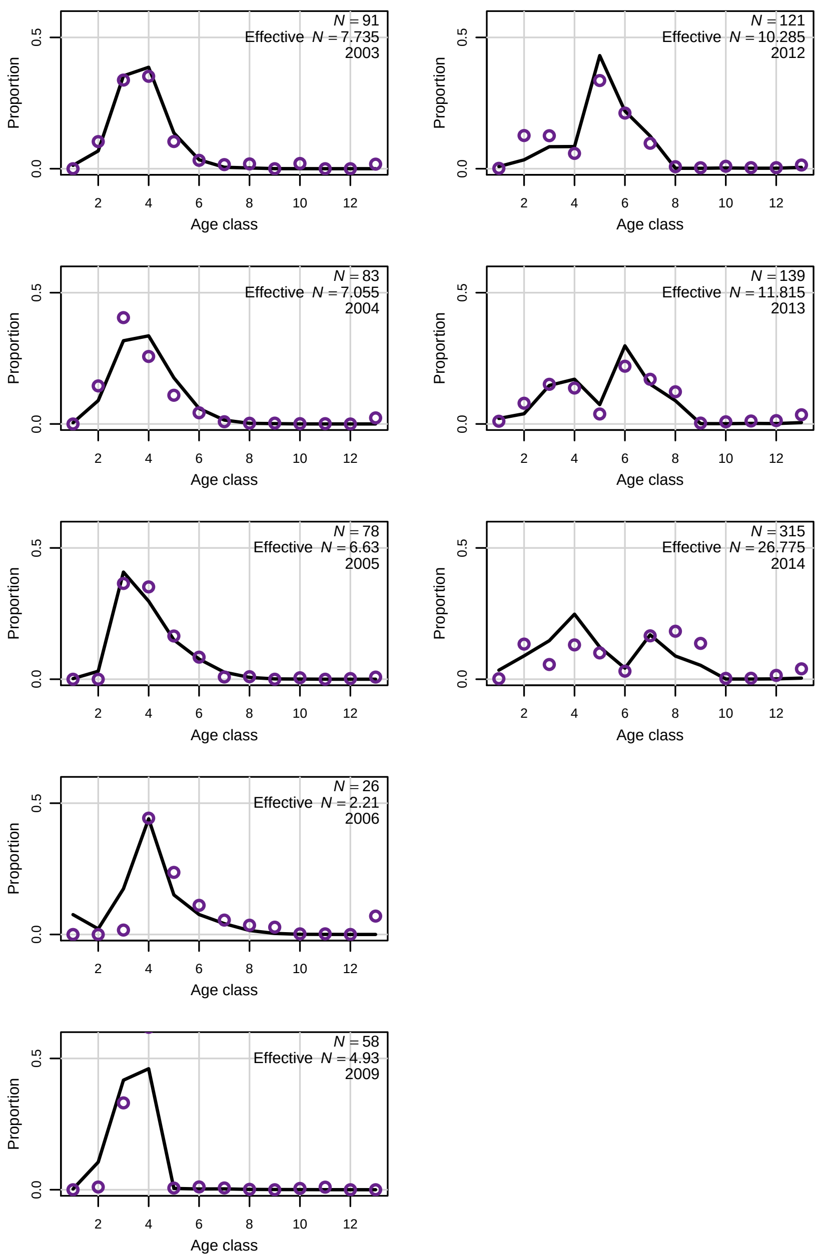

Figure 4. Observed (open circles) and estimated (solid line, circles) commercial handline landings in 1000 lb whole weight.

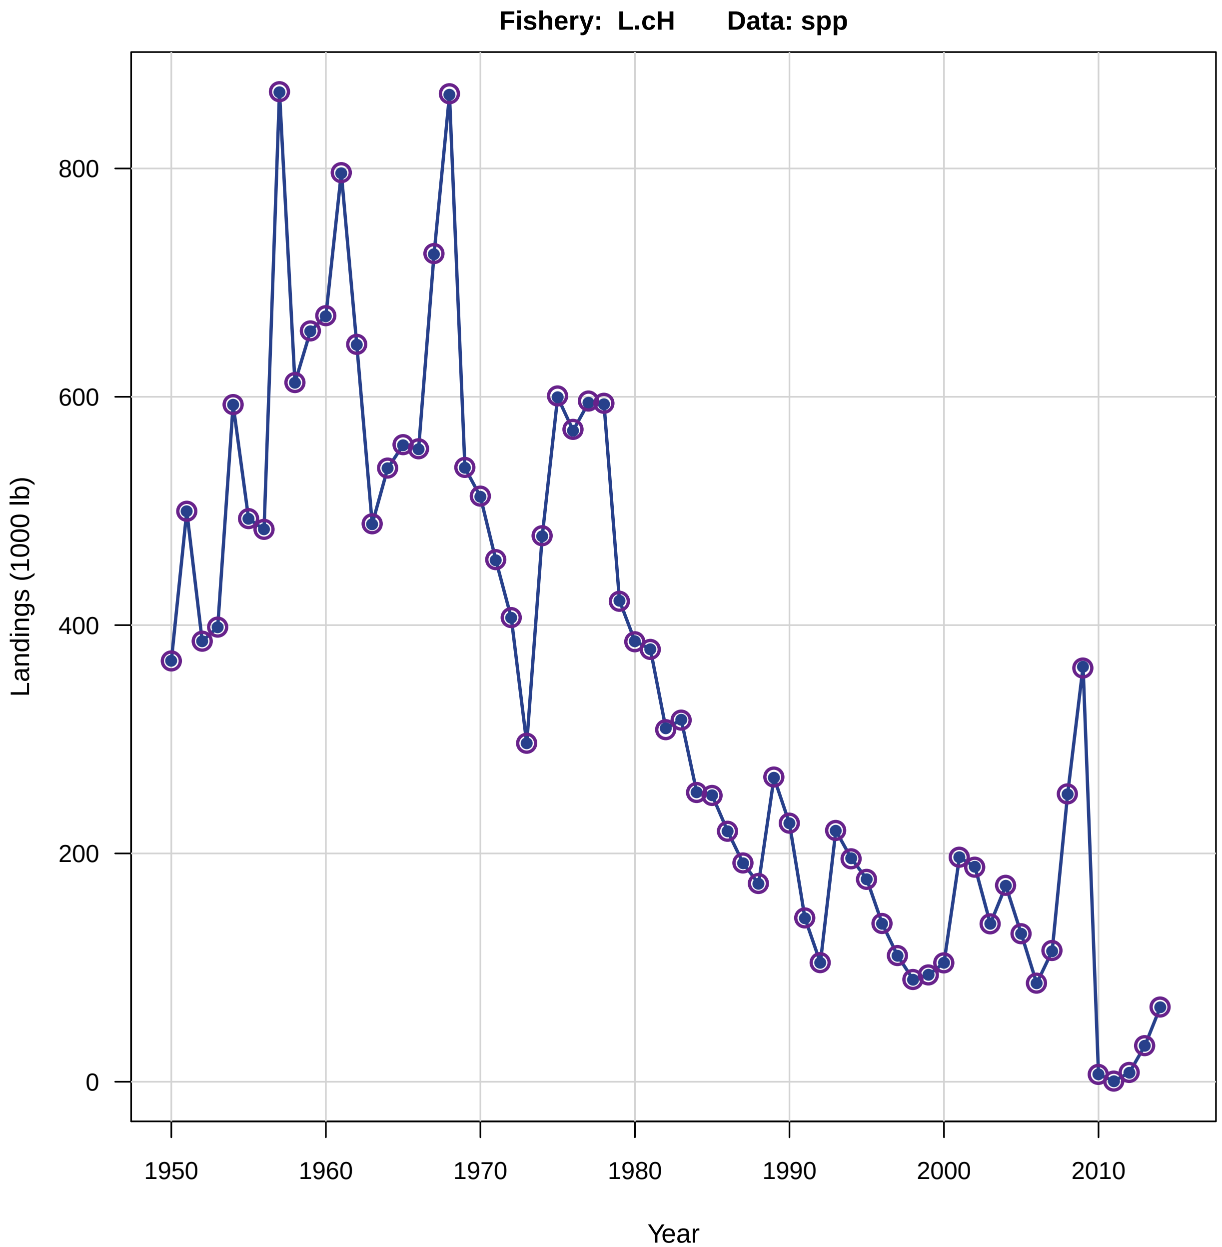

Figure 5. Observed (open circles) and estimated (solid line, circles) headboat landings in 1000s of fish.

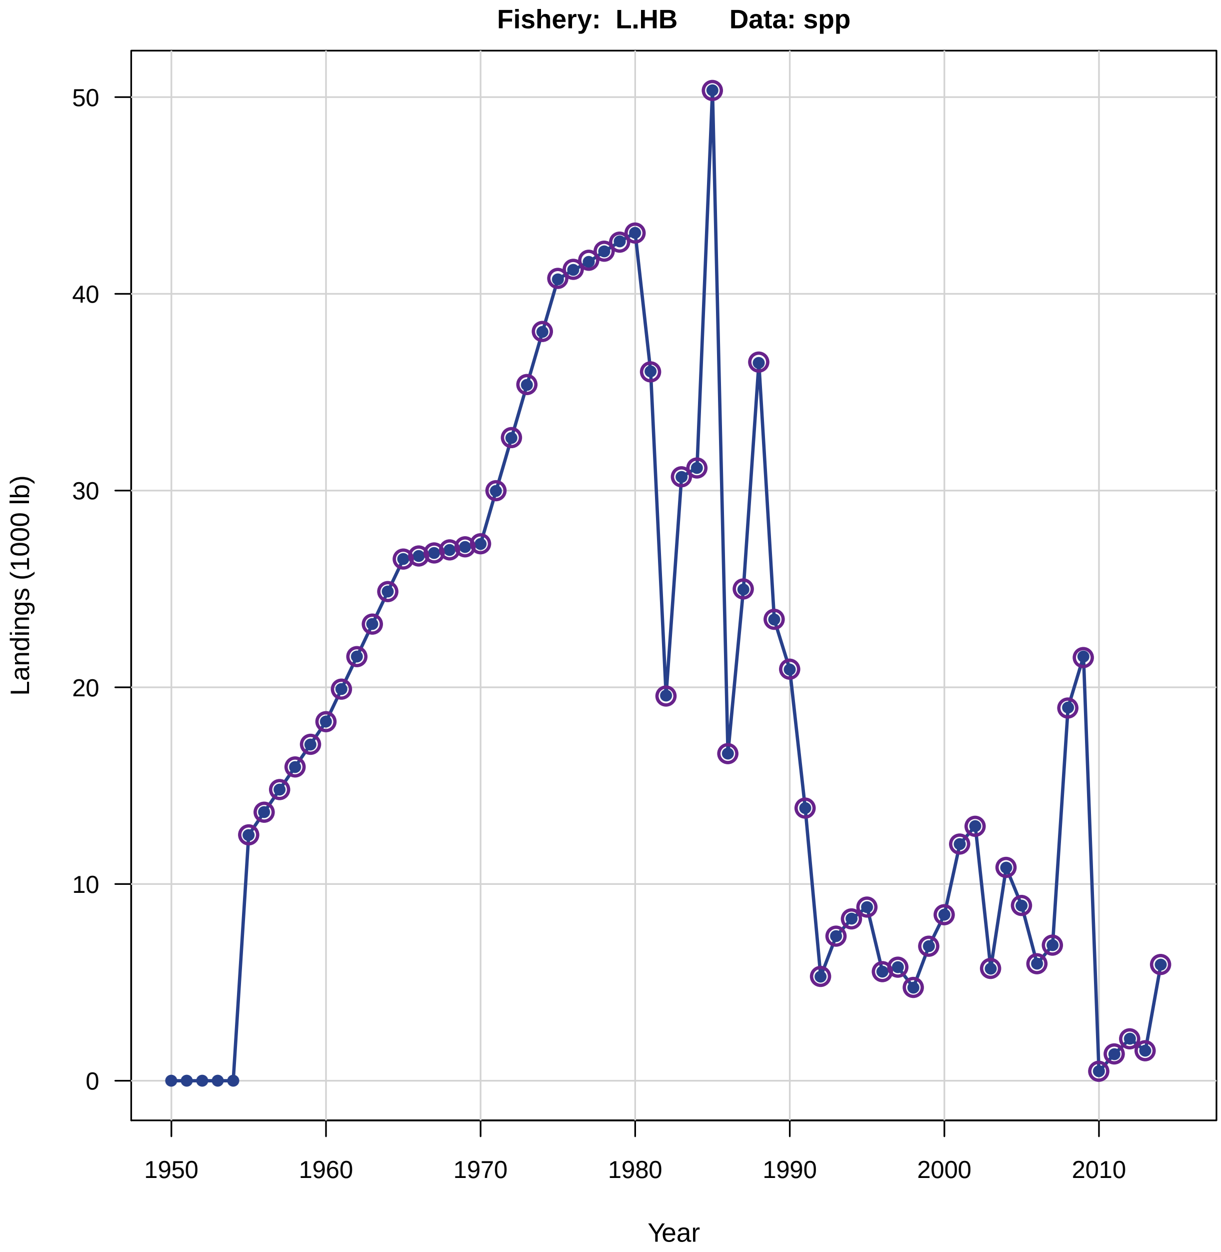

Figure 6. Observed (open circles) and estimated (solid line, circles) general recreational landings in 1000s of fish.

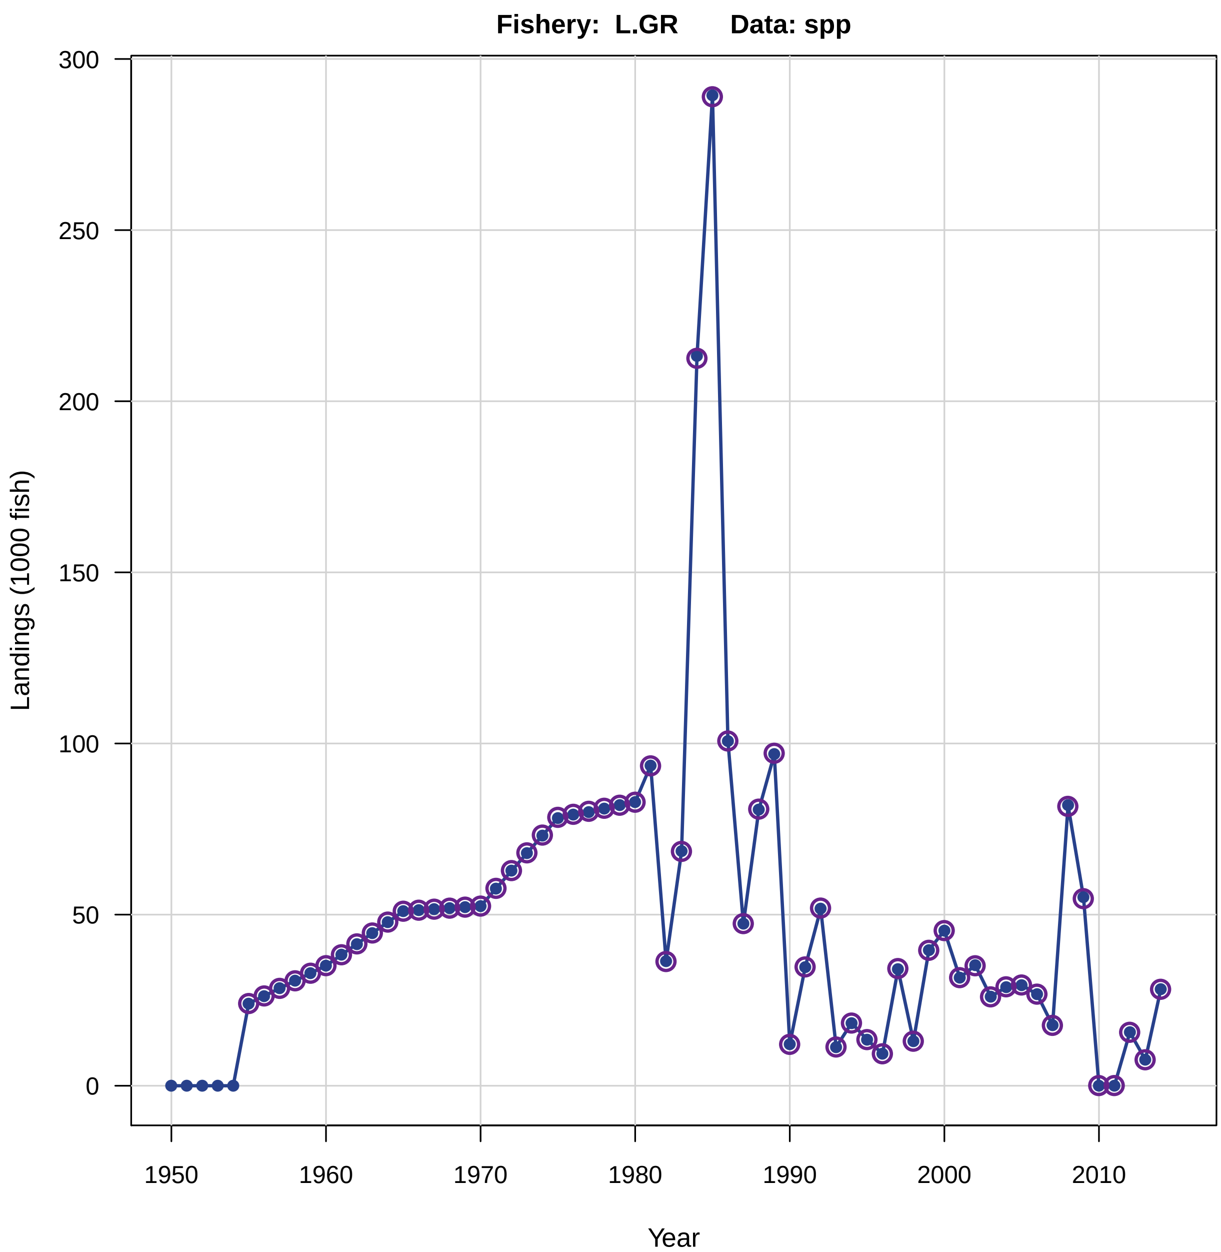

Figure 7. Observed (open circles) and estimated (solid line, circles) commercial handline discard mortalities.

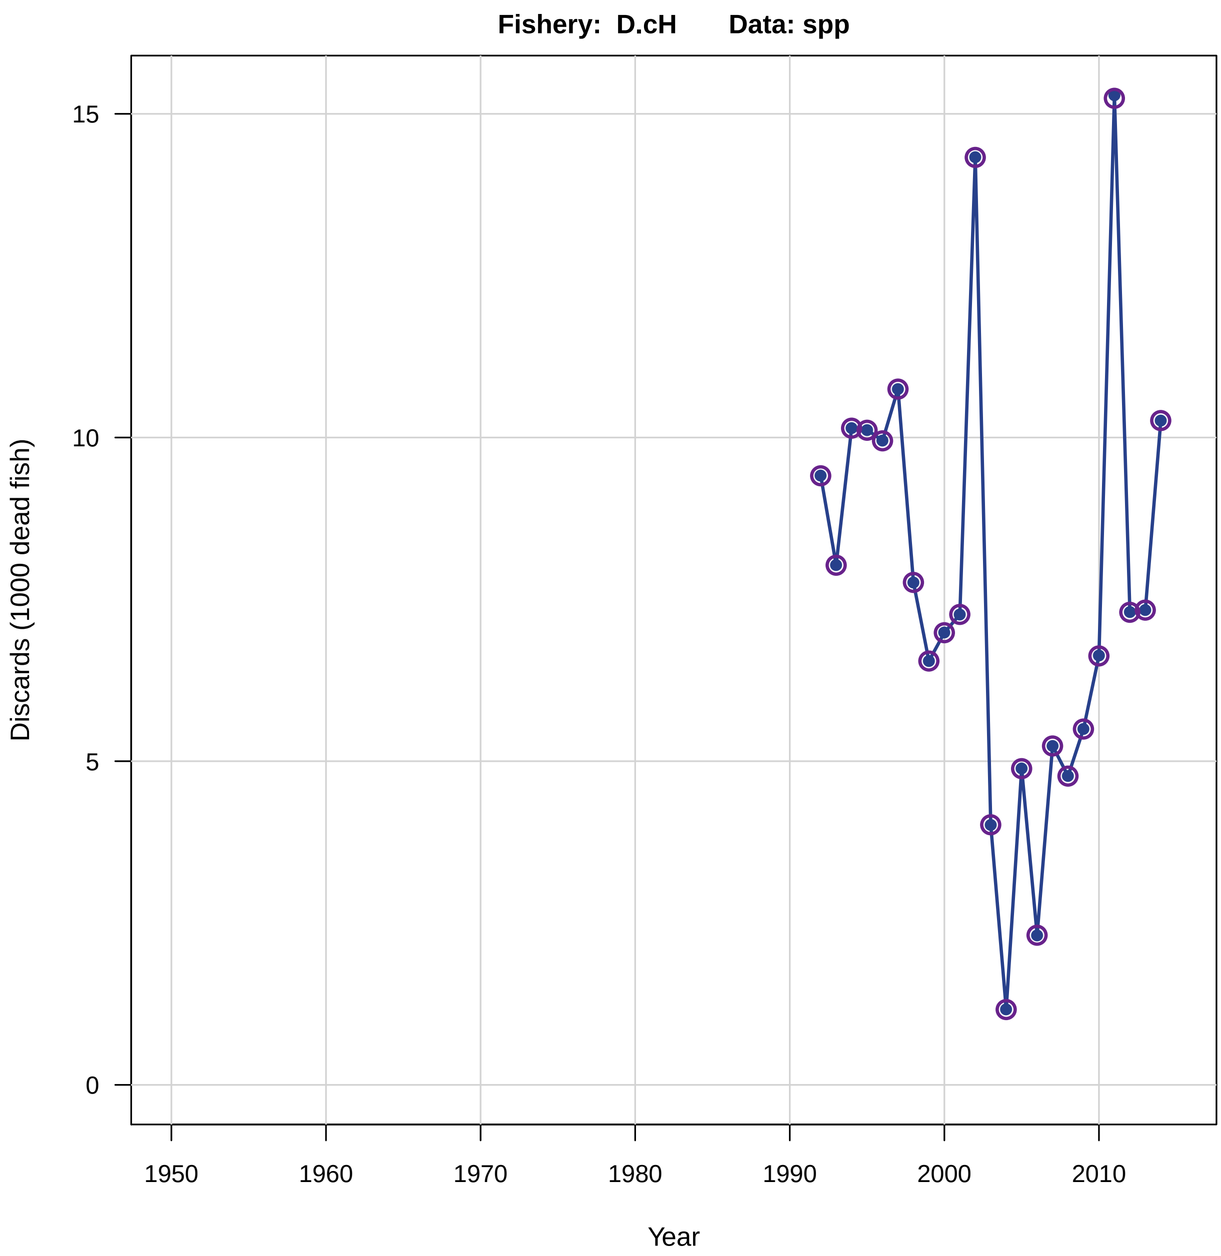

Figure 8. Observed (open circles) and estimated (solid line, circles) headboat discard mortalities.

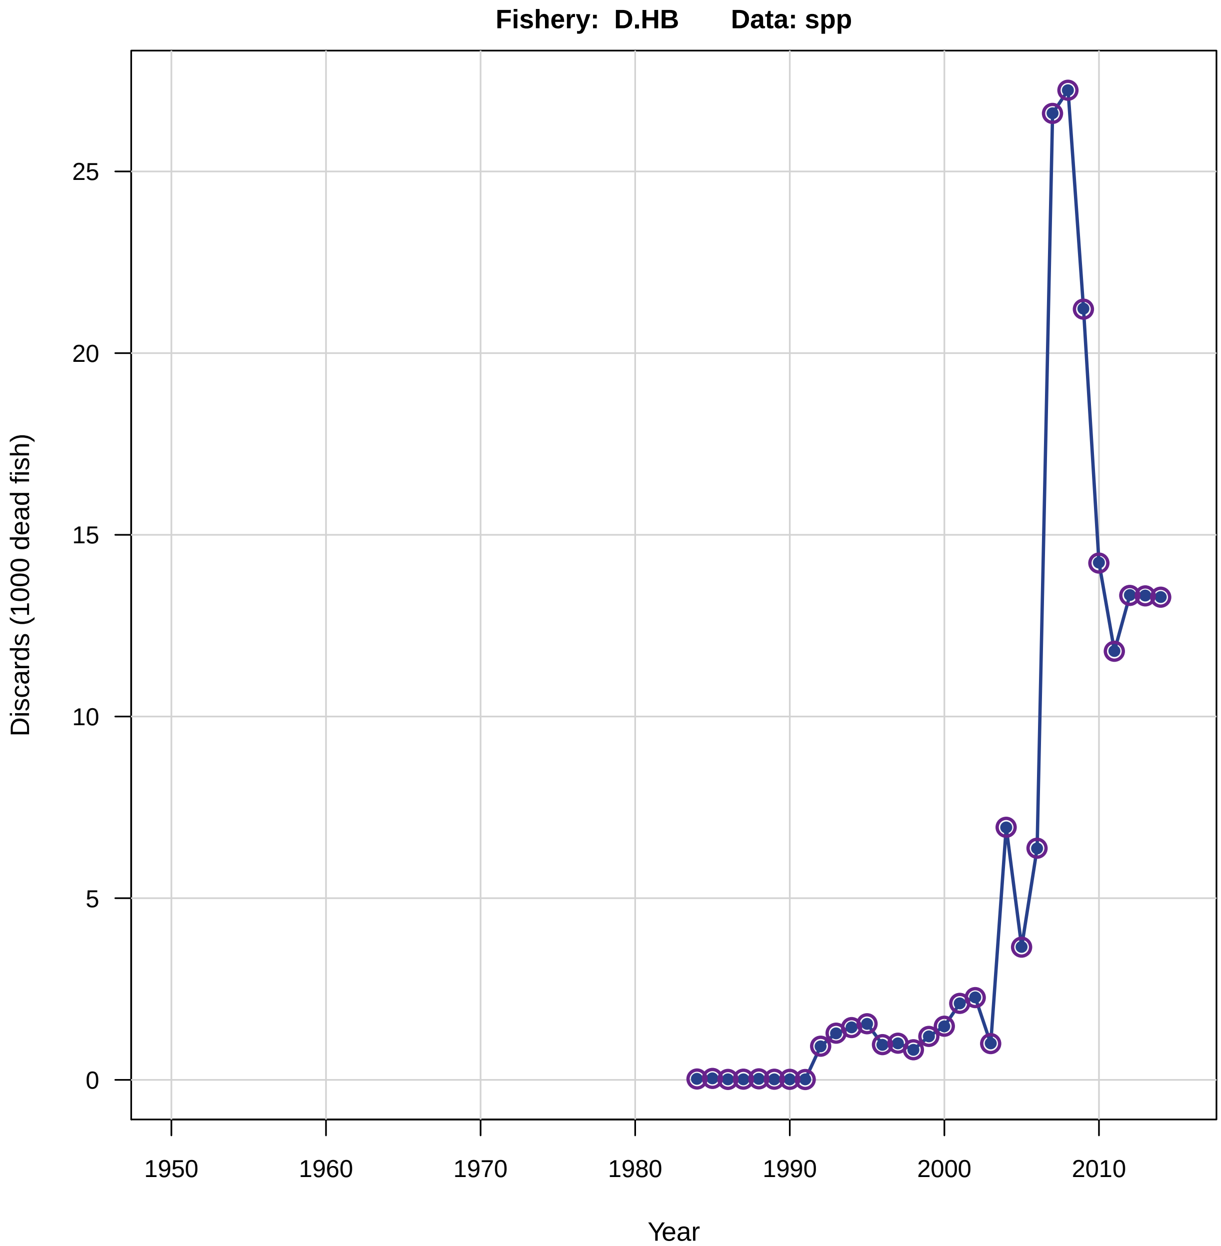

Figure 9. Observed (open circles) and estimated (solid line, circles) general recreational discard mortalities.

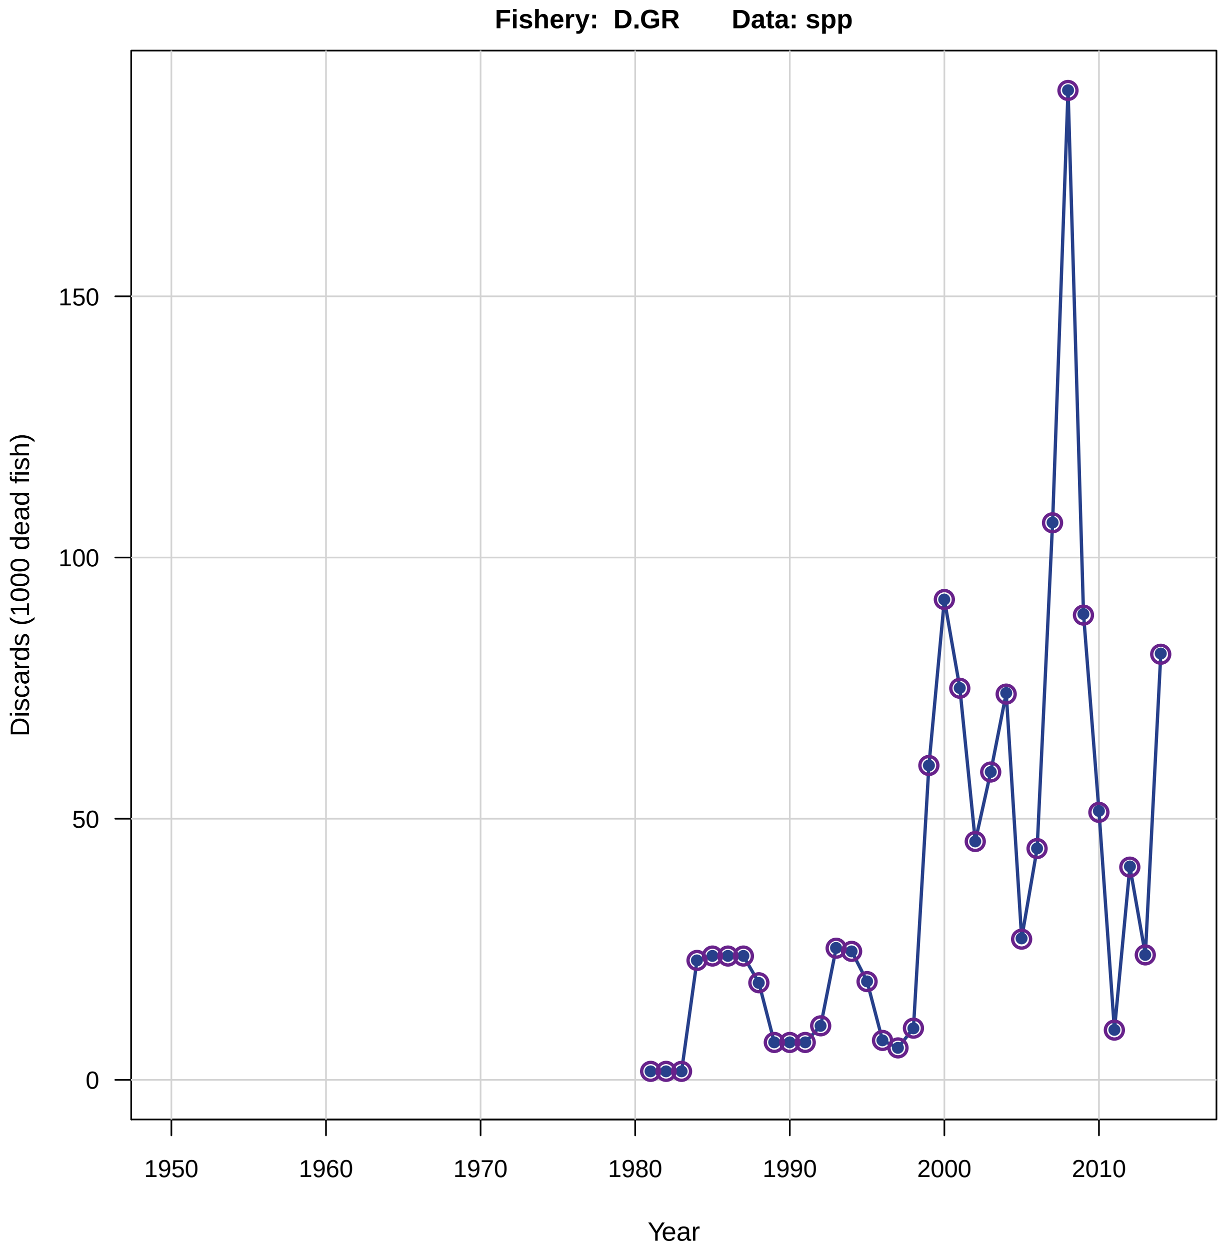

Figure 10. Observed (open circles) and estimated (solid line, circles) index of abundance from the SERFS combined trap and video index. The error bars represent the annual CV provided by the GLM standardization divided by the likelihood weight on the index.

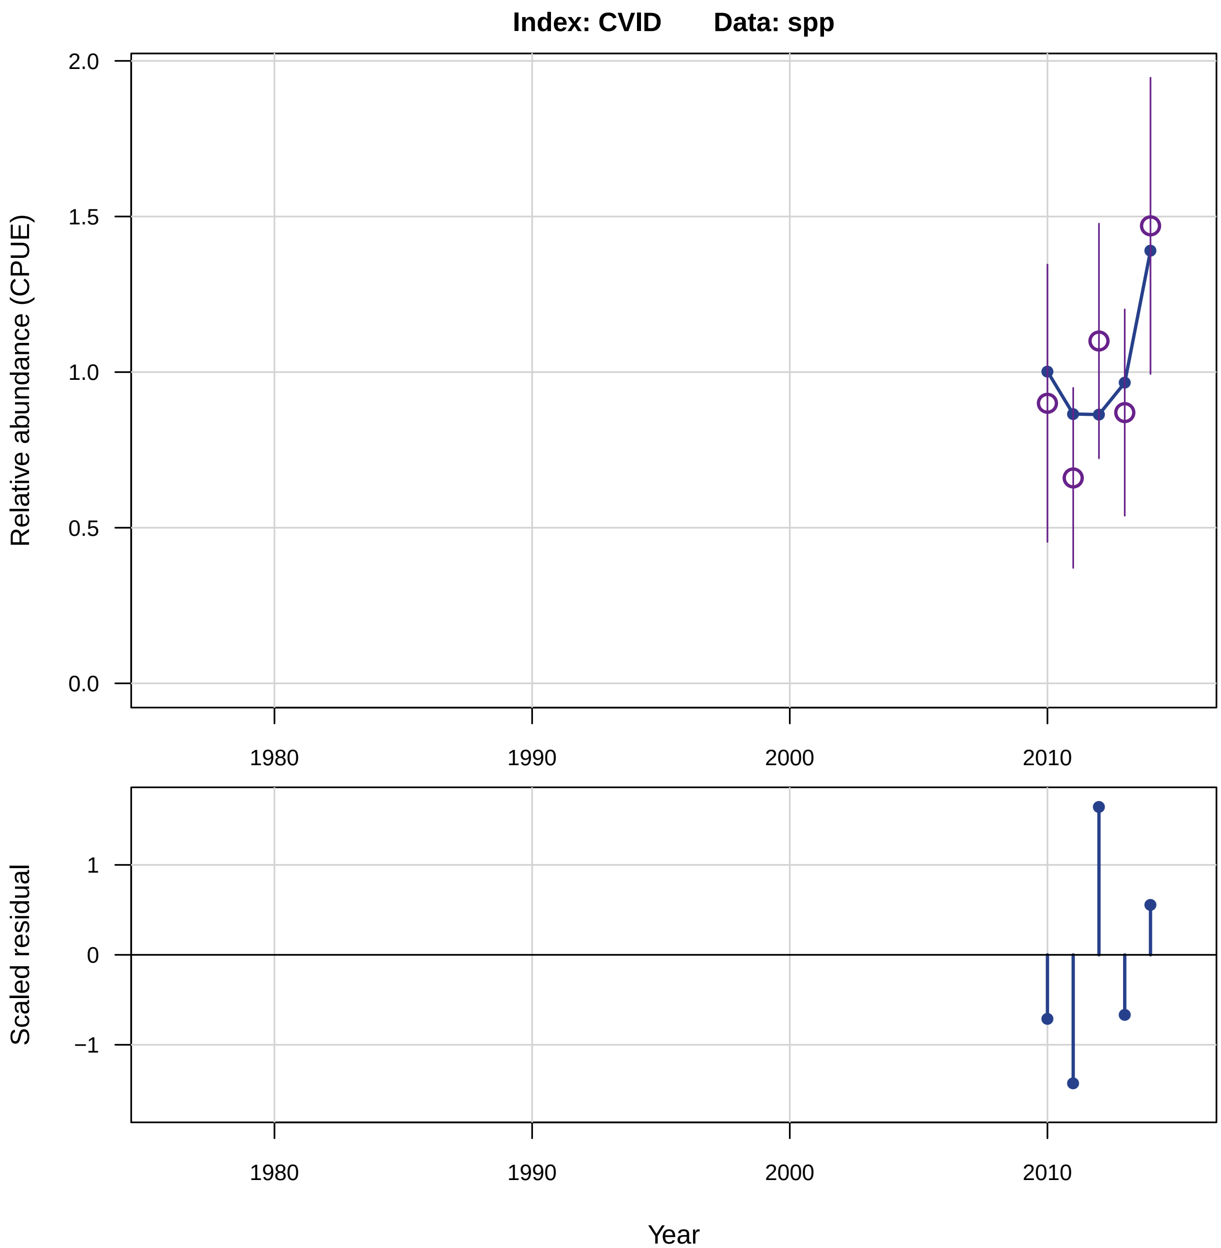

Figure 11. Observed (open circles) and estimated (solid line, circles) index of abundance from the commercial handline fleet. The error bars represent the annual CV of the index (0.2) divided by the likelihood weight on the index.

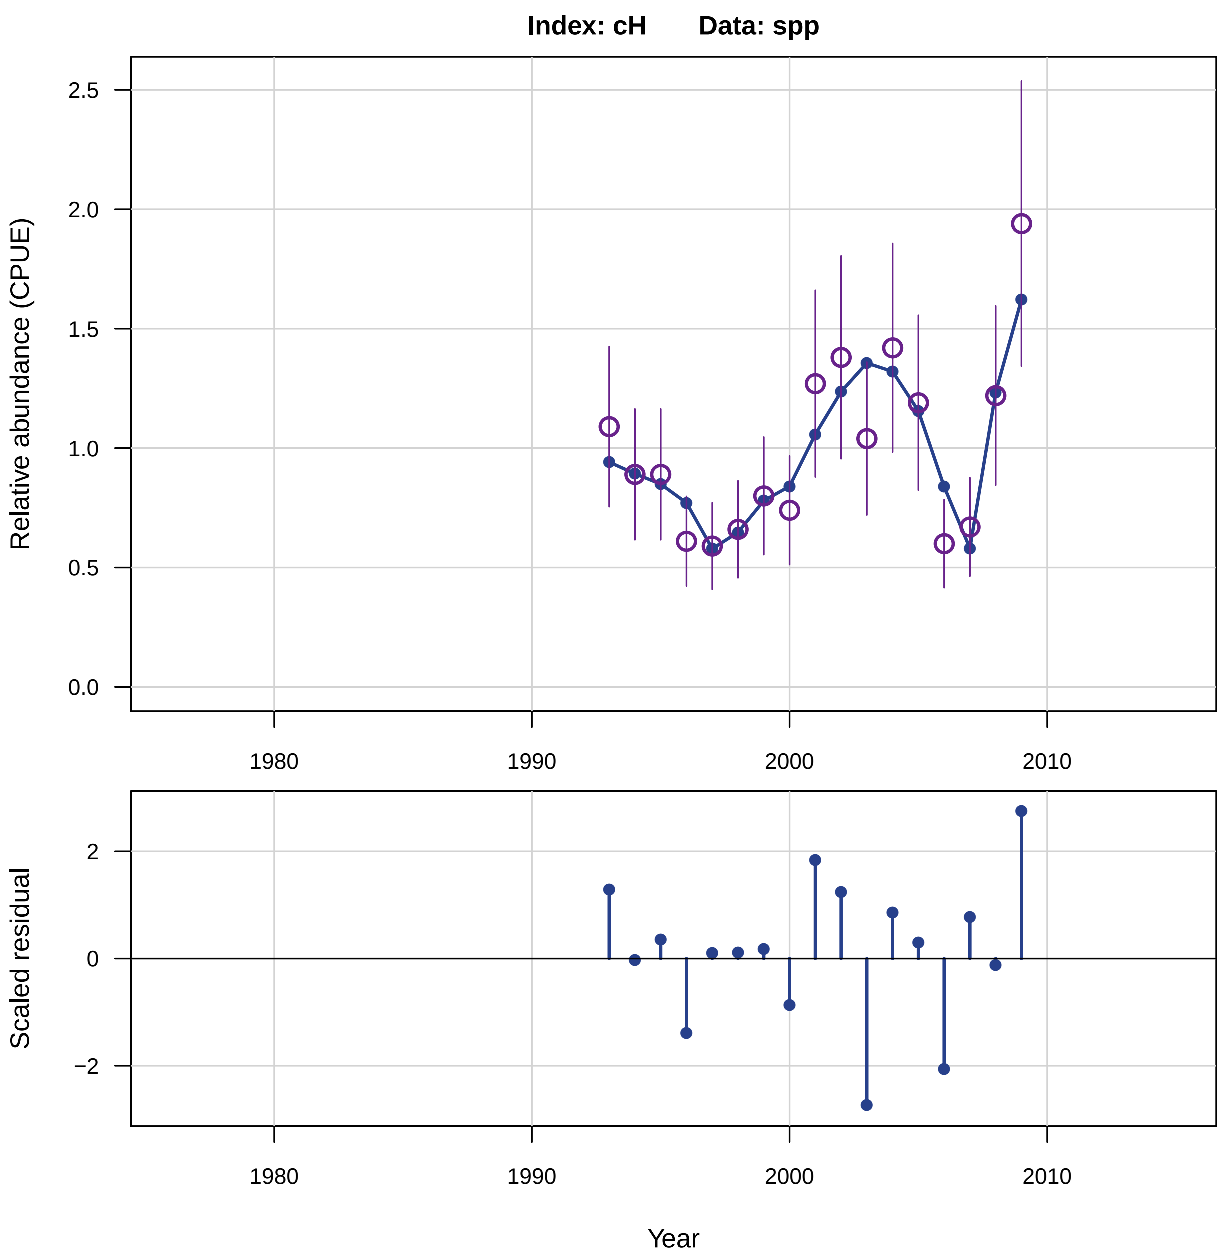

Figure 12. Observed (open circles) and estimated (solid line, circles) abundance from the headboat fleet. The error bars represent the annual CV of the index (0.2) divided by the likelihood weight on the index.

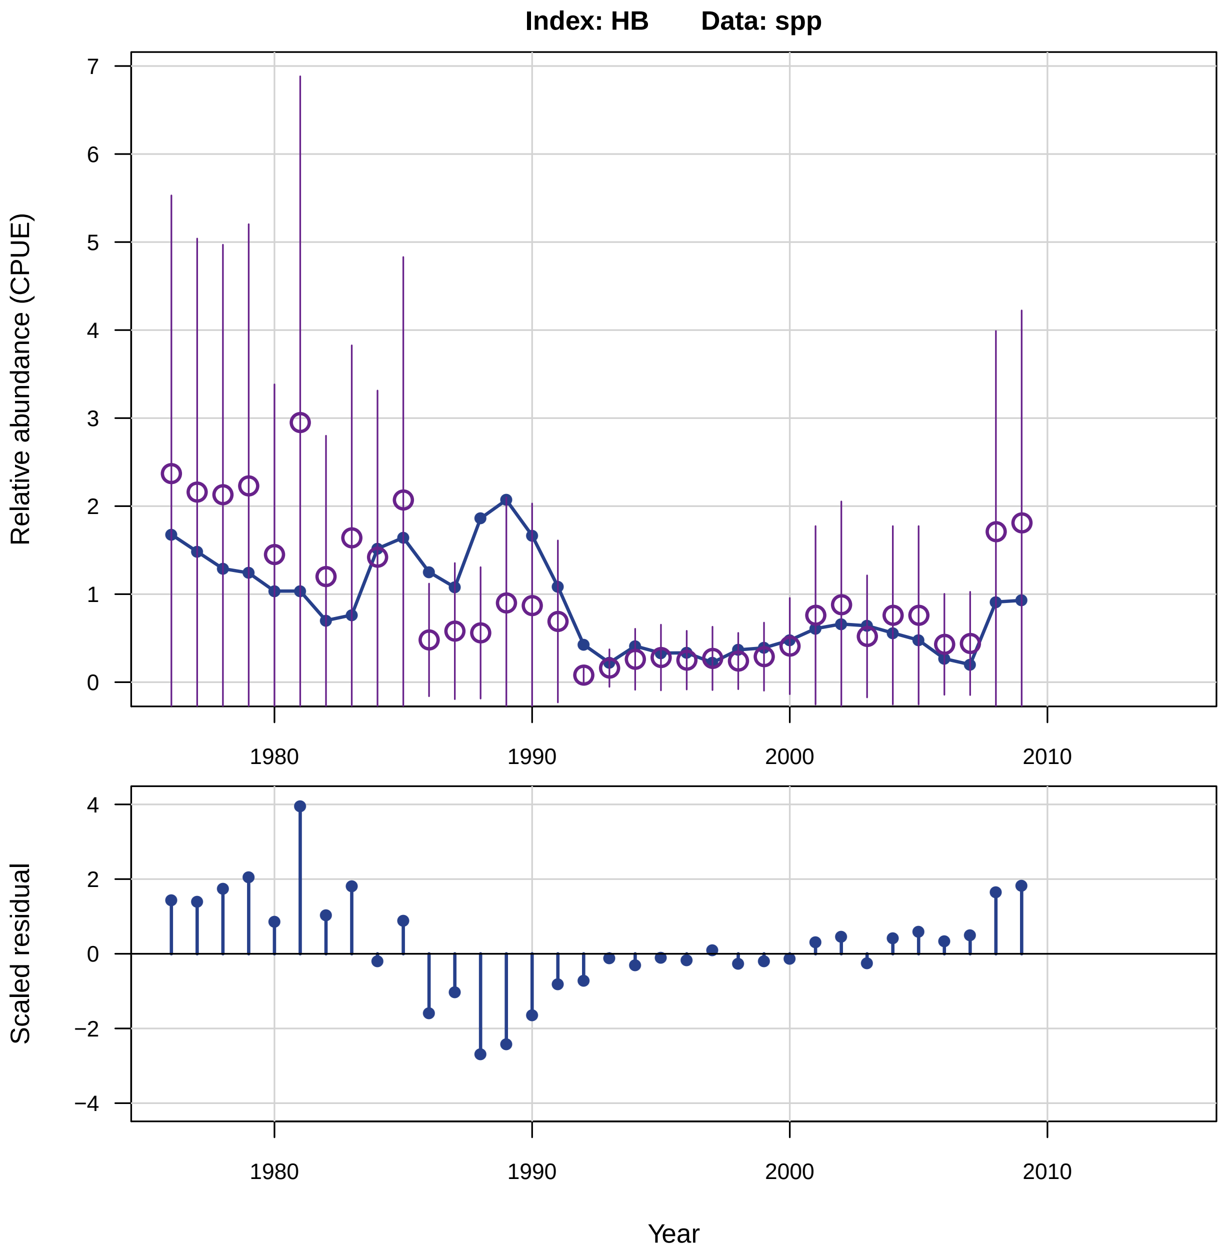

Figure 13. Observed (open circles) and estimated (solid line, circles) abundance from the headboat fleet (discards). The error bars represent the annual CV provided by the GLM standardization divided by the likelihood weight on the index.

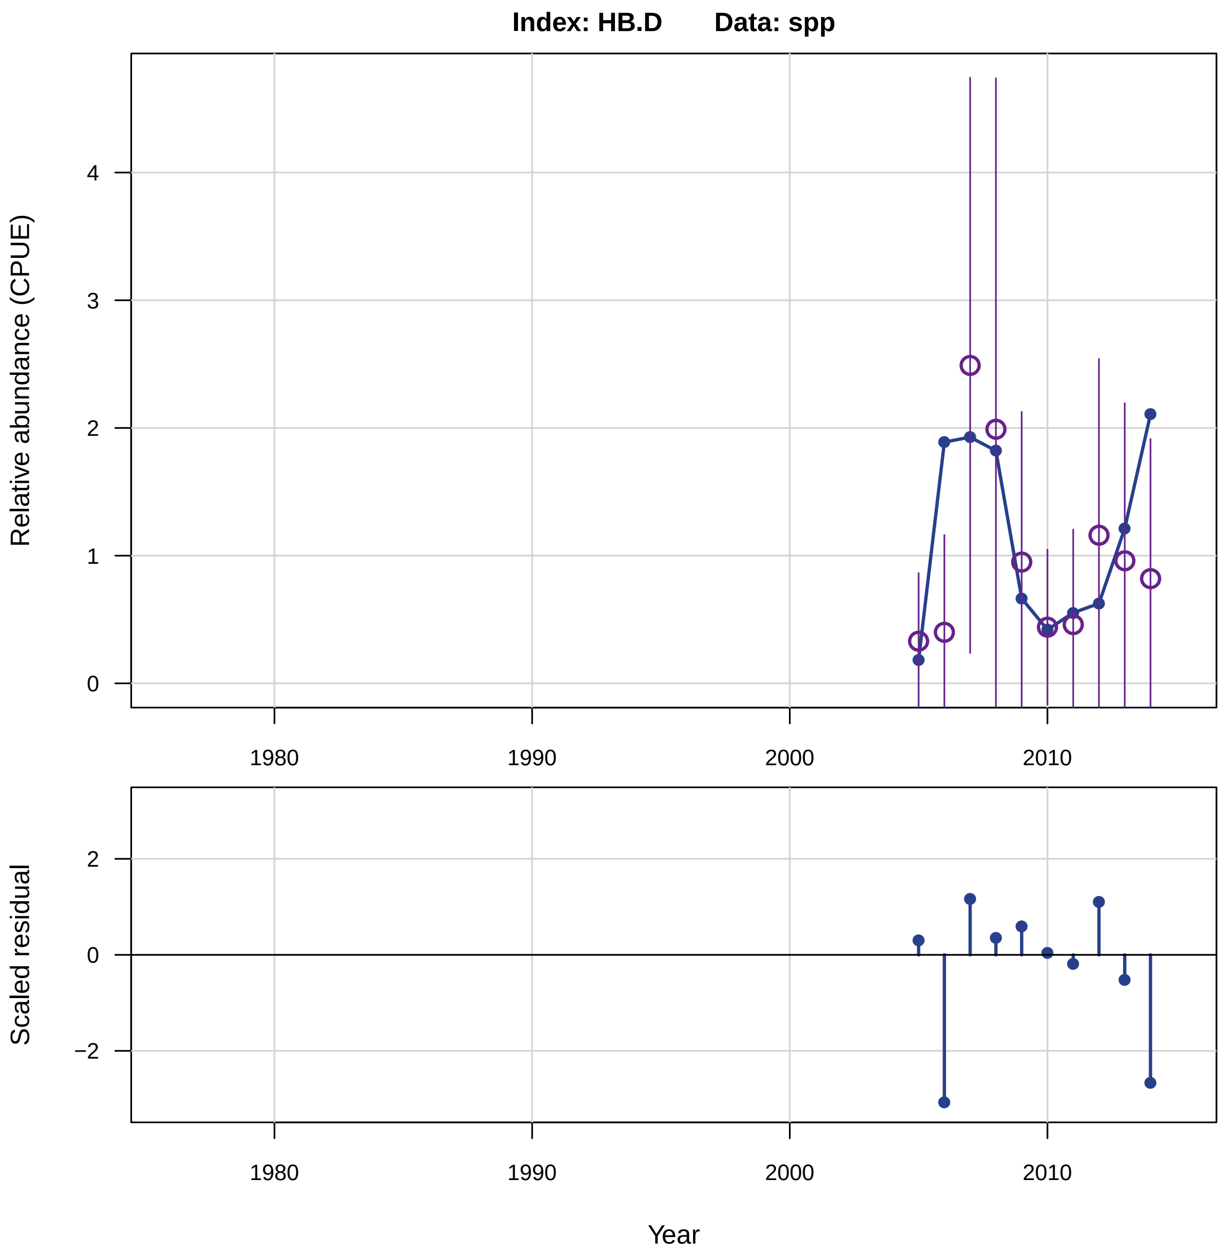

Figure 14. Estimated abundance at age at start of year.

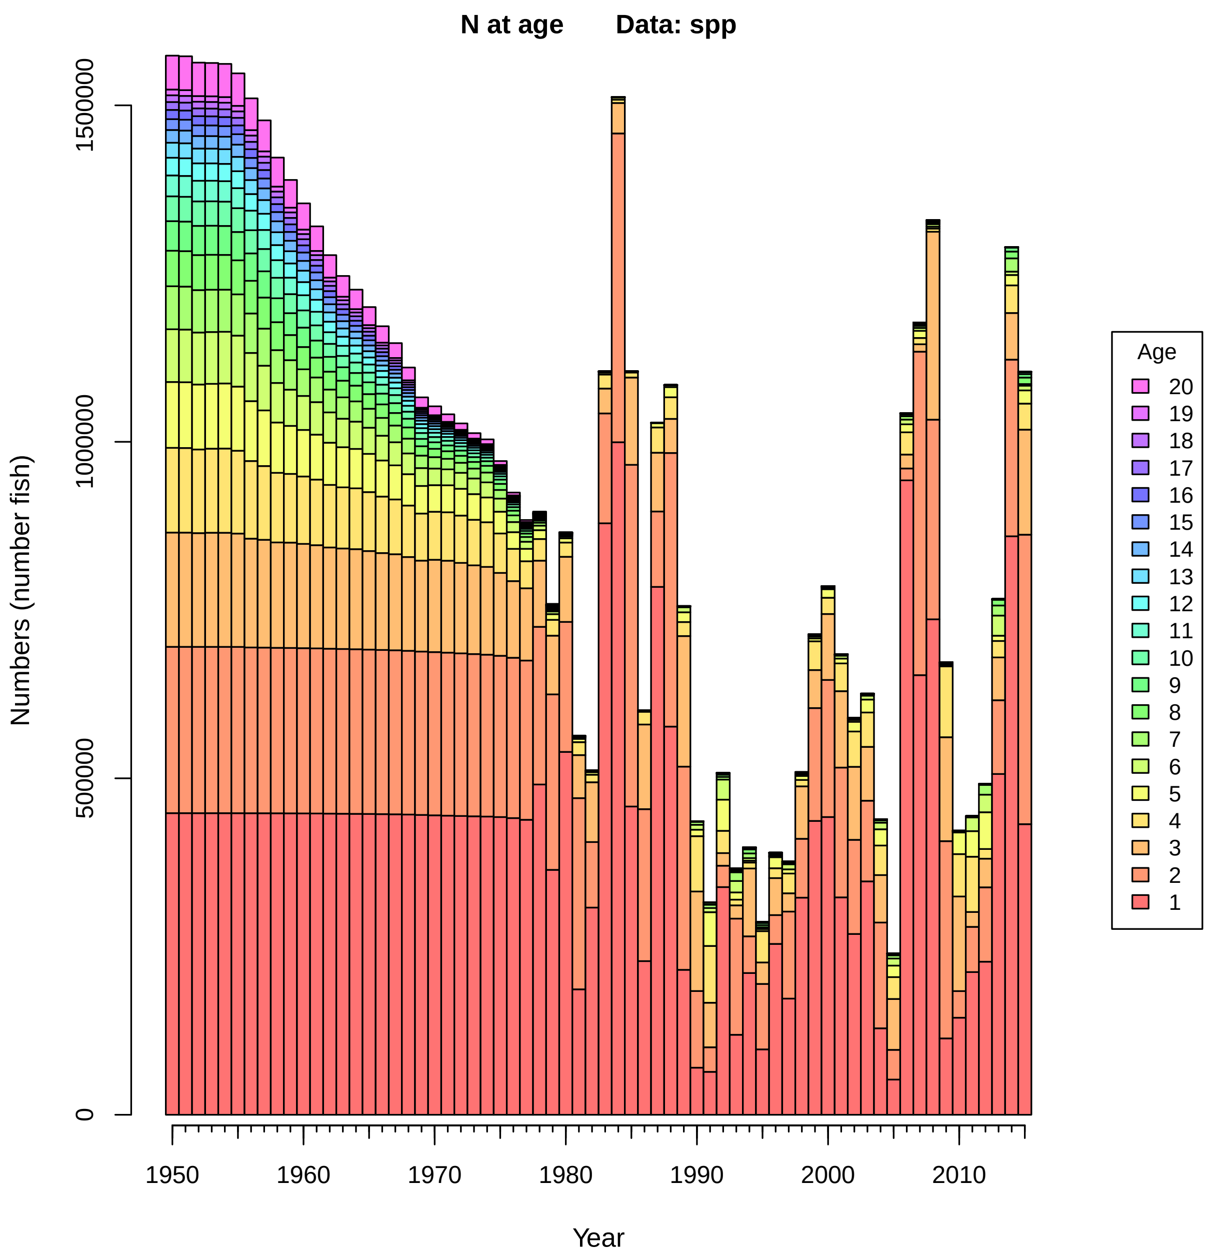

Figure 15. Top panel: Estimated recruitment of age-1 fish. Horizontal dashed line indicates $R_{F30\%}$. Bottom panel: log recruitment residuals.

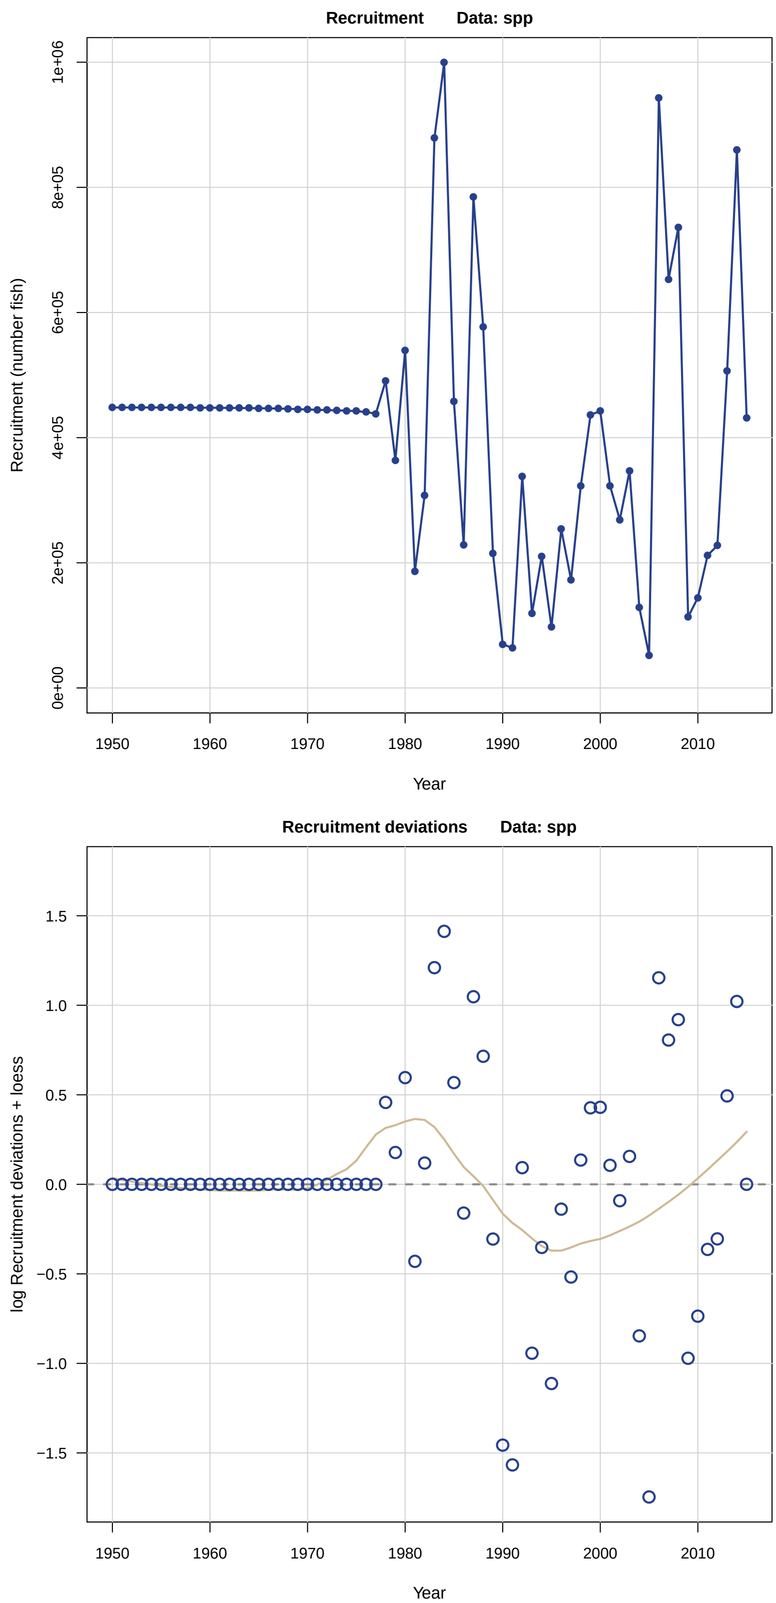

Figure 16. Estimated biomass at age at start of year.

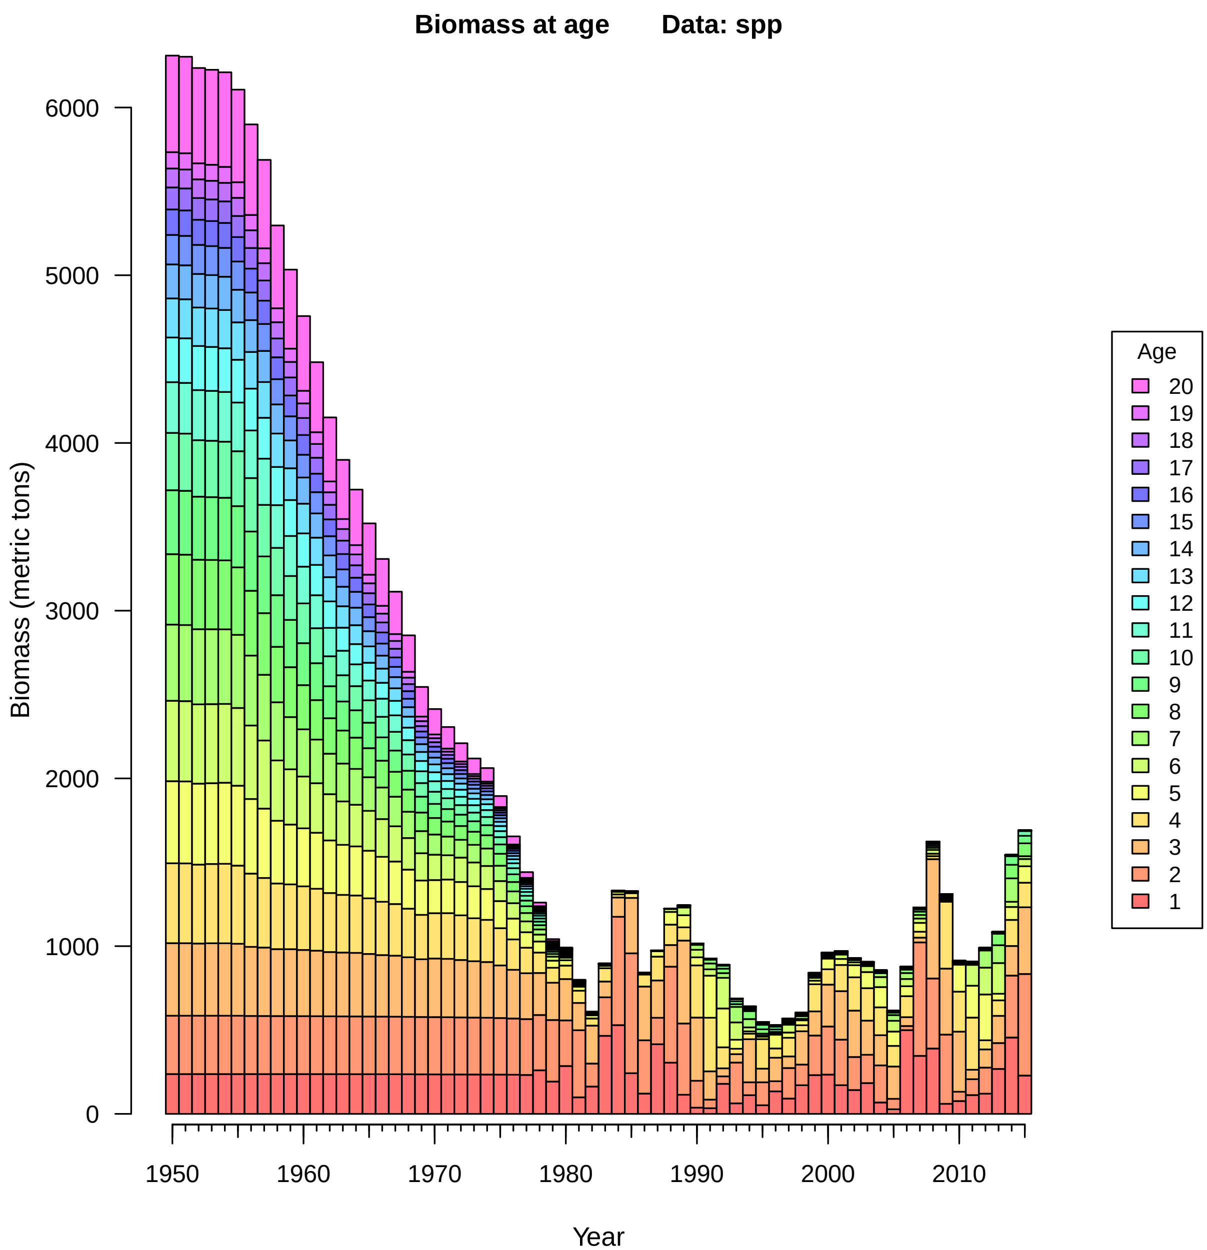

Figure 17. Top panel: Estimated total biomass (metric tons) at start of year. Horizontal dashed line indicates $B_{F30\%}$. Bottom panel: Estimated spawning stock (population fecundity) at time of peak spawning.

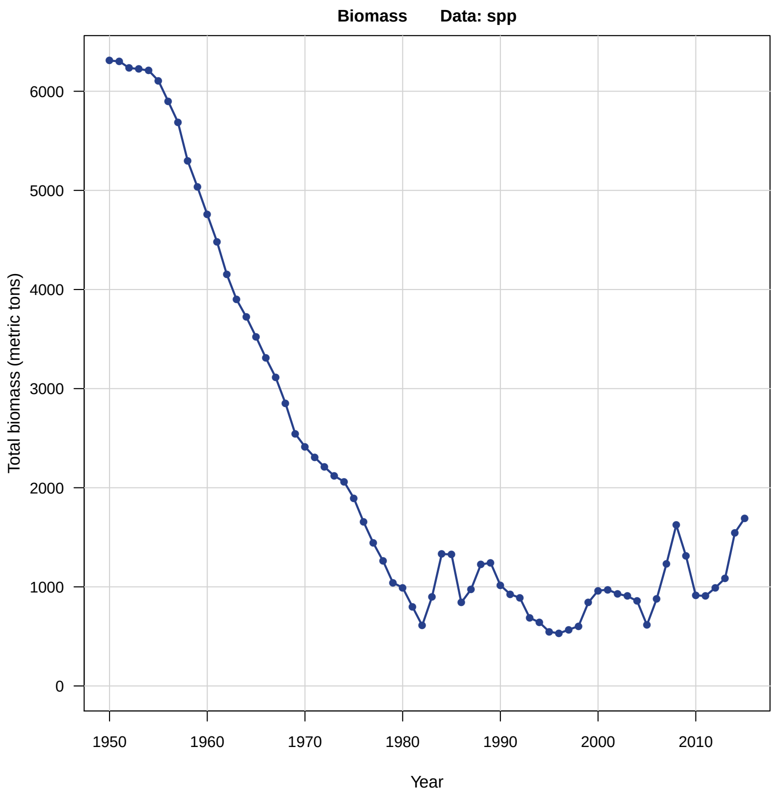

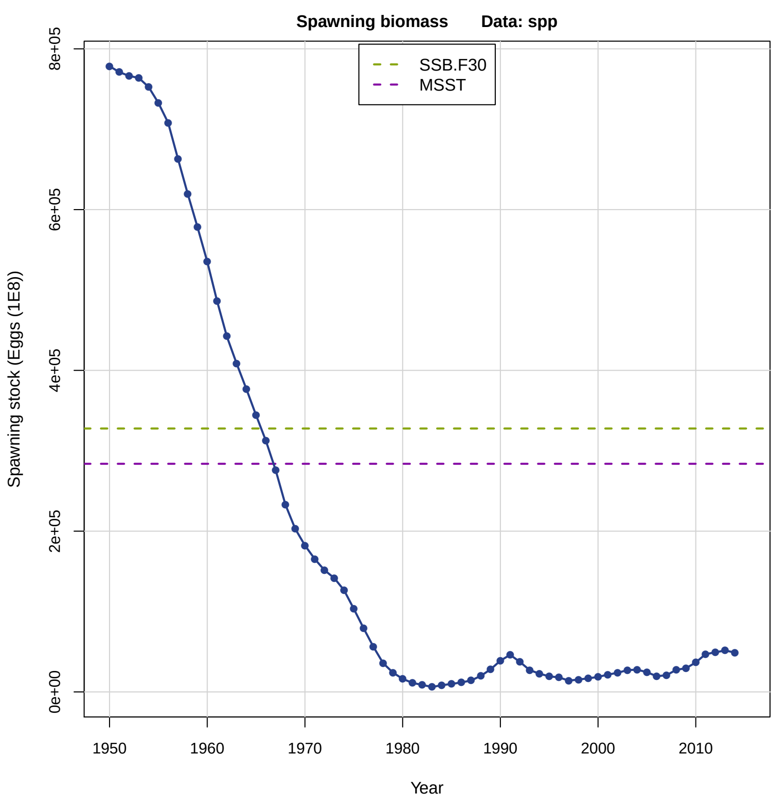

Figure 18. Monte Carlo Bootstrap estimates of population abundance. Top panel is all ages, and the bottom panel represents age 2+.

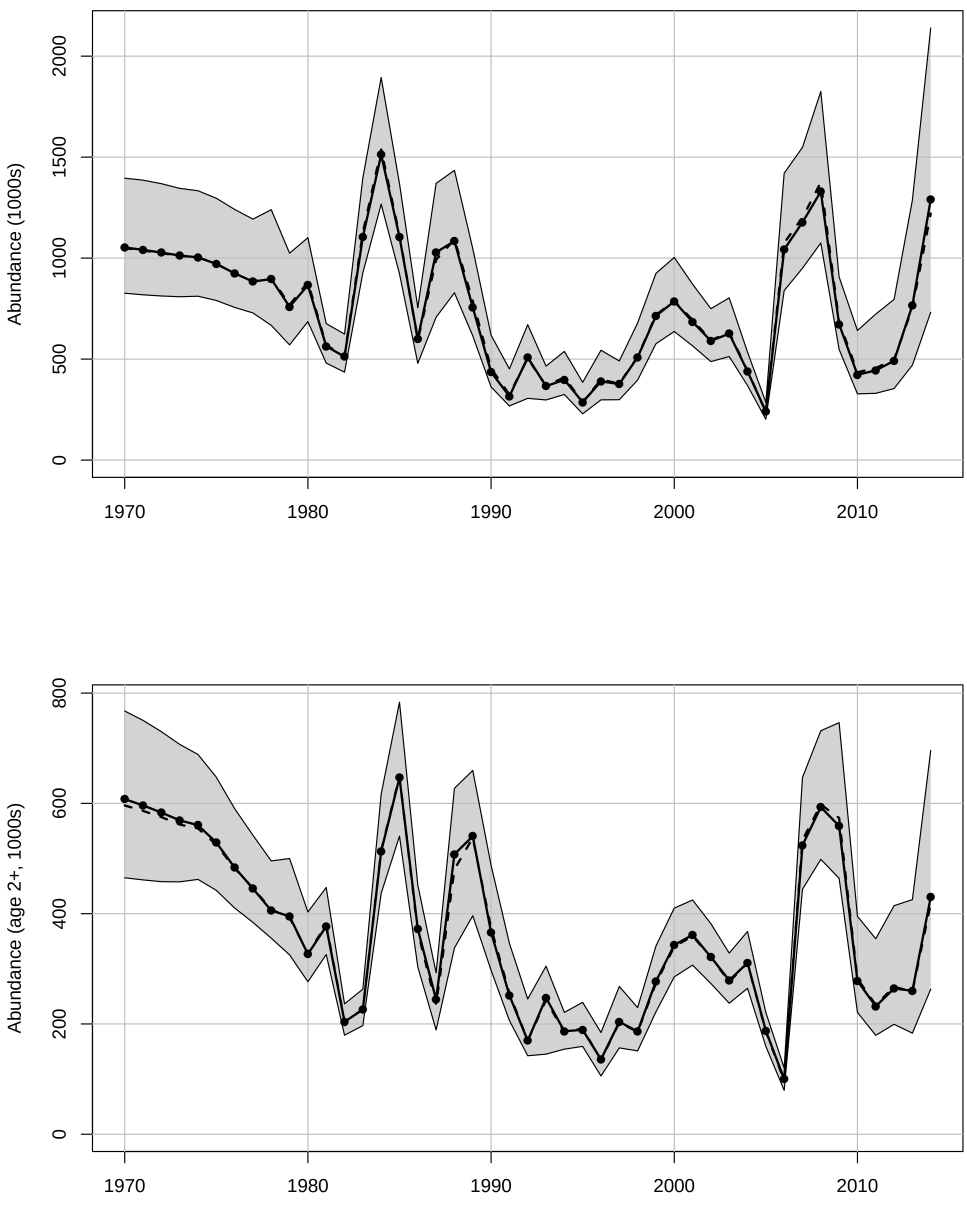

Figure 19. Selectivity of SERFS index.

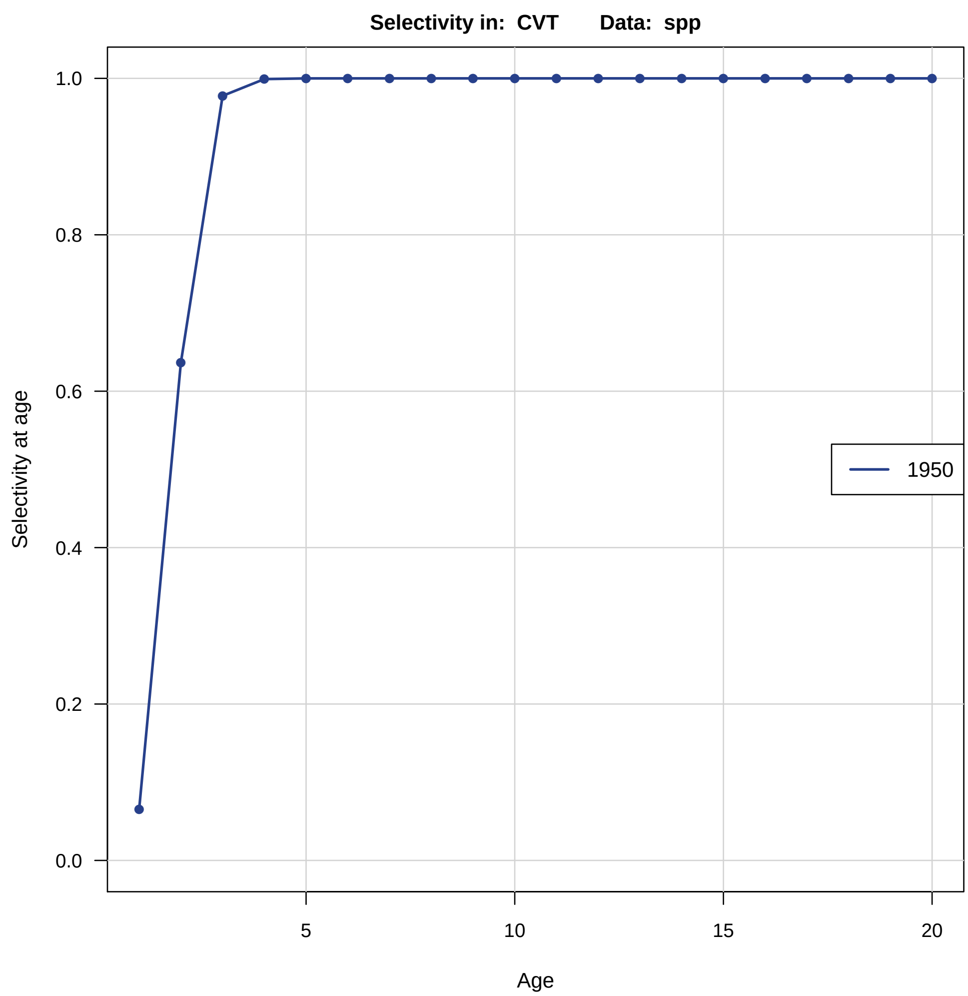

Figure 20. Selectivities of commercial handline landings. The legend indicates the first year each selectivity curve applies to the fleet.

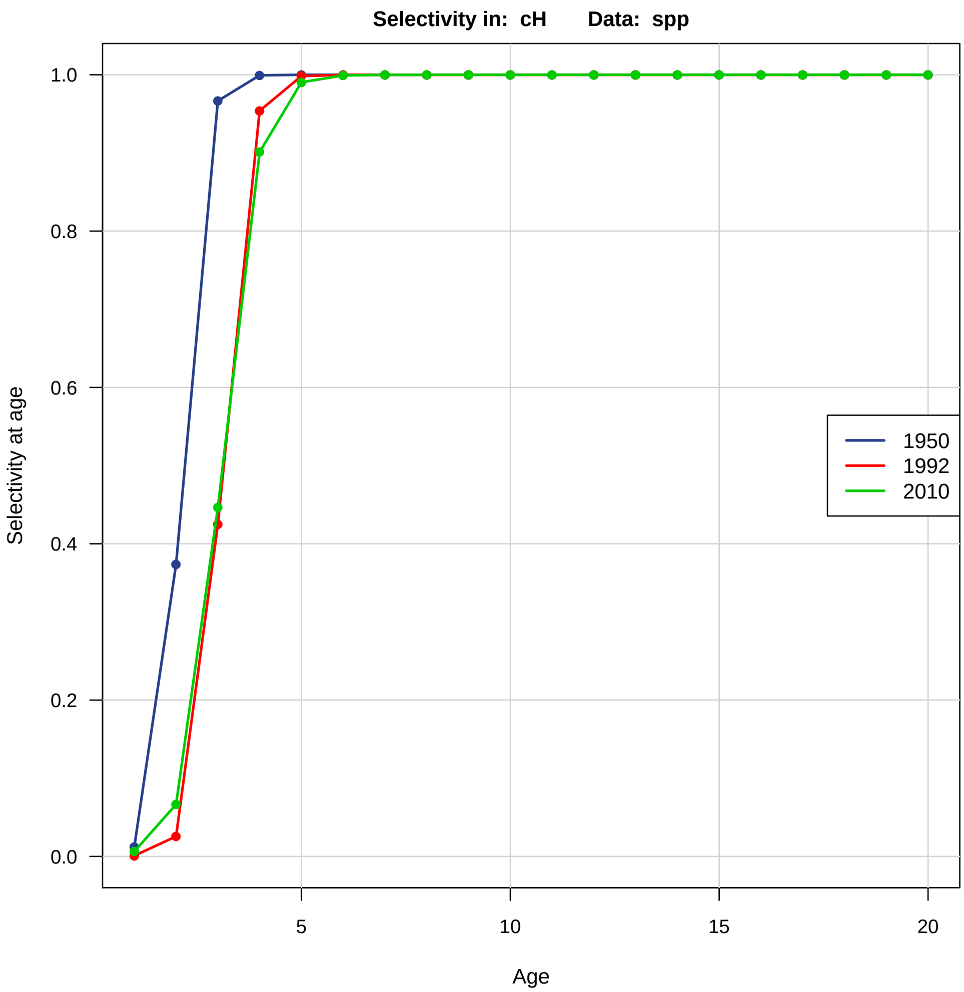

Figure 21. Selectivities of headboat landings. The legend indicates the first year each selectivity curve applies to the fleet.

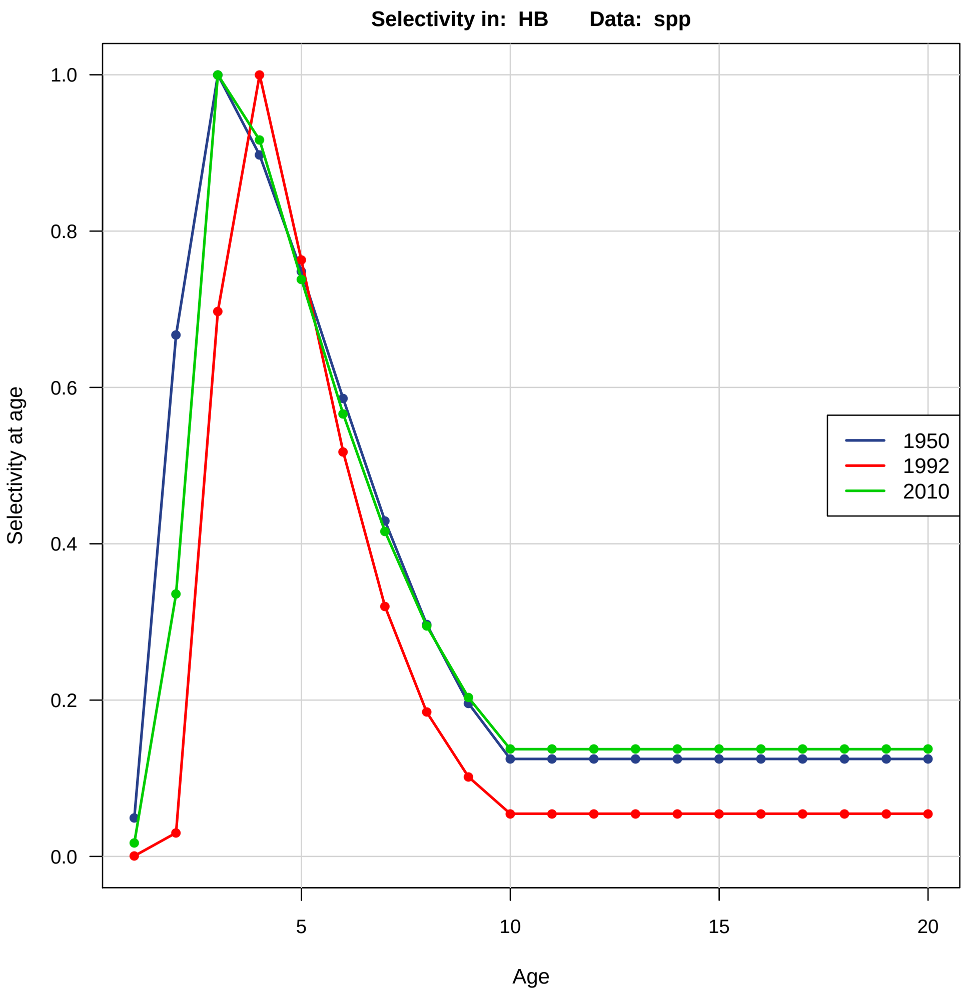

Figure 22. Selectivities of general recreational landings. The legend indicates the first year each selectivity curve applies to the fleet.

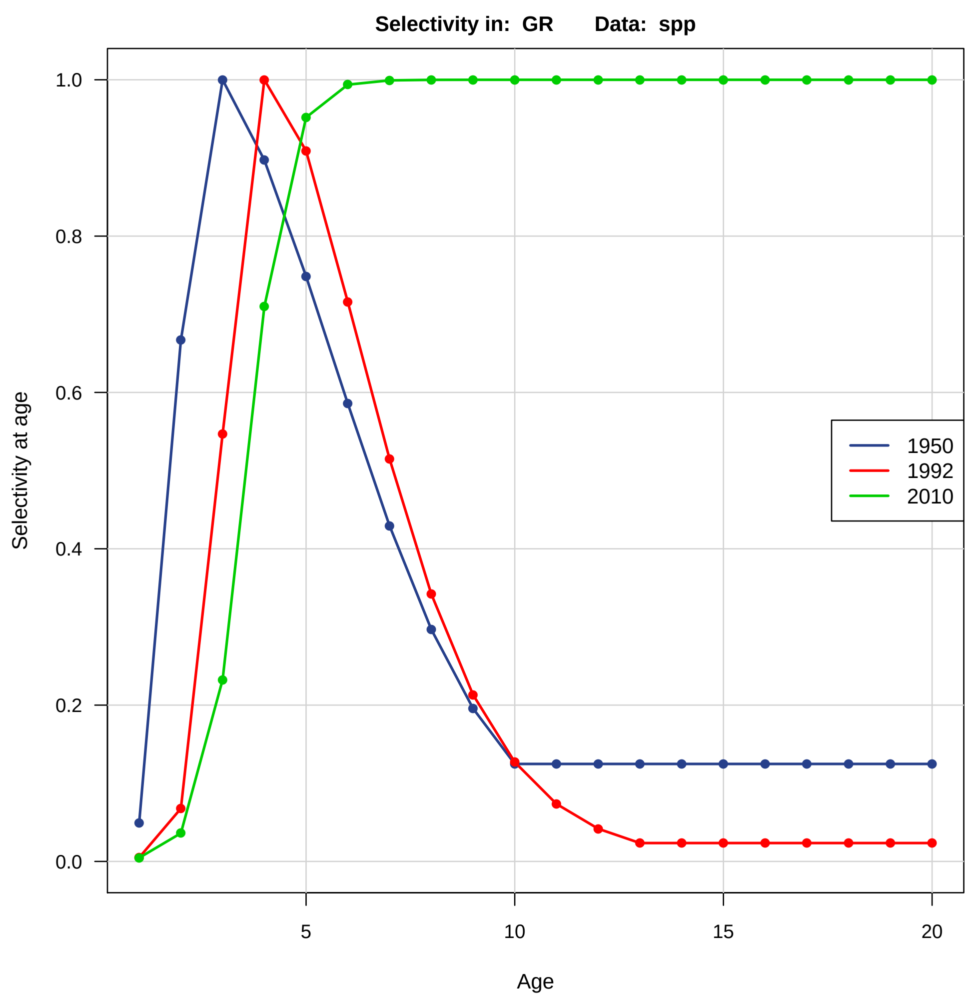

Figure 23. Selectivities of commercial handline discards. The legend indicates the first year each selectivity curve applies to the fleet.

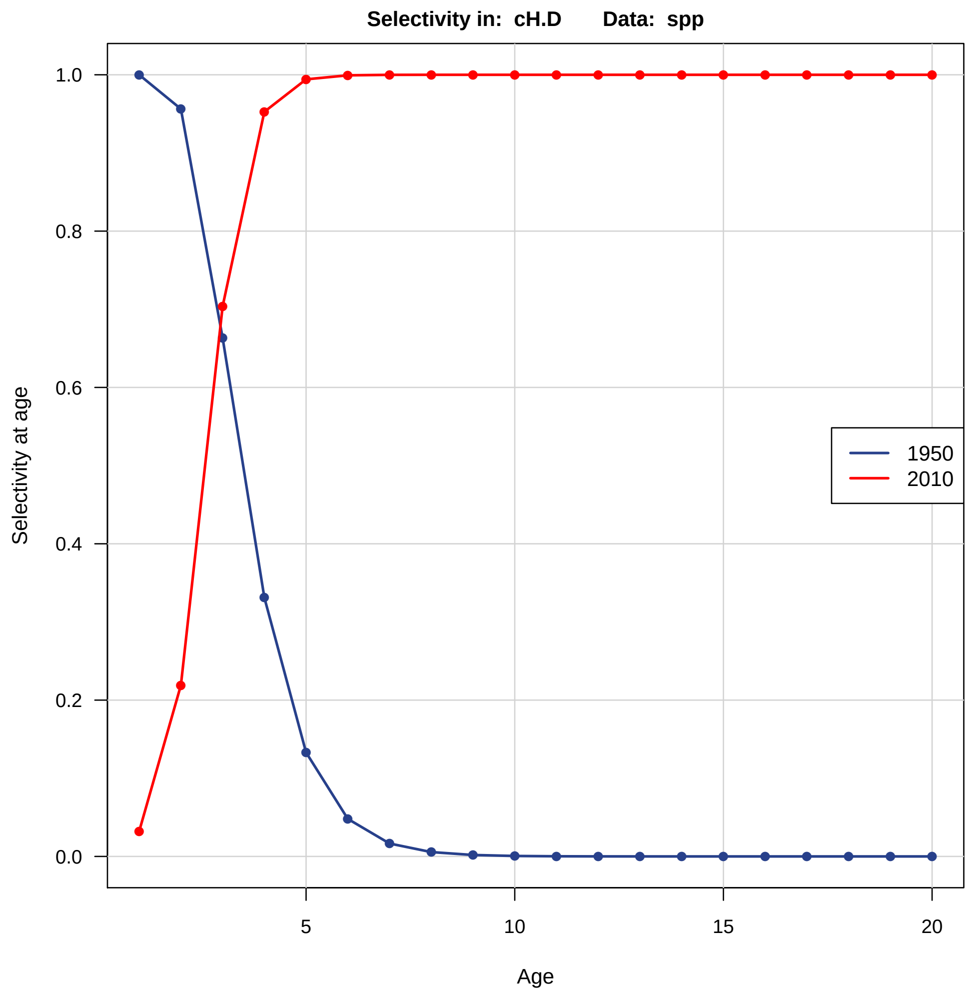

Figure 24. Selectivities of headboat discards. The legend indicates the first year each selectivity curve applies to the fleet.

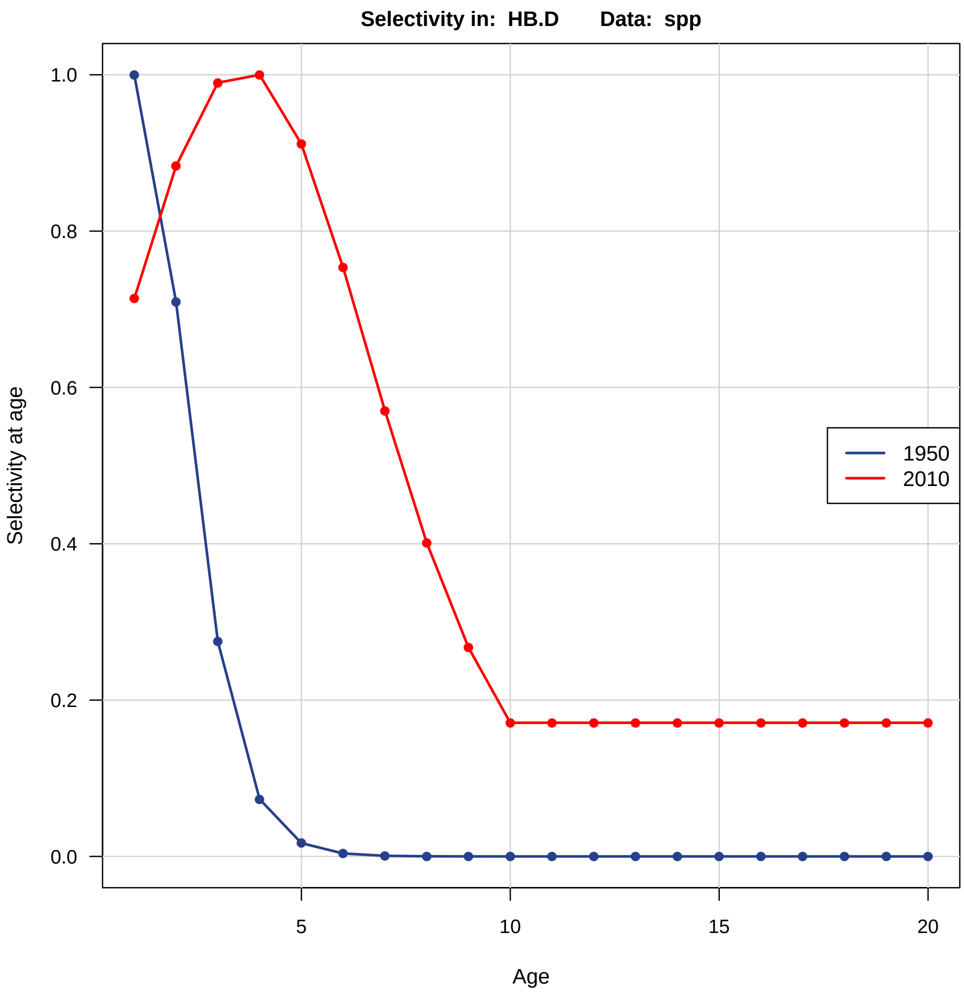

Figure 25. Selectivities of general recreational discards. The legend indicates the first year each selectivity curve applies to the fleet.

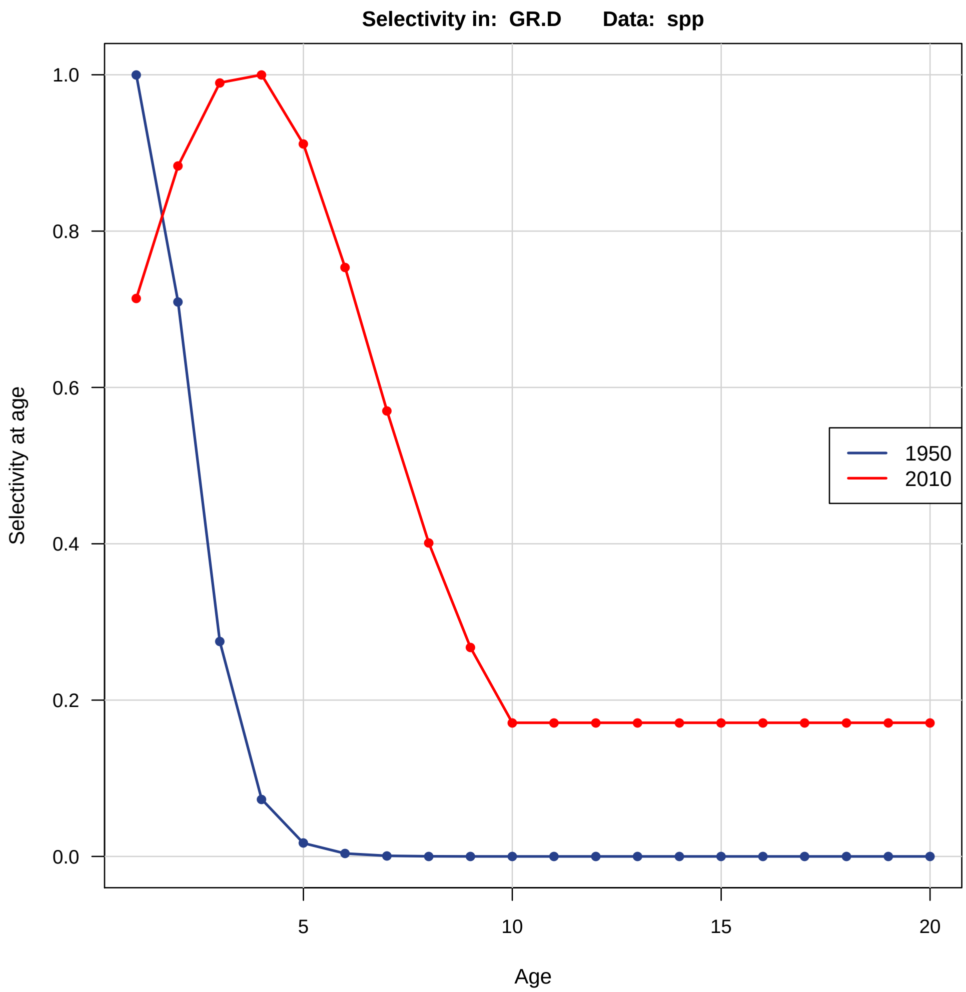

Figure 26. Average selectivity of discards(top left), landings (top right), and total weighted average (bottom) from the terminal assessment years, weighted by geometric mean F's from the last three assessment years, and used in computation of benchmarks and projections.

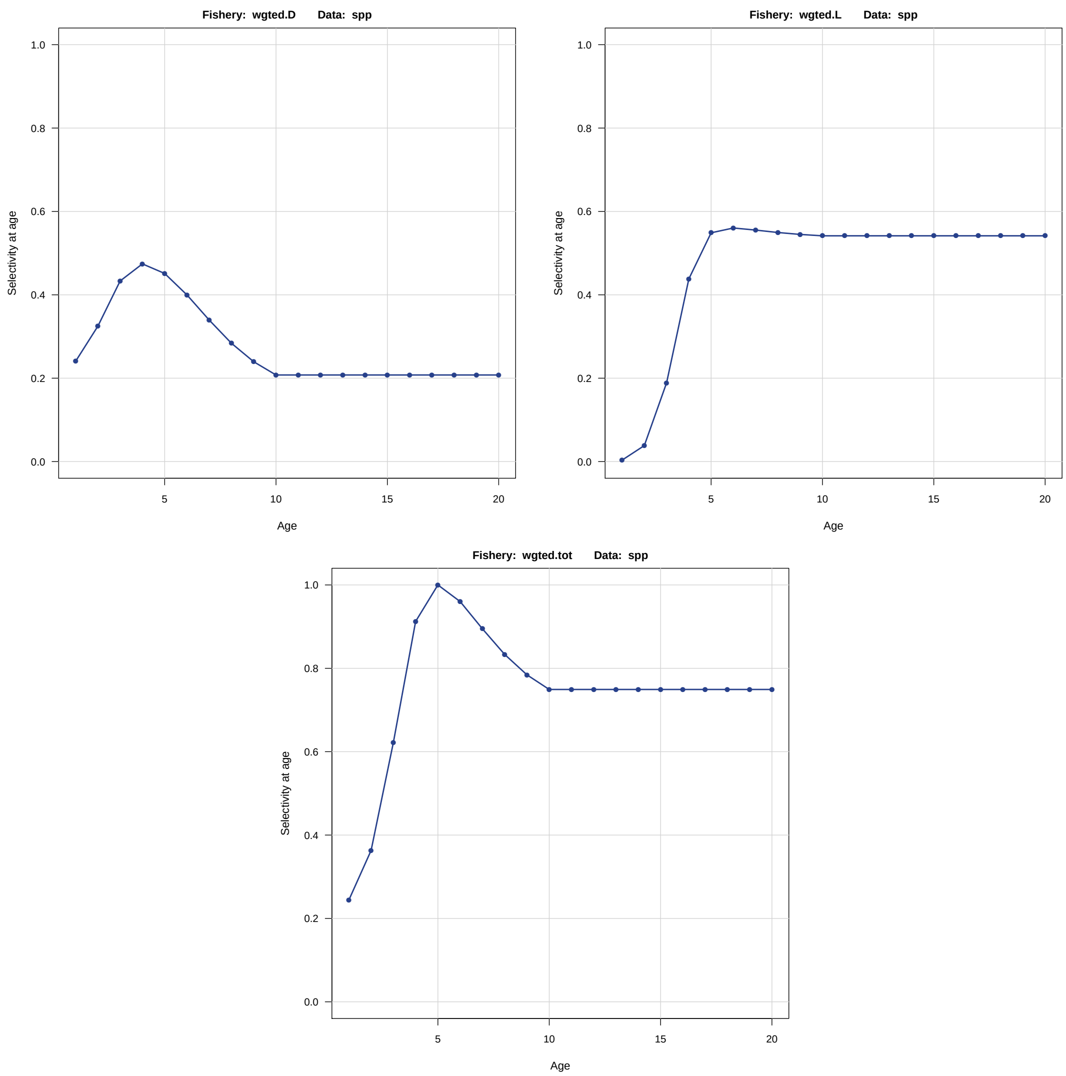

Figure 27. Estimated fully selected fishing mortality rate (per year) by fleet. cH refers to commercial handlines, HB to headboat, GR to general recreational, and D refers to discard mortality.

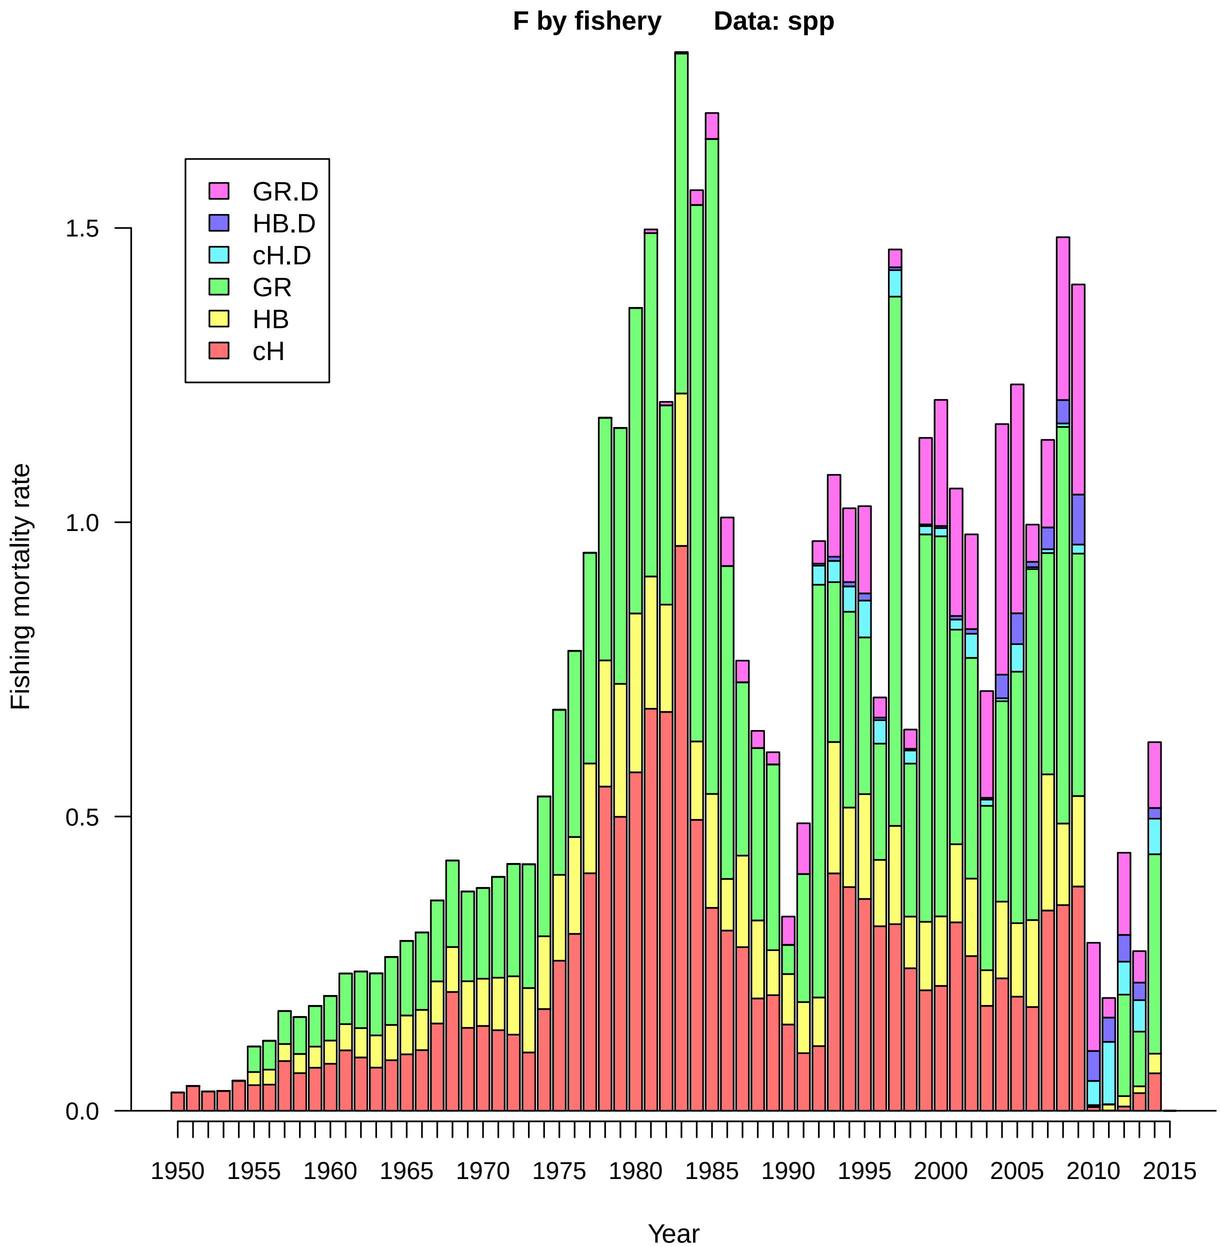

Figure 28. Estimated landings in numbers by fleet from the catch-age model. cH refers to commercial handlines, HB to headboat, and GR to general recreational. Horizontal dashed line in the top panel corresponds to the point estimate of $L_{F30\%}$ in numbers.

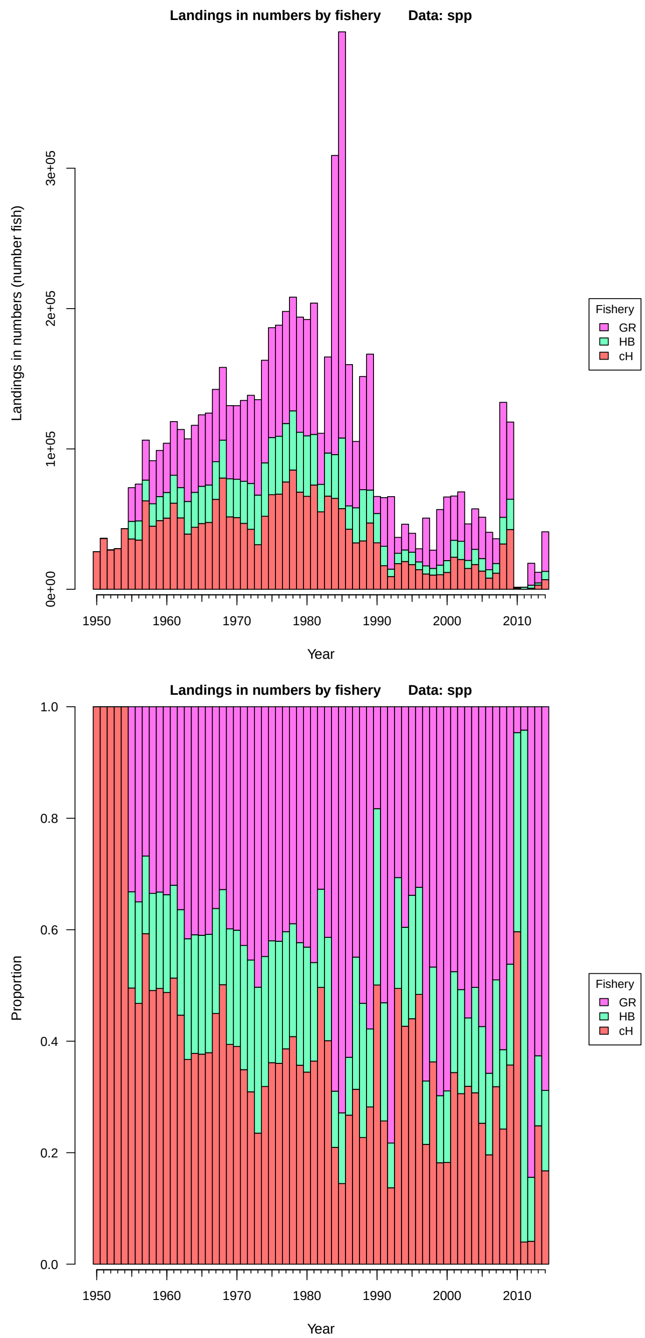

Figure 29. Estimated landings in whole weight by fleet from the catch-age model. cH refers to commercial handlines, HB to headboat, and GR to general recreational. Horizontal dashed line in the top panel corresponds to the point estimate of $L_{F30\%}$ in weight.

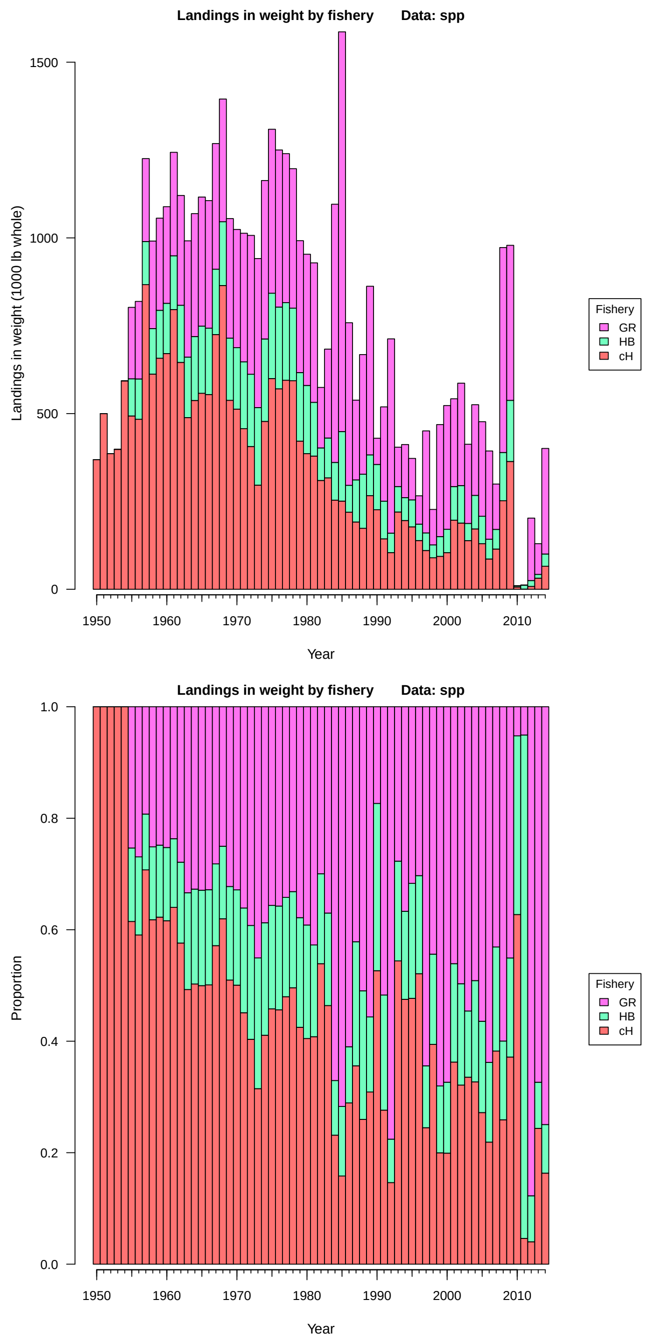

Figure 30. Estimated discard mortalities by fleet from the catch-age model. cH refers to commercial lines, hb to headboat, rec to general recreational. Horizontal dashed line in the top panel corresponds to the point estimate of $D_{F_{30\%}}$ *in numbers.*

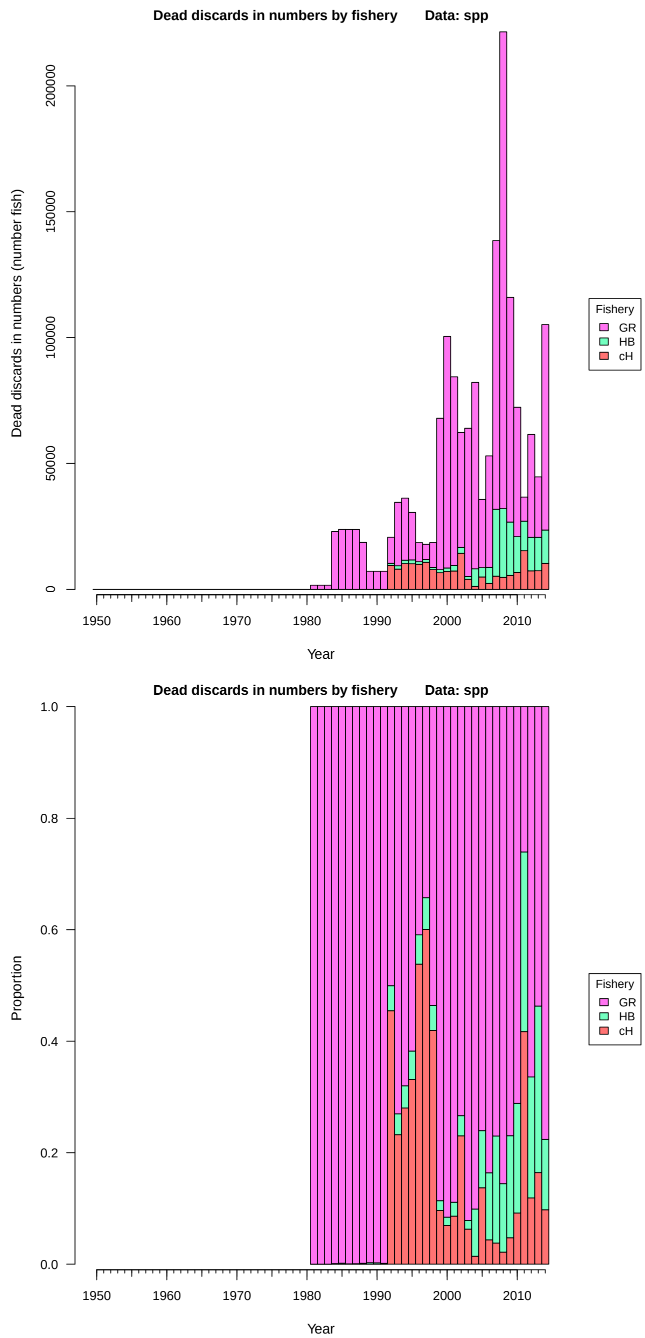

Figure 31. Top panel: Beverton–Holt spawner-recruit curves, with and without lognormal bias correction. The expected (upper) curve was used for computing management benchmarks. Bottom panel: log of recruits (number age-1 fish) per spawner as a function of spawners.

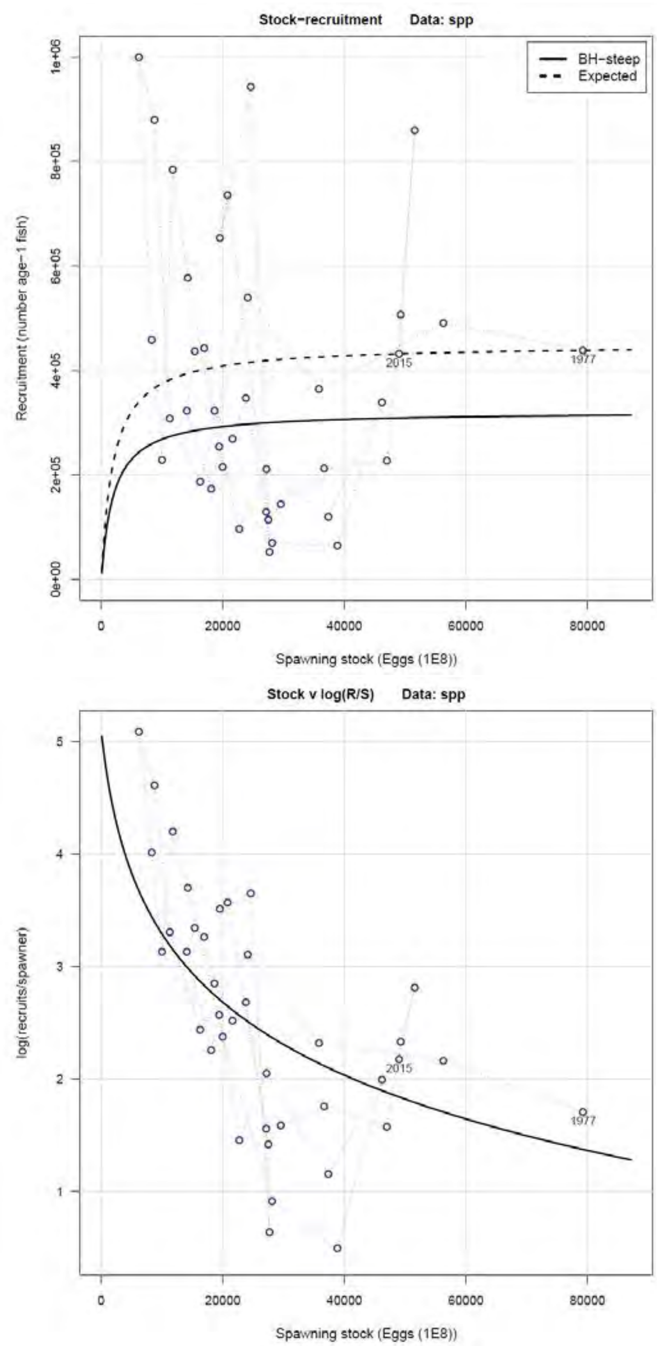

Figure 32. Probability densities of spawner-recruit quantities R0 (unfished recruitment of age-1 fish), steepness (fixed at 0.99), unfished spawners per recruit, and standard deviation of recruitment residuals in log space. Solid vertical lines represent point estimates or values from the base run of the Beaufort Assessment Model; dashed vertical lines represent medians from the MCB runs.

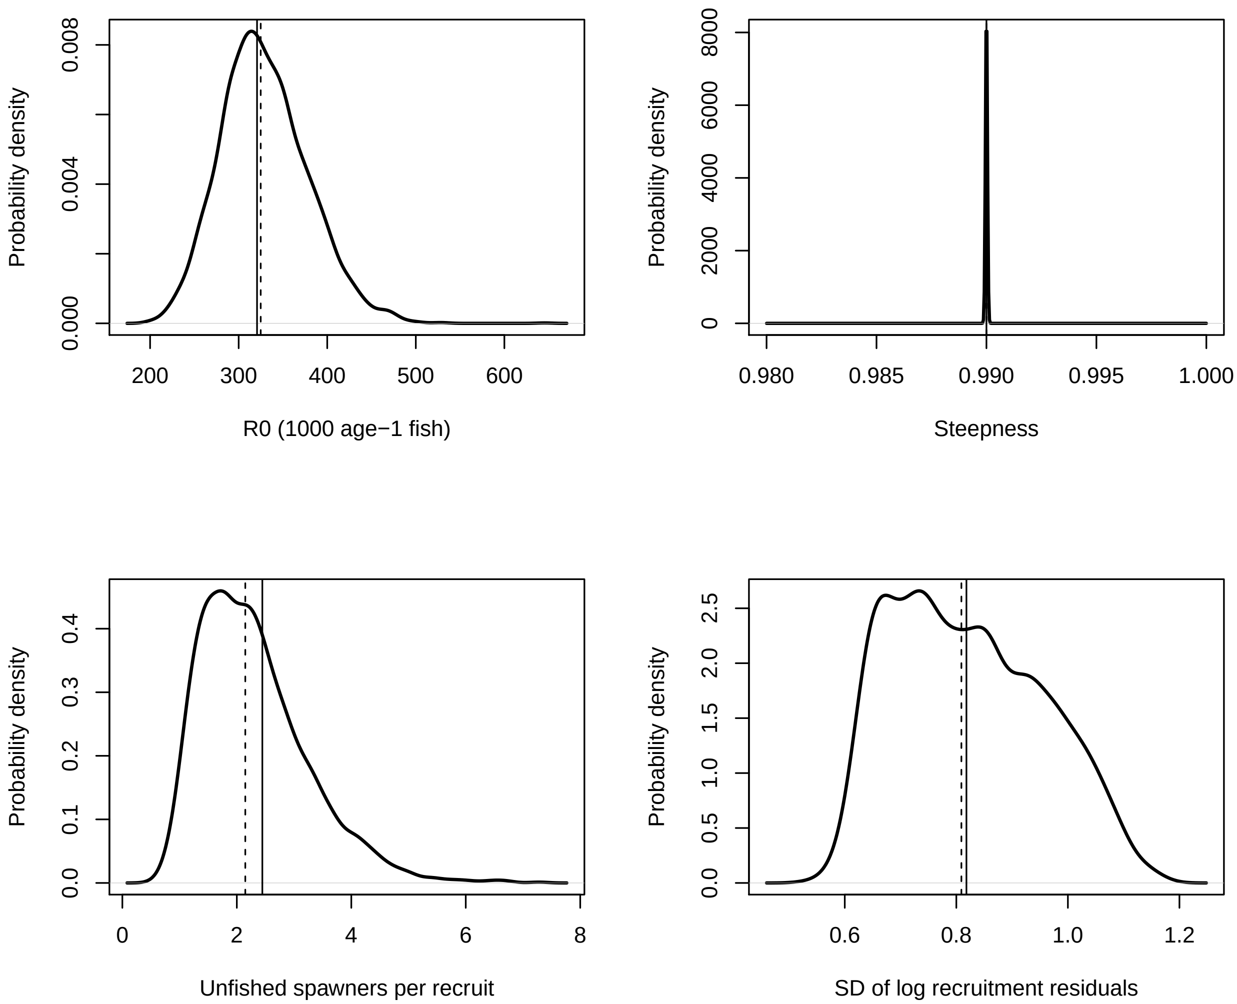

Figure 33. Yield per recruit based on average selectivity from the end of the assessment period.

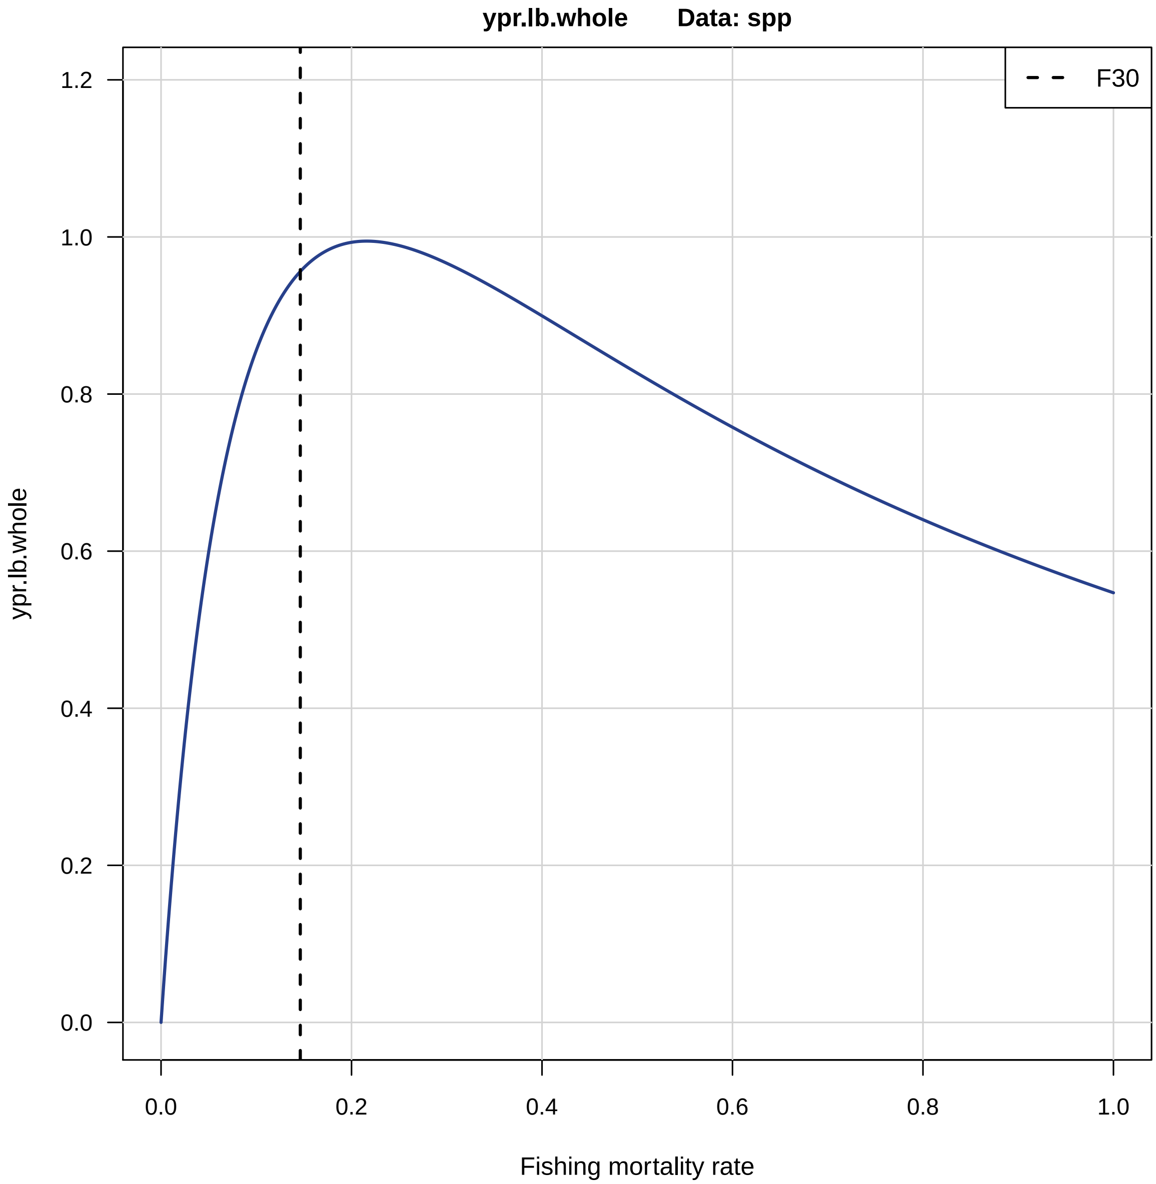

Figure 34. Spawning potential ratio (spawning biomass per recruit relative to that at the unfished level), from which the X% level of SPR provides $F_{X\%}$. SPR is based on average selectivity from the end of the assessment period.

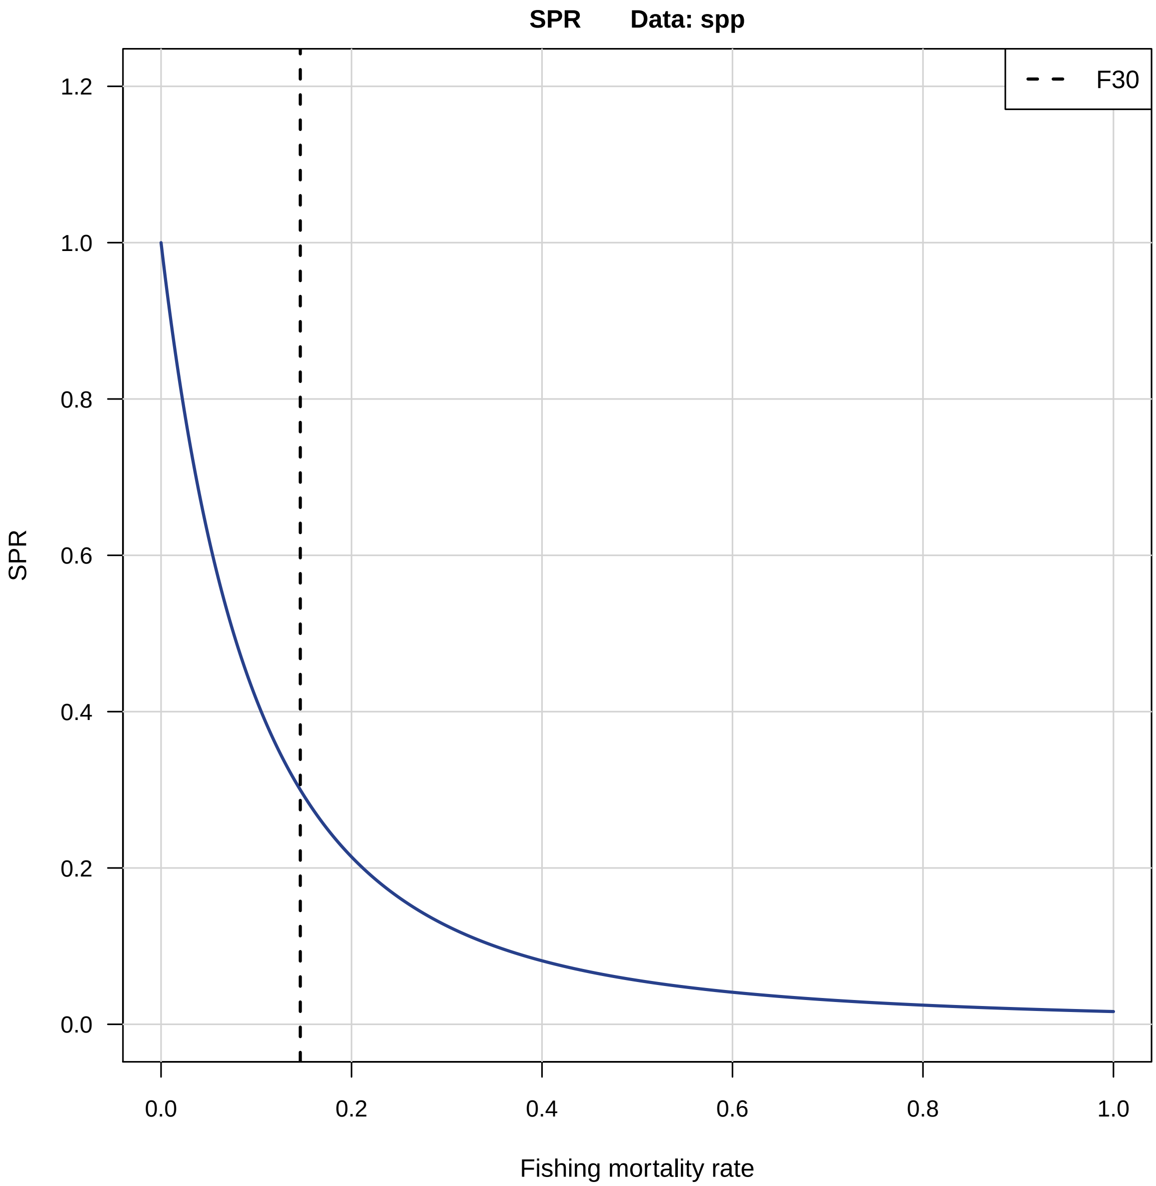

Figure 35. Equilibrium spawning biomass based on average selectivity from the end of the assessment period.

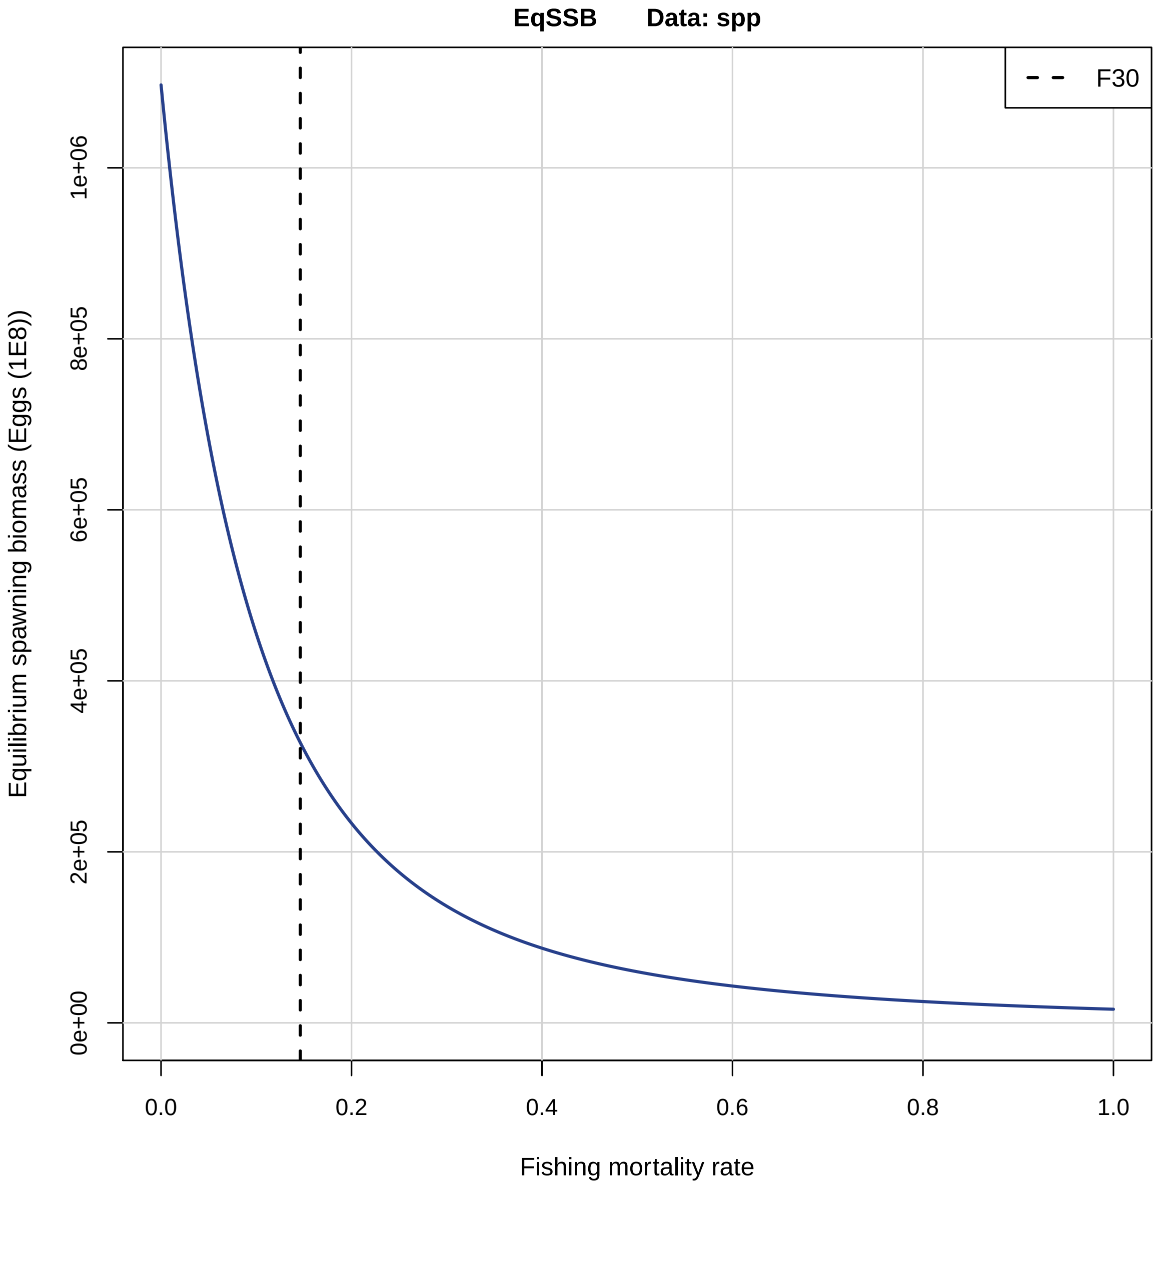

Figure 36. Probability densities of $F_{30\%}$-related benchmarks from MCB analysis of the Beaufort Assessment Model. Solid vertical lines represent point estimates from the base run; dashed vertical lines represent median values.

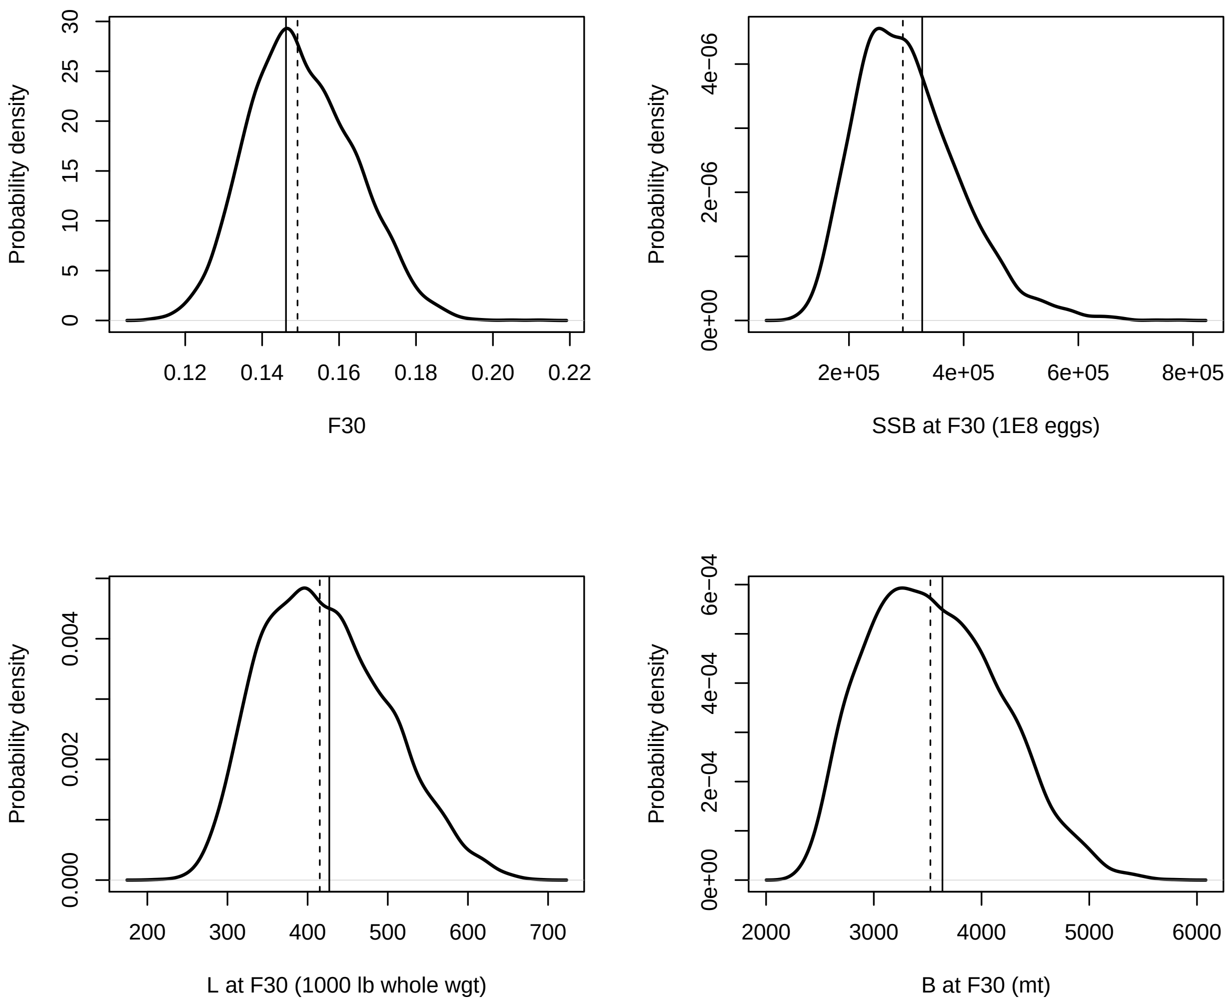

Figure 37. Estimated time series relative to benchmarks. Solid line indicates estimates from base run of the Beaufort Assessment Model; dashed lines represent median values; gray error bands indicate 5^{th} and 95^{th} percentiles of the MCB trials. Top panel: spawning biomass relative to $\mathrm{SSB}_{\mathrm{F30\%}}$. Bottom panel: F relative to $F_{30\%}$.

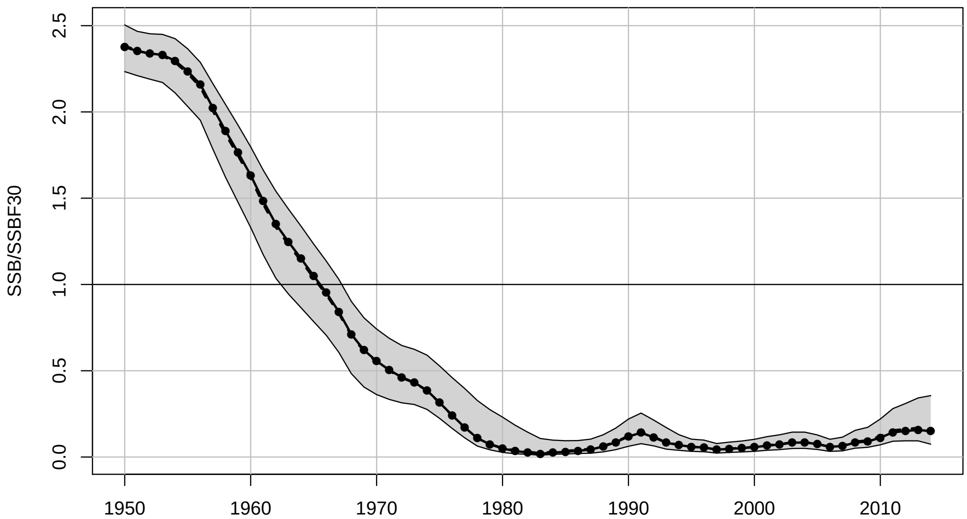

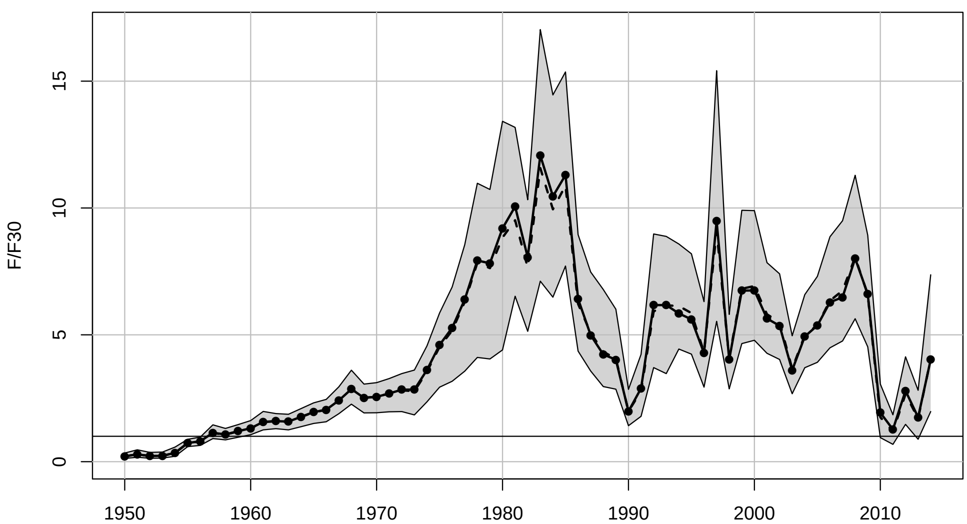

Figure 38. Probability densities of terminal status estimates from MCB analysis of the Beaufort Assessment Model. Solid vertical lines represent point estimates from the base run; dashed vertical lines represent median values.

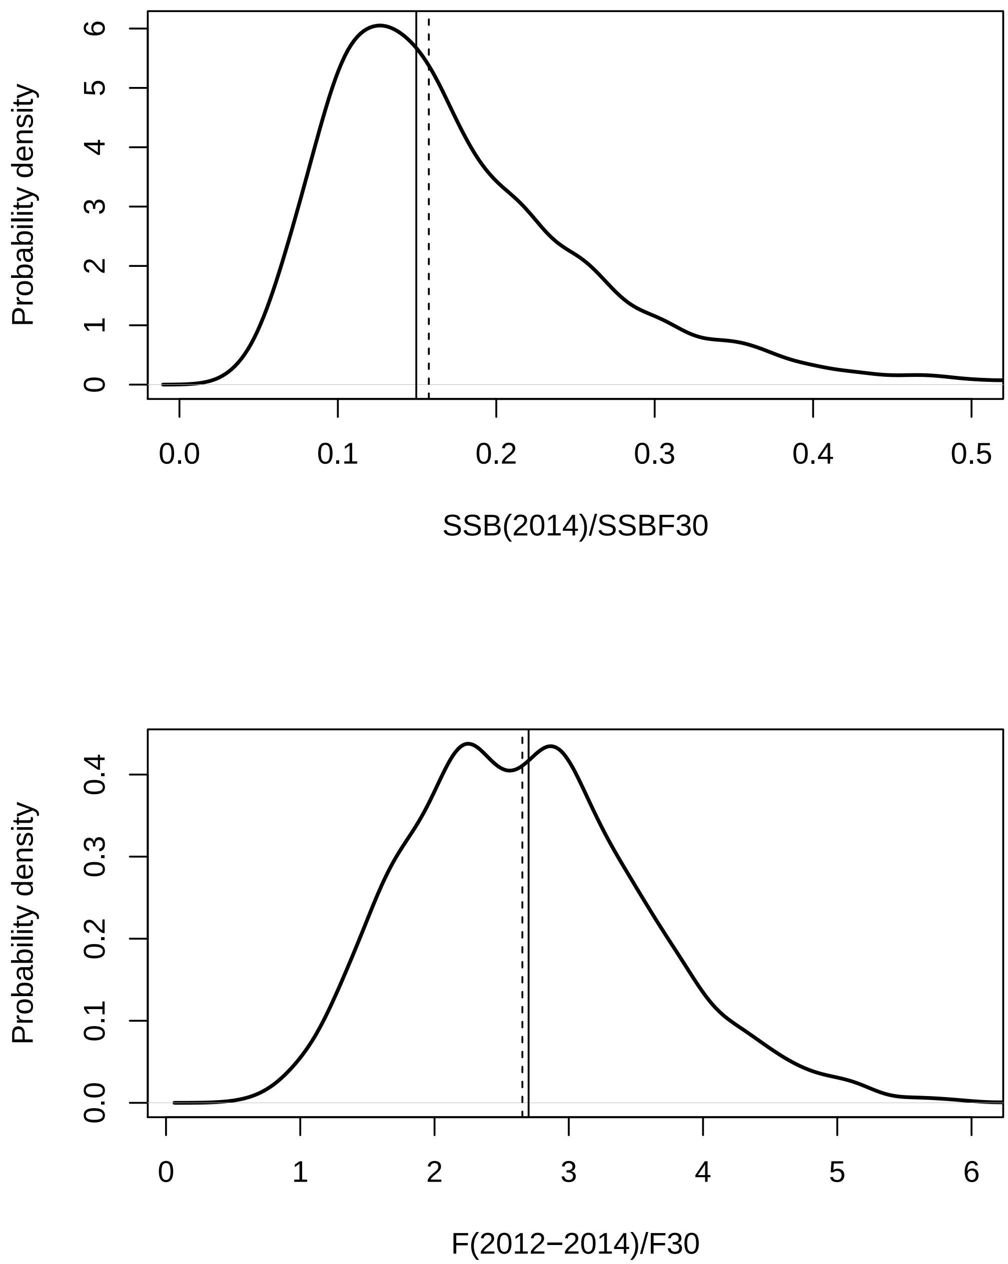

Figure 39. Phase plots of terminal status estimates from MCB analysis of the Beaufort Assessment Model. The intersection of crosshairs indicates estimates from the base run; lengths of crosshairs defined by 5^{th} and 95^{th} percentiles. Proportion of runs falling in each quadrant indicated.

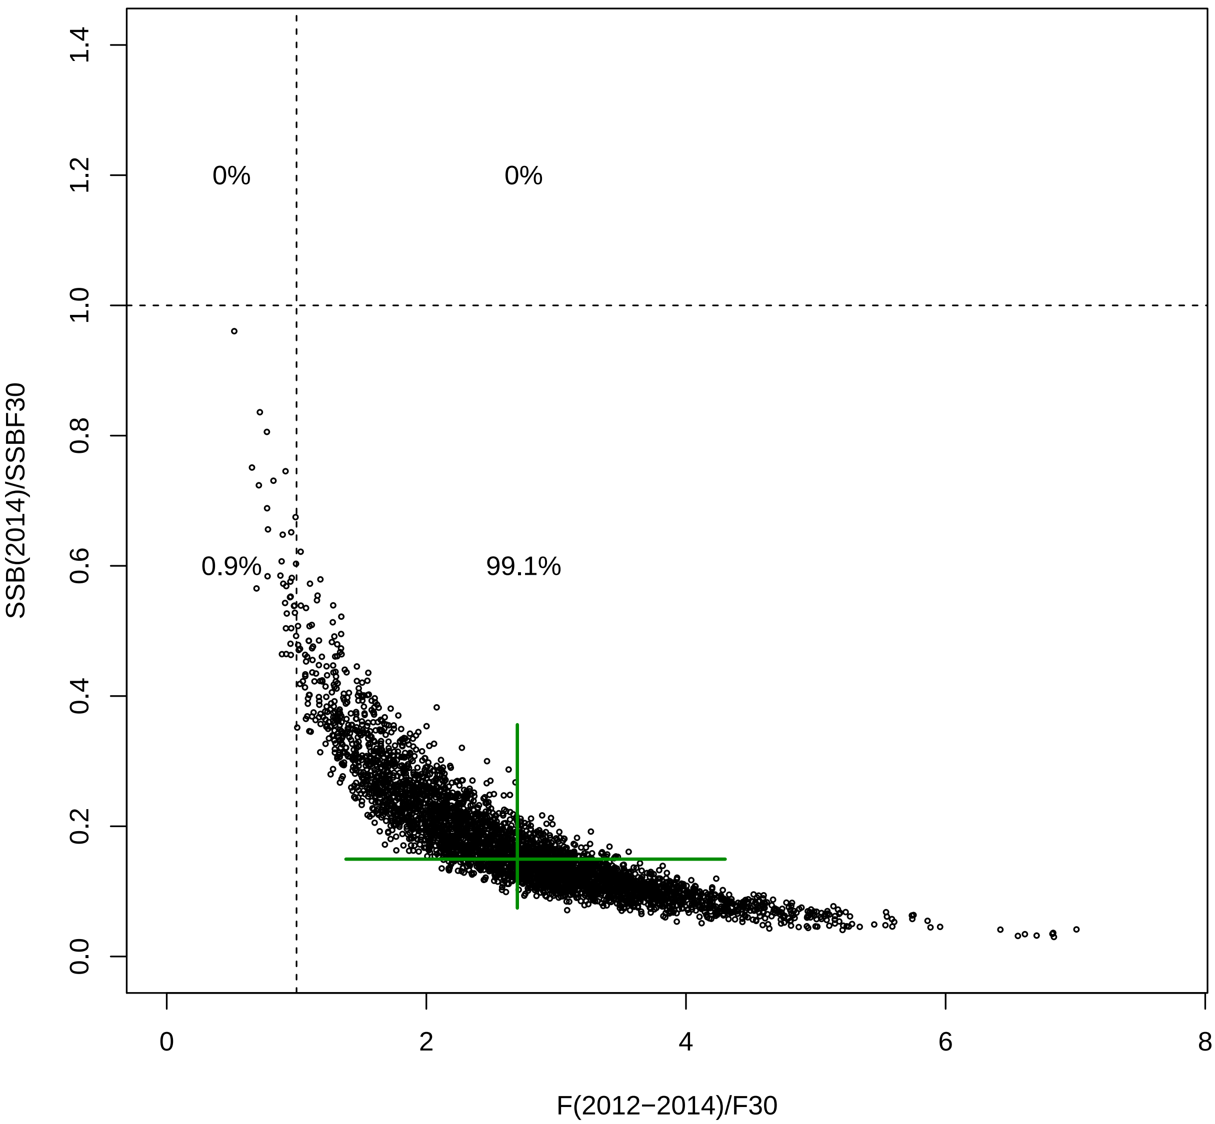

Figure 40. Age structure relative to the equilibrium expected at $F_{30\%}$.

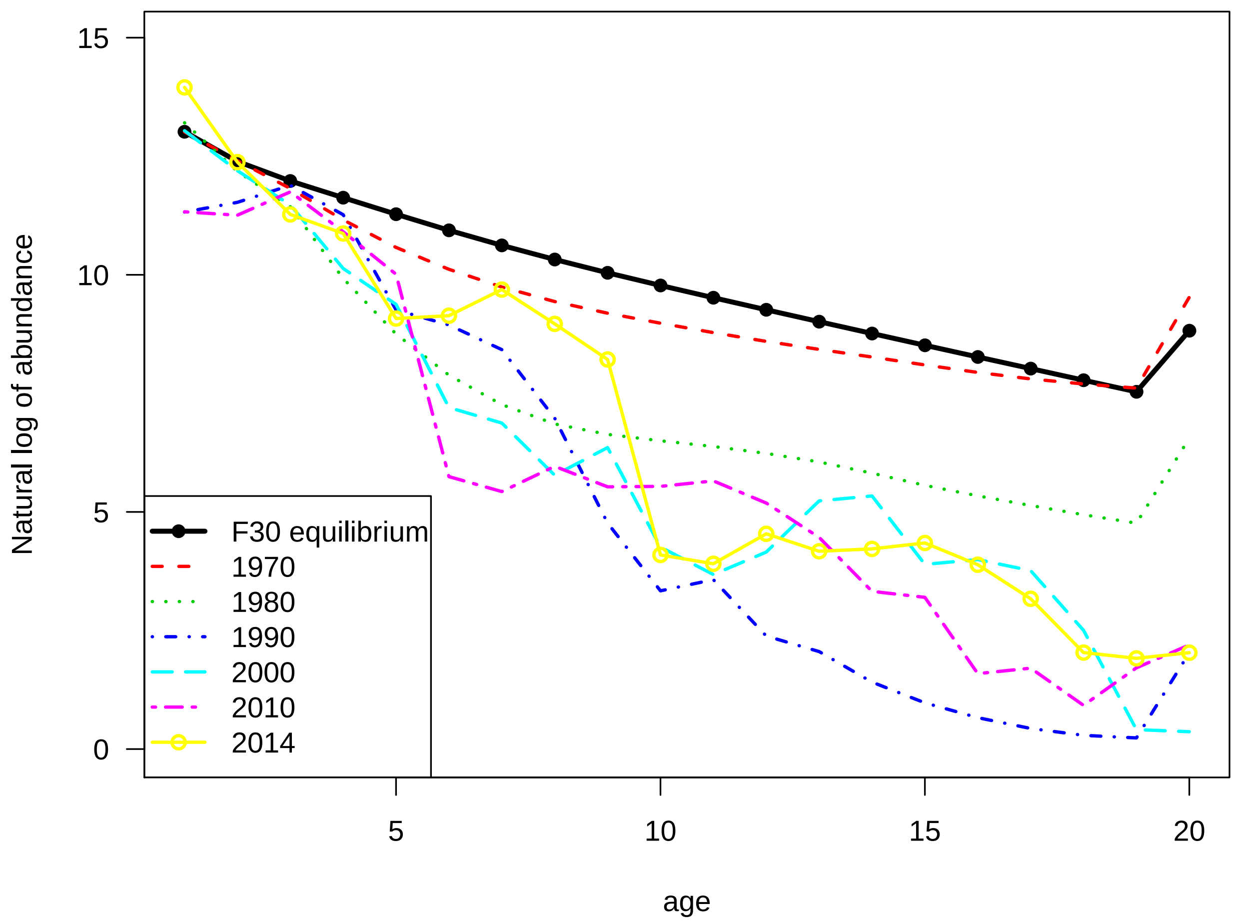

Figure 41. Sensitivity to changes in natural mortality (sensitivity runs S5 and S6). Top panel: Ratio of F to $F_{30\%}$*. Bottom panel: Ratio of* SSB *to* $SSB_{F30\%}$.

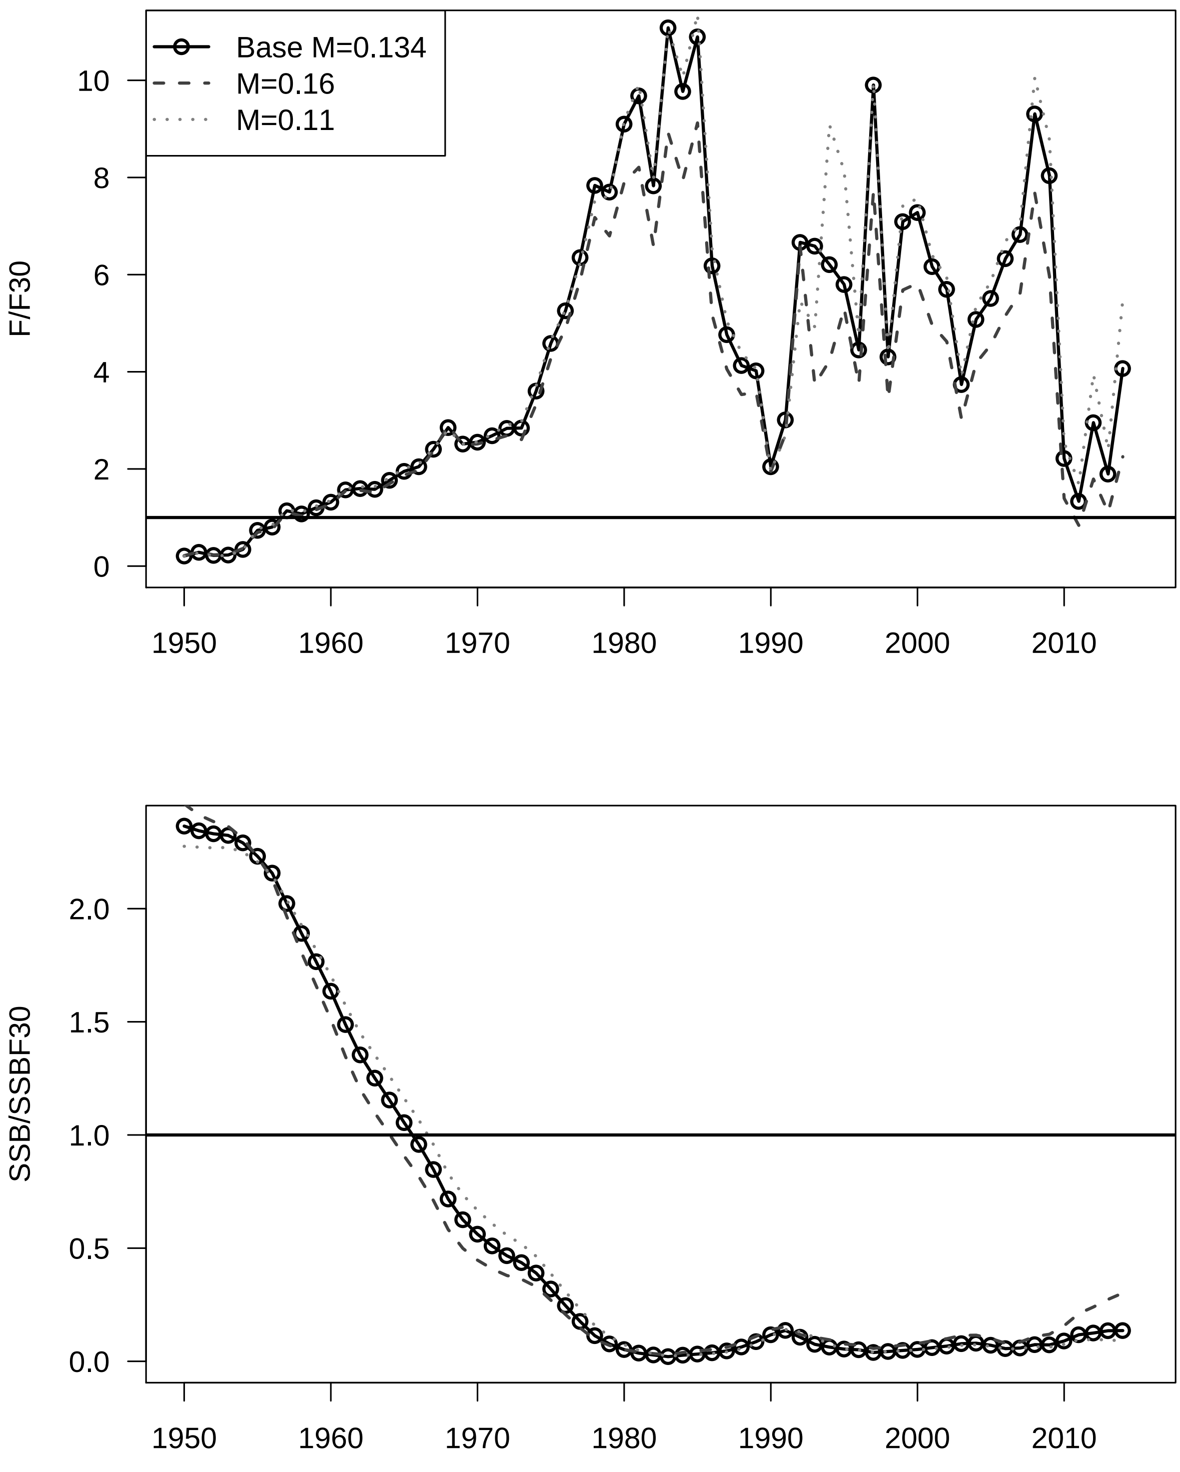

Figure 42. Sensitivity to steepness (sensitivity run S11). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

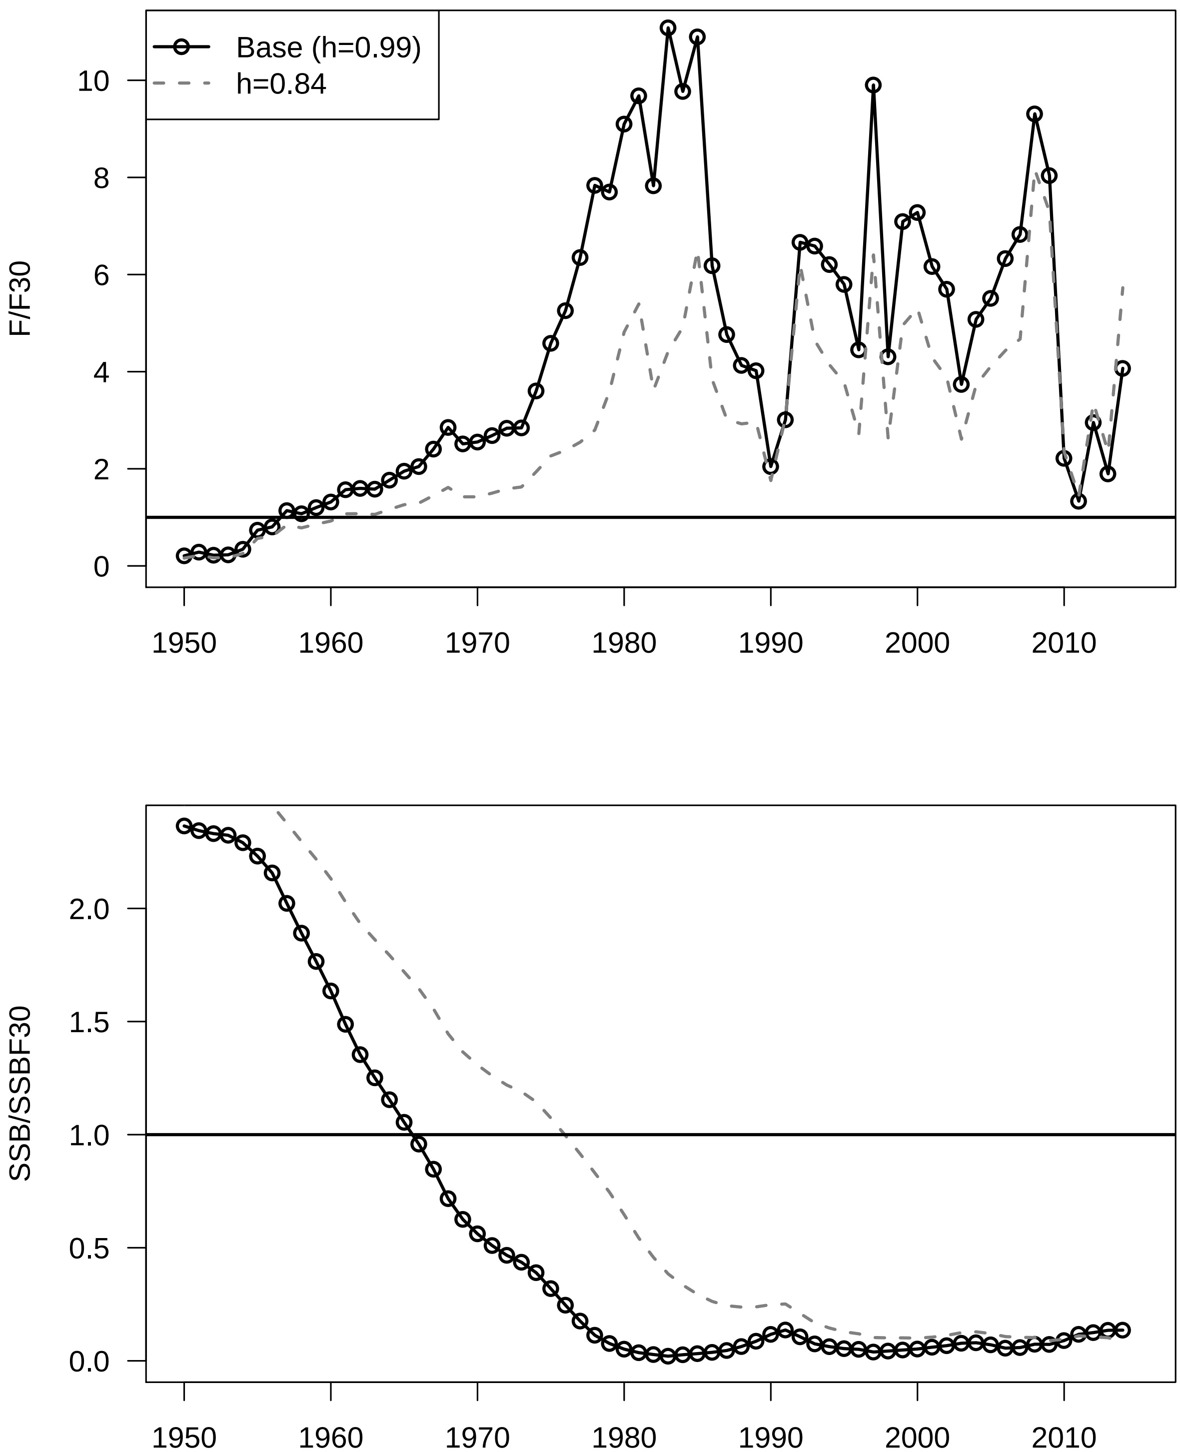

Figure 43. Sensitivity to start year (1978 compared to 1950) (sensitivity run S26). Top panel: Ratio of F to $F_{30\%}$. *Bottom panel: Ratio of* SSB *to* $SSB_{F30\%}$.

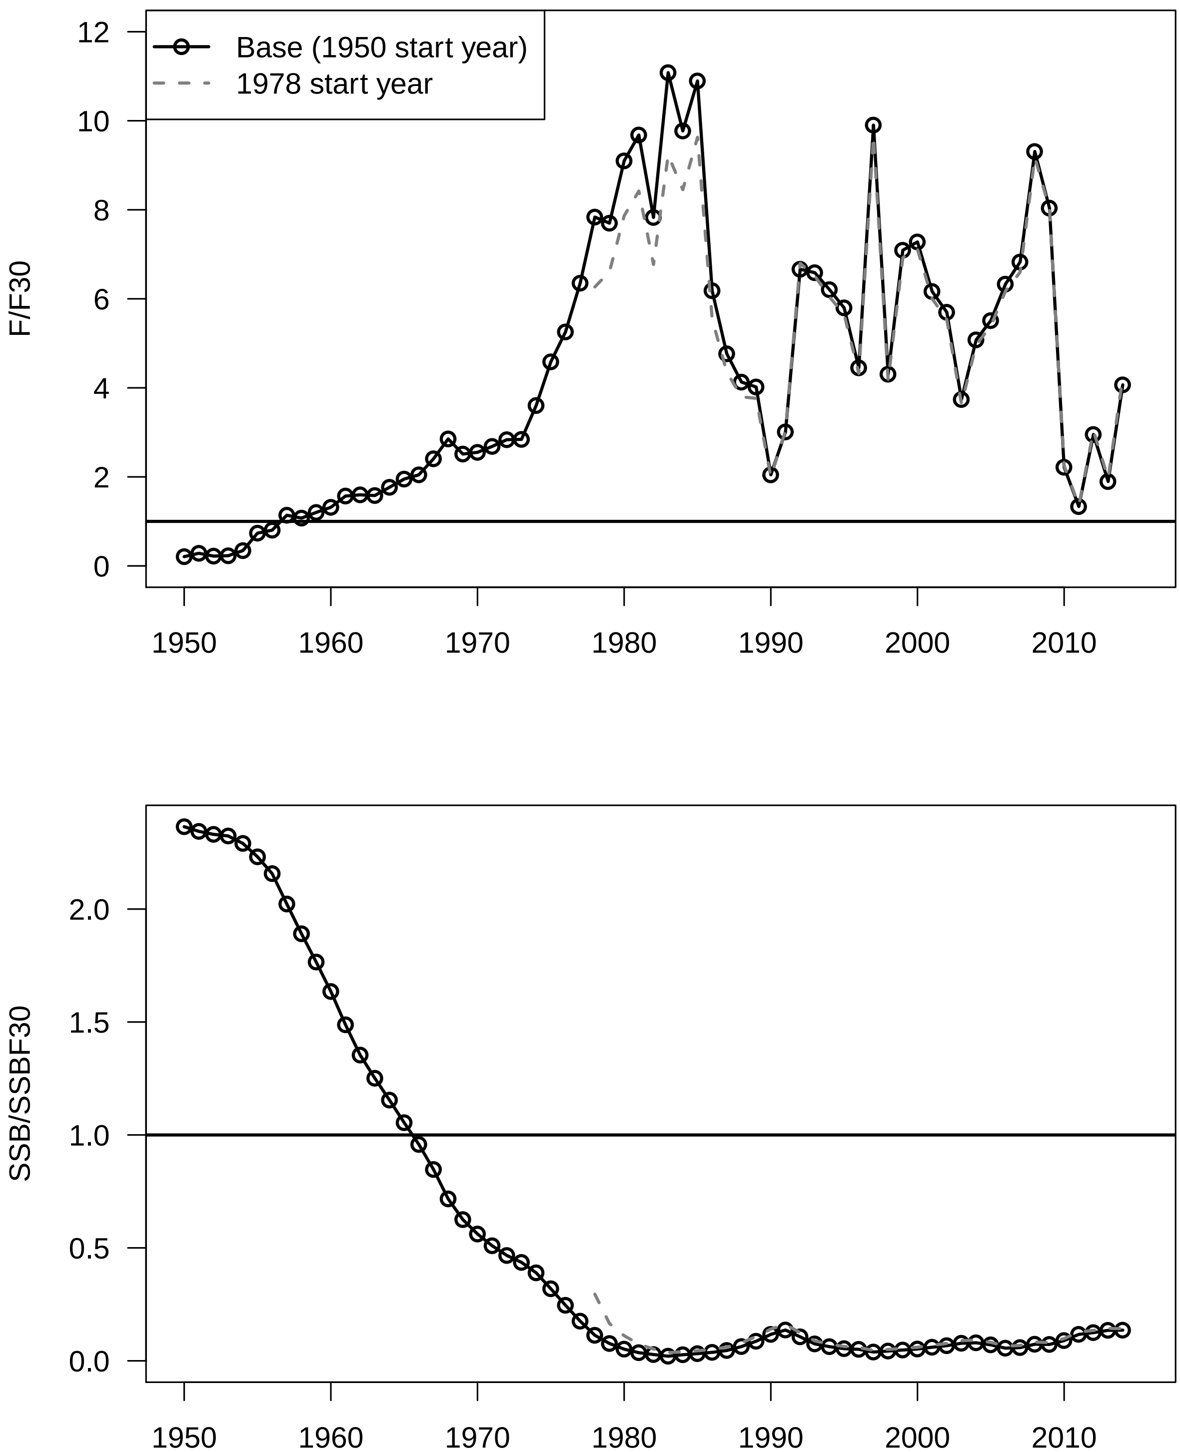

Figure 44. Sensitivity to aging error matrix (sensitivity run S13). Top panel: Ratio of F to $F_{30\%}$. *Bottom panel: Ratio of* SSB *to* $SSB_{F30\%}$.

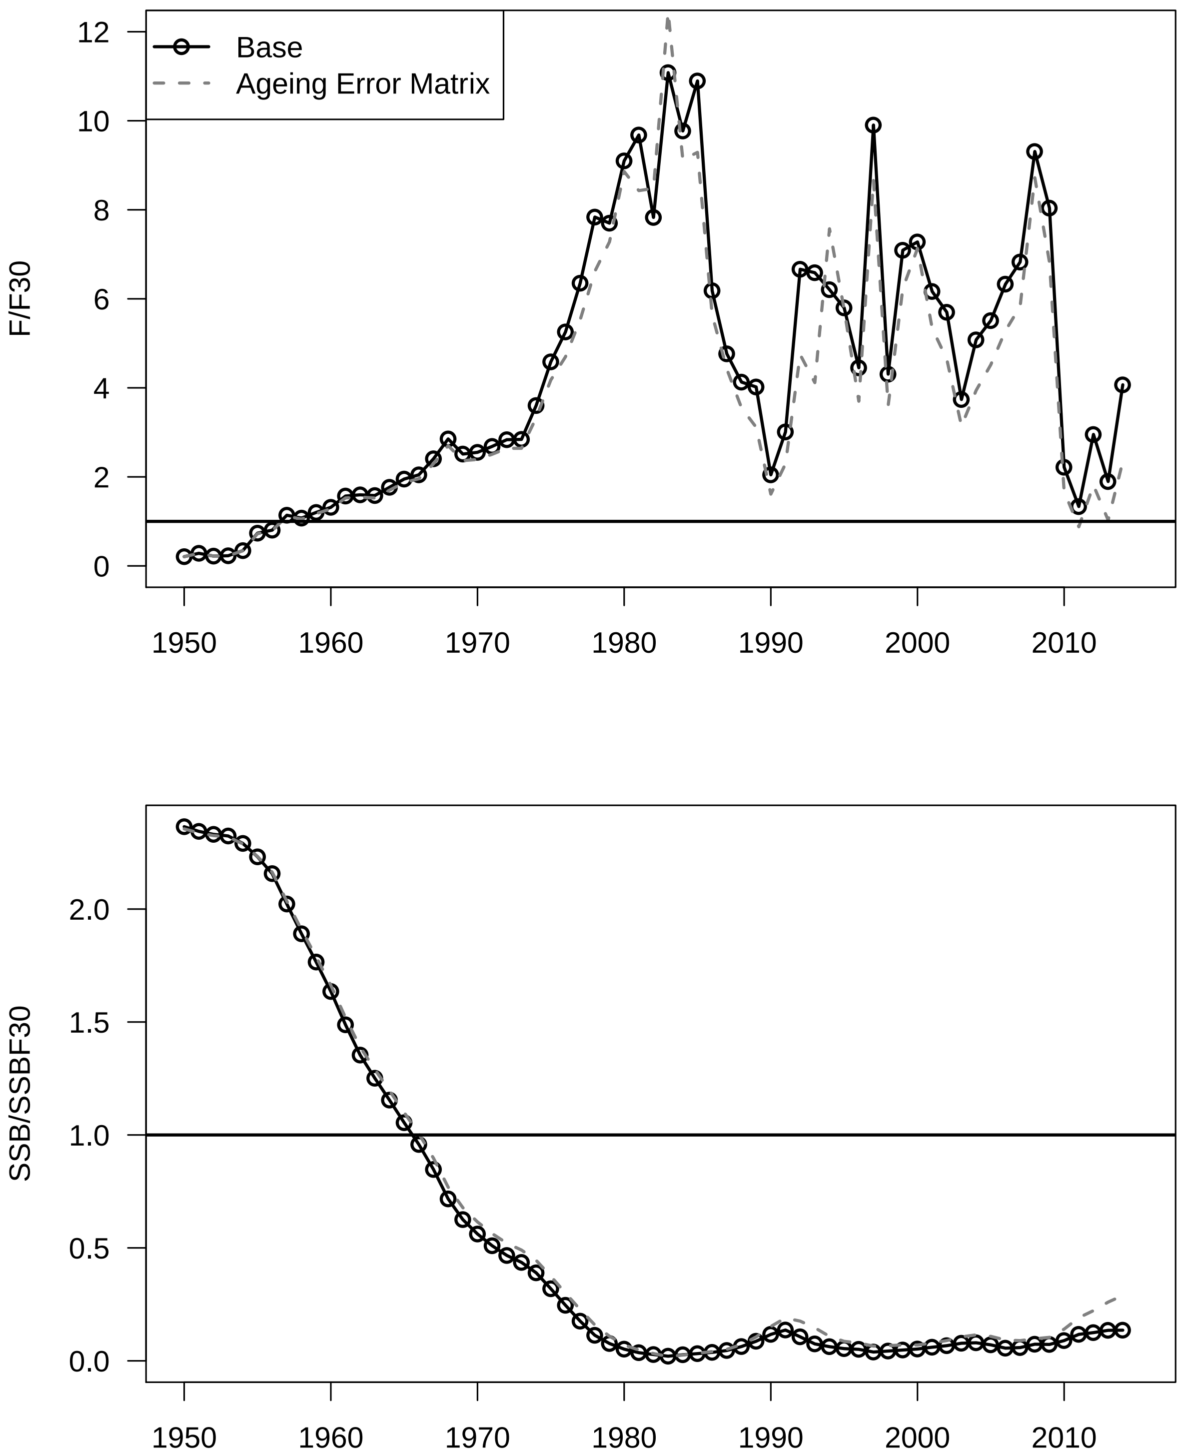

Figure 45. Sensitivity to batch number (sensitivity runs S14 and S15). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

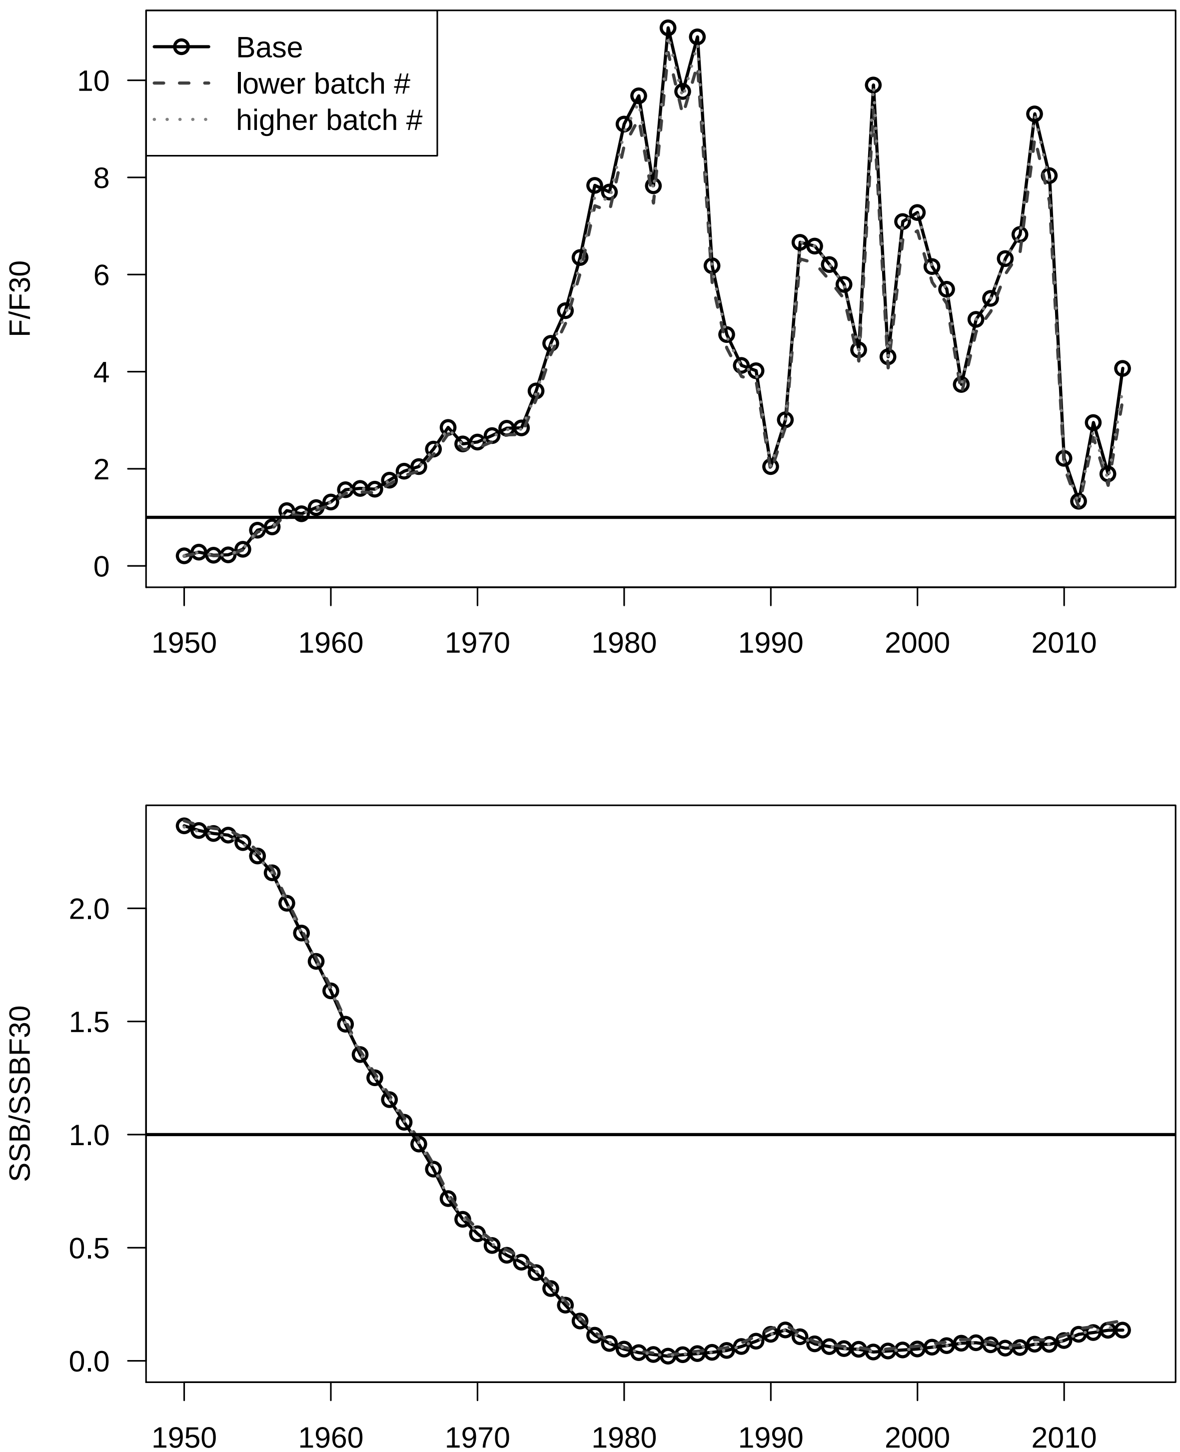

Figure 46. Sensitivity to various changes to SERFS video and trap indices (sensitivity runs S2, S9, S22 and S23). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB to $SSB_{F30\%}$.

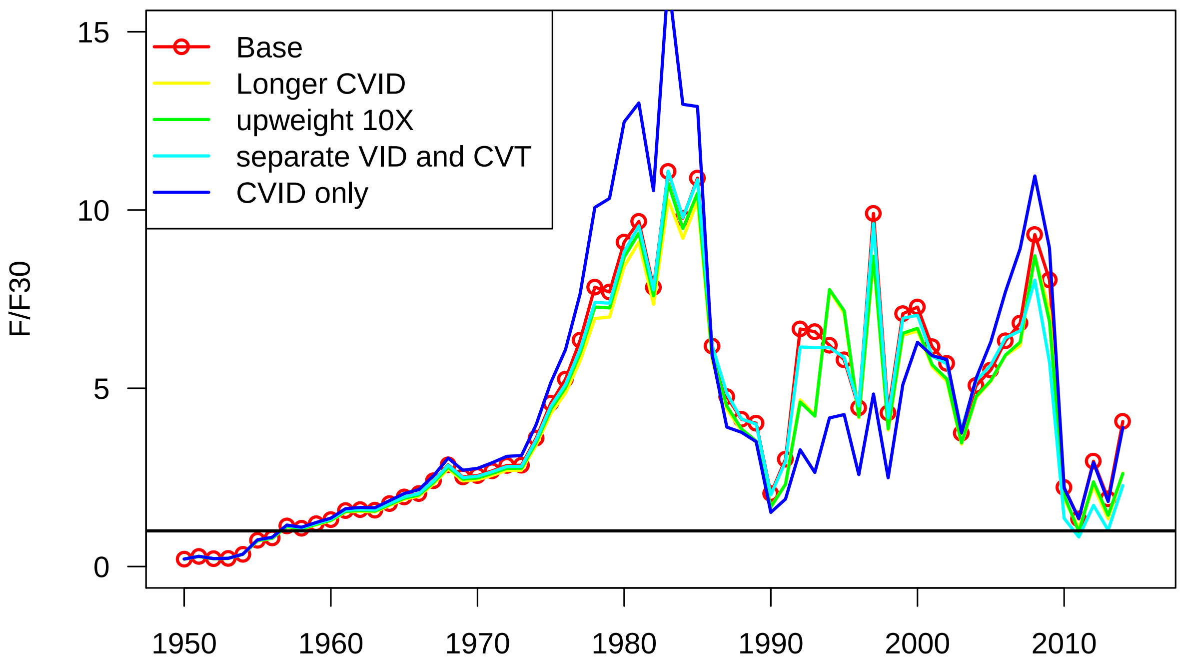

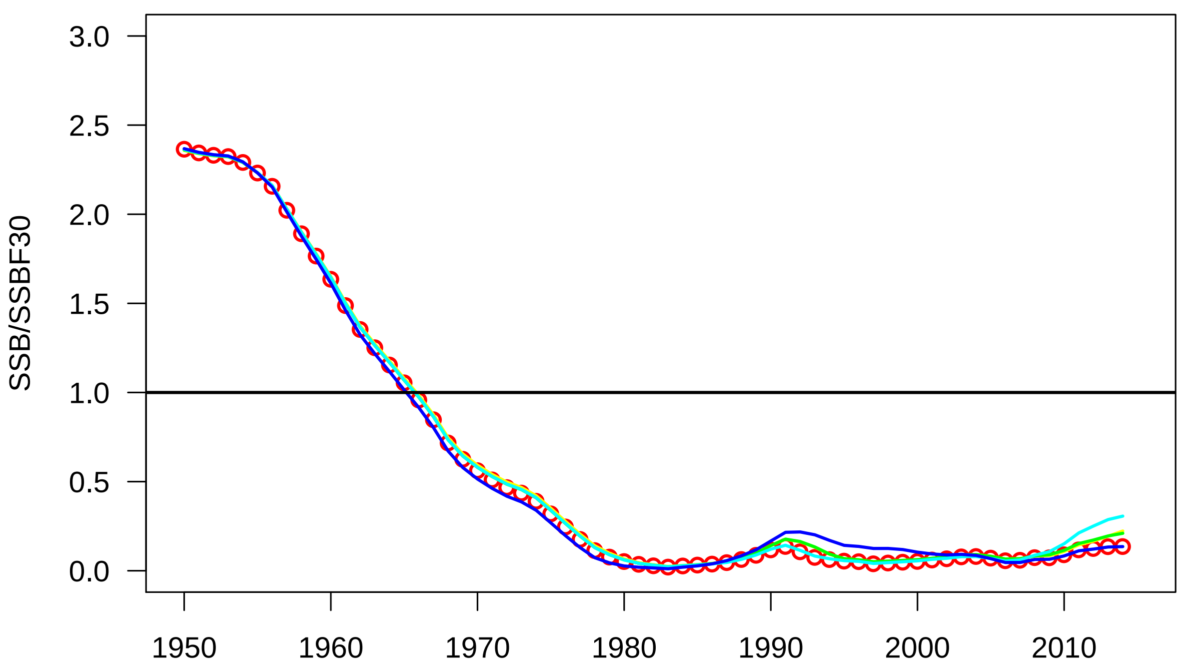

Figure 47. Sensitivity to discard mortality (sensitivity run S7 and S8). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $SSB_{F30\%}$.

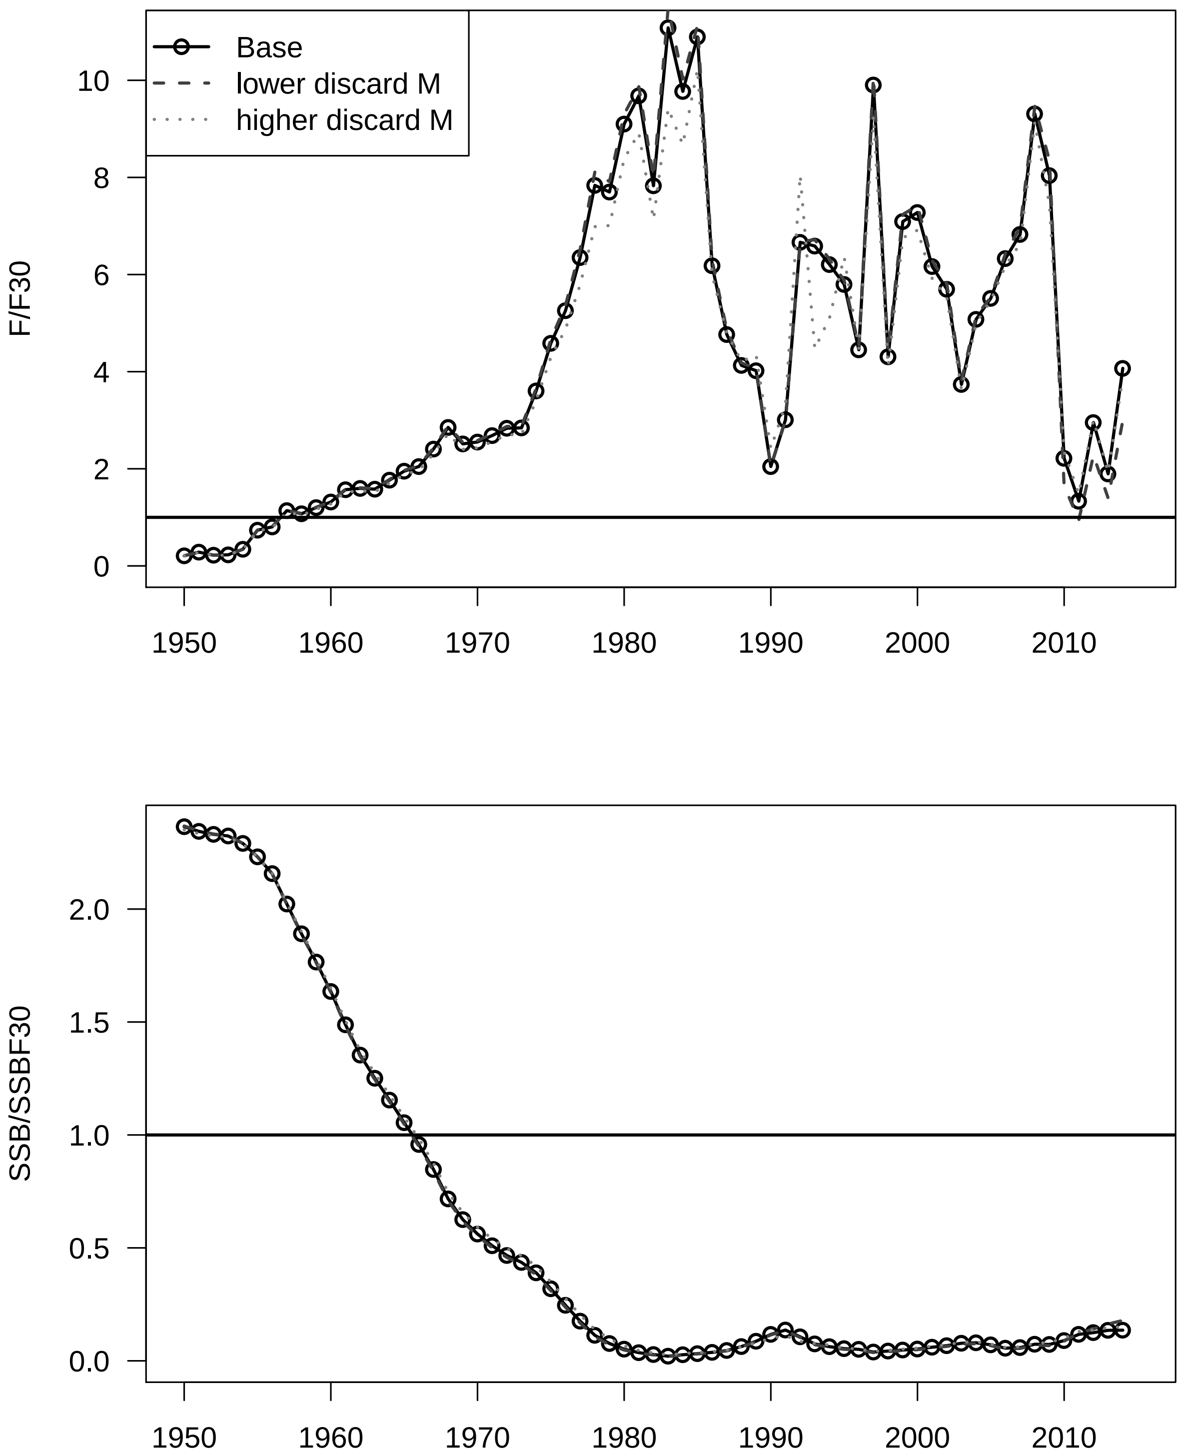

Figure 48. Sensitivity to dome-shaped selectivity for commercial handline (sensitivity run S21). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

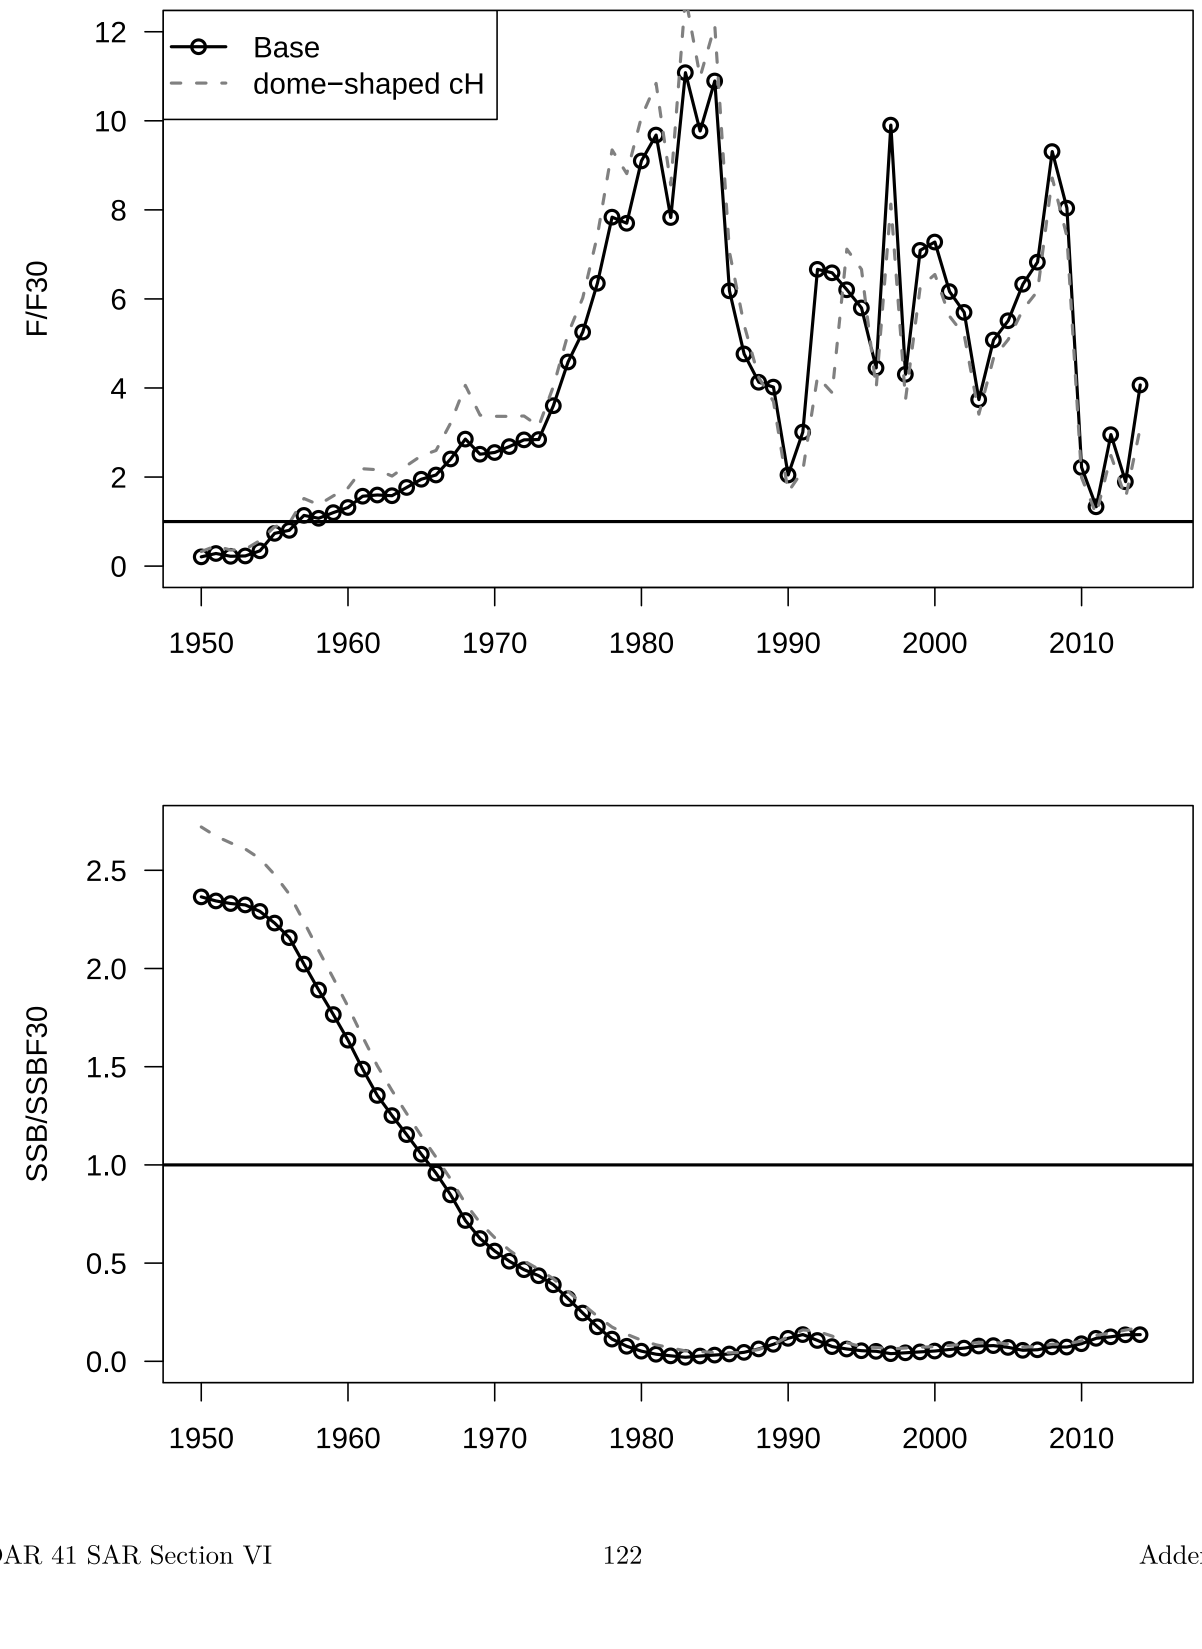

Figure 49. Sensitivity to various changes to fishery dependent indices (sensitivity runs S1, S3, S4, and S25). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\text{SSB}_{\text{F30\%}}$.

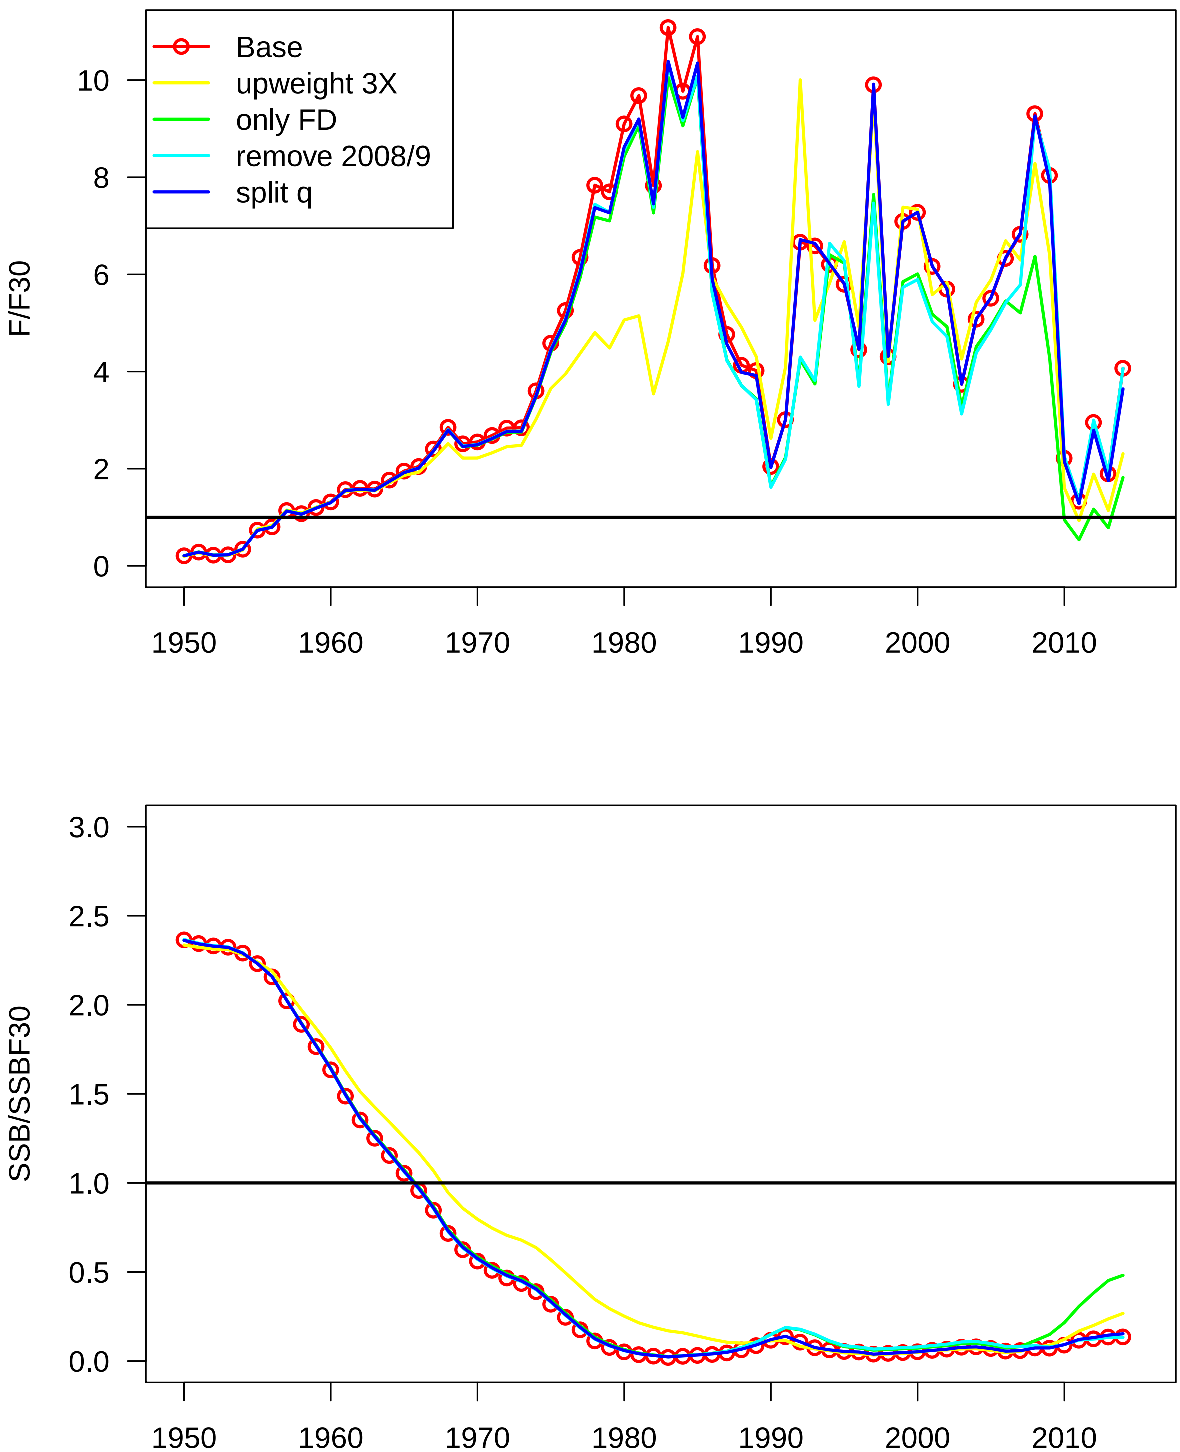

Figure 50. Sensitivity to not fixing selectivities (sensitivity run S27). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\mathrm{SSB}_{F30\%}$.

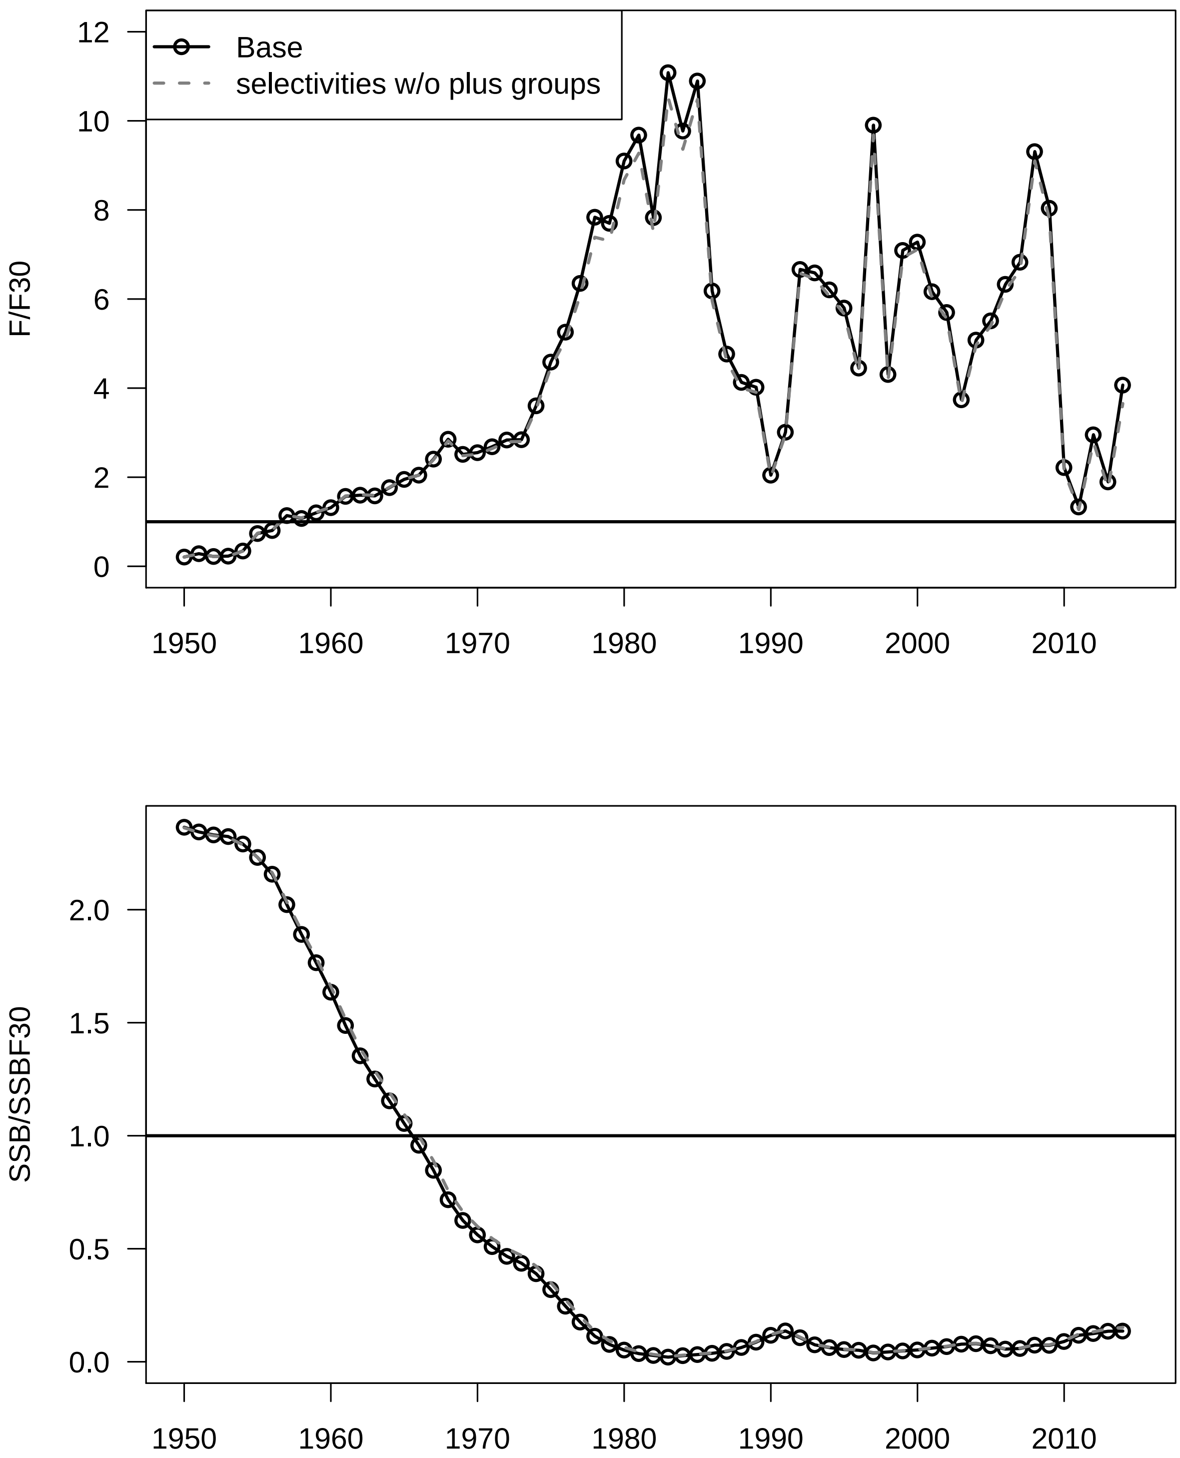

Figure 51. Sensitivity to dropping or truncating headboat discard index (sensitivity runs S12 and S16). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

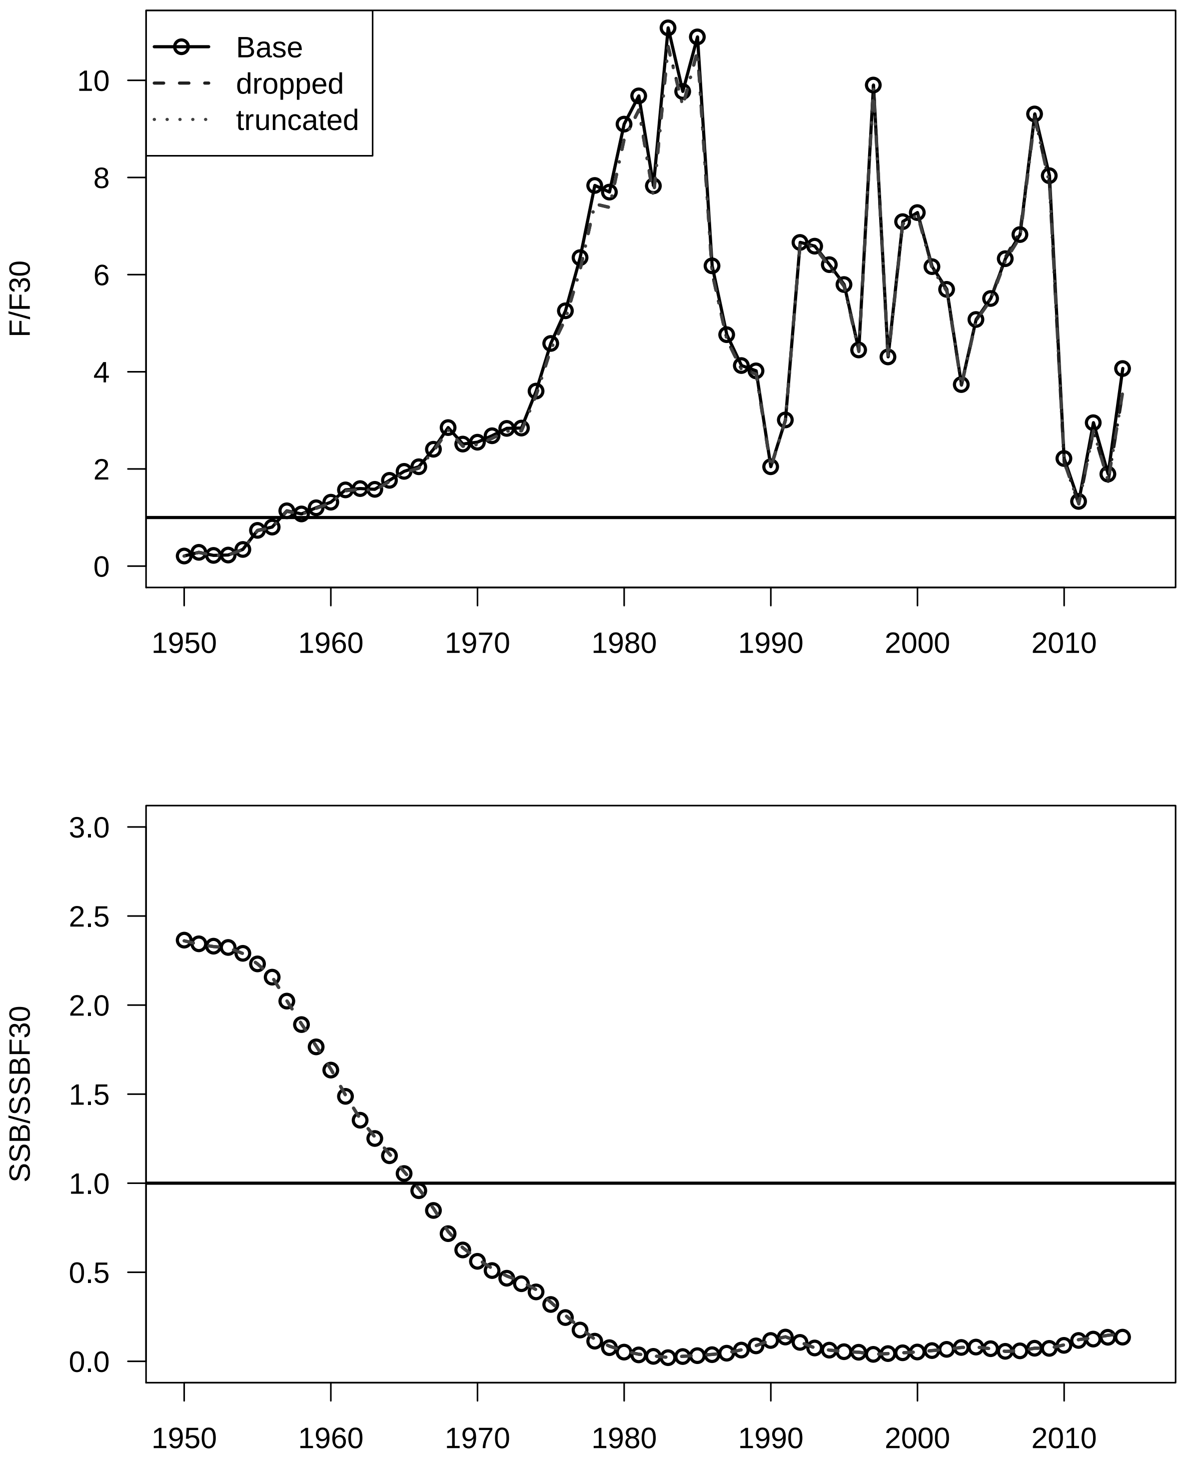

Figure 52. Sensitivity to higher or lower estimates of landings and discards (sensitivity runs S17–S20). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

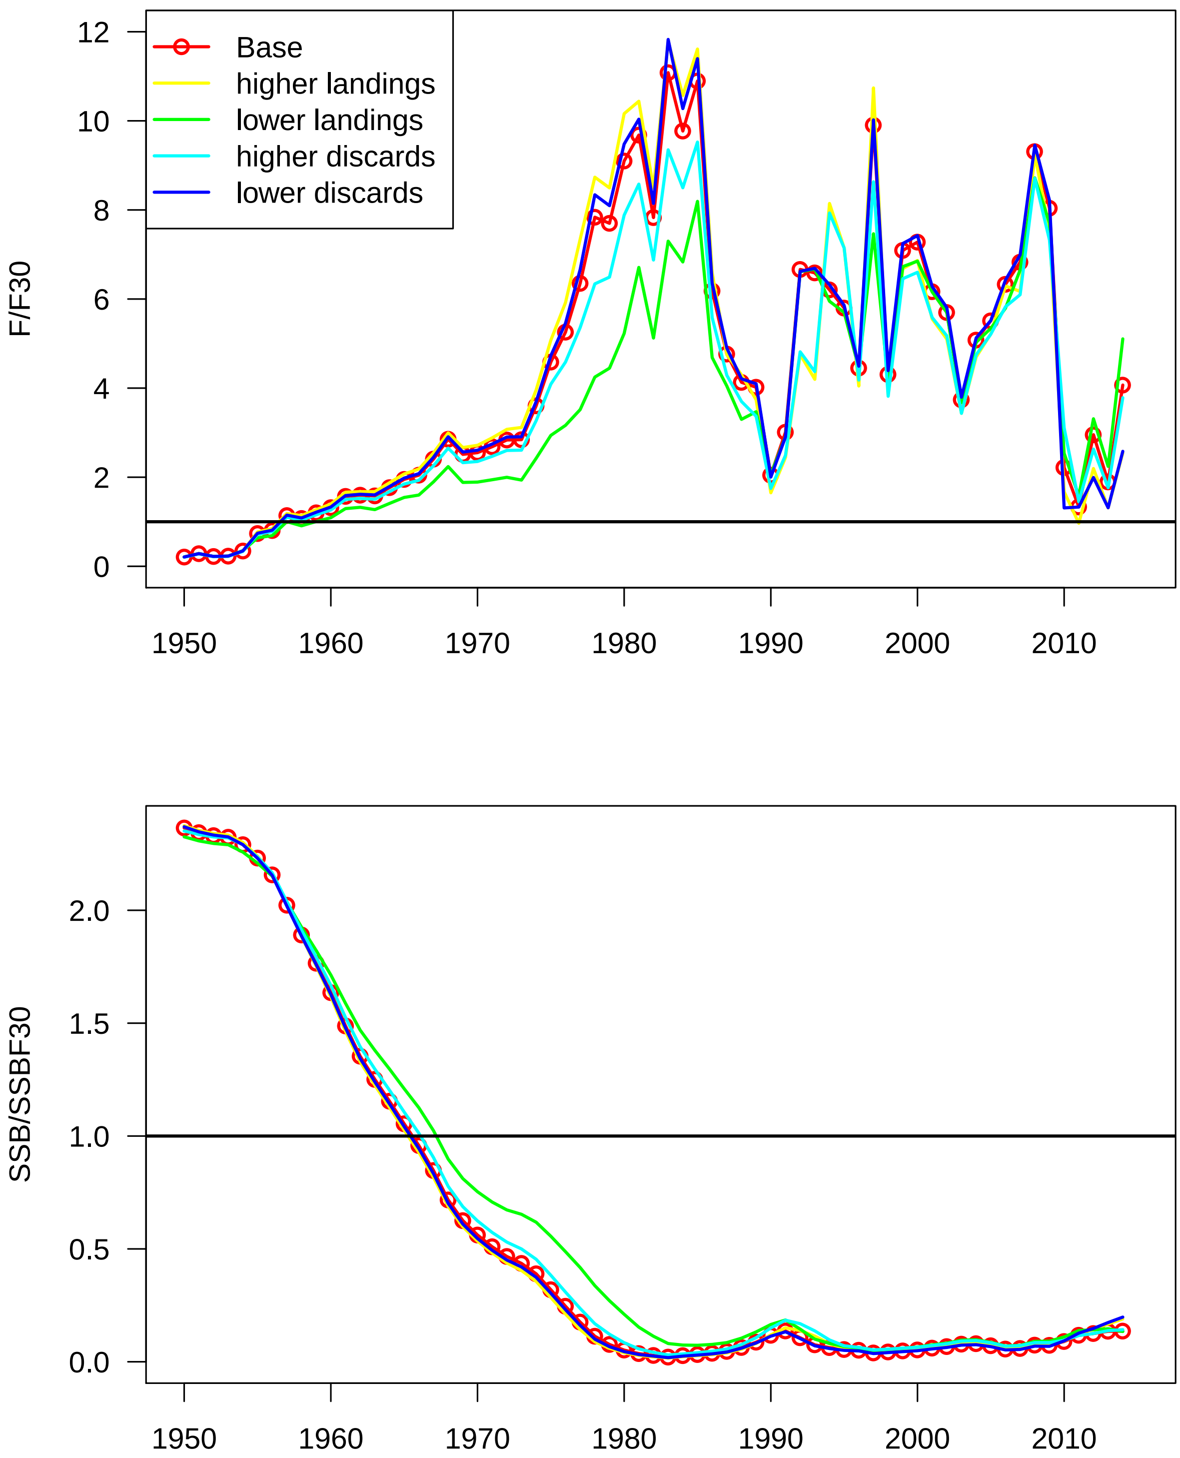

Figure 53. Sensitivity to smoothed 1984 and 1985 MRIP landings (sensitivity run S10). Top panel: Ratio of F to $F_{30\%}$*. Bottom panel: Ratio of* SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$*.*

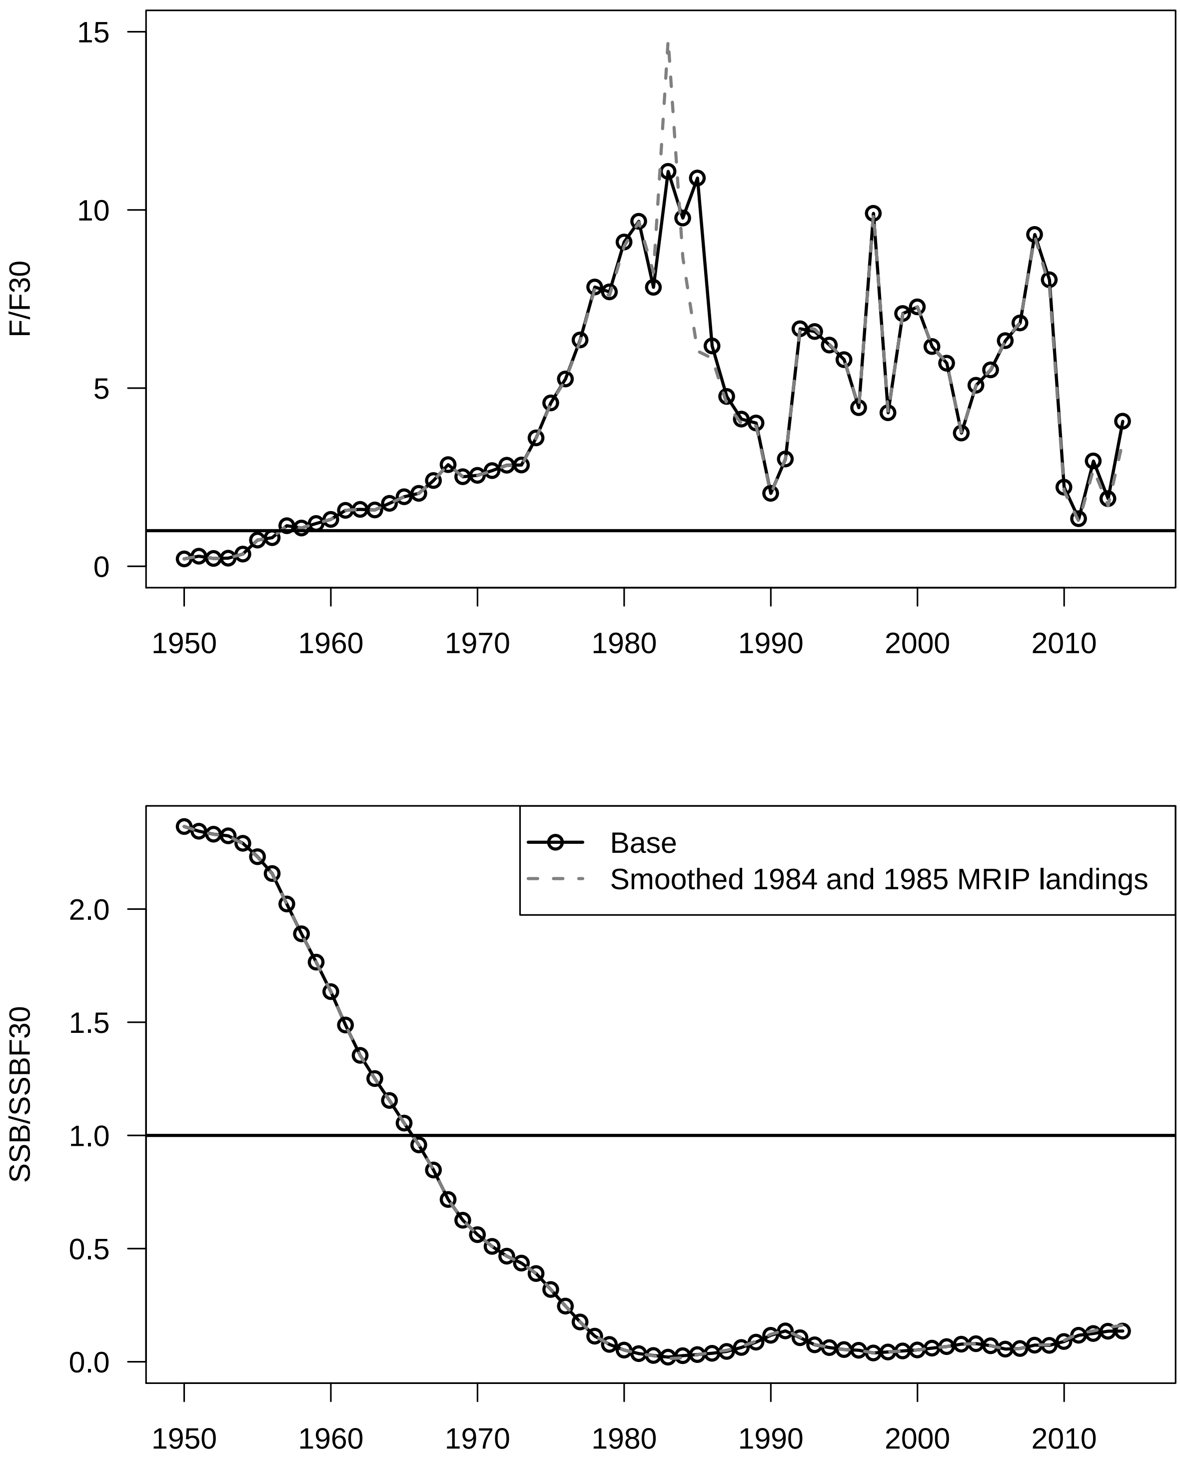

Figure 54. Sensitivity to continuity assumptions from SEDAR 24 (sensitivity run S24). Top panel: Ratio of F to $F_{30\%}$. Bottom panel: Ratio of SSB *to* $\mathrm{SSB}_{\mathrm{F30\%}}$.

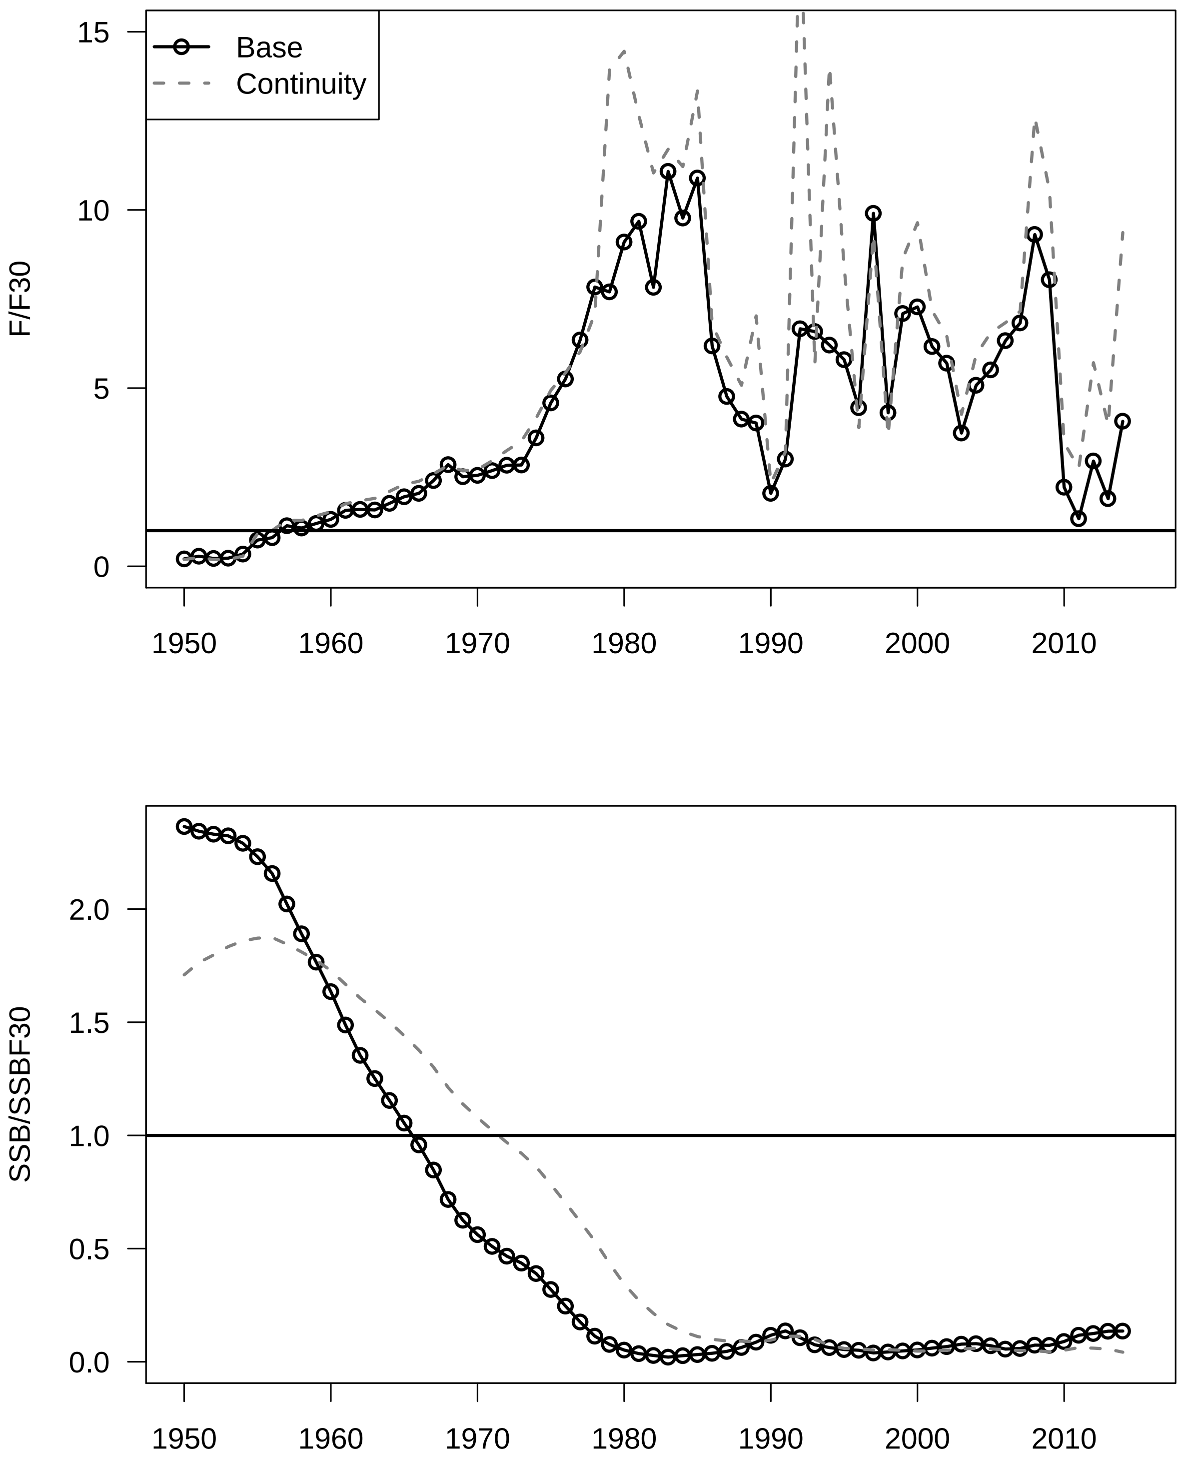

Figure 55. Phase plot of terminal status indicators from sensitivity runs of the Beaufort Assessment Model.

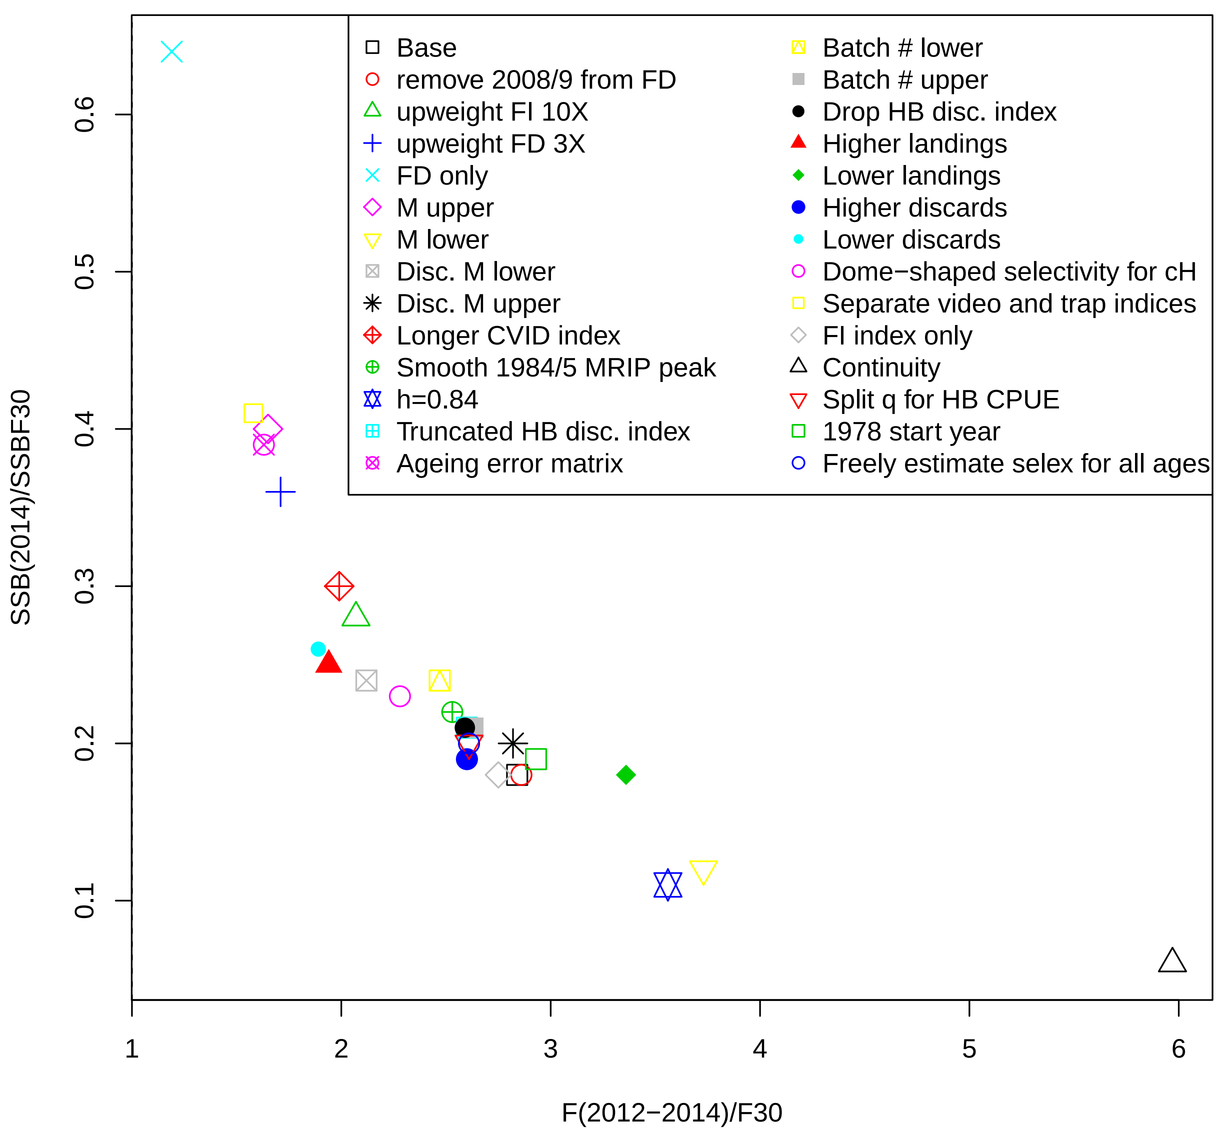

Figure 56. Retrospective analyses. Sensitivity to terminal year of data. Top panel: Fishing mortality rates. Middle panel: Recruits. Bottom panel: Spawning biomass. Closed circles show terminal-year estimates. Imperceptible lines overlap results of the base run.

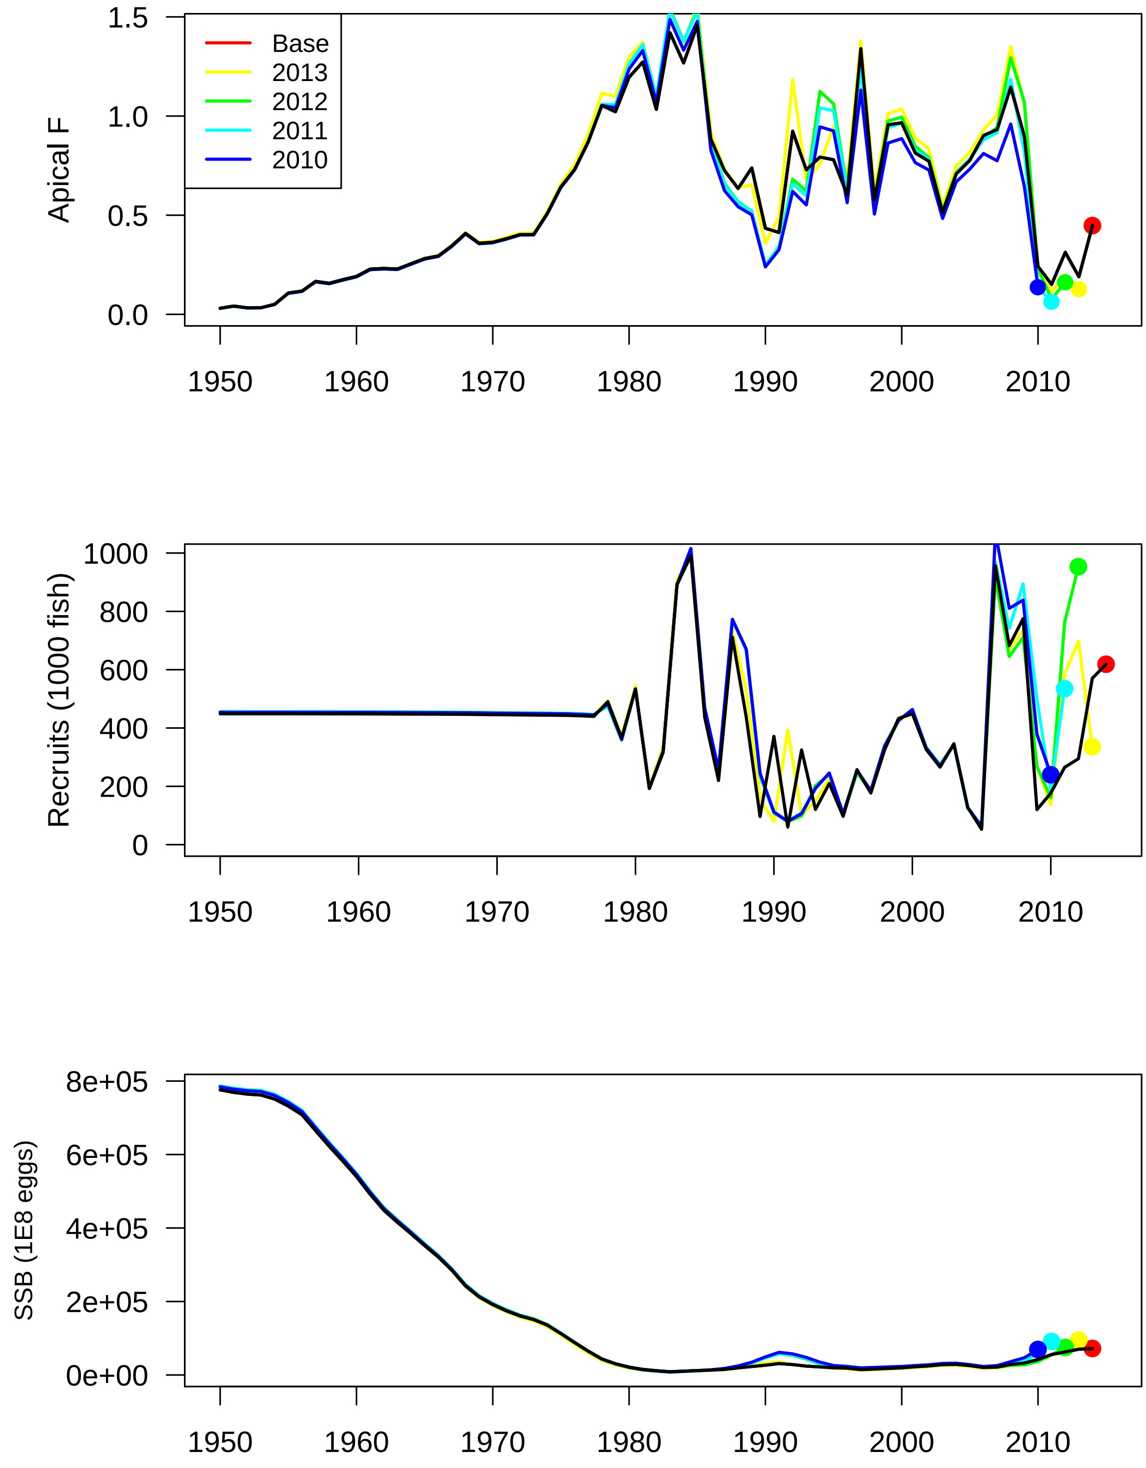

Figure 57. Projection results under scenario 1—fishing mortality rate at $F = 0$. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} and 95^{th} percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $\mathrm{SSB}_{\mathrm{F30\%}}$.

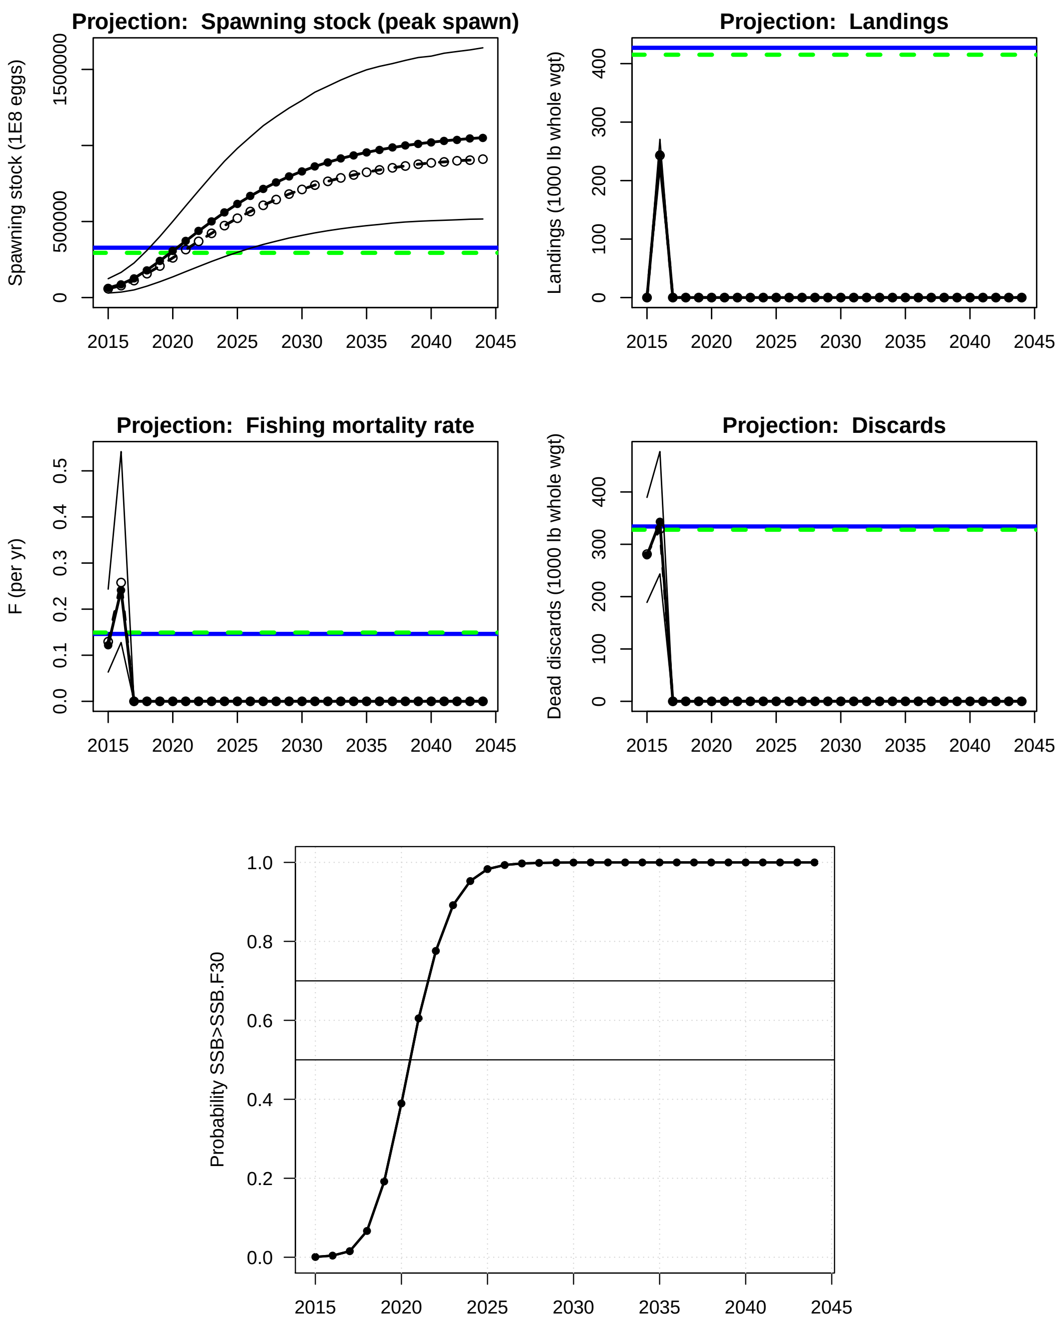

Figure 58. Projection results under scenario 2—fishing mortality rate at $F = F_{\mathrm{current}}$*. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to* 5^{th} *and* 95^{th} *percentiles of replicate projections. Solid horizontal lines mark* $F_{30\%}$*-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific* $\mathrm{SSB}_{\mathrm{F30\%}}$*.*

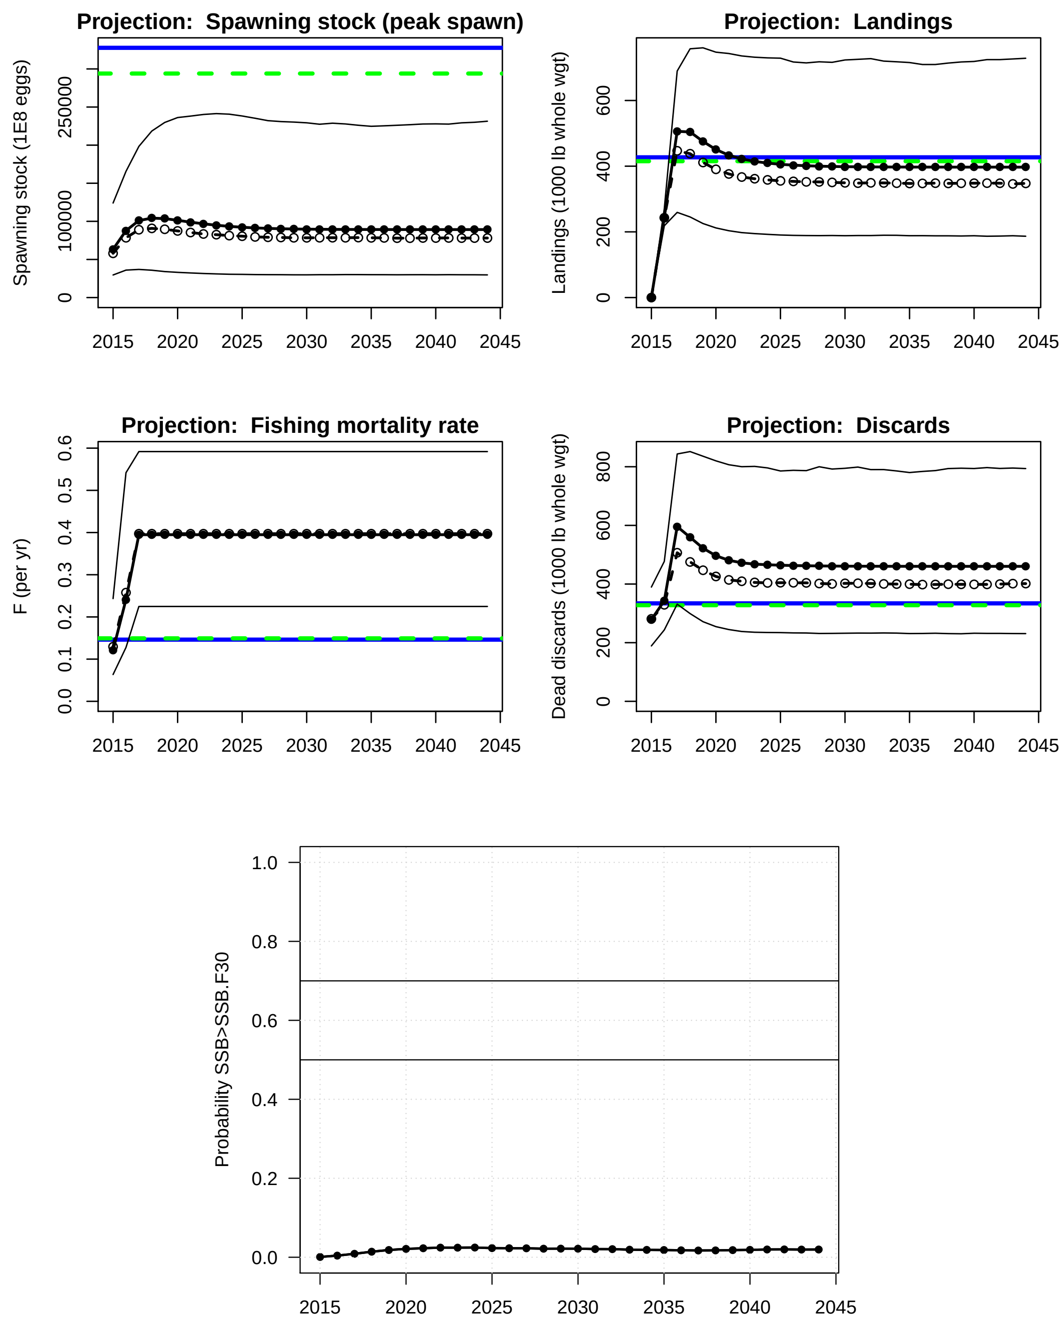

Figure 59. Projection results under scenario 3—fishing mortality rate at $F = F_{30\%}$. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} and 95^{th} percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $\mathrm{SSB_{F30\%}}$.

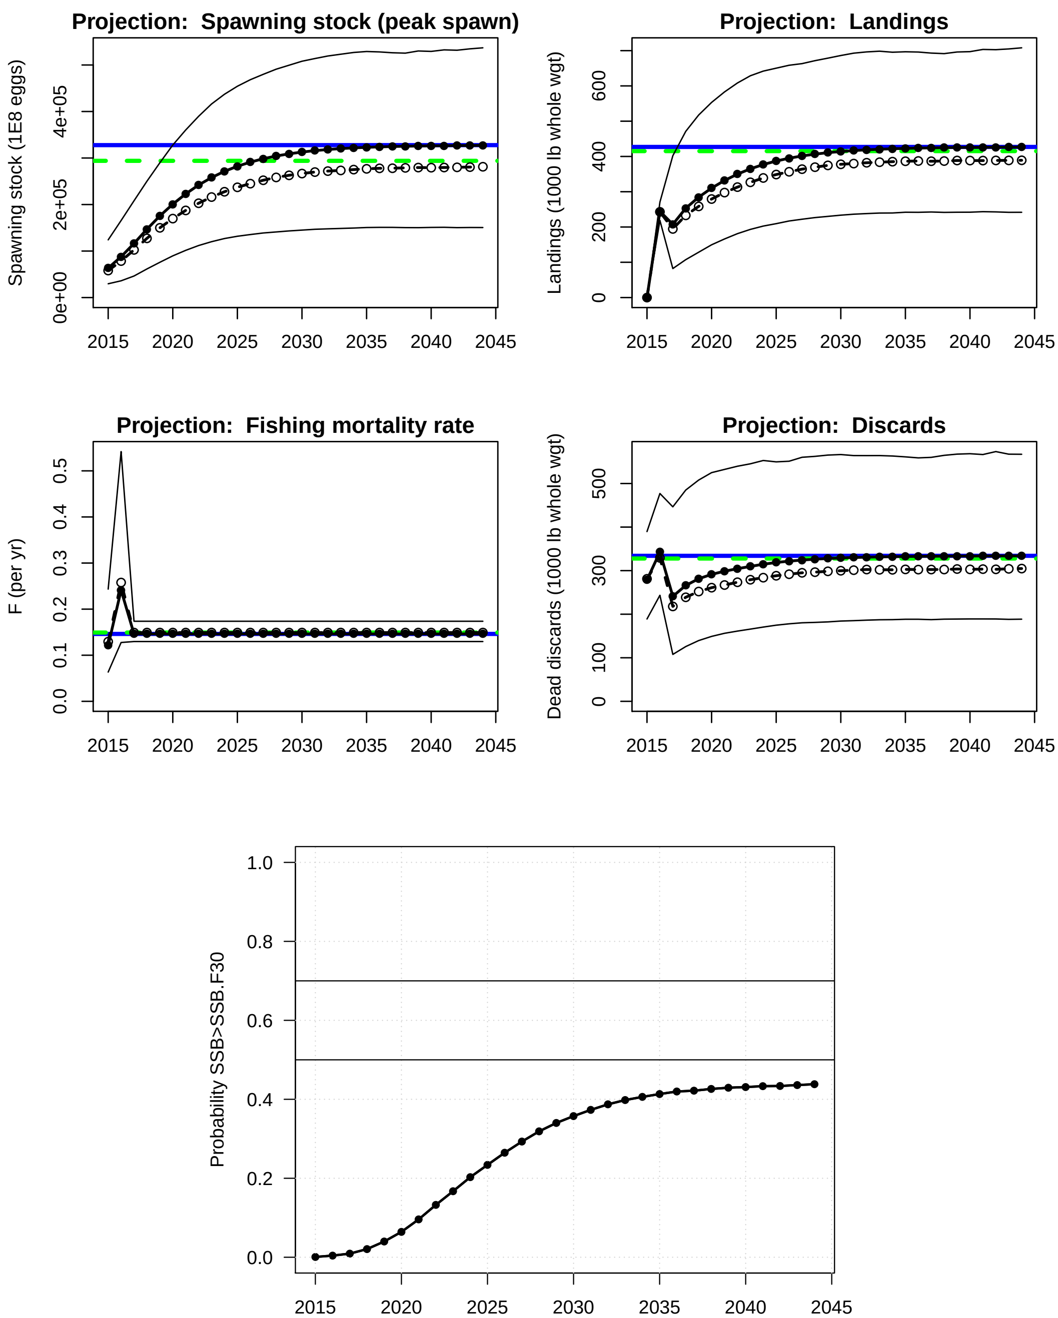

Figure 60. Projection results under scenario 4—fishing mortality rate at $F = 98\% F_{30\%}$. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} and 95^{th} percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $\mathrm{SSB}_{\mathrm{F30\%}}$.

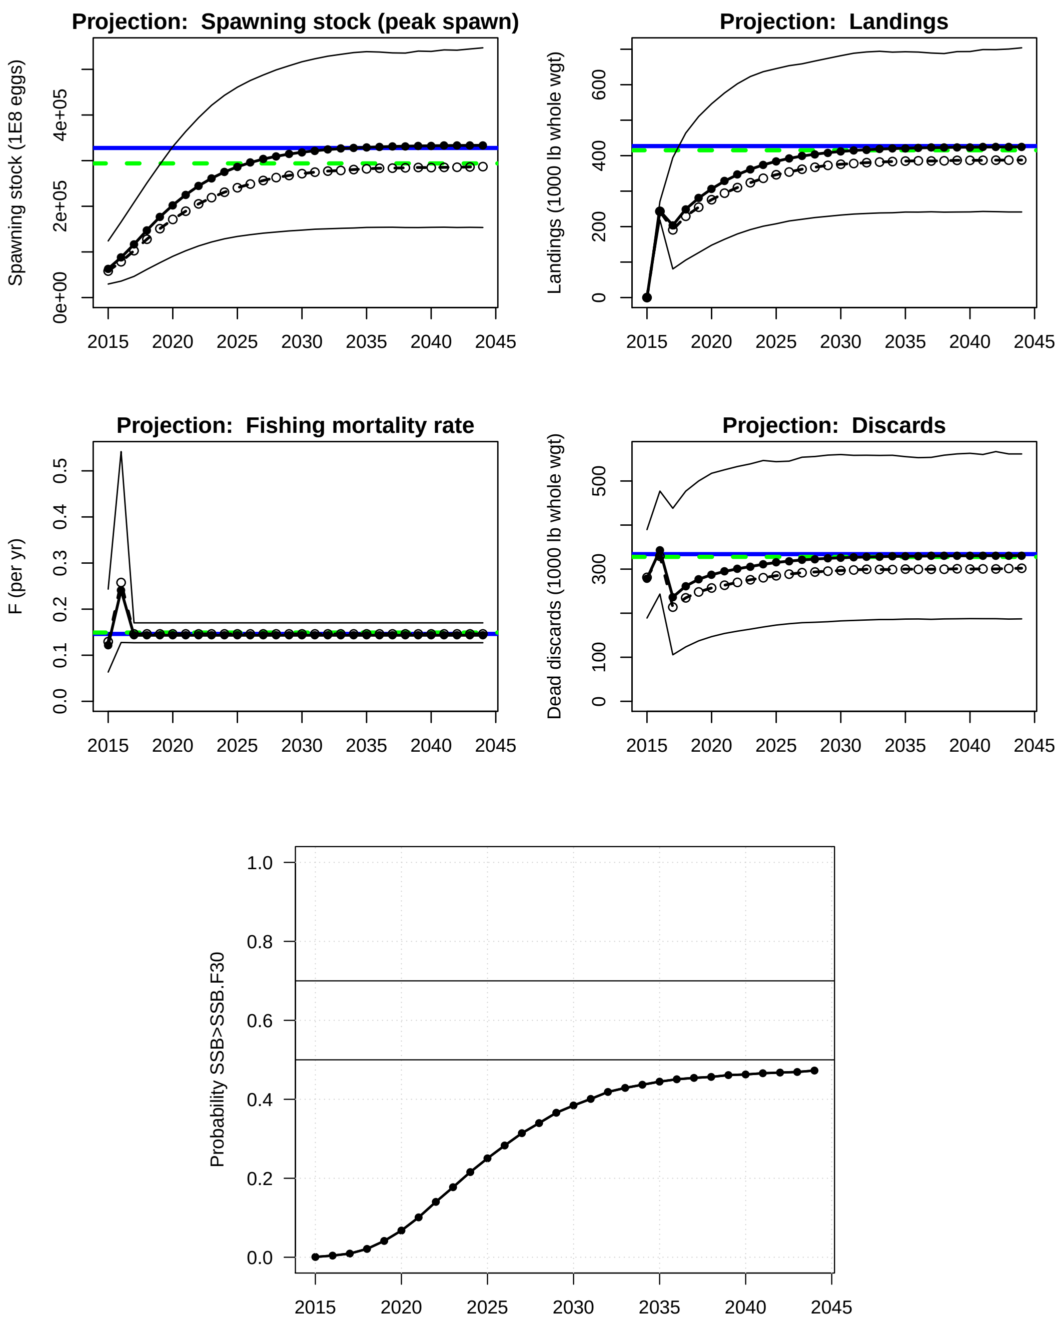

Figure 61. Projection results under scenario 5—fishing mortality rate at $F = F_{\text{rebuild}}$, with rebuilding probability of 0.5 in 2044. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} and 95^{th} percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $\text{SSB}_{\text{F30\%}}$.

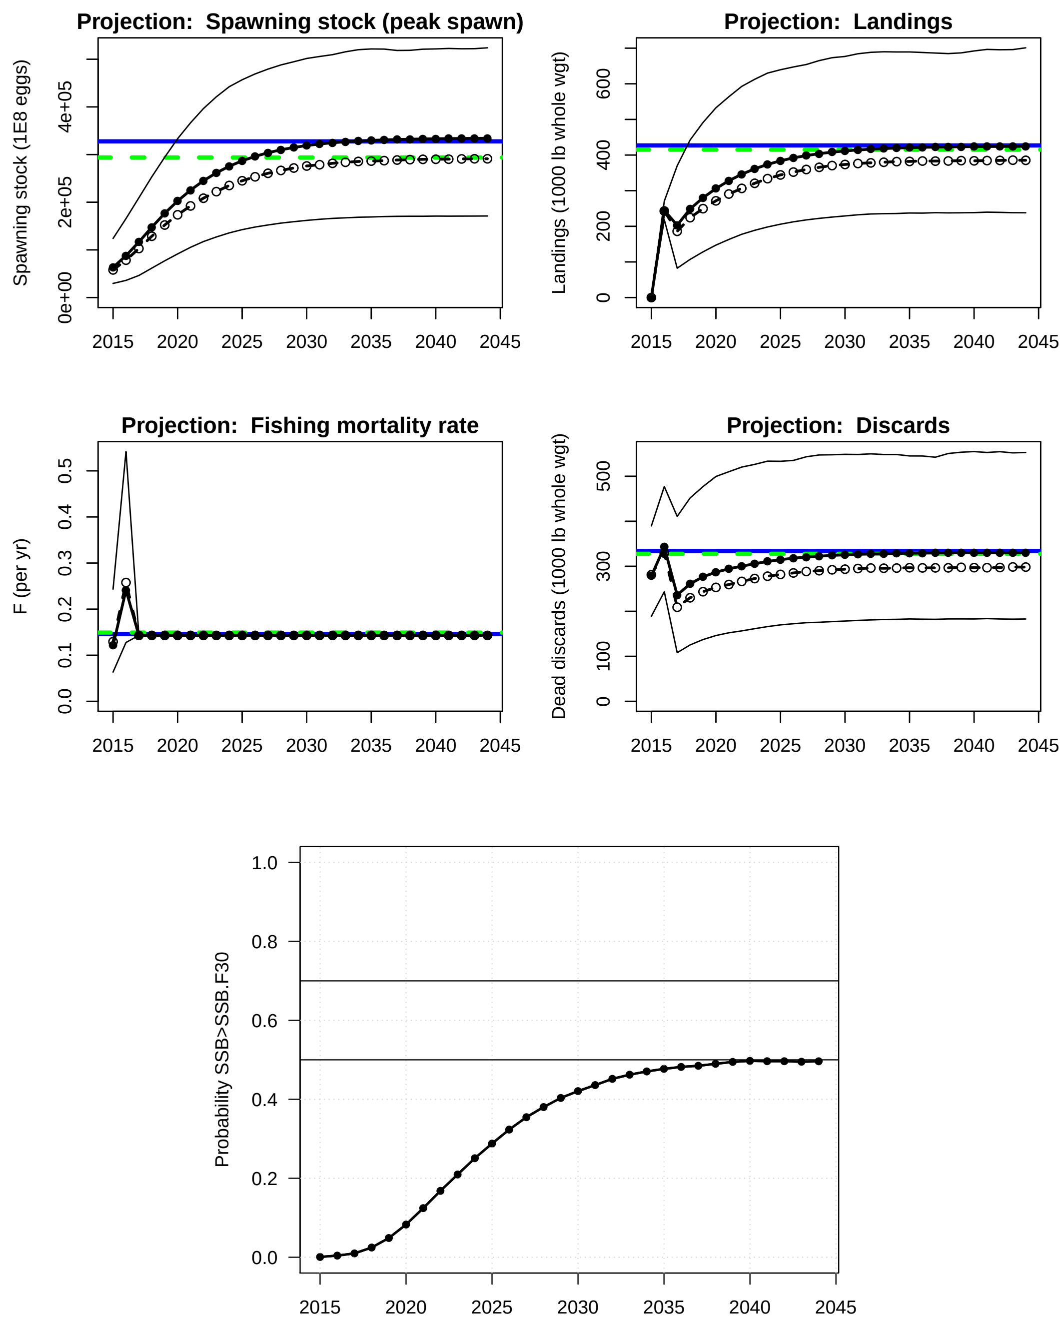

Figure 62. Projection results under scenario 6—fishing mortality rate set to average discard mortality rate only. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5^{th} and 95^{th} percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $\mathrm{SSB}_{\mathrm{F30\%}}$.

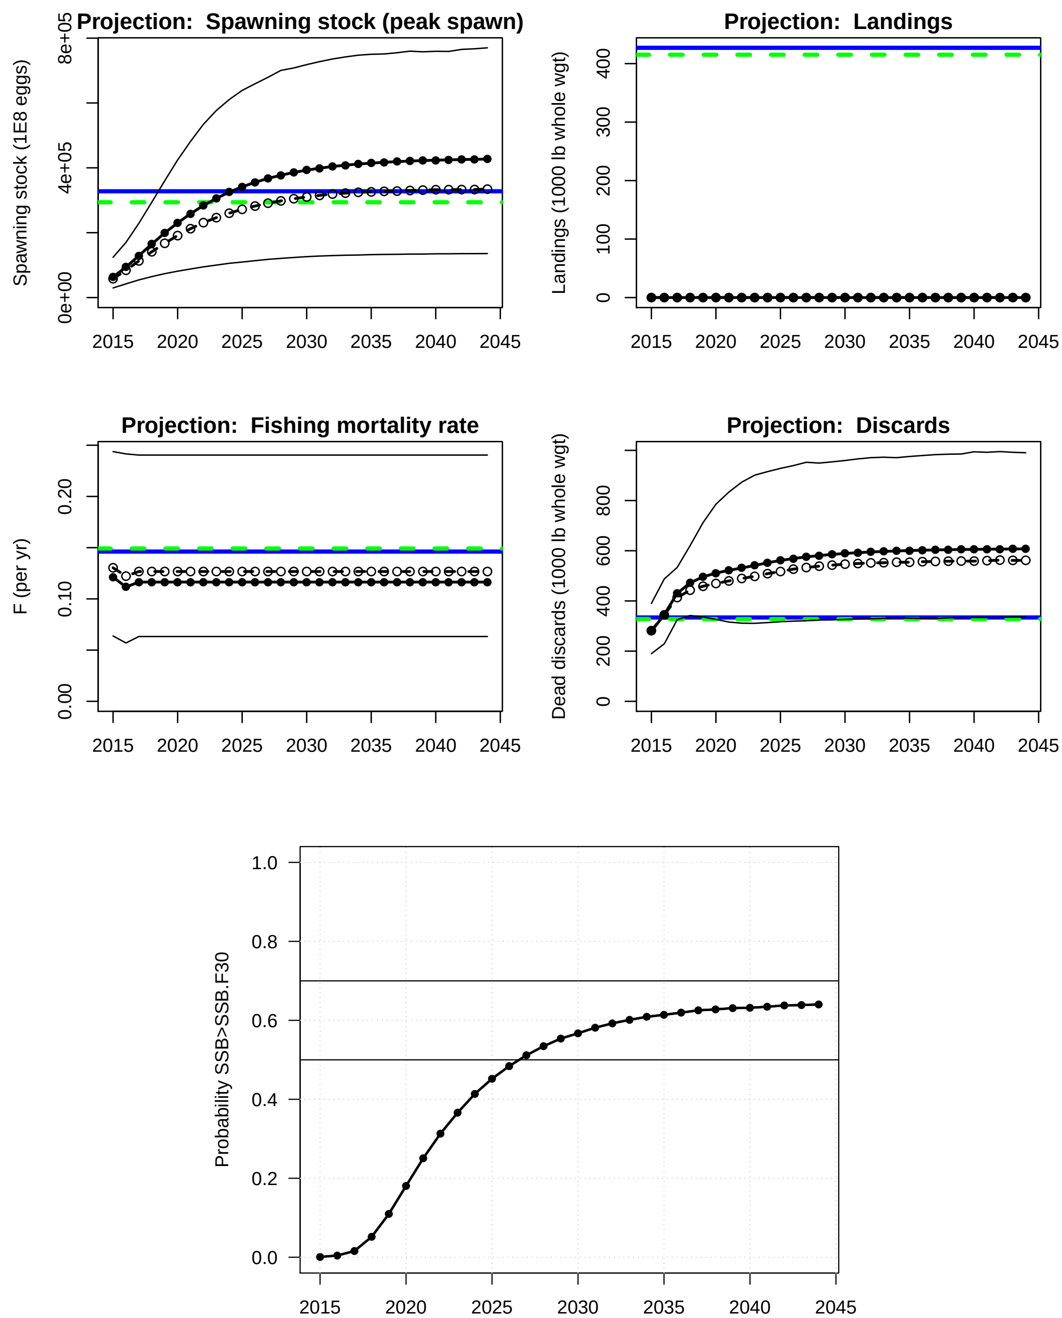

Figure 63. Abundance indices observed (obs.) and predicted (pred.) by the ASPIC surplus production model, and observed total removals (100,000 lbs) for South Atlantic red snapper. Comm = commercial, HB = headboat, HB.at.sea = headboat at sea discards, CVID = combined chevron trap-video index.

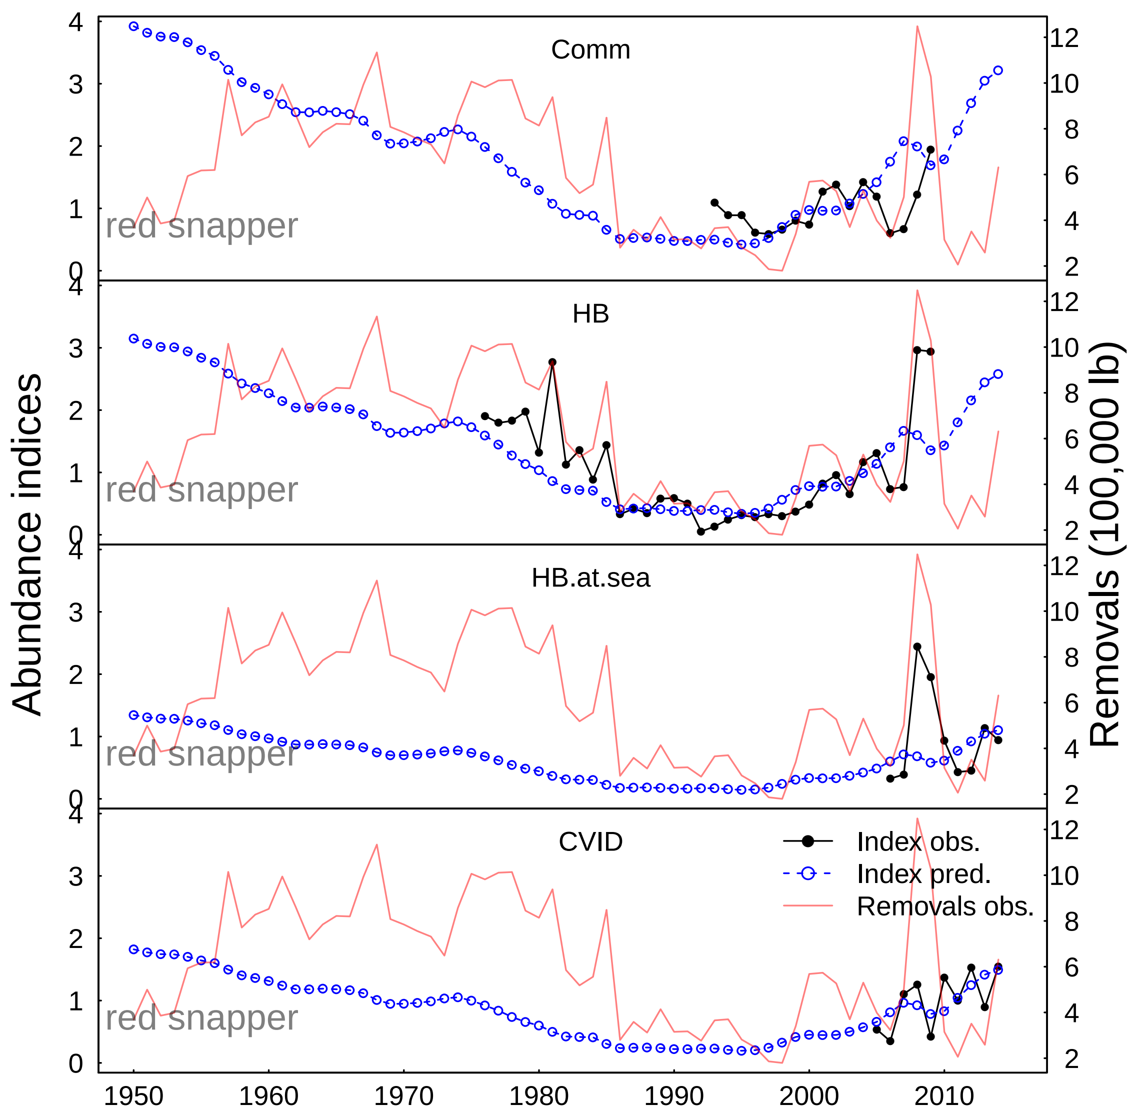

Figure 64. Prior distributions (blue shapes) and estimated parameter values (vertical black lines) for the South Atlantic red snapper ASPIC surplus production model.

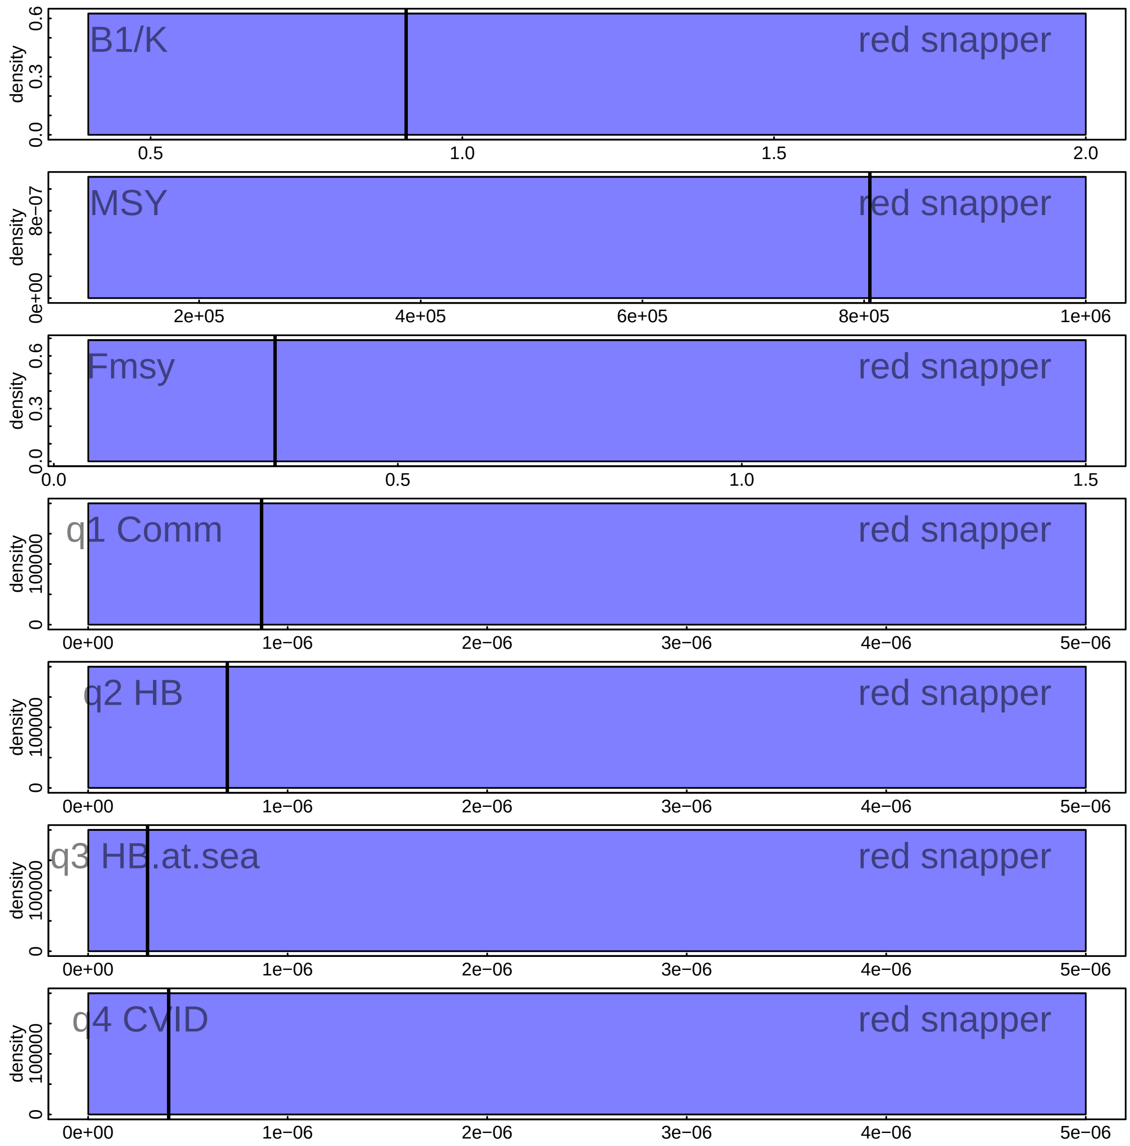

Figure 65. Bootstrap parameter values from ASPIC surplus production model run 320. Thick vertical lines represent ASPIC parameter estimates (solid) and 95% bootstrap percentile confidence intervals (dashed). Thin solid vertical lines are drawn at one in plots of F/F_{MSY} and B/B_{MSY} for reference.

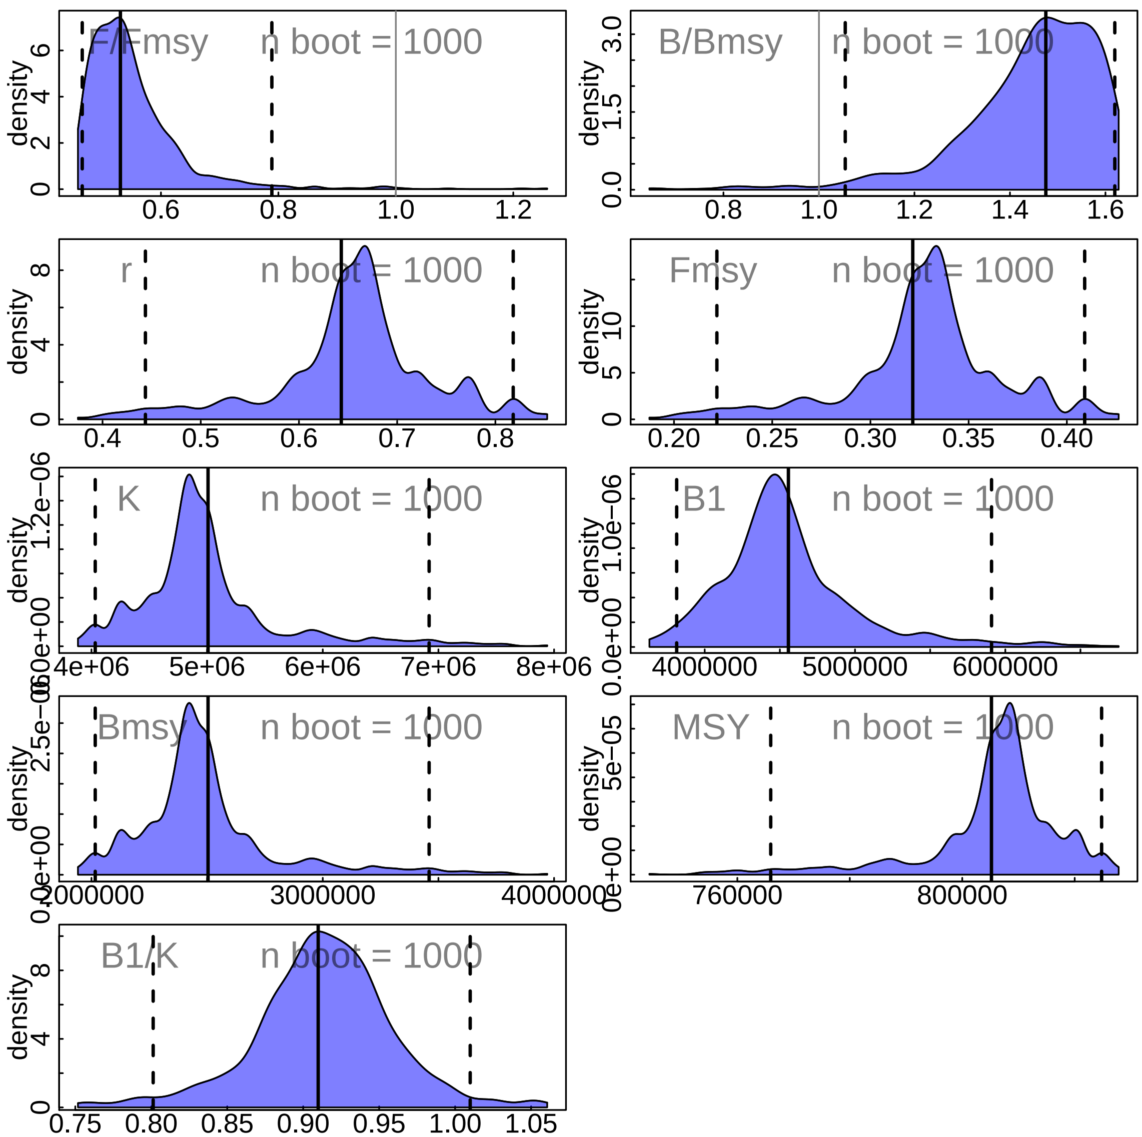

Figure 66. ASPIC surplus production model estimates of relative fishing rate (F/F_{MSY}) and biomass (B/B_{MSY}).

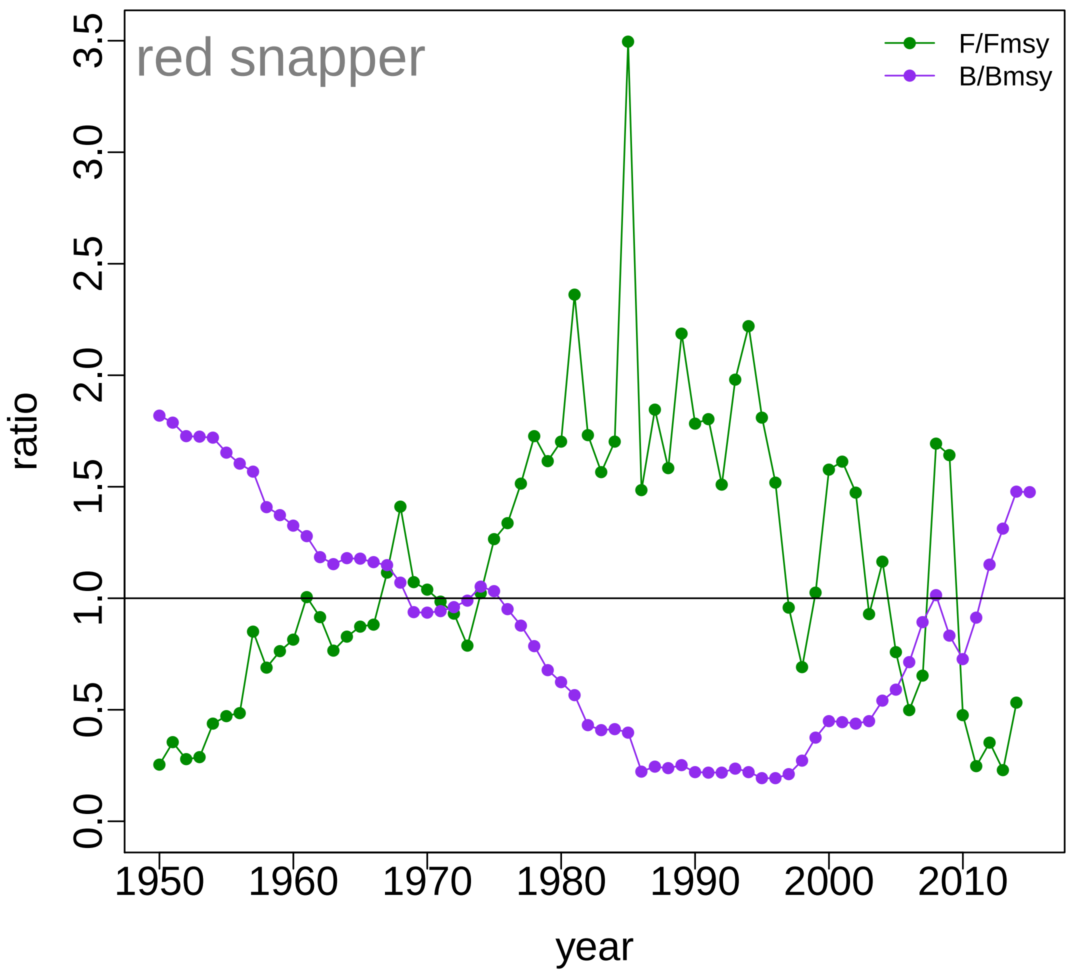

Appendix A Abbreviations and symbols

Table 33. Acronyms and abbreviations used in this report

Symbol	Meaning
ABC	Acceptable Biological Catch
AW	Assessment Workshop (here, for red snapper)
ASY	Average Sustainable Yield
B	Total biomass of stock, conventionally on January 1
BAM	Beaufort Assessment Model (a statistical catch-age formulation)
CPUE	Catch per unit effort; used after adjustment as an index of abundance
CV	Coefficient of variation
CVID	SERFS combined chevron trap and video survey
DW	Data Workshop (here, for red snapper)
F	Instantaneous rate of fishing mortality
$F_{30\%}$	Fishing mortality rate at which $F_{30\%}$ can be attained
F_{MSY}	Fishing mortality rate at which MSY can be attained
FL	State of Florida
FHWAR	The National Survey of Fishing, Hunting, and Wildlife-Associated Recreation Survey
GA	State of Georgia
GLM	Generalized linear model
K	Average size of stock when not exploited by man; carrying capacity
kg	Kilogram(s); 1 kg is about 2.2 lb.
klb	Thousand pounds; thousands of pounds
lb	Pound(s); 1 lb is about 0.454 kg
m	Meter(s); 1 m is about 3.28 feet.
M	Instantaneous rate of natural (non-fishing) mortality
MARMAP	Marine Resources Monitoring, Assessment, and Prediction Program, a fishery-independent data collection program of SCDNR
MCB	Monte Carlo/Bootstrap, an approach to quantifying uncertainty in model results
MFMT	Maximum fishing-mortality threshold; a limit reference point used in U.S. fishery management; often based on F_{MSY}
mm	Millimeter(s); 1 inch = 25.4 mm
MRFSS	Marine Recreational Fisheries Statistics Survey, a data-collection program of NMFS, predecessor of MRIP
MRIP	Marine Recreational Information Program, a data-collection program of NMFS, descended from MRFSS
MSST	Minimum stock-size threshold; a limit reference point used in U.S. fishery management. The SAFMC has defined MSST for red snapper as $(1-M)\mathrm{SSB}_{\mathrm{MSY}} = 0.7\mathrm{SSB}_{\mathrm{MSY}}$.
MSY	Maximum sustainable yield (per year)
mt	Metric ton(s). One mt is 1000 kg, or about 2205 lb.
N	Number of fish in a stock, conventionally on January 1
NC	State of North Carolina
NMFS	National Marine Fisheries Service, same as “NOAA Fisheries Service”
NOAA	National Oceanic and Atmospheric Administration; parent agency of NMFS
OY	Optimum yield; SFA specifies that OY $\leq$ MSY.
PSE	Proportional standard error
R	Recruitment
SAFMC	South Atlantic Fishery Management Council (also, Council)
SC	State of South Carolina
SCDNR	Department of Natural Resources of SC
SDNR	Standard deviation of normalized residuals
SEDAR	SouthEast Data Assessment and Review process
SERFS	Southeast Regional Fishery-independent Sampling
SFA	Sustainable Fisheries Act; the Magnuson–Stevens Act, as amended
SL	Standard length (of a fish)
SRHS	Southeast Region Headboat Survey, conducted by NMFS-Beaufort laboratory
SPR	Spawning potential ratio
SSB	Spawning stock biomass; mature biomass of males and females
$\mathrm{SSB}_{\mathrm{MSY}}$	Level of SSB at which MSY can be attained
$\mathrm{SSB}_{\mathrm{F30\%}}$	Level of SSB at which $F_{30\%}$ can be attained
TIP	Trip Interview Program, a fishery-dependent biodata collection program of NMFS
TL	Total length (of a fish), as opposed to FL (fork length) or SL (standard length)
VPA	Virtual population analysis, an age-structured assessment
WW	Whole weight, as opposed to GW (gutted weight)
yr	Year(s)

Appendix B Parameter estimates from the Beaufort Assessment Model

SEDAR 41 Red Snapper: Projection Supplement for SSC's ABC Working Group

Prepared by NMFS Southeast Fisheries Science Center

Draft date: February 27, 2018

The SAFMC's SSC requested additional projections of the Red Snapper stock, based on the SEDAR 41 assessment model, for consideration by the SSC's ABC working group.

Using the most recent estimates of actual landings and discard estimates for all fleets in 2015 and 2016, this document describes the following two scenarios:

Scenario 1 – Yield based on fishing the stock at the Fmsy proxy (30% SPR) with management taking effect in 2017.

Scenario 2 – Yield based on fishing the stock at $F_{rebuild}$ with management taking effect in 2017.

The most complete data available for 2015 and 2016 landings and discards are shown in Table 1. These data were provided by the SEFSC for each fleet (commercial, headboat, and general recreational from MRIP). The commercial data are electronically reported and have not yet gone through the quality control process in each state.

In the Assessment Workshop projections, average selectivities were used to characterize the fish taken for landings and discards from all fleets throughout the projection time period. Here, fleet-specific selectivities were used for landings and discards to calculate fishing mortality by fleet during the interim period (i.e. the period before new management takes effect). Projection results are shown in Figures 1–4, and tabulated in Tables 2–5.

Table 1. Estimates of landings and discards for Red Snapper in the South Atlantic by fleet in 2015.

	Commercial		Headboat		MRIP	
	Landings	Discards	Landings	Discards	Landings	Discards
2015	4,762 lb	31,565 fish	750 fish	54,405 fish	1,111 fish	508,196 fish
2016	4,151 lb	34,568 fish	331 fish	66,511 fish	72 fish	788,460 fish

Table 2. Projection results with fishing mortality rate fixed at F = $F_{30\%}$ starting in 2017. R = number of age-1 recruits (in 1000s), F = fishing mortality rate (per year), B = biomass (mt), S = spawning stock (1E8 eggs), L = landings expressed in numbers (1000s) or whole weight (1000 lb), and D = dead discards expressed in numbers (1000s) or whole weight (1000 lb), pr.rebuild = proportion of stochastic projection replicates with SSB greater than or equal to $SSB_{F30\%}$. The extension .base indicates expected values (deterministic) from the base run; the extension .med indicates median values from the stochastic projections. Highlighted values are those analogous to the fields the SSC has used to set OFL.

Figure 1. Projection results under scenario 1—fishing mortality rate at $F = F_{30\%}$ starting in 2017. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5th and 95th percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $SSB_{F30\%}$.

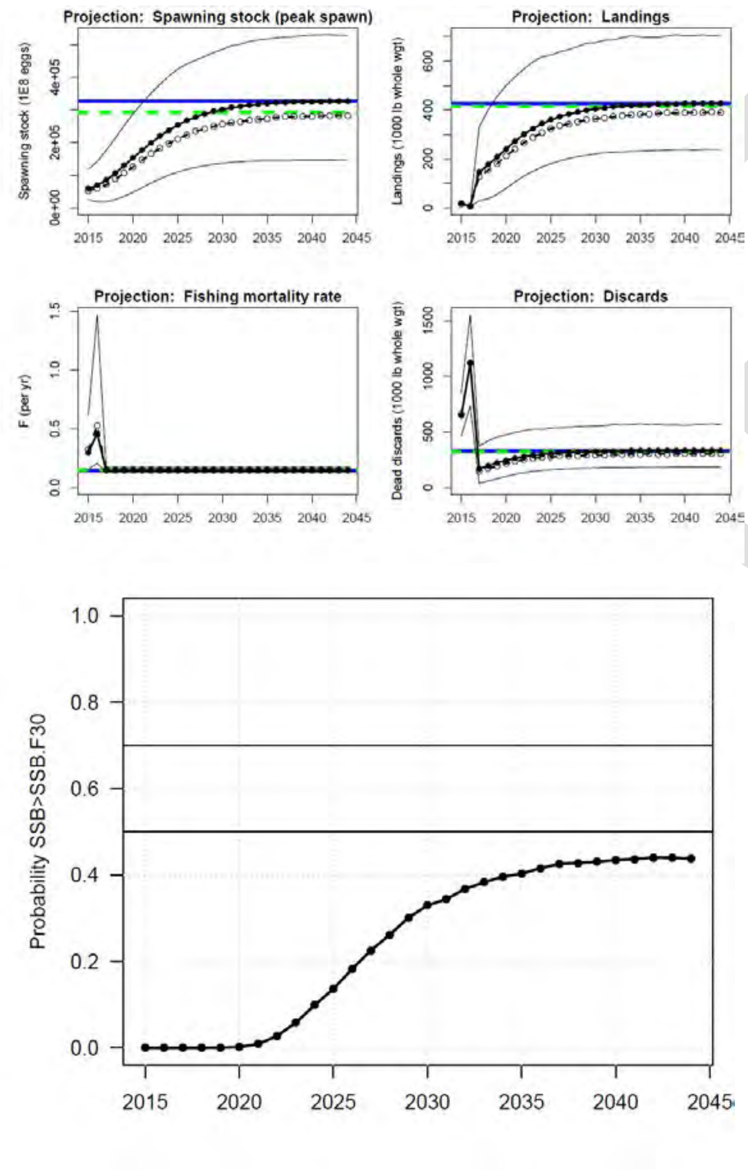

Figure 2. Projection results under scenario 2—fishing mortality rate at $F = F_{rebuild}$ starting in 2017, with rebuilding probability of 0.5 in 2044. In top four panels, expected values (base run) represented by solid lines with solid circles, medians represented by dashed lines with open circles, and uncertainty represented by thin lines corresponding to 5th and 95th percentiles of replicate projections. Solid horizontal lines mark $F_{30\%}$-related quantities; dashed horizontal lines represent corresponding medians. Spawning stock (SSB) is at time of peak spawning. In bottom panel, the curve represents the proportion of projection replicates for which SSB has reached the replicate-specific $SSB_{F30\%}$.

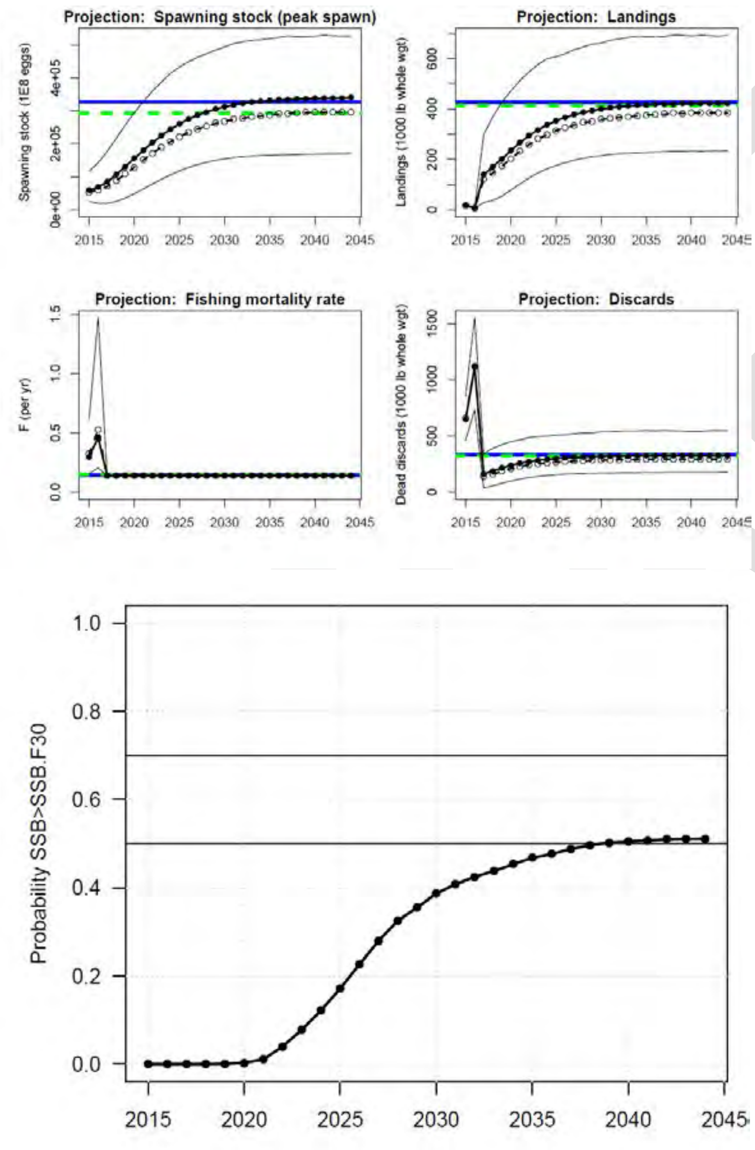

Summary of Red Snapper Indices for ABC Subcommittee

ACTION: Assessment of the appropriateness of the indices available for red snapper; do any indices cross MSY or B_{MSY}, have catch at MSY, AND evidence that catch was not negatively impacting stock. Provide a table. - *Genny and Amy*.

Notes:

- No reliable estimate of MSY available. Proxies for MSY and B_{MSY} are landings at $F_{30\%}$ ($L_{F30\%}$) and $B_{F30\%}$, respectively, as in SEDAR 41. MSY proxy= 427 (1,000 lb), B_{MSY} proxy=3,637 mt (SEDAR 41 pdf p. 722)
- Four indices used in final base run (Table 1, Figure 1). Several additional indices considered at data workshop are shown below as well (Table 1).
- Potential time frames for defining reference period of relatively low red snapper exploitation:
    - 1950-1953 when L largely $<L_{F30\%}$ (Figure 2)
    - 1950-1965 when $B>B_{F30\%}$ (Figure 3)
    - 1950-1965, if SSB relative to $SSB_{30\%}$ (327,706 eggs) is also considered as a metric of low impact (Figure 3)
    - 1950-1976 if h=0.84 and SSB relative to $SSB_{30\%}$ is also considered as a metric of low impact (Figure 4). This was also a period of expanded age structure as indicated by headboat landings weight vs. number and estimated biomass at age (Figure 5).
- Conclusion: No individual index covers both an obvious period of low exploitation and recent years. If the mid-70s can be considered a period of light exploitation with relatively low negative impact on stock, generation of a long-term composite index could be explored for use in setting an ABC. However, issues regarding differing selectivities among long-term and recent surveys (e.g. headboat vs. CVID) would need to be resolved.
- Recommendation: No index sufficiently addresses the questions posed above.

Table 1. Summary of available indices. RS=red snapper.

Index	FI or FD	Start Year	Last year with reliable RS catch	Covers period of low exploitation/impact	Used in base run
Headboat[1]	FD	1976	2009	Maybe?	Yes
Headboat discards[1]	FD	2005	present	No	Yes

Abstract

Standardized video counts of red snapper were generated from video cameras deployed by the Southeast Reef Fish Survey for 2010 – 2013. Samples between Cape Hatteras, North Carolina, and St. Lucie Inlet, Florida, were included in the analyses. The index is meant to describe population trends for red snapper in the region. A zero-inflated negative binomial model was used to standardize video count data by a variety of predictor variables that could influence abundance and video counts, and a camera calibration study was used to calibrate counts of red snapper between the two cameras used during monitoring.

Background

The Marine Resources Monitoring, Assessment, and Prediction (MARMAP) program has conducted most of the historical fishery-independent sampling in the U.S. South Atlantic (North Carolina to Florida). MARMAP has used a variety of gears over time, but chevron traps are one of the primary gears used to monitor reef fish species and have been deployed since the late 1980s. In 2009, MARMAP began receiving additional funding to monitor reef fish from the SEAMAP-SA program. In 2010, the SouthEast Fishery-Independent Survey (SEFIS) was initiated by NMFS to work collaboratively with MARMAP/SEAMAP-SA using identical methods to collect additional fishery-independent samples in the region. Together, these three programs are now called the Southeast Reef Fish Survey (SERFS). In 2010, video cameras were attached to some traps deployed by SERFS, and beginning in 2011 all traps included video cameras (Figure 1).

The SERFS survey currently samples between Cape Hatteras, North Carolina, and St. Lucie Inlet, Florida. This survey targets hardbottom habitats between approximately 15 and 100 meters deep. SERFS began affixing high-definition video cameras to chevron traps on a limited basis in 2010 (Georgia and Florida only), but since 2011 has attached cameras to all chevron traps as part of their normal monitoring efforts. All four years of data are included here, as recommended by Bacheler and Carmichael (2014; SEDAR41-RD23).

Hard-bottom sampling stations were selected for sampling in one of three ways. First, most sites were randomly selected from the SERFS sampling frame that consisted of approximately 3,000 sampling stations on or very near hard bottom habitat. Second, some stations in the sampling frame were sampled opportunistically even though they were not randomly selected for sampling in a given year. Third, new hard-bottom stations were added during the study period through the use of information from various sources including fishermen, charts, and historical surveys. These new locations were investigated using a vessel echosounder or drop cameras and sampled if hard bottom was detected. Only those new stations landing on hardbottom habitat were included in the analyses. All sampling for this study occurred during daylight hours between April and October on the R/V *Savannah*, R/V *Palmetto*, NOAA Ship

Nancy Foster, or the NOAA Ship *Pisces* using identical methodologies as described below. Samples were intentionally spread out spatially on each cruise (see Figure 2 in Bacheler and Carmichael 2014).

Chevron fish traps with attached video cameras were deployed at each station sampled in our study (Figure 1). Chevron traps were constructed from plastic-coated, galvanized 2-mm diameter wire (mesh size = 3.4 cm2) and measured 1.7 m × 1.5 m × 0.6 m, with a total volume of 0.91 m3. Trap mouth openings were shaped like a teardrop and measured approximately 18 cm wide and 45 cm high. Each trap was baited with 24 menhaden (*Brevoortia* spp.). Traps were typically deployed in groups of six, and each trap in a set was deployed at least 200 m from all other traps to provide some measure of independence between traps. A soak time of 90 minutes was targeted for each trap deployed.

GoPro Hero (2010) or Canon Vixia HFS-200 high-definition video cameras in Gates underwater housings (2011 – 2013) were attached to chevron traps. A second high-definition GoPro Hero video or Nikon Coolpix S210/S220 still camera was attached over the nose of most traps in an underwater housing, and was used to quantify microhabitat features in the opposite direction. Cameras were turned on and set to record before traps were deployed, and were turned off after trap retrieval. Trap-video samples were excluded from our analysis if videos were unreadable for any reason (e.g., too dark, camera out of focus, files corrupt) or the traps did not fish properly (e.g., bouncing or dragging due to waves or current, trap mouth was obstructed).

Relative abundance of reef fish on video was estimated using the MeanCount approach (Conn 2011; Schobernd et al. 2014). MeanCount was calculated as the mean number of individuals of each species over a number of video frames in the video sample. Video reading time was limited to an interval of 20 total minutes, commencing 10 minutes after the trap landed on the bottom to allow time for the trap to settle. One-second snapshots are read every 30 seconds for the 20-minute time interval, totaling 41 snapshots read for each video. The mean number of individuals for each target species in the 41 snapshots is the MeanCount for that species in each video sample. Zero-inflated modeling approaches used below require count data instead of continuous data like MeanCount. Therefore, these analyses used a response variable called SumCount that was simply the sum of all individuals seen across all video frames. SumCount and MeanCount track exactly linearly with one another when the same numbers of video frames are used in their calculation. Therefore, SumCount values were only used from videos where 41 frames were read (~99% of all samples).

SERFS employs video readers to count fish on videos. There was an extensive training period for each video reader, and all videos from new readers are re-read by fish video reading experts until they are very high quality. After that point, 10% or 15 videos (whichever is larger) are re-read annually by fish video reading experts. Video readers also quantify microhabitat features (i.e., percent of bottom that is hardbottom, maximum substrate relief, substrate size, coverage of attached biota, predominant biotic type, and maximum biotic height), in order to standardize for habitat types sampled over time. Water clarity was also scored for each sample as poor, fair, or good. If bottom substrate could not be seen, then water clarity was considered poor, and if bottom habitat could be seen but the horizon was not visible, water clarity was considered fair. If the horizon could be seen in the distance, water clarity was considered to be good. Including water clarity in index models allowed for a standardization of fish counts based on variable water clarities over time and across the study area. A CTD cast was also taken for each simultaneously deployed group of traps, within 2 m of the bottom, and water temperature from these CTD casts was available for standardization models.

Camera calibration

GoPro cameras were used for fish counts in 2010, while Canon cameras were used in 2011 – 2013. To calibrate fish count between these two cameras, side-by-side Canon-GoPro videos were taken during the summer of 2013 and read for red snapper. Additionally, a lab experiment was conducted to quantify differences in field of view between the two cameras. Results indicated the Canon cameras saw 51% of the field of video of GoPro cameras, but the quality of GoPro videos was perhaps slightly lower than that of Canon videos. A total of 15 calibration videos were read that included red snapper. Based on a regression analysis applied to the calibration video results, there were 53% (1 minus the regression slope parameter) fewer red snapper seen on Canon cameras compared to GoPro cameras, which is almost exactly what one would predict based on the reduction of field of view on Canon cameras compared to GoPro cameras (see Figures 7-9 in Bacheler and Carmichael 2014). Therefore, it was recommended that the 2010 relative abundance data point be reduced by 53% to account for differences in viewing areas among the cameras.

Data and Treatment

Data subsetting

Overall, there were 3987 survey videos with red snapper present during the examined 4 year sampling period (2010-2013). We removed any data points in which the survey video was considered unreadable by an analyst, or if the survey point was located in water greater than 100 meters, due to very limited samples in waters deeper than 100 m). Additionally, any survey video for which less than 41 video frames were read was removed from the full data set. Standardizing the number or readable frames for any data point was essential due to our use of SumCount as a response variable (see above). We also identified any video sample in which corresponding predictor variables were missing and removed them from the final data set.

Of the total 3987 video samples considered for inclusion in our modeling analysis, 885 were removed based on the data subsetting approach described above, leaving 3102 samples in the red snapper analyses for 2010 – 2013 (Figure 2).

Standardization

Response Variable

For the video index of red snapper we modeled the SumCount, or total number of red snapper observed across 41 video frames. There were a number of viable candidate response variables applicable for the estimation of abundance from video surveys, the relative merits of which were discussed at length during the video index development workshop (Bacheler and Carmichael 2014). The panel accepted the rational for using MeanCount, or the average number of individuals observed during a video reading, and recommended the use of SumCount as a response variable suitable for a zero-inflated modeling approach. The use of SumCount requires that an equal number of video frames (*n* = 41) be considered for each data point considered in the model estimation.

Explanatory Variables

We considered 9 explanatory variables in our model analysis: year, depth, latitude, water temperature, turbidity, and current direction, all of which were recommended during the video index development workshop (Bacheler and Carmichael 2014). The workshop panel also suggested including habitat variables, for which we included biotic density and substrate composition.

YEAR (*y*) – Year was include because standardized catch rates by year are the objective of this analysis. We modeled data from 2010-2013, noting that data from 2010 was spatially limited due to reduced video deployment during this initial year. Due to the high spatial overlap between the sampled region and the spatial occupancy of red snapper, data from 2010 were included in this analysis. This decision was supported by recommendations from the video index development panel (Bacheler Carmicheal 2014). Annual summaries of data points considered are outlined in Table 2.

SEASON (*t*) – A temporal parameter based on the Julian day the sample was collected (Figure 3). The season parameter is treated as an octile factor based on the recommendations of the video index development workshop.

DEPTH (*d*) – Water depth is a key component affecting the distribution of red snapper, so we considered all data points in waters shallower than 100m. Data points were excluded from deeper waters generally due to limited samples and rare occurrence (Figure 3). Annual depth distribution for survey data are outlined in Table 2.

LATITUDE (*lat*) – The latitudes of video samples were included as a spatial parameter in the model (Figure 3). Based on recommendations made by the video index development workshop, latitude was treated as a factor in the model and divided into 8 levels based on octiles.

TEMPERATURE (*temp*) – bottom water temperature was collected from each station and incorporated as a predictor variable. Bottom water temperature ranged from 12 – 29 degrees Celsius (Figure 3). For the standardization, model temperature was treated as a factor with 4 levels based on quantiles.

TURBIDITY (*wc*) – Due to the effect of turbidity on both species distributions and on the ability of an analyst to process video survey samples, we included water clarity (*wc*) in our standardization model. Turbidity information was recorded during video analysis based on the ability of an analyst to perceive the horizon and surrounding habitat and was scored at 3 levels (0 – Horizon visible, 1 – Habitat but not horizon visible, 2 – Habitat not visible).

CURRENT DIRECTION (*cd*) – A categorical variable estimating current direction based on the video point of view. Current direction data was included to better account for variability in detection due to the current moving fish away or towards the camera. This variable was collected during video processing and scored as a 4-level categorical variable (Towards, Away, Sideways, Unknown) and was incorporated into the model as such.

BIOTIC DENSITY (*bd*) – An estimation of the percent cover of attached biota visible during any video. The estimation is made based on percentage cover and ranged from 0 – 98%. For our analysis *bd* was treated as a categorical variable with 4 levels: none (0%), low (1-9%), moderate (10-39%) and high (>40%).

SUBSTRATE COMPOSITION (sc) – An estimate of the amount of hardbottom in the video viewing area. This variable was treated as a categorical variable with 4 levels: none (0%), low (1-9%), moderate (10-39%) and high (>40%).

Zero-Inflated Model

The recommendation of the video index workshop was to apply a zero-inflated modeling approach to the development of fishery-independent video index for red snapper in the South Atlantic. Zero-inflated models are valuable tools for modeling distributions that do not fit standard error distribution due to excessive number of zeroes. These data distributions are often referred to as "zero-inflated" and are a common condition of count-based ecological data. Zero inflation is considered a special case of over dispersion that is not readily addressed using traditional transformation procedures (Hall 2000). Due to the high proportion of zero counts found in our data set (Figure 4), we used a zero inflated mixed model approach which models the occurrence of zero values using two different processes, a binomial and a count processes (Zuur et al. 2009). The benefit and utility of this approach was discussed at length during the video index workshop (Bacheler and Carmichael 2014) and their use was the final recommendation of the panel.

Initially, a null model (1) was considered employing both a zero-inflated Poisson (ZIP) and a zero-inflated negative binomial (ZINB) formulation.

(1) $$SumCount = y + wc + cd + sc + bd + d + t + lat + temp \mid y + wc + cd + sc + bd + d + t + lat + temp$$

We compared the variance structure of each model formulation using a likelihood ratio test (Zuur et al. 2009) to determine the most appropriate model formulation for the development of a video index for red snapper. The likelihood ratio test (Table 1) showed strong support for application of a ZINB formulation that, in addition to a comparison of model fits for both the ZIP and ZINP formulations (Figure 5), resulted in decision to use a ZINB approach. The results concurred with expectations based on the level of zero-inflation and over dispersion within the original red snapper data and with the recommendations of the video index development panel (Bacheler and Carmichael 2014).

A backwards step-wise model selection procedure was used to exclude unnecessary model parameters from the null model (1) formulation. The optimum red snapper model formulation (2) was determined using a combination of AIC and likelihood ratio tests (Zuur et al. 2009) and excluded water clarity (*wc*) and temperature (*temp*) from the binomial component of the model and excluded both water clarity (*wc*) and season (*t*) from the negative binomial component of the model (Table 3).

(2) $$SumCount = y + cd + sc + bd + d + t + lat \mid y + cd + sc + bd + d + lat + temp$$

Model diagnostics showed no discernable pattern of association between Pearson's residuals and fitted values or the fitted values and the original data (Figure 6). An examination of model residuals for the spatio-temporal (Figure 7) and environmental model parameters (Figure 8) showed no clear patterns of association, indicating correspondence to underlying model assumptions (Zuur et al. 2009). Finally, a comparison of predicted values against the original data distribution (Figure 9) visualizes how our model fits the original data.

All data manipulation and analysis was conducted using R version 3.0.2 (R Core Team 2014). Modeling was executed using the **zeroinfl** function in the **pscl** package (Jackman 2008), available from the Comprehensive R Archive Network (CRAN).

Results

Annual standardized index values for red snapper including coefficient of variation estimates are presented in Table 4. The relative nominal video counts for red snapper differed considerably in comparison to the standardized index with only the 2011 relative nominal value falling within the 2.5% and 97.5% confidence intervals of the standardized index (Figure 10). The nominal value for 2010 (2.30) was considerably higher than the standardized index value for 2010 (1.42), which was expected due to the integration of a camera calibration to the standardized index. Additionally, the standardization index procedure increased estimates of abundance for both the 2012 and 2013 survey years with the relative nominal value falling below and outside of the index confidence intervals. Due to the short temporal extent of this index (4 years), limited inferences can be discerned concerning patterns of red snapper abundance, however the index does indicate an increase in relative video counts since the 2011 survey year and relative stability for the 2012-2013 survey years.

MARMAP Technical Report # 2014-005

This work represents partial fulfillment of the Marine Resources Monitoring, Assessment, and Prediction (MARMAP) program contract (NA11NMF4540174) sponsored by the National Marine Fisheries Service (Southeast Fisheries Science Center) and the South Carolina Department of Natural Resources.

Abstract

Fishery-independent measures of catch and effort with standard gear types and deployment strategies are valuable for monitoring the status of stocks, interpreting fisheries landings data, performing stock assessments, and developing regulations for managing fish resources. This report presents a summary of the fishery-independent monitoring of Red Snapper in the US South Atlantic region and includes data from the three monitoring programs (MARMAP, SEAMAP-SA, and SEFIS, known collectively as SERFS). Specifically, it presents annual nominal catch per unit effort (CPUE) of Red Snapper in chevron traps from 1990 to 2013. Also included are annual CPUE estimates for chevron trap catches from 1990 to 2013 standardized by a delta-generalized linear model (dGLM) and a zero-inflated negative binomial model (ZINB). The standardized models account for the effects of potential covariates that may affect sampling or abundance, other than year of capture, on annual CPUE estimates. We also include length and age compositions for the chevron trap survey to describe selectivity. The ZINB model fit best to observed catches of Red Snapper. Standardized annual CPUE estimates normalized to the series' average indicated that CPUE was highly variable with little trend through the early 2000s, before declining to series' lows in the mid 2000s. Since approximately 2006, CPUE in the region has been increasing generally.

Introduction

Fishery-independent measures of catch and effort with standard gear types and deployment strategies are valuable for monitoring the status of stocks, interpreting fisheries landings data, performing stock assessments, and developing regulations for managing fish resources. Inevitably, tighter management regulations result in fishery-dependent catches reflecting the demographics of a restricted subset of the population, affecting the utility of fishery-dependent data when assessing the current status of the stock. When fisheries are highly regulated, fishery-independent surveys are often the only method available to adequately characterize population size, age and length compositions, and reproductive parameter distributions, all of which are needed to assess the status of stocks. The Marine Resources Monitoring, Assessment and Prediction (MARMAP) program has conducted fishery-independent research on the continental shelf and shelf edge between Cape Hatteras, North Carolina, and St. Lucie, Florida, for over 40 years to provide information for reliable stock assessments and evaluation of management plans. Housed at the Marine Resources Research Institute (MRRI) at the South Carolina Department of Natural Resources (SCDNR), the overall mission of the MARMAP program has been to determine the distributions, relative abundances, and critical habitats of economically and ecologically important fishes of the SAB, and to relate these features to environmental factors and exploitation activities.

Although the MARMAP program has used various gear types and methods of deployment since its inception, the program has strived to use consistent gears and sampling methodologies throughout extended time periods to allow for analyses of long-term changes in relative abundance, age compositions, length frequencies, and other information. As such, the MARMAP program primarily has used a standard sampling methodology with chevron traps for monitoring purposes on known live-bottom habitats since 1990. The focus of this report is on developing an annual catch per unit effort

(CPUE) or abundance index for Red Snapper (*Lutjanus campechanus*) based on chevron trap catches from 1990 to 2013.

Until recently, the MARMAP program was the only long-term fishery-independent program that collected the data necessary to develop indices of relative abundance for species in the South Atlantic Fisheries Management Council's (SAFMC) snapper-grouper species complex. In 2008, with a first field season occurring in 2009, the Southeast Area Monitoring and Assessment Program's South Atlantic component (SEAMAP-SA) provided funding to complement MARMAP efforts. A particular goal of the SEAMAP-SA Reef Fish complement is to assist with the expansion of the geographical sampling coverage of the current fishery-independent surveys, focusing on either shallow or deep potential live-bottom areas. In addition, the SEAMAP-SA complement funding allowed for expanded sampling in marine protected areas (MPAs).

Beginning in 2010, NOAA Fisheries made funding available to create the Southeast Fisheries Independent Survey (SEFIS) program housed at the Southeast Fisheries Science Center (SEFSC) laboratory in Beaufort, NC. This fishery-independent survey was designed to further complement the historical MARMAP/SEAMAP-SA reef fish monitoring efforts, again aimed at extending the geographical range of the surveys. SEFIS activities were coordinated closely with MARMAP/SEAMAP-SA staff, which trained SEFIS personnel and have participated in SEFIS monitoring cruises. SEFIS uses gear and methodologies identical to MARMAP/SEAMAP-SA to maintain the integrity of the long-term data set. In 2011, for logistical and cost savings reasons and since all programs were using identical sampling methods, it was decided that SEFIS vessels would concentrate sampling efforts in waters off Georgia and Florida, while MARMAP/SEAMAP-SA vessels would concentrate efforts off South Carolina and North Carolina. Given the close coordination and consistent sampling methodology used by each of the fishery-independent sampling programs, it is possible to combine catch, effort, and length data collected by each program for chevron traps for the analyses presented in this report (see **Error! Reference source not found.** for gear deployment summary). The combined efforts of MARMAP, SEAMAP-SA Reef Fish Complement, and SEFIS to conduct fishery-independent reef fish monitoring in the US South Atlantic region are now referred to as the Southeast Reef Fish Survey (SERFS).

Objective

This report presents a summary of the fishery-independent monitoring of Red Snapper in the US South Atlantic region and includes data from the three monitoring programs (MARMAP, SEAMAP-SA, and SEFIS, known collectively as SERFS). Specifically, it presents annual nominal catch per unit effort (CPUE) of Red Snapper in chevron traps from 1990 to 2013. Also included are annual CPUE estimates for chevron trap catches from 1990 to 2013 standardized by a delta-generalized linear model (dGLM) and a zero-inflated negative binomial model (ZINB). The standardized models account for the effects of potential covariates that may affect sampling or abundance, other than year of capture, on annual CPUE estimates. Data presented in this report are based on the combined SERFS database accessed in January, 2014 for the dGLM analysis and on July 14, 2014 for the nominal and ZINB analyses, and include data collected through the 2013 sampling season.

Methods

Survey Design and Gear

The standard SERFS sampling area includes waters of the continental shelf and shelf edge between Cape Hatteras, NC, and St. Lucie Inlet, FL, although over the years the majority of sampling has occurred south of Cape Lookout, NC (Figure 1). Throughout this range, we sample stations established on confirmed live bottom (monitoring) from May through September each year, though cruises have occurred prior to and after these months in some years. Traps deployed on suspected live bottom in a given year (reconnaissance) are evaluated based on catch and video or photographic evidence of bottom type for inclusion in the sampling frame the next year.

MARMAP began using chevron traps in 1988 after a commercial fisherman introduced the use of this trap design in the US South Atlantic region (Collins 1990). Subsequently, in 1988 and 1989, chevron traps were used simultaneously with blackfish and Florida Antillean traps to compare the efficiency of the three different trap designs at capturing reef fishes on live-/hard-bottom habitats (Collins 1990). Results indicated that the chevron trap was most effective overall for species of commercial and recreational interest in terms of both total weight and numbers of individuals captured (Collins 1990). Based on these results, the MARMAP program has used chevron traps for reef fish monitoring purposes in the US South Atlantic since 1990, using this single gear to replace both blackfish and Florida Antillean traps. Currently, all three fishery-independent monitoring programs composing SERFS continue to utilize the chevron trap as their primary monitoring gear.

Each year, stations are selected randomly from known live-/hard-bottom stations identified for monitoring via fish traps (low to moderate relief) in that year (currently ~ 3,500 stations are available). Stations are selected randomly in a manner such that no station selected in a given year is closer than 200 m to any other selected station, though the minimum difference typically is closer to 400 m. Chevron traps have been deployed at depths ranging from 13 to 218 m, although the depth of usage generally is less than 100 m. The vast majority of the deeper deployments occurred in 1997.

The chevron trap time series has been continuous from 1990 to present, although the distribution and extent of sampling has changed over time. The spatial coverage of the survey has expanded over the time series as we have added stations and sampling effort in the northern and southern ends of the survey. Figure 1 shows the extent of the survey for all sampling years included in this report and the locations of Red Snapper catches and Table 1 shows changes in the survey with regards to some environmental variables over all years included in this report.

Chevron traps are arrowhead shaped, with a total interior volume of 0.91 m^3 (Figure 2, Collins 1990). Each trap is constructed of 35 x 35 mm square mesh plastic-coated wire (MARMAP 2009). Each trap possesses a single entrance funnel ("horse neck") and release panel to remove the catch (Collins 1990; MARMAP 2009). Prior to deployment each chevron trap is baited with a combination of whole or cut clupeids (*Brevoortia* or *Alosa* spp., family Clupeidae), with *Brevoortia* spp. most often used. Four whole clupeids on each of four stringers are suspended within the trap and approximately 8 clupeids, with their abdomen sliced open, are placed loose in the trap (Collins 1990; MARMAP 2009). An individual trap is attached to an appropriate length of 8 mm (5/16 in) polypropylene line buoyed to the surface using a polyball buoy. We attach a 10 m trailer line to this polyball buoy, with the end of the trailer line clipped to a Hi-Flyer buoy or another polyball. Generally traps are deployed in sets of six when a sufficient number of stations are available in a given area (MARMAP 2009). Traps are retrieved in chronological order of deployment, using a hydraulic pot hauler, after an approximately 90-minute soak time.

Oceanographic Data

While traps are soaking, oceanographic variables (mainly temperature and salinity) are determined using a CTD. Bottom temperature (°C) as used in this report is defined as the temperature of the deepest recording within 5 m of the bottom.

Data and Treatment

Data and Nominal CPUE Estimation

Data available for use in CPUE estimation for each trap (deployment) included a unique collection number, date of deployment, soak time, latitude, longitude, bottom depth, catch code, number of Red Snapper captured, aggregate weight of Red Snapper captured, and bottom temperature, among other variables. We used numbers, instead of weight, of Red Snapper for all analyses. Estimates of CPUE, or relative abundance, are given as the number of Red Snapper caught per trap per hour soak time (dGLM CPUE) or number per trap (nominal CPUE and ZINB CPUE).

Prior to modeling, a subset of the available SERFS trap data was selected for CPUE estimation based on several criteria:

1) Deployments made via SERFS with a project ID of P05 (MARMAP fishery-independent samples), T59 (SEAMAP-SA Reef Fish Complement fishery-independent samples), and T60 (SEFIS fishery-independent samples)
2) Deployments with catch codes of 0 (no catch), 1 (catch with finfish), 2 (catch without finfish), 9 (recon trap deployment), 90 (recon trap deployment with no catch), 91 (recon trap deployment with finfish), and 92 (recon trap deployment without finfish catch)
    a. For development of the dGLM standardized index (i.e. index presented in the 2013 trends report), all 9, 90, 91, and 92 catch codes were removed from analysis
3) Deployments with station codes of “Random” (randomly-selected live-bottom station), “NonRandom” (non-randomly sampled live-bottom station (a.k.a. haphazard sample)), “ReconConv” (reconnaissance deployments that were subsequently converted into live-bottom stations), and “Is Null” (traps for which there is no station code value – the use of station codes is fairly new since 2010. Historically we used only the catch ID to indicate randomly-selected stations)
4) Deployments with Gear ID equal to 324 (chevron traps)
5) Deployments with Data Source not equal to “Tag-MARMAP”
    a. “Tag-MARMAP” represents special historic MARMAP cruises that were used to tag various species of fish. Because standard sampling procedures were not used (e.g.

not all fish were measured for length frequency) these samples are excluded from CPUE development

6) Deployments at depths between 15 and 74 m
    a. Represents the depth range at which 100% of Red Snapper were collected by any gear used in the SERFS (Ballenger et al. 2012b)
    b. Given previous constraints, this removes 248 traps deployed at <15 m or >74 m of depth and 2 traps for which we are missing depth data
7) Soak times outside of a window between 45 and 150 minutes, which generally indicates deviations from standard protocols
    a. Note, SERFS targets a soak time of 90 minutes for all chevron trap deployments
    b. Removes an additional 192 traps with unusually long or short soak times
8) Deployments made since 1990
    a. Removes an additional 178 traps sampled in 1988 and 1989

Delta-Generalized Linear Model (dGLM) CPUE Standardization

In the MARMAP annual trends report, Red Snapper annual CPUE is calculated using a dGLM method. In this method, CPUE is standardized among years using the "delta-GLM" technique described in Lo et al. (1992). Briefly, the standardized CPUE is the product of fitted values from two generalized linear models (GLMs). The first model examines the effects of factors or "covariates" on the presence or absence of a species using the binomial error distribution. As we assume each gear deployment is independent and identical to all other gear deployments, each gear deployment in effect represents a binomial trial with a sample size of one (n=1). In such cases, we refer to the distribution as a Bernoulli distribution, thus our reference to the Bernoulli sub-model or Bernoulli GLM of the delta-GLM in the remainder of this report. By modeling this presence/absence data using the Bernoulli distribution, we assume that the presence/absence data conform to the Bernoulli distribution density function

$$f(y;\pi) = \binom{1}{y} * \pi^y * (1-\pi)^{1-y}.$$

The mean and variance of the Bernoulli distribution are given by

$$E(Y) = \pi \qquad\qquad \mathrm{var}(Y) = \pi * (1-\pi).$$

The second model examines the effects of covariates on the CPUE of positive observations using a second assumed error distribution (e.g. gamma distribution, Gaussian distribution, lognormal distribution, etc.). This model is referred to as the positive GLM or the error distribution identified as "best" modeling the positive data (e.g. gamma sub-model and lognormal sub-model).

In the current report, only the use of the gamma and lognormal distributions were investigated to model the positive data in the dGLM. The gamma distribution is appropriate for use with a continuous response variable *Y* that has positive values (*Y* > 0), and is represented by the probability density function

$$f(y;\mu,\nu) = \frac{1}{\Gamma(\nu)} * \left(\frac{\nu}{\mu}\right)^{\nu} * y^{\nu-1} * e^{\frac{y*\nu}{\mu}} \qquad y > 0 \text{ (Zuur et al. 2009).}$$

Under the gamma distribution, the mean and variance of *Y* are

$$E(Y) = \mu \qquad \mathrm{var}(Y) = \frac{\mu^2}{\nu}.$$

The lognormal distribution is a continuous probability distribution of a response variable *Y* whose logarithm is normally distributed, and is represented by the probability density function

$$f(y;\mu,\sigma) = \frac{1}{x\sigma\sqrt{2\pi}} * e^{-\frac{(\ln y-\mu)^2}{2\sigma^2}} \qquad y > 0.$$

Under the lognormal distribution, the mean and variance of *Y* are

$$E(Y) = e^{\mu+\frac{1}{2}\sigma^2} \qquad \mathrm{var}(Y) = \left(e^{\sigma^2} - 1\right) * e^{2\mu+\sigma^2}.$$

Covariates in the initial development of the dGLM CPUE estimates include latitude, depth, bottom temperature, and season. Covariates were defined as categorical variables for this analysis based on the 50% quartiles for distribution of sampling efforts, creating 2 bins for each covariate (Bubley et al. 2014). Selection of the covariates included in the final model (both Bernoulli GLM and positive GLM) was done based on Akaike's information criteria (AIC; Akaike 1973). Year was included as a covariate in both models regardless of the selection outcome based on AIC. Further, we allowed the possibility that different covariates may appear in the Bernoulli GLM and positive GLM. The final dGLM standardized CPUE index is the product of the year effects and any selected covariates from the two models. Coefficients of variation, standard error, and standard deviations were determined by a jackknifing approach.

Zero-Inflated Model CPUE Standardization

CPUE was standardized among years using a zero-inflated count model (ZINB). Given the biological knowledge of Red Snapper and the sampling design of the SERFS chevron trap survey, we compared model fits with the ZINB method to those of the nominal CPUE estimation and dGLM method based on conclusions and recommendations drawn during SEDARs 32 and 36. Investigation of this technique to model CPUE data also was suggested during the Fishery-Independent Survey Independent Review for the South Atlantic (SEFSC 2012). As is the case with many ecological count data sets (Zuur et al. 2009), the observed CPUE data appeared to be zero-inflated based on preliminary analyses (Figure 3), suggesting the appropriateness of zero-inflated count data models.

Briefly, we provide some background information regarding zero-inflated count data models. For a more complete discussion, see Chapter 11 in Zuur et al. (2009). Zeileis et al. (2008) provides a nice overview and comparison of Poisson, negative binomial, and zero-inflated models in R. Some textbooks devoting sections to the discussion of zero-inflated models include Cameron and Trivedi (1998), Hardin and Hilbe (2007), or Hilbe (2007).

The concept of zero inflation derives from the observation that in many ecological, economic, and social studies there are far more zeros in count data than what would be expected for a Poisson or negative binomial distribution. As such, zero inflation means that we have far more zeros than we would expect. Ignoring zero inflation when it exists can have two major consequences, namely the estimated parameters and standard errors may be biased and the excessive number of zeros can cause overdispersion (Zuur et al. 2009).

Zeros due to design and observer errors are called false zeros or false negatives while structural and "animal" zeros are known as positive zeros, true zeros, or true negatives (Zuur et al. 2009). To address these different sources of zeros, two distinctive classes of zero-inflated models have been developed, two-part (hurdle) and mixture models, with the difference between the two classes arising due to differences in how they deal with zeros. Two-part models do not discriminate between the four different types of zeros and simply treat a zero as a zero whereas mixture models account for the type of zero.

Mixture models (zero-inflated Poisson (ZIP) and zero-inflated negative binomial (ZINB)) treat zeros via two different processes: the binomial process and the count process (Zuur et al. 2009). A binomial generalized linear model is used to model the probability of measuring a zero while the count process is modeled by a Poisson or negative binomial GLM. As such, the fundamental difference between hurdle and mixture models is that the count process can produce zeros in mixture models but not in hurdle models (Zuur et al. 2009). In such a setup, the zeros resulting from the count process model represent true zeros, while the binomial GLM models the probability of measuring a false zero versus all other types of data (counts and true zeros; Zuur et al. 2009). In short, the probability functions of a ZINB are:

$$f(y_i = 0) = \pi_i + (1 - \pi_i) * \left(\frac{k}{\mu_i + k}\right)^k$$

$$f(Y_i = y_i | y_i > 0) = (1 - \pi_i) * \frac{\Gamma(y_i + k)}{\Gamma(k) * \Gamma(y_i + 1)} * \left(\frac{k}{\mu_i + k}\right)^k * \left(1 - \frac{k}{\mu_i + k}\right)^k$$

for the binomial component and the non-zero component, respectively. In ZINB, the expected mean and variance are slightly different due to the definition of the probability functions. The mean and variance of a ZINB are:

$$\mathrm{E}(Y_i) = \mu_i * (1 - \pi_i)$$

$$\mathrm{var}(Y_i) = (1 - \pi_i) * \left(\mu_i + \frac{\mu_i^2}{k}\right) + \mu_i^2 * (\pi_i^2 + \pi_i).$$

If the probability of false zeros is 0, the mean and variance of the negative binomial GLM are equal.

In the development of the ZINB CPUE model for Red Snapper, we modeled CPUE as catch per trap, compared to the traditional method of calculating catch per trap per hour. We included soak time as an offset term instead of creating a catch rate by dividing the catch per trap by the soak time or sample duration. By defining this offset variable we adjust for the amount of opportunity for the gear to capture a fish (e.g. a deployment with a soak time of 120 minutes has twice the opportunity than a deployment with a soak time of 60 minutes).

Similar to dGLM, ZINB models can account for effects of different covariates on observed counts. The same or different covariates can be included in the binomial sub-model and catch sub-model. In initial investigations we considered the following covariates in addition to year:

- Depth – continuous variable
- Bottom temperature – continuous variable
- Longitude – continuous variable
- Latitude – continuous variable
- Day of Year (DOY) – continuous variable

Other covariates in the data set that could have been considered included bottom salinity, month, season, dissolved oxygen concentration, chlorophyll-A concentration, nitrite (NO_2) concentration, nitrate (NO_3) concentration, and phosphate (PO_4) concentration. We didn't consider bottom salinity as a potential covariate due to its general lack of variability in oceanic waters and preliminary investigations suggesting there was little relationship between Red Snapper CPUE and bottom salinity. We didn't consider month or season as a covariate as each is correlated to a high degree with our included covariate DOY. Given DOY gives more temporal resolution, the assumption was made that it would provide greater power in standardizing Red Snapper CPUE with regards to within year day of sampling differences. Finally, we didn't consider the last five potential covariates due to missing values on a large number of trap sets data for these variables, primarily due to the lack of equipment to collect these variables historically.

Prior to inclusion of the considered covariates in the full model, we used preliminary analyses to investigate the possibility of collinearity between any of the variables. A pairs plot of continuous covariates revealed high correlation between latitude and longitude (due to the shape of the survey region), and moderate correlation between bottom temperature and depth and bottom temperature and DOY (Figure 4). Variance inflation factor (VIF) estimates for all considered covariates were all <2, though there was some concern regarding the higher VIF for bottom temperature (Table 2). When bottom temperature is excluded, all VIFs fall to <1.2. Given the weak ecological relationships expected between CPUE and the considered covariates, that bottom temperature was moderately correlated with both latitude and depth, and that we are missing bottom temperature data on numerous stations throughout the history of the SERFS due to CTD failure, we removed bottom temperature from consideration as a potential covariate.

Box plots of the remaining covariates (depth, latitude, and DOY) among years showed no obvious strong collinearity (Figure 5). With regards to sampling depth, sampling throughout the entire period appeared fairly homogenous, with the possible exception of 1992. With regards to latitude, it appears there has been a general expansion at two points during the survey, 1996, and 2010 (Figure 1). Most notable is the expansion in 2010, which corresponds to the first sampling season including SEFIS. Since 2010 the median latitude of sampling has shifted south with an overall broader range of sampling.

1999 was slightly anomalous in that the latitude distribution is restricted compared to surrounding years, with it being more similar to the early years of the survey. Finally, for DOY there does seem to be more year to year variability in days sampled. This is to be expected given the nature of the survey and weather constraints. Most notably, sampling appeared to occur earlier than average in 1990 and 1992 and later than average in 1991 and 2010. Also, sampling in 1999 was restricted temporally compared to other years.

Due to the desire to include continuous variables in the zero-inflated standardization model, we used generalized additive models (GAM) to investigate the relationship of continuous covariates with CPUE. We investigated two sets of GAMs, one looking at the relationship of continuous covariates to the presence/absence of Red Snapper and one looking at the relationship of continuous covariates to Red Snapper catch.

For the presence/absence GAMs, each of the covariates had a non-linear effect on the presence of Red Snapper (Figure 6 and Table 3). Probability of presence of Red Snapper peaked at depths of 25-70 m, declining at shallower and deeper depths. The decline in presence at depths between 40 and 55 m may be explained by a lack of stations in this depth zone at latitudes where red snapper are commonly found relative to other depths. Probability of presence shows two distinct peaks at latitudes of 28-30^{o}N and >34.5^{o}N, with a smaller peak around 32^{o}N. In general, latitude has a greater effect on probability of capture than the other covariates. Finally, the relationship between DOY and probability of presence is either flat or parabolic with highest probabilities of presence occurring at the beginning and end of the sampling season. These peaks could be driven by low sample sizes near the beginning and end of the sampling seasons.

For the catch GAMs, each of the covariates had a non-linear effect on the catch of Red Snapper (Figure 7 and Table 3). Highest catches of Red Snapper occurred at the shallowest depths, generally declining as depth increases. Highest catches of Red Snapper showed a trimodal peak compared to latitude, with similar peaks at around 28.5°N, 31°N, and 33°N. Finally, Red Snapper catch compared to DOY was fairly flat, except for a slight peak around 275 days.

Based on these GAM analyses, in addition to year, we included the continuous covariates depth, latitude and DOY as polynomials in the full ZI model to allow for non-linear effects of these covariates on Red Snapper CPUE. To determine the order of the polynomials, we rounded the GAM effective degrees of freedom (Table 3) to the nearest whole number, letting this number represent the highest polynomial order. Prior to model development, these continuous variables were centered and scaled to improve statistical convergence.

Selection of the covariates included in the final model (both zero-inflation and count sub-models) was done based on Bayesian information criterion (BIC; Schwarz 1978). We allowed the possibility that different covariates may appear in each of the sub-models. All analyses were performed in R (Version 3.1.0; R Development Core Team 2014). The zero-inflated models in R were developed using the function zeroinfl available in the package *pscl* (Jackman 2011; Zeileis et al. 2008).

Chevron Trap Length and Age Composition

Red Snapper lengths were measured following retrieval of each chevron trap set to the nearest centimeter prior to 2010 and to the nearest millimeter from 2010 to 2013. Lengths were measured either as fork length or maximum (pinched) total length at the time of capture. Here, we report length in maximum (pinched) total length and any fork lengths were converted to such based on conversions developed by Ballenger et al. (2012b) from over 1,700 fish. All measurements done in mm were rounded to the nearest whole cm prior to analysis. Length percent compositions were calculated for each year using 1-cm length bins centered on the integer. Although the resolution of the majority of the time series and all analyses were done in cm, length compositions are presented in mm to be consistent with other reports, including life history. Following length measurements, sagittal otoliths were removed from all Red Snapper to serve as the aging structure for Red Snapper. Ages presented here are calendar age based on increment counts, estimated increment formation on July 1st, and edge type (White et al. 2010, SEDAR 24-DW14).

Results

Sampling Summary

A data set for analysis was obtained from a query of the SERFS database on July 14, 2014. Given the constraints mentioned above and removing any collections we are missing covariate data (1 station removed because of missing latitude data), from 1990 to 2013 we made 10,664 chevron trap monitoring deployments (Table 1), averaging 444 collections per year (range: 219-1,331), following standard monitoring station sampling protocol. The average depth for these collections was 37 m, with annual averages ranging from 33 to 41 m. The average latitude was 32.10°N, with annual averages ranging from 31.25°N to 32.79°N. The average DOY was 194, with annual averages ranging from 151 to 222 days.

Nominal CPUE

Nominal catch per trap averaged 0.136 for the entire time series, with annual averages ranging from a low of 0.016 in 1996 to a high of 0.367 in 2012 (Table 4 and Figure 8).

Delta-GLM CPUE

Results of the dGLM standardization reported here were initially reported in an annual report of trends in catch of snapper-grouper species (Bubley et al. 2014) and were not updated for this report. These results are presented here purely for comparative purposes, as the authors felt that a newer approach such as the zero-inflated methods would be more appropriate for the Red Snapper data set.

DGLM-standardized CPUE estimates were variable (range: 0.01 – 0.9; Table 4) with no clear directional trend throughout the time series until the last 4 years (Figure 8). Since 2010, the trend was upward, reaching historically high levels in 2013, topping previous series' high levels in 2011 and 2012. The standardization method reduced variability due to sampling differences among years and reduced the extent of recent years' increase in relative abundance compared to the nominal estimates, suggesting that some of the increase in abundance was due to changes in sampling.

Zero-Inflated CPUE

Preliminary model analyses clearly suggested that a zero-inflated negative binomial model (ZINB) was superior to a Poisson GLM, a negative binomial GLM, or zero-inflated Poisson model (ZIP). Both the best-fit Poisson GLM and best-fit negative binomial GLM, with overdispersions of 3.404 and 1.445, respectively, suggested overdispersion remained given these model structures (Table 5). Continued overdispersion despite these model structures suggests the catch data is zero-inflated and likely should be modeled using a zero-inflated model structure. While the overdispersion for the best-fit negative binomial GLM was mild, this model had a hard time converging and was unstable statistically. Comparing the ZIP and ZINB full models, BIC clearly suggested that a negative binomial error structure for the count model was superior to a Poisson error structure (Table 5), likely due to its ability to better account for the dispersion parameter by estimating theta directly in the model.

Step-wise selection using BIC starting with the full model removed a number of covariate polynomials from both the zero-inflation and count sub-models (Table 5). The only constraint on this selection was that the variable "Year" must be retained in the count sub-model of ZINB model. The resulting final model had the following form:

Zero-Inflation Sub-Model

$$\text{Abund}^* = offset(\ln(\text{soak time})) + \text{Depth}^2 + \text{Depth}^7 + \text{Latitude} + \text{Latitude}^2 + \text{Latitude}^3 + \text{Latitude}^4 + \text{Latitude}^6 + \text{Latitude}^8 + \text{DOY} + \text{DOY}^2$$

Count Sub-Model

$$\text{Abund} = offset(\ln(\text{soak time})) + \text{Year} + \text{Depth}^2 + \text{Depth}^3 + \text{Depth}^4 + \text{Depth}^5 + \text{Depth}^6 + \text{Depth}^7 + \text{Depth}^9 + \text{Latitude}^2 + \text{DOY}^3$$

where Abund* represents the catch data transformed to presence/absence data and Abund represents the observed catch data.

Standardized annual CPUE estimates normalized to the series average indicates that CPUE was highly variable with little trend through the early 2000s, before declining to series' lows in the mid 2000s (Figure 9). Since approximately 2006, CPUE in the region has been increasing generally (Figure 9). This is similar to the pattern observed for CPUE estimates based upon the dGLM (Figure 8; Bubley et al. 2014).

Plots of annual variance and coefficient of variation (CV) estimates indicate that 10,000 bootstraps were sufficient for these measures to stabilize (Figure 11). Standardization using the ZINB resulted in annual CV estimates of approximately 45%. Individual year CV estimates ranged from a low of 20% to a high of 138% in 2011 and 2003, respectively (Table 4). Though not directly comparable due to different measures of CPUE used and the different criteria used to include collections in the dGLM, it appears that annual CVs estimated using the ZINB are similar to those estimated using the dGLM standardization (Table 4).

A plot of the observed and predicted number of Red Snapper caught suggests that the ZINB was moderately successful at capturing the observed catch pattern (Figure 11). While the ZINB does a fair job predicting the number of traps that had 0 catch, it does a poor job predicting the number of Red Snapper captured given a trap is positive for Red Snapper. In this case it predicts many more traps would catch only a single Red Snapper than observed. Further, it predicts at most only 3 Red Snapper would be caught in any given trap, though we have observed as many as 28 Red Snapper in an individual trap.

Residual diagnostics suggest that there were some outlier observations in the dataset represented by large Pearson residuals (in excess of 30; Figure 12), though overall there is no strong indication of a pattern in the residuals or heteroscedascity when the residuals are plotted against included covariates (Figures 13 and 14). When Pearson residuals are compared to several potential covariates excluded from the final model (Chlorophyll-A concentration, dissolved oxygen concentration, Event (all traps included in a given trap set), longitude, month, salinity, season, and bottom temperature), first glance suggests there is no strong indication of a pattern to the residuals or heteroscedascity, which indicates that no excluded covariates are critical to the model (Figures 15 and 16). The mean Pearson residuals versus dissolved oxygen and bottom temperature show patterns to the residuals that cause some concern (Figure 16). For dissolved oxygen the long string of mainly negative residuals at higher dissolved oxygen concentrations (Figure 16) suggests that Red Snapper catch may be related to dissolved oxygen concentrations. However, we are missing dissolved oxygen measurements from a large number of stations, particularly in earlier years, making the use of this variable as a covariate difficult. For bottom temperature the mean of the residuals indicate a long string of negative residuals at either end (low temperatures (particularly) and high temperatures; Figure 16) that causes some concern. Finally, looking at the spatial distribution of positive and negative Pearson residuals suggests no obvious spatial patterning of the residuals (Figure 17). The one concern may be the group of negative residuals (blue dots) occurring near the northern end of our sampling range north of about 34^{o}N latitude. This lack of spatial structure to the residuals also is supported by the sample variogram, which doesn't show any indication of spatial correlation in trap catches closer than 10 km to each other (Figure 18).

The final ZINB model suggests highly non-linear relationships among Red Snapper catch and included covariates (depth, latitude, and day of year; Figure 19). For depth, as originally suggested, Red Snapper catch peaks at depths between 35 and 40 m, with smaller peaks around 23 and 55 m. For latitude, we see a generally bimodal distribution with catch peaking at around 28-29^{o}N and then again north of approximately 34.5^{o}N. There is a much smaller peak at around 31.5^{o}N. Finally, DOY tends to have little effect on Red Snapper catch until late in the season, after approximately day 250 when Red Snapper catch tends to increase.

Addendum 1

A Zero-Inflated Model of CPUE of Red Snapper in US South Atlantic Waters Based on Fishery-Independent Chevron Trap Surveys

SEDAR41-WP06
MARMAP Technical Report # 2014-005

This work represents partial fulfillment of the Marine Resources Monitoring, Assessment, and Prediction (MARMAP) program contract (NA11NMF4540174) sponsored by the National Marine Fisheries Service (Southeast Fisheries Science Center) and the South Carolina Department of Natural Resources.

Objective

This report presents a summary of the fishery-independent monitoring of gray triggerfish in the US South Atlantic region and includes data from the three monitoring programs (MARMAP, SEAMAP-SA, and SEFIS, known collectively as the Southeast Reef Fish Survey (SERFS)). Specifically, it presents annual catch per unit effort (CPUE) of gray triggerfish from chevron traps. Included here are annual CPUE estimates for chevron trap catches standardized by a zero-inflated statistical model for the years 1990-2013. The zero-inflated model accounts for the effects of potential covariates, other than year of capture, on annual CPUE estimates. Data presented in this report are based on the combined SERFS database accessed on July 14, 2012, and include data collected through the 2013 sampling season. The original report above presents a nominal index, a delta-GLM standardized index, and a zero-inflated standardized index based on the same chevron trap catches. The difference between the two zero-inflated indices presented (original in above report and current model reported here) is how the covariates are treated in the model with the former treating the covariates as continuous variables that are modeled using polynomials in the model and the latter treating the covariates as categorical variables.

Methods

Survey Design and Gear

See the original report above for a description of the sample collection methods

Oceanographic Data

See the original report above for details regarding the collection of oceanographic data via a CTD.

Data and Treatment

Data and Nominal CPUE Estimation

Data available for use in CPUE estimation for each trap (deployment) included a unique collection number, date of deployment, soak time, latitude, longitude, bottom depth, catch code, number of Red Snapper captured, aggregate weight of Red Snapper captured, and bottom temperature, among other variables. We used numbers, instead of weight, of Red Snapper for all analyses. Estimates of CPUE, or relative abundance, are given as the number of Red Snapper caught per trap.

Prior to modeling, a subset of the available SERFS trap data was selected for CPUE estimation based on several criteria:

9) Deployments made via SERFS with a project ID of P05 (MARMAP fishery-independent samples), T59 (SEAMAP-SA Reef Fish Complement fishery-independent samples), and T60 (SEFIS fishery-independent samples)
10) Deployments with catch codes of 0 (no catch), 1 (catch with finfish), 2 (catch without finfish), 9 (recon trap deployment), 90 (recon trap deployment with no catch), 91 (recon trap deployment with finfish), and 92 (recon trap deployment without finfish catch)

    a. For development of the dGLM standardized index (i.e. index presented in the 2013 trends report), all 9, 90, 91, and 92 catch codes were removed from analysis

11) Deployments with station codes of “Random” (randomly-selected live-bottom station), “NonRandom” (non-randomly sampled live-bottom station (a.k.a. haphazard sample)), “ReconConv” (reconnaissance deployments that were subsequently converted into live-bottom stations), and “Is Null” (traps for which there is no station code value – the use of station codes is fairly new since 2010. Historically we used only the catch ID to indicate randomly-selected stations)
12) Deployments with Gear ID equal to 324 (chevron traps)
13) Deployments with Data Source not equal to “Tag-MARMAP”
    a. “Tag-MARMAP” represents special historic MARMAP cruises that were used to tag various species of fish. Because standard sampling procedures were not used (e.g. not all fish were measured for length frequency) these samples are excluded from CPUE development
14) Deployments at depths between 15 and 74 m
    a. Represents the depth range at which 100% of Red Snapper were collected by any gear used in the SERFS (Ballenger et al. 2012b)
    b. Given previous constraints, this removes 248 traps deployed at <15 m or >74 m of depth and 2 traps for which we are missing depth data
15) Soak times outside of a window between 45 and 150 minutes, which generally indicates deviations from standard protocols
    a. Note, SERFS targets a soak time of 90 minutes for all chevron trap deployments
    b. Removes an additional 192 traps with unusually long or short soak times
16) Deployments made since 2010
    a. Removes an additional 6754 traps sampled in 1988-2009 – prior to this period sampling was somewhat limited in the heart of Red Snapper habitat off northern Florida and southern Georgia. Only since has the percent positive samples for Red Snapper in chevron traps exceeded 5%.
    b. Exclusion of early years was made via consensus within the SEDAR 41 Index Working Group and during a SEDAR 41 Data Workshop plenary session.

Zero-Inflated Model CPUE Standardization

CPUE was standardized among years using a zero-inflated count model (ZINB). Given the biological knowledge of Red Snapper and the sampling design of the SERFS chevron trap survey, we compared model fits with the ZINB method to those of the nominal CPUE estimation and dGLM method based on conclusions and recommendations drawn during SEDARs 32 and 36. Investigation of this technique to model CPUE data also was suggested during the Fishery-Independent Survey Independent Review for the South Atlantic (SEFSC 2012). As is the case with many ecological count data sets (Zuur et al. 2009), the observed CPUE data appeared to be zero-inflated based on preliminary analyses (Figure 3), suggesting the appropriateness of zero-inflated count data models.

Briefly, we provide some background information regarding zero-inflated count data models. For a more complete discussion, see Chapter 11 in Zuur et al. (2009). Zeileis et al. (2008) provides a nice overview and comparison of Poisson, negative binomial, and zero-inflated models in R. Some textbooks devoting sections to the discussion of zero-inflated models include Cameron and Trivedi (1998), Hardin and Hilbe (2007), or Hilbe (2007).

The concept of zero inflation derives from the observation that in many ecological, economic, and social studies there are far more zeros in count data than what would be expected for a Poisson or negative binomial distribution. As such, zero inflation means that we have far more zeros than we would expect. Ignoring zero inflation when it exists can have two major consequences, namely the estimated parameters and standard errors may be biased and the excessive number of zeros can cause overdispersion (Zuur et al. 2009).

Zeros due to design and observer errors are called false zeros or false negatives while structural and "animal" zeros are known as positive zeros, true zeros, or true negatives (Zuur et al. 2009). To address these different sources of zeros, two distinctive classes of zero-inflated models have been developed, two-part (hurdle) and mixture models, with the difference between the two classes arising due to differences in how they deal with zeros. Two-part models do not discriminate between the four different types of zeros and simply treat a zero as a zero whereas mixture models account for the type of zero.

Mixture models (zero-inflated Poisson (ZIP) and zero-inflated negative binomial (ZINB)) treat zeros via two different processes: the binomial process and the count process (Zuur et al. 2009). A binomial generalized linear model is used to model the probability of measuring a zero while the count process is modeled by a Poisson or negative binomial GLM. As such, the fundamental difference between hurdle and mixture models is that the count process can produce zeros in mixture models but not in hurdle models (Zuur et al. 2009). In such a setup, the zeros resulting from the count process model represent true zeros, while the binomial GLM models the probability of measuring a false zero versus all other types of data (counts and true zeros; Zuur et al. 2009). In short, the probability functions of a ZINB are:

$$f(y_i = 0) = \pi_i + (1 - \pi_i) * \left(\frac{k}{\mu_i + k}\right)^k$$

$$f(Y_i = y_i | y_i > 0) = (1 - \pi_i) * \frac{\Gamma(y_i + k)}{\Gamma(k) * \Gamma(y_i + 1)} * \left(\frac{k}{\mu_i + k}\right)^k * \left(1 - \frac{k}{\mu_i + k}\right)^k$$

for the binomial component and the non-zero component, respectively. In ZINB, the expected mean and variance are slightly different due to the definition of the probability functions. The mean and variance of a ZINB are:

$$\mathrm{E}(Y_i) = \mu_i * (1 - \pi_i)$$

$$\mathrm{var}(Y_i) = (1-\pi_i) * \left(\mu_i + \frac{\mu_i^2}{k}\right) + \mu_i^2 * \left(\pi_i^2 + \pi_i\right).$$

If the probability of false zeros is 0, the mean and variance of the negative binomial GLM are equal.

In the development of the ZINB CPUE model for Red Snapper, we modeled CPUE as catch per trap, compared to the traditional method of calculating catch per trap per hour. We included soak time as an offset term instead of creating a catch rate by dividing the catch per trap by the soak time or sample duration. By defining this offset variable we adjust for the amount of opportunity for the gear to capture a fish (e.g. a deployment with a soak time of 120 minutes has twice the opportunity than a deployment with a soak time of 60 minutes).

Similar to dGLM, ZINB models can account for effects of different covariates on observed counts. The same or different covariates can be included in the binomial sub-model and catch sub-model. In initial investigations we considered the following covariates in addition to year:

- Depth – categorical variable
- Bottom temperature – categorical variable
- Longitude – categorical variable
- Latitude – categorical variable
- Day of Year (DOY) – categorical variable

Other covariates in the data set that could have been considered included bottom salinity, month, season, dissolved oxygen concentration, chlorophyll-A concentration, nitrite (NO_2) concentration, nitrate (NO_3) concentration, and phosphate (PO_4) concentration. We didn't consider bottom salinity as a potential covariate due to its general lack of variability in oceanic waters and preliminary investigations suggesting there was little relationship between Red Snapper CPUE and bottom salinity. We didn't consider month or season as a covariate as each is correlated to a high degree with our included covariate DOY. Given DOY gives more temporal resolution, the assumption was made that it would provide greater power in standardizing Red Snapper CPUE with regards to within year day of sampling differences. Finally, we didn't consider the last five potential covariates due to missing values on a large number of trap sets data for these variables, primarily due to the lack of equipment to collect these variables historically.

Prior to inclusion of the considered covariates in the full model, we used preliminary analyses to investigate the possibility of collinearity between any of the variables. A pairs plot of continuous covariates revealed high correlation between latitude and longitude (due to the shape of the survey region), and moderate correlation between bottom temperature and depth and bottom temperature and DOY (Figure 4). Variance inflation factor (VIF) estimates for all considered covariates were all <2 (Table 2).

Box plots of the covariates (depth, latitude, bottom temperature, and DOY) among years showed no obvious strong collinearity (Figure 20). With regards to sampling depth, sampling throughout the entire period appeared fairly homogenous. With regards to latitude, it appears that the sampling distribution has been fairly homogenous, though there is a slight indication of more northern sampling in 2012. For bottom temperature, sampling throughout the entire period appeared fairly homogenous. Finally, for DOY while the overall range of DOY sampled annually was similar, there is some indication that the median DOY sampled in 2010 was later than in the other three years.

Due to the desire to inform the binning structure of covariates in the zero-inflated standardization model, we used generalized additive models (GAM) to investigate the relationship of each covariate with CPUE. We investigated two sets of GAMs, one looking at the relationship of continuous covariates to the presence/absence of Red Snapper and one looking at the relationship of continuous covariates to Red Snapper catch.

For the presence/absence GAMs, all covariates except bottom temperature had a non-linear effect on the presence of Red Snapper (Figure 20 and Table 8). Probability of presence of Red Snapper peaked at depths of 25-70 m, declining at shallower and deeper depths. The decline in presence at depths between 40 and 55 m may be explained by a lack of stations in this depth zone at latitudes where red snapper are commonly found relative to other depths. Probability of presence shows two distinct peaks at latitudes of 28-30^{o}N and >34.5^{o}N, with a smaller peak around 32^{o}N. In general, latitude has a greater effect on probability of capture than the other covariates. Probability of presence shows no discernible trend with respect to bottom temperature. Finally, the relationship between DOY and probability of presence is either flat or parabolic with highest probabilities of presence occurring at the beginning and end of the sampling season. These peaks could be driven by low sample sizes near the beginning and end of the sampling seasons.

For the catch GAMs, each of the covariates had a non-linear effect on the catch of Red Snapper (Figure 21 and Table 8). Catch of red snapper shows three distinct peaks at depths of 20-25 m, 35-40 m, and 50-60 m, though some of this high frequency variability is likely driven by station distribution. There is a marked decrease in the catch of red snapper at depths shallower than 20 m and deeper than 60 m. Highest catches of Red Snapper occurred at the shallowest depths, generally declining as depth increases. Catches of Red Snapper clearly peaked at around 29^{o}N, with smaller peaks occurring at 32^{o}N and >34^{o}N. With regards to bottom temperature, catch of Red Snapper generally increased as temperature increased through approximately 27^{o}C. At higher temperatures, catch of Red Snapper appeared to rapidly decline though sample size at these high temperatures is small. Finally, Red Snapper catch compared to DOY showed the same trend as the presence/absence data, with highest catches occurring at the beginning and end of the sampling seasons.

Based on these GAM analyses, in addition to year, we decided to include the categorical covariates depth, latitude, bottom temperature and DOY in the full ZI model (Table 8). To inform the bin structure, we used the GAM analyses relating catch of Red Snapper to each covariate (Figures 21 and 22) to identify periods or relatively homogenous catch of Red Snapper with respect to the covariate. This resulted in 4, 5, 3, and 4 bins for the covariates depth, latitude, bottom temperature, and DOY, respectively (Table 8). Members of the SEDAR 41 Index Working Group provided guidance on the number of bins and potential bin break points during the SEDAR 41 data workshop.

Selection of the covariates included in the final model (both zero-inflation and count sub-models) was done based on Akaike's information criterion (AIC; Akaike 1973). We allowed the possibility that different covariates may appear in each of the sub-models. All analyses were performed in R (Version 3.1.0; R Development Core Team 2014). The zero-inflated models in R were developed using the function zeroinfl available in the package *pscl* (Jackman 2011; Zeileis et al. 2008).

Results

Sampling Summary

A data set for analysis was obtained from a query of the SERFS database on July 14, 2014. Given the constraints mentioned above and removing any collections we are missing covariate data (410 stations removed because of missing bottom temperature data), from 2010 to 2013 we made 3,679 chevron trap monitoring deployments (Table 9), averaging 920 collections per year (range: 610-1,304), following standard monitoring station sampling protocol. The average depth for these collections was 38 m, with annual averages ranging from 37 to 40 m. The average latitude was 31.39°N, with annual averages ranging from 30.84°N to 31.80°N. The average bottom temperature was 21.9°C, with annual averages ranging from 21.1 to 22.2°C. The average DOY was 200, with annual averages ranging from 194 to 222 days. Please note that due to missing bottom temperature data and the desire of SEDAR 41 index working group panelists to include bottom temperature as a covariate, we removed greater than 10% of available collections for the years 2010 and 2011 (Table 10).

Zero-Inflated CPUE

Step-wise forward selection using AIC add the covariates depth, latitude, and bottom temperature to both the zero-inflation and count sub-models (Table 11). In addition, the covariate year was added to the zero-inflation sub-model. The covariate DOY was not added to either sub-model. The only constraint on this selection was that the variable "Year" must be retained in the count sub-model of ZINB model. The resulting final model had the following form:

Zero-Inflation and Count Sub-Model

$$\text{Abund} = offset(\ln(\text{soak time})) + \text{Year} + \text{Depth} + \text{Latitude} + \text{Temperature}$$

where Abund represents the catch data transformed to presence/absence data in the zero-inflation model and the observed catch data in the count model.

Standardized annual CPUE estimates normalized to the series average indicates that CPUE was below average in 2010 and 2011 and above average in 2012 and 2013 (Figure 23).

In the bootstrap to estimate variability in the annual relative abundance index we observed a convergence rate of 57.6%, resulting in 2880 individual bootstraps being used in variability estimation. For each of these bootstraps we calculated an observed relative index based on the bootstrap sampling (Figure 24), with those giving the same overall pattern of relative abundance observed in the base model. Plots of annual variance and coefficient of variation (CV) estimates indicate that 2,880 bootstraps were sufficient for these measures to stabilize (Figure 25). Standardization using the ZINB resulted in annual CV estimates of approximately 18%. Individual year CV estimates ranged from a low of 11% to a high of 23% in 2012 and 2010, respectively (Table 12).

A plot of the observed and predicted number of Red Snapper caught suggests that the ZINB was moderately successful at capturing the observed catch pattern (Figure 26). While the ZINB does a fair job predicting the number of traps that had 0 catch, it does a poor job predicting the number of Red Snapper captured given a trap is positive for Red Snapper. In this case it predicts many more traps would catch only a single Red Snapper than observed. Further, it predicts at most only 3 Red Snapper would be caught in any given trap, though we have observed as many as 28 Red Snapper in an individual trap.

Residual diagnostics suggest that there were some outlier observations in the dataset represented by large Pearson residuals (in excess of 20; Figure 27), though overall there is no strong indication of a pattern in the residuals or heteroscedascity when the residuals are plotted against included covariates (Figures 28 and 29). When Pearson residuals are compared to several potential covariates excluded from the final model (Chlorophyll-A concentration, dissolved oxygen concentration, Event (all traps included in a given trap set), longitude, month, salinity, season, and bottom temperature), first glance suggests there is no strong indication of a pattern to the residuals or heteroscedascity, which indicates that no excluded covariates are critical to the model (Figures 30 and 31). Finally, looking at the spatial distribution of positive and negative Pearson residuals suggests no obvious spatial patterning of the residuals (Figure 32). This lack of spatial structure to the residuals also is supported by the sample variogram, which doesn't show any indication of spatial correlation in trap catches closer than 10 km to each other (Figure 33).

The final ZINB model suggests non-linear relationships among Red Snapper catch and depth and latitude, a linear relationship between Red Snapper catch and bottom temperature, and no effect of DOY on Red Snapper catch (Figure 34). For depth, as originally suggested, Red Snapper catch peaks in bin 2, which corresponds to depths between at depths between 30 and 44 m. For latitude, we see a generally bimodal distribution with catch peaking in bins 2 (28-29.99^{o}N) and 5 (>=34^{o}N). For bottom temperature, the catch of Red Snapper increases as bottom temperature increases. Finally, because DOY is excluded from the final ZINB model, there is no predicted effect of DOY on the catch of Red Snapper.

Table 4. Red Snapper nominal catch per unit effort (CPUE), delta-GLM (dGLM) standardized CPUE*, and zero-inflated negative binomial (ZINB) standardized CPUE for chevron traps. N = number of included traps, positive = proportion of included collections positive for Red Snapper, fish = number of individuals captured, CV = coefficient of variation, and normalized = annual index value normalized to its long-term mean to give relative abundance over time. *From Bubley et al. (2014) – note the number of stations used annually (and thus # positive and % positive) for this model is different due to the exclusion of all "ReconConv" stations from this analysis and earlier database access date.

				Nominal			dGLM Standardized*			ZINB Standardized

***Addendum at end of document reflecting changes made at Data Workshop**

Abstract
Standardized catch rates were generated from the Southeast headboat survey trip records (logbooks) from 1976-2009. The analysis included areas from central North Carolina through south Florida. Data filtering and subsetting steps were applied to the data to model trips that were likely to have directed red snapper effort. The preliminary decisions made prior to the data workshop are presented here. The final results of the headboat index will be presented in the SEDAR 41 Data Workshop Report.

Background

The headboat fishery in the south Atlantic includes for-hire vessels. The fishery uses hook and line gear, generally targets hard bottom reefs as the fishing grounds, and generally targets multiple species in the snapper-grouper complex. One of the key characteristics defining a headboat from other recreational fishing such as charter boats is the number of anglers. Prior to 2000 headboats were defined as vessels carrying 15 or more recreational anglers. This criteria changed to 7 or more passengers in 2000 in the Atlantic (Ken Brennan, pers. comm. Dec. 2011).

Headboats in the south Atlantic are sampled from North Carolina to the Florida Keys.
Data have been collected since 1972, but logbook reporting did not start until 1973. In addition, only North Carolina and South Carolina were included in the earlier years of the data set. In 1976, data were collected from North Carolina, South Carolina, Georgia, and northern Florida, and starting in 1978, data were collected from southern Florida (Areas 1-17, Figure 1).

Variables reported in the data set include year, month, day, area, location, trip type, number of anglers, species, catch, and vessel id. Biological data and discard data were recorded for some trips in some years.

A 20” TL minimum size limit for red snapper has been in place since 1992. A 2 fish bag limit began in 1992. The red snapper fishery closed in 2010.

The headboat logbook index was used for SEDAR 24. Additional headboat records from 2010 to 2013 were examined to determine if sufficient data exists to extend this standardized index of abundance for south Atlantic red snapper. Due to the closure and potential effect on the index, these data were not considered.

Data treatment

Data from area 1 (Figure 1) were excluded as this area was not recorded during most of the time series. The minimum number of anglers per vessel was set at 6, which excluded the lower 0.1% of trips. These trips were excluded because they were possibly misreported and likely don't reflect the behavior of headboats in general.

Subsetting trips

Trips to be included in the computation of the index need to be determined based on effort directed at red snapper. Effort can be determined directly for trips which had positive red snapper catches, but some trips likely directed effort at red snapper, but were unsuccessful at landing red snapper. Given that information on directed effort for trips without red snapper harvest is not available, another method must be used to compute total effort.
In order to determine effort that was likely directed at red snapper and which trips should be used to compute an index, the method of Stephens and MacCall (2004) was applied. The Stephens and MacCall method uses multiple logistic regression to estimate a probability for each trip that the focal species was caught, given other species caught on that trip. Species compositions differ across the south Atlantic; thus, the method was applied separately for two different regions: north (areas 2-10) and south (areas 11, 12, and 17; Shertzer *et al.* 2009). To avoid computation errors, the number of species in each analysis was limited to those species that occurred in 1% or more of trips. The most general model therefore included all species in the snapper-grouper complex which occurred in 1% or more of trips as main effects, excluding red porgy. Red porgy was removed because of regulation changes, which could erroneously remove trips likely to have caught red snapper in recent years. A backwards stepwise AIC procedure (Venables and Ripley 1997) was then used to perform further selection among possible species as predictor variables. In this procedure, a generalized linear model with Bernoulli response was used to relate presence/absence of red snapper in headboat trips to presence/absence of other species (Figure 2 – Figure 5).

Model Input

Response and explanatory variables

CPUE – catch per unit effort (CPUE) has units of fish/angler and was calculated as the number of red snapper caught divided by the number of anglers.

Year – Because year is the explanatory variable of interest, it was necessarily included in the analysis. A summary of the total number of trips with red snapper effort per year and area is provided in Table 1 and 2.

Area – Areas were pooled into regions of North Carolina (NC=2,3,9,10), South Carolina (SC=4,5), Georgia and North Florida (GNFL=6,7,8), and south Florida (sFL=11,12,17).

Season – The seasons were defined as winter (January, February, March), spring (April, May, June), summer (July, August, September) and fall (October, November, December).

Party – Five categories for the number of anglers on a boat were considered in the standardization process. The categories included: ≤20 anglers, 20-40 anglers, 40-60 anglers, 60-80 anglers, and >80 anglers. The minimum number of anglers per vessel was set at 6, which excluded the lower 0.5% of trips. These trips were excluded because they were possibly misreported and likely don't reflect the behavior of headboats in general.

Trip Type – Trip types of half and full day trips were included in the analysis. Three-quarter day trips were pooled with half-day trips (<10%). Multi-day trips were removed because most were in Florida and likely targeting deepwater species for some portion of the trip. The codes for first and second half-day trips designation for day and night trips were combined.

Standardization

CPUE was modeled using the delta-glm approach (Lo et al. 1992; Dick 2004; Maunder and Punt 2004). In particular, fits of lognormal and gamma models were compared for positive CPUE. Also, the combination of predictor variables was examined to best explain CPUE patterns (both for positive CPUE and or positive CPUE). All analysis were performed in the R programming language, with much of the code adapted from Dick (2004).

BERNOULLI SUBMODEL

One component of the delta-GLM is a logistic regression model that attempts to explain the probability of either catching or not catching red snapper on a particular trip. First, a model was fit with all main effects in order to determine which effects should remain in the binomial component of the delta-GLM. Stepwise AIC (Venables and Ripley1997) with a backwards selection algorithm was then used to eliminate those that did not improve model fit.

POSITIVE CPUE SUBMODEL

Then, to determine predictor variables important for predicting positive CPUE, the positive portion of the model was fitted with all main effects using both the lognormal and gamma distributions. Stepwise AIC (Venables and Ripley1997) with a backwards selection algorithm was then used to eliminate those that did not improve model fit. All predictor variables were modeled as fixed effects (and as factors rather than continuous variables).

Both components of the model were then fit together (with the code adapted from Dick 2004) using the lognormal and gamma distributions and compared them using AIC. With CPUE as the dependent variable.

Preliminary model diagnostics are presented in Figures 6-7.

It should be noted that the Stephens and MacCall method is most appropriate for species which have strong species associations. In other words, if a species is ubiquitous in the catch, or does not have well-defined effort, Stephens and MacCall may not work well to identify directed effort.

ADDENDUM

Standardized catch rates of Southeast US Atlantic red snapper (*Lutjanus campechanus*) from headboat logbook data

Sustainable Fisheries Branch, National Marine Fisheries Service,
Southeast Fisheries Science Center,
101 Pivers Island Rd, Beaufort, NC 28516
August 2014

Abstract
Standardized catch rates were generated from the Southeast headboat survey trip records (logbooks) from 1976-1991 and from 1992-2009. The analysis included areas from central North Carolina through south Florida. Data filtering and subsetting steps were applied to the data to model trips that were likely to have directed red snapper effort.

SEDAR 41 Index Working Group Review

The SEDAR 41 index working group (IWG) reviewed the methods used to develop an index of abundance for red snapper from headboat logbook data. The following topics were discussed at the data workshop and include the final decisions and justification.

Start year
For a fisheries dependent index like the headboat logbook index, identifying changes in angler behavior are important when developing an index. Beginning in 1992, a 20" minimum size regulation influenced angler behavior. Because of these changes in angler behavior before and after 1992, the IWG agreed to split the index (1976-1991 & 1992-2009).

End year
SEDAR 41 IWG participants along with fisherman present at the meeting discussed the red snapper closure in 2010 and its potential impact on the red snapper headboat logbook index in 2010-2013. Because of this shift in behavior (avoidance), the IWG recommended to end the red snapper headboat logbook index in 2009.

Subsetting technique- Stephens & MacCall

A run using a 5% cutoff was explored. Red snapper in the southern region did not meet this upper cutoff so the 1% was used in the final model run.

The following information represents the final model input and dGLM results for the red snapper headboat logbook index.

Model Input

Response and explanatory variables

CPUE – catch per unit effort (CPUE) has units of fish/angler and was calculated as the number of red snapper caught divided by the number of anglers.

Year – Because year is the explanatory variable of interest, it was necessarily included in the analysis. Early time period (1976-1991), Late time period (1992-2009)

Area – Areas were pooled into regions of North Carolina (NC=2,3,9,10), South Carolina (SC=4,5), Georgia and North Florida (GNFL=6,7,8), and south Florida (sFL=11,12,17).

Season – The seasons were defined as winter (January, February, March), spring (April, May, June), summer (July, August, September) and fall (October, November, December).

Party – Five categories for the number of anglers on a boat were considered in the standardization process. The categories included: ≤20 anglers, 20-40 anglers, 40-60 anglers, 60-80 anglers, and >80 anglers. The minimum number of anglers per vessel was set at 6, which excluded the lower 0.5% of trips. These trips were excluded because they were possibly misreported and likely don't reflect the behavior of headboats in general.

Trip Type – Trip types of half and full day trips were included in the analysis. Three-quarter day trips were pooled with half-day trips (<10%). Multi-day trips were removed because most were in Florida and likely targeting deepwater species for some portion of the trip. The codes for first and second half-day trips designation for day and night trips were combined.

Standardization

CPUE was modeled using the delta-glm approach (Lo et al. 1992; Dick 2004; Maunder and Punt 2004). In particular, fits of lognormal and gamma models were compared for positive CPUE. Also, the combination of predictor variables was examined to best explain CPUE patterns (both for positive CPUE and or positive CPUE). All analysis were performed in the R programming language, with much of the code adapted from Dick (2004).

BERNOULLI SUBMODEL
One component of the delta-GLM is a logistic regression model that attempts to explain the probability of either catching or not catching red snapper on a particular trip. First, a model was fit with all main effects in order to determine which effects should remain in the binomial component of the delta-GLM. Stepwise AIC (Venables and Ripley1997) with a backwards selection algorithm was then used to eliminate those that did not improve model fit.

POSITIVE CPUE SUBMODEL
Then, to determine predictor variables important for predicting positive CPUE, the positive portion of the model was fitted with all main effects using both the lognormal and gamma distributions. Stepwise AIC (Venables and Ripley1997) with a backwards selection algorithm

was then used to eliminate those that did not improve model fit. All predictor variables were modeled as fixed effects (and as factors rather than continuous variables).

Both components of the model were then fit together (with the code adapted from Dick 2004) using the lognormal and gamma distributions and compared them using AIC. With CPUE as the dependent variable.

In the model for the earlier time period (1976-1991) the lognormal was the preferred model (Table 3 & Figures 2-8). But in the later time period, the gamma was the preferred model (Table 4 & Figures 9-15).

Standardized catch rates of red snapper (*Lutjanus campechanus*) from headboat at-sea-observer data

Sustainable Fisheries Branch, National Marine Fisheries Service,
Southeast Fisheries Science Center, 101 Pivers Island Rd, Beaufort, NC 28516

***Addendum at end of document reflecting changes made at Data Workshop**

Abstract
Standardized catch rates were generated from the Southeast headboat at-sea-observer program for 2005-2013. The analysis included areas from central North Carolina through south Florida. The index is meant to describe population trends of fish in the size/age range of fish discarded by headboat vessels. Data filtering and subsetting steps were applied to the data to model trips that were likely to have directed red snapper effort.

Background and Data Description

The data used for this index were all trips in the headboat at-sea observer database which discarded red snapper from 2005-2013. The at-sea-observer program occurred from 2004-2009 in North and South Carolina, but did not occur in Florida and Georgia in 2004. In addition, after 2007 the Florida Keys were no longer included in the at-sea observer program.
Trip-level information included state, county, Florida region, year, month, day, dock to dock hours (total trip hours), the number of hours fished (to the nearest half hour), the total number of anglers on the boat, the number of anglers observed on a trip, the number of red snapper discarded, minimum depth of the fishing trip, and maximum depth of the fishing trip. Depth information was not collected for South Carolina, North Carolina, and Georgia; therefore, it was not used in this analysis. Refer to working paper SEDAR41-DW33 for more details regarding this program.

Methods

Data treatment
Data from 2004 were dropped from the analysis because Georgia and Florida were not sampled. Observer trips by year and area relative to all headboat trips as well as total red snapper observed are presented in Table 1.

~~Data were subsetted to include trips with the presence of at least one of the following associated species identified in Shertzer and Williams (2008) (bank seabass, black seabass, gag, gray triggerfish, greater amberjack, knobbed porgy, red porgy, red snapper, scamp, tomtate, vermillion snapper, white grunt, whitebone porgy).~~

A 20" TL minimum size regulation has been in place since 1992. In SEDAR 24, headboat at-sea observer data was used to index discards below 20" TL minimum. A 2010 closure has created a scenario where all fish observed are discarded (mini-seasons in 2012 & 2013 were removed). During this closure period, discards greater than 20" were removed.

Response and explanatory variables

CPUE – Discards per unit effort (DPUE) is defined as units of fish/ angler interviewed and was calculated as the number red snapper discarded divided by the number of anglers interviewed. CPUE relative to each explanatory variable is provided in Figure 1-6.

YEAR – A summary of the total number of trips with red snapper effort per year is provided in Table 1.

AREA –Area was defined as North Carolina, South Carolina and Georgia, north Florida (nFL), south Florida, (excluding the keys, flreg=3)

SEASON – The seasons were defined as winter (January, February, March), spring (April, May, June), summer (July, August, September) and fall (October, November, December).

PARTY – Four categories for the number of anglers on a vessel were considered in the standardization process.

HRSF– Four categories for the number of hours fished were considered in the standardization process.

Objective for SEDAR 41 Data Workshop

- Approve or modify proposed factors and factor definitions
- Discuss cpue definition (anglers vs angler-hours)
- Discuss filtering using associated species (bank seabass, black seabass, gag, gray triggerfish, greater amberjack, knobbed porgy, red porgy, red snapper, scamp, tomtate, vermillion snapper, white grunt, whitebone porgy)
- Disscuss management regulations and their potential influence on index
- Run GLM based on DW decisions regarding data and factors
- Estimate uncertainty
- Update working paper and provide text, figures, and research recommendations for the SEDAR 41 DW report

ADDENDUM

Standardized catch rates of red snapper (*Lutjanus campechanus*)
from headboat at-sea-observer data

Sustainable Fisheries Branch, National Marine Fisheries Service,
Southeast Fisheries Science Center, 101 Pivers Island Rd, Beaufort, NC 28516

Abstract
Standardized catch rates were generated from the Southeast headboat at-sea-observer program for ~~2005-2013~~two time periods (2005-2009 and 2010-2013. The analysis included areas from central North Carolina through south Florida. The index is meant to describe population trends of fish in the size/age range of fish discarded by headboat vessels.

SEDAR 41 Index Working Group Review

Data workshop findings

Changes to data treatment

Trips that fished at night targeting sharks or trips that were designated drift fishing were removed from the analysis. All other trips were thought to be fishing for snapper-grouper species.

The IWG, along with headboat captains, discussed several key issues related to this index:

- Beginning in 1992, a 20” TL minimum size regulation influenced the fishing behavior of headboats that relied heavily on red snapper catch. Prior to 1992, red snapper was reportedly a target species, whereas after 1992, red snapper was sought more as by-catch. Because of these changes that likely affected catchability of red snapper, the IWG decided to split the index (1976-1991 & 1992-2009).
- Similarly, the red snapper closure starting in 2010 led to a shift in fishing behavior (avoidance). Because of that, and because this index is based on landings only (i.e., no discards included), the IWG decided to end the index in 2009.

Standardization

CPUE was modeled using the delta-glm approach (Lo *et al*. 1992; Dick 2004; Maunder and Punt 2004). In particular, fits of lognormal and gamma models were compared for positive CPUE. Also, the combination of predictor variables was examined to best explain CPUE patterns (both for positive CPUE and the Bernoulli submodels). All analyses were performed in the R programming language (R Development Core Team 2012), with much of the code adapted from Dick (2004).

Bernoulli submodel. One component of the delta-GLM is a logistic regression model that attempts to explain the probability of either catching or not catching red snapper on a particular trip. First, a model was fit with all main effects to determine which effects should remain in the binomial component of the delta-GLM. Stepwise AIC (Venables and Ripley1997) with a backward selection algorithm was then used to eliminate those that did not improve model fit. In this case, the stepwise AIC procedure did not remove any predictor variables. No concerning patterns were apparent in the quantile residuals (Dunn and Smyth 1996).

Positive CPUE submodel. To determine predictor variables important for describing positive CPUE, the positive portion of the model was fitted with all main effects using both the lognormal and gamma distributions. Stepwise AIC (Venables and Ripley1997) with a backward selection algorithm was then used to eliminate those that did not improve model fit. All predictor variables were modeled as factors rather than continuous variables.

Both submodels (Bernoulli and either lognormal or gamma) were then combined, and the models were compared using AIC. In this case, the lognormal distribution outperformed the gamma distribution in the earlier time series while the gamma outperformed the lognormal distribution in the later time series. No concerning patterns were apparent in standard diagnostic plots of residuals. The gamma model with all factors was used for computing the positive component of the index (2005-2009), and the binomial with all factors was used for computing the Bernoulli component of the index. The lognormal model with all factors was used for computing the positive component of the index (2010-2013), and the binomial with all factors was used for computing the Bernoulli component of the index.

The following data represents the dGLM results for the red snapper headboat at sea observer indices (2005-2009 & 2010-2013).

1.1 Introduction

Landings and fishing effort of commercial vessels operating in the southeast U.S. Atlantic have been monitored by the NMFS Southeast Fisheries Science Center through the Coastal Fisheries Logbook Program (CFLP). The program collects information about each fishing trip from all vessels holding federal permits to fish in waters managed by the Gulf of Mexico and South Atlantic Fishery Management Councils. Initiated in the Gulf in 1990, the CFLP began collecting logbooks from Atlantic commercial fishers in 1992, when 20% of Florida vessels were targeted. Beginning in 1993, sampling in Florida was increased to require reports from all vessels permitted in coastal fisheries, and since then has maintained the objective of a complete census of federally permitted vessels in the southeast U.S.

Catch per unit effort (CPUE) from the logbooks was used to develop an index of abundance for red snapper landed with vertical lines (manual handline and electric reel), the dominant gear for this red snapper stock (Tables 1 and 2). Thus, the size and age range of fish included in the index is the same as that of landings from this same fleet. The time series used for construction of the index spanned 1993 to 2009, when all vessels with federal snapper-grouper permits were required to submit logbooks on each fishing trip. For this southeast U.S. Atlantic stock, areas used in analysis were those between 24 and 37 degrees latitude, inclusive of the boundaries (Figure 1). A red snapper closure was implemented in January, 2010 which prevents the use of the CFLP data as an index for 2010-present.

1.2 Commercial Diving

The CFLP diving data was considered and rejected due to small sample sizes and limited spatial coverage (Tables 1 and 2, Figure 2).

1.3 Commercial Handline

1.3.1 Data filtering

For each fishing trip, the CFLP database included a unique trip identifier, the landing date, fishing gear deployed, areas fished, number of days at sea, number of crew, gear-specific fishing effort, species caught, and weight of the landings (reported fields described in Appendix). Fishing effort data available for vertical line gear included number of lines fished, hours fished, and number of hooks per line.

Data were restricted to include only those trips with landings and effort data reported within 45 days of the completion of the trip (some reporting delays were longer than one year). Reporting delays beyond 45 days likely resulted in less reliable effort data (landings data may be reliable even with lengthy reporting delays if trip ticket reports were referenced by the reporting fisher). This restriction excluded approximately 24% of the full data set (i.e., the data set with all gears and all areas, including Gulf of Mexico). Also excluded were records reporting multiple gears fished, which prevents designating catch and effort to specific gears. Therefore, only trips which reported one gear fished were included in these analyses. For records where more than one area was reported, the first area reported was used to determine the latitude associated with the trip.

Clear outliers in the data used as factors in the model or to calculate cpue were excluded from the analyses. Outliers were defined as values falling outside the 99.5 percentile of the data. For trip-level data (crew, days at sea, hours fished, number of lines, and number of hooks per line) all snapper-grouper trips were evaluated instead of the positive red snapper trips as in SEDAR 24 (Table 3). For hours fished, both upper and lower outliers were removed. Outliers related to CPUE for positive red snapper trips were removed (Table 3).

The analysis of data from the CFLP was completed through 2009 in SEDAR 24 for handline gear (electric and manual reels combined). The analysis could not be extended further due to the January 2010 closure of the red snapper fishery. Minimal open seasons that were implemented in recent years are biased due to targeting and could not be used in the development of an index of abundance.

1.3.2 Explanatory variables considered

YEAR - Year was necessarily included, as standardized catch rates by year are the desired outcome. Years modeled were 1993-2009. The total number of red snapper trips by year is provided in table 1 and catch per year is provided in table 2.

SEASON - Season included four levels: winter (JanuaryMarch), spring (AprilJune), summer (JulySeptember), and fall (OctoberDecember). The relative number of trips per month is shown in figure 3. The annual cpue associated with each season is given figure 4.

AREA - Area (latitude) is reported in the logbook on a one degree grid (Figure 1). For SEDAR 41, we propose keeping the data at the level it was collected with the exception of pooling the latitudes at the fringe of the range. Pooling latitudes 24 to 29 to 29 degrees and 34 to 38 to 34 degrees (Figure 3). This pooling gives 2000 to 3000 trips per latitude bin. Other methods for pooling areas were considered including quantiles. However, these methods require assigning latitude bins with large sample size to pooled bins when the geographical boundary (e.g. states) or quartile value falls in the middle of a latitude bin. The annual cpue associated with each latitude is given figure 5.

DAYS AT SEA - 'Days at sea' were pooled into three levels: one to two days, three to four days (twotofour), and five or more days (fiveplus). The relative number of trips per year by days at sea is shown in Figure 3. The annual cpue associated with days at sea is given figure 6.

CREW SIZE - Crew size (crew) could influence the total effort and could be a psuedo–factor for vessel size. The quantile split values (at 25, 50, and 75%) for red snapper crew size fall at 2, 2, and 3 crew per trip. Therefore crew size was pooled more subjectively into three levels: one (one), two (two), and three or more days (threeplus). The relative number of trips in each level is given in figure 3. Trips with one crew member were not pooled even though the relative sample size is small because it is believed there would be a significant difference trip efficiency between a crew size of one and two. The annual cpue associated with crew size is given figure 7.

1.3.3 Response variable (CPUE) data considerations

The distribution of positive red snapper trips generally showed a maximum off NC and SC with a moderate decline to about cape canaveral and then a precipitous decline further South (Figure 8). However, the trend in CPUE the mean nominal CPUE has the opposite spatial pattern with larger values further south (Figure 9). This may partially be explained by much shorter trips in South Florida on average. Fishermen are known to target other species at night on multi–day trips and this effort is counted towards the total effort for the trip.

The response variable, CPUE, was calculated for each trip as,

CPUE = pounds of red snapper/hook-hours

where hook-hours is the product of number of lines fished, number of hooks per line, and total hours fished. Spatio-temporal trends were examined for cpue and each of its components (Figures 10 – 9). The mean cpue increased dramatically from 2006–2009 in GA and North Florida while other areas showed no increase (Figure 9). Mean cpue was examined by latitude with northern latitudes grouped 34 degrees and southern latitudes pooled at 29 degrees (Figure 5). The trends in cpue diverge at approximately 32 degrees (near Savannah, GA) after 2005 with the South showing a dramatic increase in CPUE. Inversely, at the beginning of the series the South has the lowest CPUE values. The recent divergence appears to be driven more by catch than effort (Figures 14 – 16).

1.4 Objectives for SEDAR 41 Data Workshop

- Approve or modify proposed factors and factor definitions
- Discuss other possible factors (fuel price index, lunar phase) if time pemits
- Approve or modify cpue definition
  - Discuss possible issue with correlation between cpue denominator component, hours fished, and days at sea factor (Figure 17)
- Discuss filtering (Stephens and MacCall method)
  - The Stephens and MacCall approach used in SEDAR 24 is problematic for habitats with many correlated species. Trips that have split effort among habitats or modified fishing behavior (hook size or bait size) within a trip excaserbate the problem because species assemblages become nonsense. Vermilion snapper was one of the highest correlated species with red snapper and and although they occur in the same locations as red snapper the typical method to prosecute vermilion snapper is quite different then red snapper in most regions. For these reasons we propose running a GLM on positive red snapper trips for SEDAR 41.
- Run GLM based on DW decisions regarding data and factors
- Estimate uncertainty
- Update working paper and provide text, figures, and research recommendations for the SEDAR 41 DW report

Addendum

1.5 Workgroup decisions and justifications

- The proposed factors and definitions were accepted by the panel.
- Since the 2010 closure of red snapper mini-seasons were established for commercial fishermen in 2012 and 2013. These short openings had a restrictive trip limit of 75 pounds. Commercial fishermen indicated they would target red snapper briefly to catch the limit and move to other habitats. This makes the limited data available for 2012 and 2013 invalid and would be biased toward low CPUE for red snapper.
- Lunar phase and a fuel price index were discussed briefly. Lunar phase can be calculated for each trip and might be of possible use after further investigation but was not recommended for inclusion in SEDAR 41. It was not clear how annual fuel price index would be incorporated and would be currently be absorbed in the year effect.
- The "days at sea" factor correlation with the hours fished which is a component of the CPUE denominator was discussed. The "days at sea" factor was binned into 3 categories. The workgroup did not have a concern that the correlation would influence the model.
- The use of the Stephens and MacCall (2004) approach was discussed and the panel felt, even though there are caveats with the method, it is still the best method to define effective effort. The usual method of determining species association based on presence–absence of both target and predictor species was evaluated. In addition, the species associations were evaluated using presence-absence of the target species and the catch of the predictor species. The species and distribution of species associations were very similar. However, there was some concern that trip limits might influence the regression coefficients when using catch as a predictor. The group also evaluated a positive–only model. The Stephens and MacCall approach was recommended through 2009 as in SEDAR 24 because it is based on effective effort.

1.6 Subsetting

Effective effort was based on those trips from areas where red snapper were available to be caught. Without fine-scale geographic information on fishing location, trips to be included in the analysis must be inferred, which was done here using the method of Stephens and MacCall (2004) The method uses multiple logistic regression to estimate a probability for each trip that the focal species was caught, given other species caught on that trip. Because a zoogeographic boundary is apparent near Cape Canaveral (Shertzer et al. 2009), the method was applied separately to data from regions north and south of 29 degrees latitude (near Cape Canaveral). To avoid undue influence of rare species on regression estimates, species included in each analysis were limited to those occurring in 1% or more of trips . Red porgy was also omitted because of strict harvest regulations since 1999 (including a temporary moratorium), which creates the potential for erroneously removing trips likely to have caught red snapper during years of red porgy restrictions. A backwards stepwise AIC procedure (Venables and Ripley 1997) was then used to perform further selection among possible species as predictor variables, where the most general model included all listed species as main effects. In this procedure, a generalized linear model with Bernoulli response was used to relate presence/absence of gray triggerfish in each trip to presence/absence of other species. For the northern sampling area (NC, SC, GA, north FL), stepwise AIC eliminated mutton snapper and sand tilefish; for the southern sampling area (south FL), it eliminated black grouper and almaco jack. Regression coefficients of included species for the northern sampling areas are shown in figure 18, and for the southern areas in figure 19. A trip was then included if its associated probability of catching red snapper was higher than a threshold probability (Figures 20, 21). The threshold was defined to be that which resulted in the same number of predicted and observed positive trips, as suggested by Stephens and MacCall (2004). After applying the Stephens and MacCall method, and the constraints described above, the resulting subsetted data set contained 17,255 trips in the northern sampling areas, of which 63% were positive, and 1,724 trips from the southern sampling area, of which 43% were positive.

1.7 Standardization

CPUE was modeled using the delta-GLM approach (Lo et al. 1992; Dick 2004; Maunder and Punt 2004). This approach combines two separate generalized linear models (GLMs), one to describe presence/absence of the focal species, and one to describe catch rates of successful trips (trips that caught the focal species). Estimates of variance were based on 1000 bootstrap runs where trips were chosen randomly with replacement (Efron and Tibshirani 1993). All analyses were programmed in R, with much of the code adapted from Dick (2004).

1.8 Bernoulli submodel

The bernoulli component of the delta-GLM is a logistic regression model that attempts to explain the probability of either catching or not catching red snapper on any given trip. Initially, all explanatory variables were included in the model as main effects, and then stepwise AIC (Venables and Ripley 1997) with a backwards selection algorithm was used to eliminate those variables that did not improve model fit. In this case, the stepwise AIC procedure did not remove any explanatory variables (Table 5). Diagnostics, based on randomized quantile residuals (Dunn and Smyth 1996), suggested reasonable fits of the Bernoulli submodel (Figure 22).

1.9 Explanatory variables considered

All explanatory factors considered in the data evaluation were included in the model. Year, season (3–month intervals), latitude (29.5–34.5 degrees pooled at the tails), number of crew including captain (1,2 and 3–plus), and days at sea (1–2,3–4, and 5–plus).

1.10 Positive CPUE submodel

Two parametric distributions were considered for modeling positive values of CPUE, lognormal and gamma. For both distributions, all explanatory variables were initially included as main effects, and then stepwise AIC (Venables and Ripley 1997) with a backwards selection algorithm was used to eliminate those variables that did not improve model fit. For both lognormal and gamma distributions, the best model fit included all explanatory variables (lognormal shown in Table 5). The two distributions, each with their best set of explanatory variables (all of them), were compared using AIC lognormal(AIC=58) highly outperformed gamma (AIC=2793), and was therefore applied in the final delta–GLM. Diagnostics suggested reasonable fits of the lognormal submodel (Figures 23, 24).

1.11 Results

The Stephens and MacCall (2004) method had the effect of concentrating the higher CPUE values at the center of the population distribution (Figure 25). The standardization process adjusted the CPUE values higher from 2000 to 2006 and lower for 2008 and 2009 (Figure 26 and Table 6). Overall, the SEDAR 41 index developed using the Stephens and MacCall (2004) approach is only slightly different then the alternative approach using the positive red snapper trips (Figure 26).Over the last four years of the index (2006–2009), the pattern has been one of strict increase, culminating in the highest expected value of the full series.

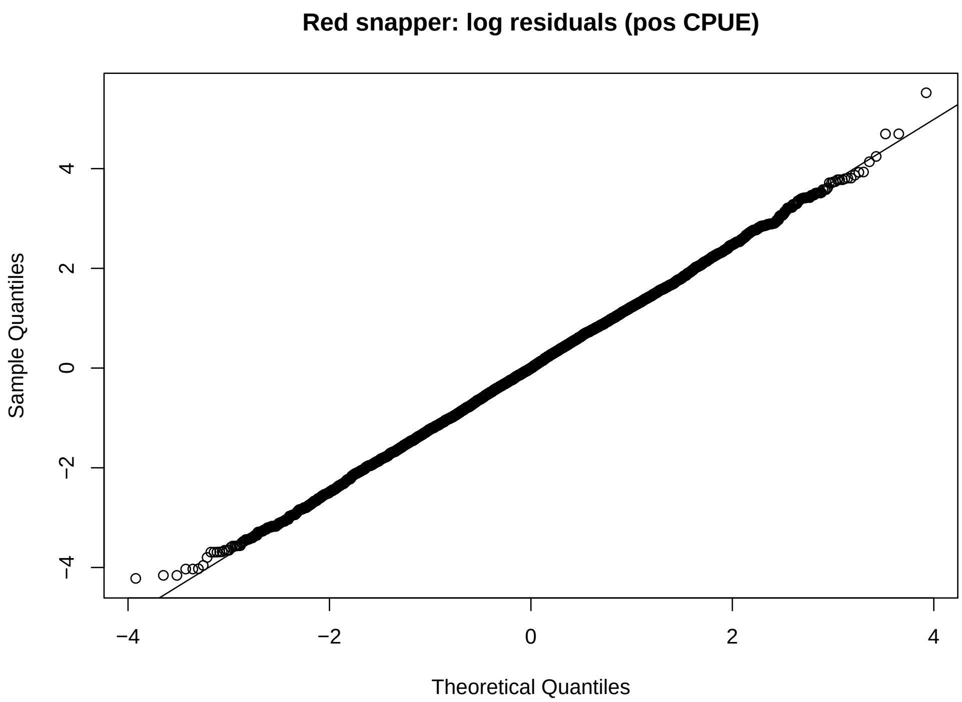

Figure 25. Red snapper handline mean nominal cpue (whole pounds/hook-hour) by year and latitude after applying the Stephens and MacCall method. The symbol size is relative to cpue.

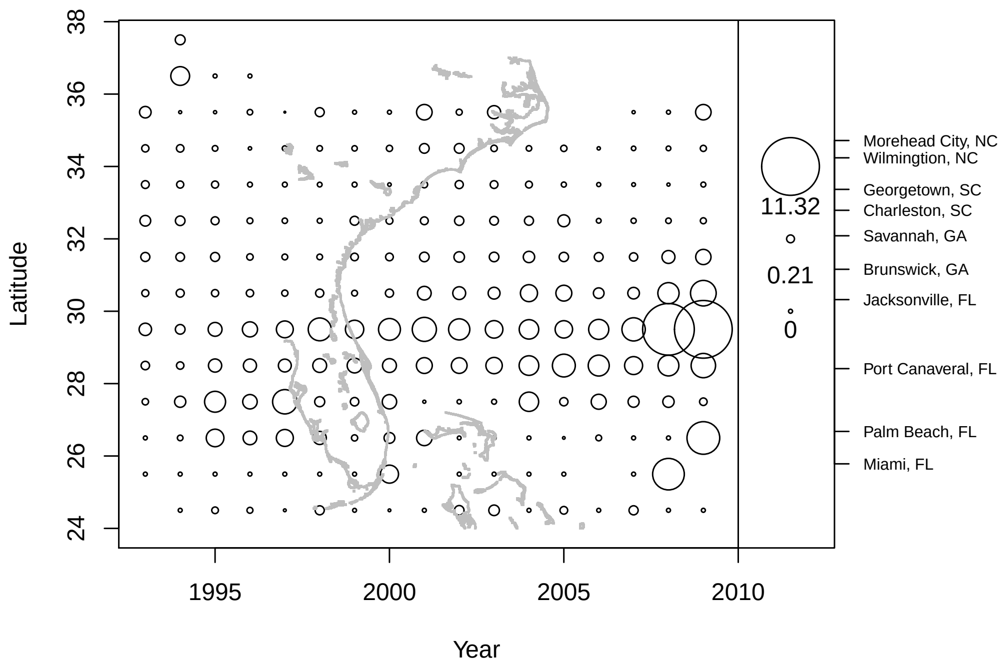

Figure 26. Relative standardized index (solid line, black circles, 95% error bars), relative nominal index (dashed), and alternative positive–only model (dash–dot).

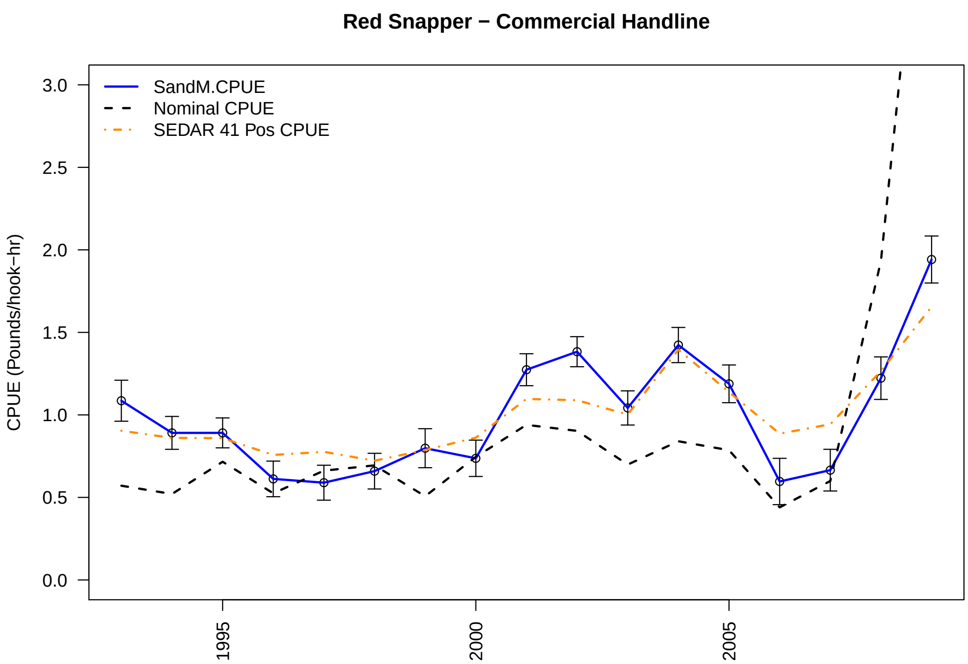

2 Appendix A. The commercial logbook data set contains the following variables (all are numeric unless otherwise noted)

schedule: this is a unique identifier for each fishing trip and is a character variable

species: a character variable to identify species caught.

gear: a character variable, the gear type, multiple gear types may be used in a single trip, L = longline, H = handline, E = electric reels, B = buoy gear, GN = gill net, P = diver using power head gear, S = diver using spear gun, T = trap, TR = trolling

area: area fished, in the south Atlantic these codes have four digits- the first two are degrees of latitude and the second two are the degrees of longitude

totlbs: a derived variable that sums the gutted (with conversion factor) and whole weights, this is the total weight in pounds of the catch for a particular species, trip, gear, and area

length: length of longline (in miles) or gill net (in yards)

numgear: the amount of a gear used, number of lines (handlines, electric reels), number of sets (longlines), number of divers, number of traps, number of gill nets

fished: hours fished on a trip, this is problematic for longline data as discussed later

effort: like numgear, the data contained in this field depends upon gear type; number of hooks/line for handlines, electric reels, and trolling; number of hooks per longline for longlines; number of traps pulled for traps; depth of the net for gill nets, this field is blank for divers

vesid: a character variable, a unique identifier for each vessel

landed: numeric (mmddyy8) variable, date the vessel returned to port

unload: numeric (mmddyy8) variable, date the catch was unloaded

received: numeric (mmddyy8) variable, date the logbook form was received from the fisherman

away: number of days at sea, this value should equal (landed-started+1)

crew: number of crew members, including the captain

state: character variable, the state in which the catch was sold

area1 - area3: areas fished, if the trip included catch from multiple areas, those areas will be listed here

SCDNR Charterboat Logbook Program Data, 1993-2013

SCDNR Charterboat Logbook Program Data, 1993 - 2013

Date: **7/25/2014**

Prepared by: **Eric Hiltz, South Carolina Department of Natural Resources**

For: **SEDAR 41 Data Workshop, August 2014**

Abstract:

The South Carolina Department of Natural Resources (SCDNR) charterboat logbook program was used to develop indices of abundance for red snapper from 1993 – 2010. The indices of abundance are standardized catch per unit effort (CPUE; catch per angler hour). A delta-gamma GLM was used to produce annual abundance estimates. The indices are meant to describe the population trends of fish caught by V1 (6-pack) charter vessels operating in or off of South Carolina.

Background:

The South Carolina Department of Natural Resources (SCDNR) issues three types of charter vessel licenses: V1 (vessels carrying six or fewer passengers), V2 (vessels carrying 7 to 49 passengers), and V3 (vessels carrying 50 or more passengers). In 1993, SCDNR's Marine Resources Division (MRD) initiated a mandatory logbook reporting system for all charter vessels to collect basic catch and effort data. Under state law, vessel owners/operators purchasing South Carolina Charter Vessel Licenses (V1, V2, or V3) and carrying fishermen on a for-hire basis are required to submit trip level reports of their fishing activity in waters off of SC. Logbook reports are submitted by mail or fax to the SCDNR Fisheries Statistics section monthly. Reporting compliance is tracked by staff, and charter vessel owners/operators failing to submit reports can be charged with a misdemeanor. The charterboat logbook program is a complete census and should theoretically represent the total catch and effort of the charterboat trips in waters off of SC.

Logbook Data:

The charterboat logbook reports include: date, number of fishermen, fishing locale (inshore, 0-3 miles, >3miles), fishing location (based on a 10x10 mile grid map), fishing method, hours fished, target species, and catch (number of landed and released fish by species) per vessel per trip. The logbook forms have remained similar throughout the program's existence with a few exceptions: in 1999 the logbook forms were altered to begin collecting the number of fish released alive and the number of fish released dead (prior to 1999 only the total numbers of fish released were recorded) and in 2008 additional fishing methods were added to the logbook forms, including 4) cast, 5) cast and bottom, and 6) gig.

After being tracked for compliance each V1 charterboat logbook report is coded and entered into an existing Access database. (V2 and V3 charterboat logbook reports are tracked for compliance but are currently not coded and entered electronically. Most of these vessels participate in the NMFS Beaufort Headboat Logbook Survey.) Since the inception of the program, a variety of staff have coded the charterboat logbook data. From ~1999 to 2006, only information that was explicitly filled out by the charterboat owners/operators on the logbook forms was coded and entered into the database. No efforts were made to fill in incomplete reports. From 2007 to the present, staff have tried to fill in incomplete trip reports through conversations with charterboat owners/operators and by making assumptions based on the submitted data (i.e. if a location description was given instead of a grid location – a grid location was determined, if fishing method was left blank – it was determined based on catch, etc.). From 1999 to 2006 each individual trip record was reviewed to look for anomalies in the data. Starting in 2007 queries were used to look for and correct anomalous data and staff began checking a component of the database records against the raw logbook reports. Coding and QA/QC measures prior to 1999 were likely similar to those used from 1999 to the present. However, details on these procedures were not available since staff members working on this project prior to 1998 are no longer with the SCDNR. Data are not validated in the field and currently no correction factors are used to account for reporting errors. Recall periods for logbook records are typically one month or less. However, in the case of delinquent reports recall periods could be up to several months.

Data:

SCDNR charterboat logbook vessel trips included in the analysis for red snapper represent reported fishing trips that caught red snapper or other species that were caught at least 35% of the time when red snapper were caught. These species include: black seabass, vermillion snapper, triggerfishes, gag grouper, red porgy, scamp, and white grunt. For a list of percent occurrences of species when red snapper were caught see table 1.

For all model runs for, catch per unit effort was calculated as the total number of fish caught per angler-hour. Management measures (bag and size limits) have been in place for red snapper throughout most of the dataset's time series (see management histories on red snapper provided for SEDAR 41 in RD12). To limit the possible influence of bag limits, total catch (includes harvest and discards) was used to calculate the CPUE instead of harvest.

Methods:

The indices were standardized using a delta generalized linear model (GLM) approach. All analyses were conducted in R, based primarily on code adapted from Dick (2004). A delta GLM model was chosen due to the significant amount of zeros in the CPUE data. A delta model has 2 components to it. First, the probability of a positive catch is modeled. Then the positive catch rates are modeled separately. Finally, the two are multiplied together to get the predicted CPUE (Dick 2004, Li et al. 2011, Siquan et al. 2009, and Yu et al. 2011)

$$\widehat{CPUE} = \hat{d}\ x\ \hat{q}$$

Where $\widehat{CPUE}$ is the standardized CPUE, $\hat{d}$ is the predicted catch rate of the positive catches, and $\hat{q}$ is the probability of a positive catch. The models for red snapper were built assuming a gamma distribution. The model of the positive catch rates used was:

$$ln(\hat{d}) = \beta_0 + \sum_{i=1} \beta_i X_i$$

Where β_0 is the intercept and β_i is the coefficient for the i^{th} explanatory variable X_i. The probability of a positive catch was modeled as:

$$ln\left(\frac{\hat{q}}{1-\hat{q}}\right) = \alpha_0 + \sum_{i=1} \alpha_i X_i$$

Where α_0 is the intercept and α_i is the coefficient for the i^{th} explanatory variable X_i.

The modeling approach used the year and the month as explanatory variables. A Jackknife approach was used to estimate the amount of variation in the model runs as per Dick (2004).

Results:

The SCDNR charterboat logbook data used to create the index represent 23,223 fishing trips in which anglers caught 12,972 red snapper and harvested 4,450 red snapper. Summarized catch and effort data are presented in Table 2. The indices are presented in Table 3 and Figure 2. Diagnostics for the monthly model run are found in Figures 3 and 4.

Detailed information on the size and release condition of discarded fish is not collected in traditional dockside surveys of recreational fisheries. At-sea observer surveys provide valuable information on the size and condition of discarded fish. Such surveys have been conducted on headboat vessels in the south Atlantic since 2004. Coverage was expanded in 2013 to include charter vessels on the east coast of Florida. This report provides a summary of available information on the size, release condition, and disposition of red snapper collected from headboats and charter boats from the Atlantic coast of Florida through North Carolina.

Coverage

Fishery observer coverage for headboats and charter vessels operating in the South Atlantic is summarized in Table 1.

Headboat Coverage

In 2004, at-sea observer surveys were conducted on headboats from North Carolina and South Carolina, and coverage was extended to east Florida in 2005. In the Florida Keys, the at-sea headboat survey was funded by the Gulf Fisheries Information Network (Gulf FIN) from 2005 through 2007. In 2010, the state of Florida secured alternative funds to continue limited at-sea observer coverage for headboats in the Keys through 2013. There were no headboats sampled in the Keys in 2014 due to loss of funding.

Charter Vessel Coverage

In 2010, observer coverage in the Florida Keys was expanded to include charter vessels. In 2013, a MARFIN project that employs fishery observers on charter vessels on the entire Atlantic coast of Florida was initiated. The MARFIN project is funded through 2015.

Table 1. Fishery observer coverage for headboats (H) and charter vessels (C).

	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013	2014
NC	H	H	H	H	H	H	H	H	H	H	H
SC	H	H	H	H	H	H	H	H	H	H	H
GA	H	H	H	H	H	H	H	H	H	H	H
EFL		H	H	H	H	H	H	H	H	H, C	H, C
Keys		H	H	H			H, C	H, C	H, C	H, C	C

Cooperative vessels in each state were randomly selected each week for observer coverage. Sampling occurred year-round. The state of Florida was stratified into three regions: Northeast (Nassau through Brevard Counties, sub-region=5), Southeast (Indian River through Dade Counties, sub-region=4), and Keys (Monroe County, sub-region=3). Operators from selected vessels were contacted by state biologists and one or two observers were scheduled to sample a single trip in a selected week. For trips in Florida with 15 or less passengers, only one observer accompanied passengers during the scheduled trip.

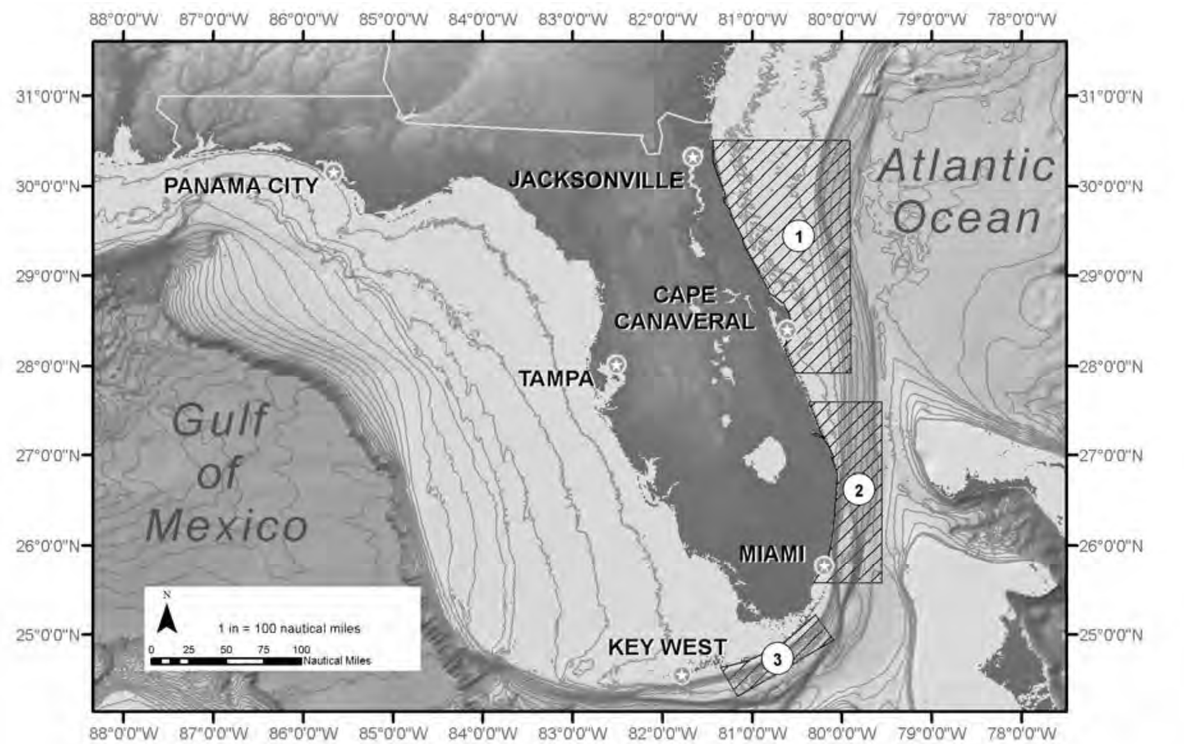

Figure 1. Areas in Florida with at-sea observer coverage. Area 1 is the northeast region, area 2 is the southeast region, and area 3 is the Key West Region.

Data Elements:

All sampled trips
Trip level data are available for all regions and years of observer coverage (Table 1). Trip level information for each sampled trip includes:

- Year, month and day of trip
- area where the majority of fishing took place,
    - coded as 3 miles or less from shore or more than 3 miles from shore
- duration of fishing (to the nearest half hour)
- total number of anglers on board
- number of anglers observed
- minimum and maximum depths fished (collected in Florida only)

A brief interview with each angler observed during a trip was also conducted to collect information on primary and secondary target species, angler avidity, and state and county of residence (discontinued in Florida when new methods were implemented, discussed in next section).

For each angler observed during a sampled trip, the following information was collected:
- total number of fish retained by species
- total number of fish discarded alive by species
- total number of fish discarded dead by species

For each fish caught by an observed angler during a sampled trip, biologists recorded:
- species
- size (fork length in mm)
- disposition, coded as:
    - 1: thrown back alive, legal
    - 2: thrown back alive, not legal
    - 3: plan to eat
    - 4: used for bait or plan to use for bait
    - 5: sold or plan to sell
    - 6: thrown back dead or plan to throw away
- Release condition, collected in Florida only, coded as:
    - 1 = Good, fish swam toward bottom immediately upon entry into the water
    - 2 = Fair, fish was disoriented upon release and slowly swam towards the bottom
    - 3 = Poor, fish was very disoriented upon release and remained at the surface
    - 4 = Dead, fish was either dead or unresponsive upon entering the water
    - 5 = Eaten, fish was eaten by a bird, another fish, or a marine mammal
    - 9 = Unobserved, unable to observe or not applicable (fish retained)

Florida only
Data collection methods were modified in Florida to collect more detailed station-level information beginning in 2010 in the Keys and 2011 on the east coast of Florida (Table 2).

For each location fished during a sampled trip, the following station-level information was recorded:

- latitude and longitude (degrees and minutes)
- fishing zone and subzone (same as commercial zones)
- depth (meters)
- up to three target species and percentage of time targeting each

For each angler observed at a given station, the following information was collected:

- total number of fish retained by species
- total number of fish discarded alive by species
- total number of fish discarded dead by species

For each rod fished by an observed angler at a given station, the following information was recorded:

- leader type and strength
- hook type (circle hook, J hook, kahle hook, treble hook, other)
- hook offset (yes or no)
- hook size (using a standard hook sizing chart)
- bait type (live, whole dead fish, cut fish, squid, cocktail, artificial)

For each fish observed from a given rod at a given station, the following information was recorded:

- species
- mid-line length (mm)
- disposition (same as above)
- release condition (same as above)
- anatomical location of embedded hooks (lip, mouth, throat, gill, gut, eye, external)
- method of hook removal (easy or difficult; by hand, dehooking tool, pliers, or left in place)
- presence of barotrauma symptoms (inflated bladder, everted stomach, extruded intestines, exopthalmia)
- venting method (released without venting, bladder vented, stomach vented)
- presence of gill injury (visible bleeding from gills)

Table 2. Availability of detailed station level data for headboats (H) and charter trips (C).

Sample Weights:

Headboat vessels report fishing effort in logbook trip reports, and effort data were provided by the NMFS Southeast Fisheries Science Center in Beaufort, NC. To generate weighting factors for sampled headboat trips throughout the survey area, fishing effort for the years 2005 through 2013 was used to calculate proportional fishing effort by state or region (for Florida). Sample weights were calculated as:

$$W_{ay} = (N_{ay}/N_y) / (n_{ay}/n_y) \qquad \text{Equation 1}$$

Where N_{ay} /N is the total number of headboat trips reported from area a (state or region) during year y divided by total number of trips reported in the South Atlantic, and n_{ay}/n is the number of trips sampled in area a during year y, divided by the total number of sampled trips in the South Atlantic. Areas with $W_{ay} < 1$ are down weighted to account for higher sampling effort and areas with $W_t > 1$ are upweighted to account for undersampling.

Numbers of headboat trips sampled in each state/region are provided in Table 3, and calculated sample weights are provided in Table 4.

Table 3. Headboat at-sea observer trips sampled by state/region and year.

2012	0.178	1.444	0.587	1.450
2013	0.213	0.970	0.563	1.367
2014	0.198	1.186	0.511	2.034

Length Frequency

Raw, unweighted sample sizes for red snapper lengths are provided in Table 5. Fork length (in mm) was converted to maximum total length using the equation provided by the SEDAR41 Life History Workgroup (TL_{max} = 2.22 + 1.07FL). Individual fish were then assigned to one cm length bin categories (40 cm bin = fish 39.5 cm to 40.4 cm). The numbers of fish in each length bin category were summed by area (state or region), year and disposition (harvested, released), and multiplied by appropriate sample weights. Weighted values for each area within a length bin were then summed so that weighted proportions of fish in each length bin could be calculated (Figure 2).

Table 5. Raw (unweighted) sample sizes for red snapper lengths.

Year	Disposition	NC	SC	GA-NEFL	SEFL	Total

	Harvest	0	0	0	0	0

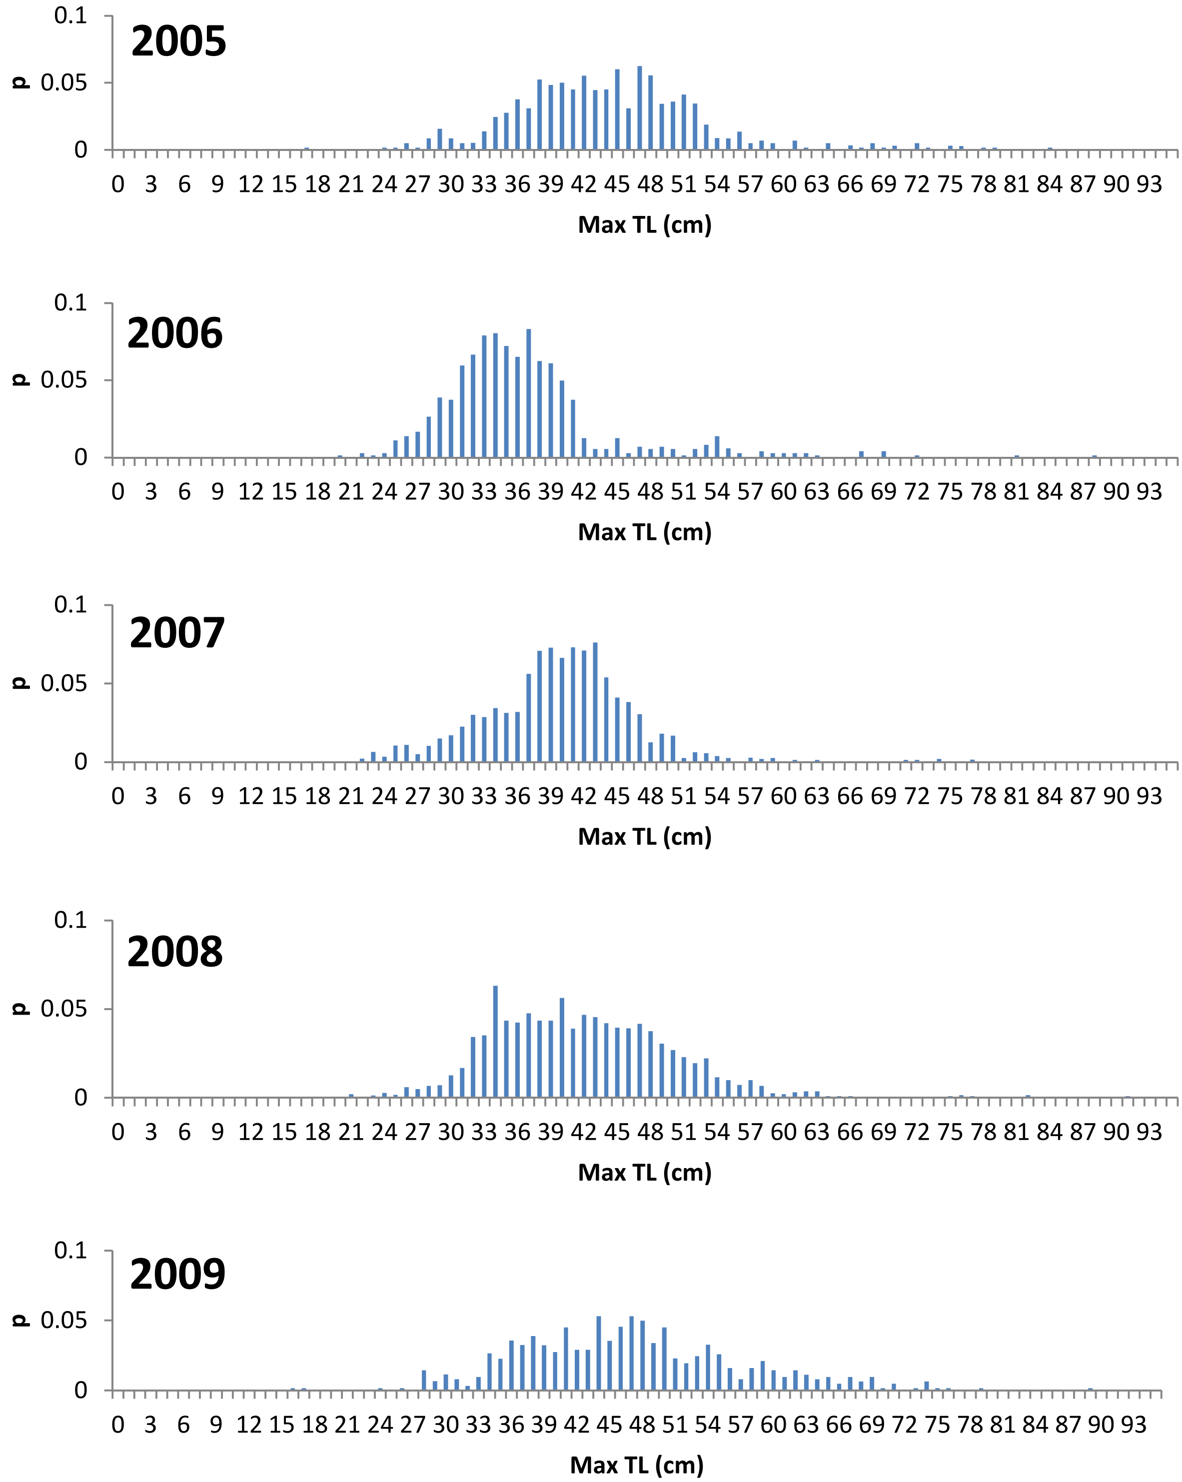

Figure 2. Weighted length frequency of red snapper discards. Continued on next page.

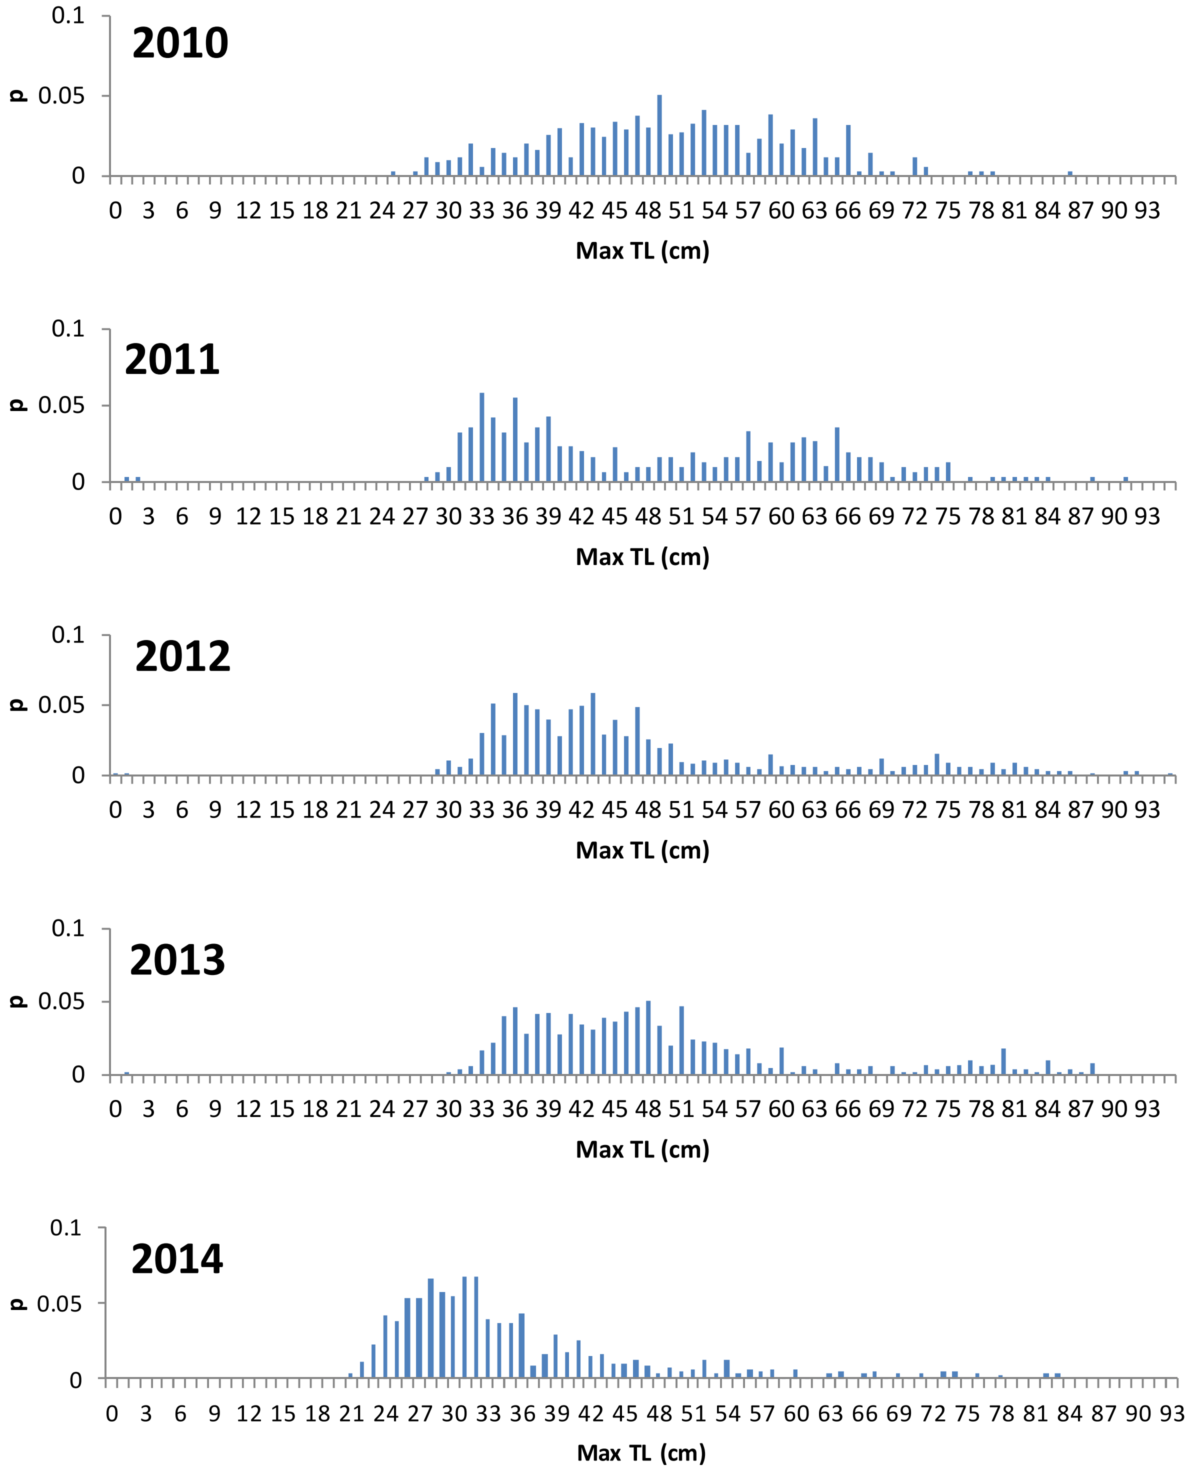

Figure 2. Continued.

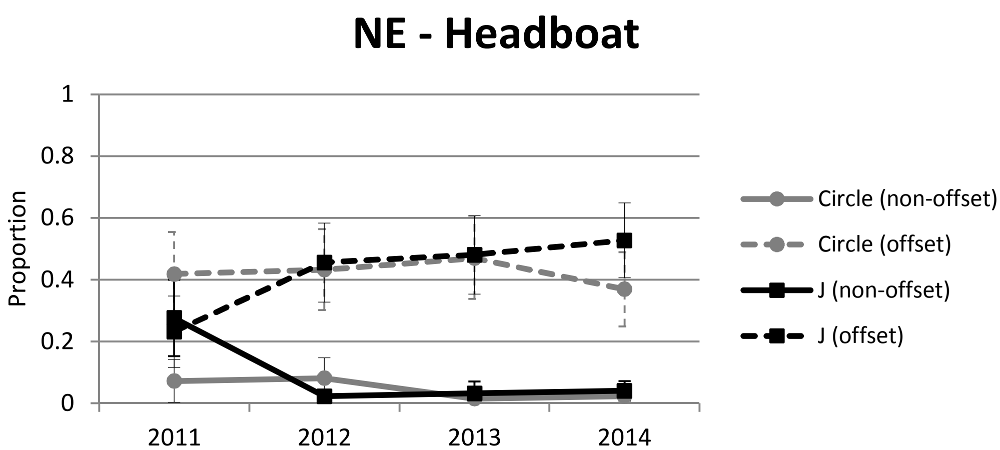
Hook Type Usage in the For-Hire Fishery
Circle hooks have been required in the South Atlantic since 3/3/2011 when fishing for species in the snapper-grouper management group north of 28 degrees north latitude (the boundary between Brevard and Indian River Counties in Florida). Among trips sampled off the Atlantic coast of Florida, the prevalence of circle hook use on headboats and charter vessels varied north and south of this demarcation (Figures 3 and 4).

On headboat trips in the SE region of Florida, non-offset (flat) J hooks were used almost exclusively, although there was a slight increase during 2014 in the use of offset circle hooks (Figure 3). In the NE region, where circle hooks are required when fishing for snapper and grouper, offset circle hooks and offset J hooks were equally prevalent on headboats (Figure 3).

On charter trips, in the SE region of Florida, both offset and non-offset J hooks were prevalent. Non-offset circle hooks was the most prevalent gear used on charter trips observed in the NE region (Figure 4).



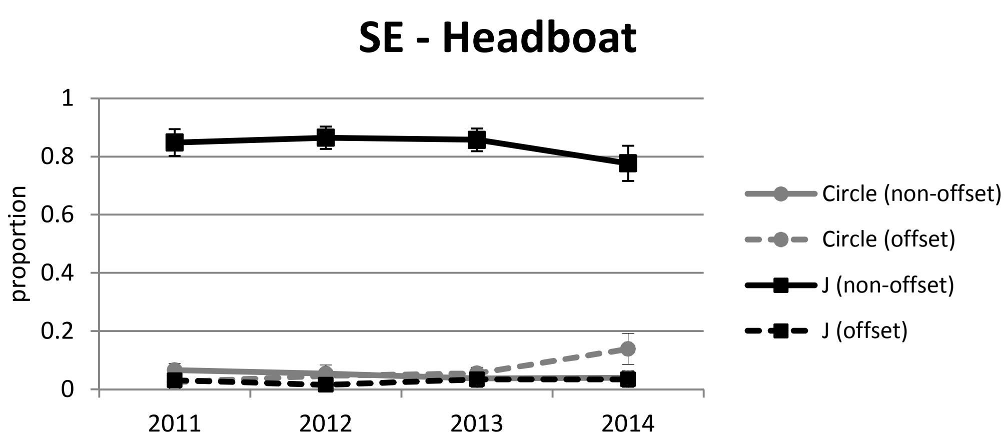


Figure 3. Mean proportion of fishing rigs by hook type observed during headboat trips sampled on the Atlantic coast of Florida for regions north (top panel) and south (bottom panel) of 28 degrees north latitude. Circle hooks were required after 3/3/2011 when fishing for snapper and grouper north of 28 degrees north latitude.

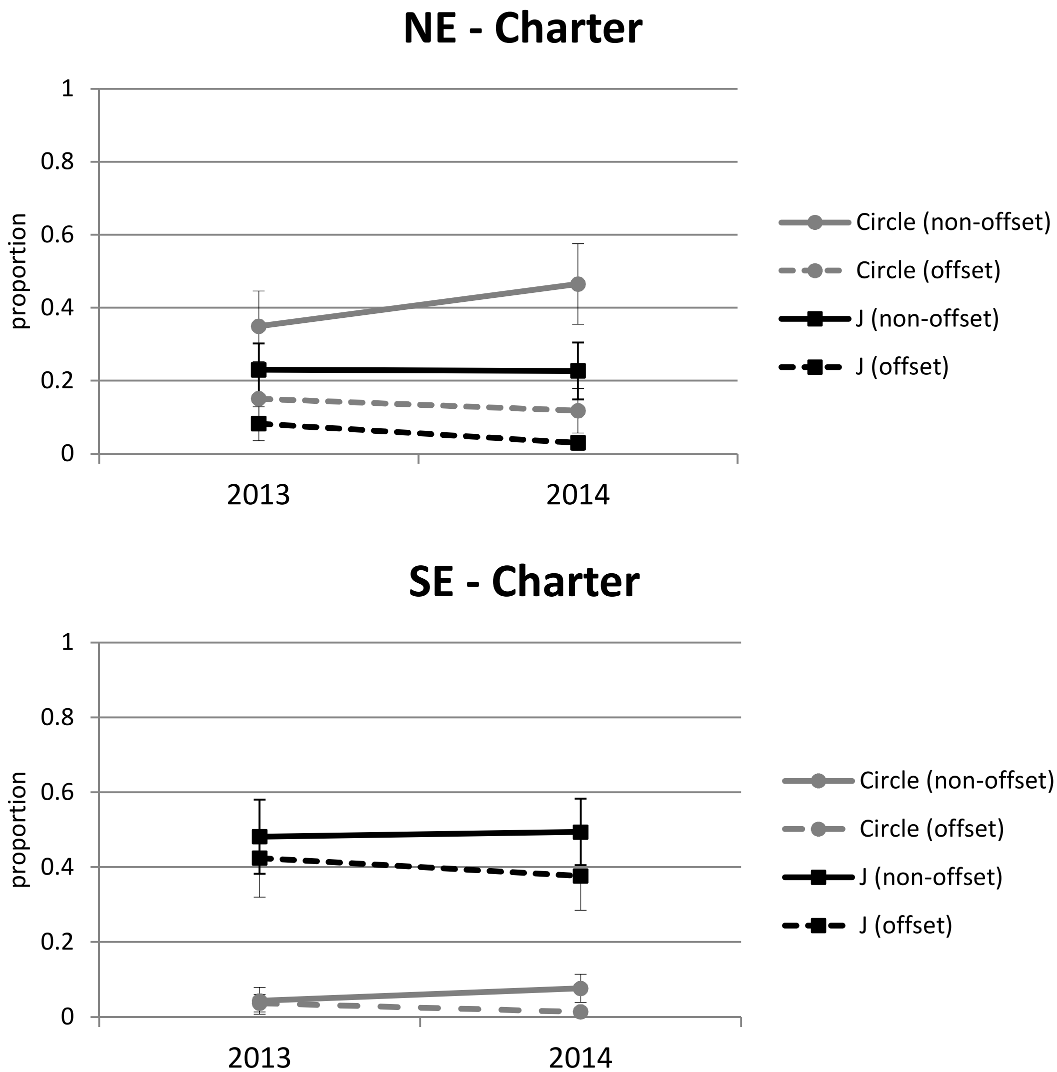

Figure 4. Mean proportion of fishing rigs by hook type observed during charter trips sampled on the Atlantic coast of Florida for regions north (top panel) and south (bottom panel) of 28 degrees north latitude. Circle hooks were required after 3/3/2011 when fishing for snapper and grouper north of 28 degrees north latitude.

Hook Injuries

Out of 3,116 red snapper observed on the Atlantic coast of Florida, 65% were caught with circle hooks, 35% were caught with J hooks, and <1% were caught with kahle or treble hooks. Among red snapper caught with circle hooks, 66% were caught with offset hooks; and among those caught with J hooks, 85% were caught on offset hooks. The overall percentage of potentially lethal hook locations (including eyes, gills, esophagus and gut) was lowest among red snapper caught with non-offset circle hooks (Table 6). Logistic regression was used to test the significance of hook type on the probability that hooks embed in a potentially lethal location (versus in the lip or jaw). When compared to flat non-offset circle hooks, circle hooks with an offset were 1.6 times more likely to embed in potentially lethal locations, flat non-offset J hooks were 2.4 times more likely, and offset J hooks performed the worst and were 4.8 times more likely to embed internally in a harmful location (Table 7). Offset circle hooks and flat non-offset J hooks performed similarly, and offset J hooks performed worse than all other hook types (Table 7).

Table 6. Numbers of red snapper observed by hook-type and location where the hook was embedded, and percent of red snapper with potentially lethal hook injuries.

Hook-type	Lip or jaw	Potentially lethal location	Percent potentially lethal
Non-offset circle hook	652	31	4.54
Offset circle hook	1,245	96	7.16
Non-offset J hook	141	16	10.19
Offset J hook	743	170	18.62
Other (kahle, treble)	19	3	13.64

Table 7. Results of a logistic regression that modeled the probability for hooks to embed in potentially lethal locations. For odds ratios >1.0, confidence intervals that do not overlap with 1.0 indicate a significantly higher probability for potentially lethal hook injuries.

Hook-type Comparison	Odds Ratio	95% Confidence Interval
Offset circle vs. non-offset circle	1.621	1.070, 2.457
Non-offset J vs. non-offset circle	2.386	1.271, 4.481
Non-offset J vs. offset circle	1.472	0.843, 2.569 (not significant)
Offset J vs. non-offset circle	4.811	3.235, 7.155
Offset J vs. offset circle	2.967	2.274, 3.873
Offset J vs. non-offset J	2.016	1.171, 3.471

Implications of Circle Hook Requirement for Discard Mortality

Data on hook type were not collected from at-sea surveys in Florida until the first year that circle hook use was required in the South Atlantic; therefore, characteristics of the fishery prior to the circle hook requirement are not available. However, some inferences can be made. The four year time series for headboats in the NE region of Florida (the area north of 28 degrees latitude where the circle hook requirement is in effect) indicates an increasing trend in offset circle hook use and a decrease in flat non-offset J hooks since 2011 when the circle hook rule went into effect (Figure 3, top panel). Circle hook use is not required in the SE region and non-offset J hooks were used almost exclusively across all four years. Assuming the NE region shifted to offset circle hooks as a result of the circle hook requirement, no net conservation benefit is expected, since performance for this hook type is similar to non-offset J hooks. If the NE region was using offset J hooks prior to 2011, a potential net benefit could be expected, since this gear performed the worst among all hook types (Table 7). However, the prevalence of offset J hooks increased over the four years of observation (Figure 3, top panel); although this has not led to a noticeable decline in the proportion of red snapper observed on headboats that were hooked in the lip or jaw over the time series (Figure 5).

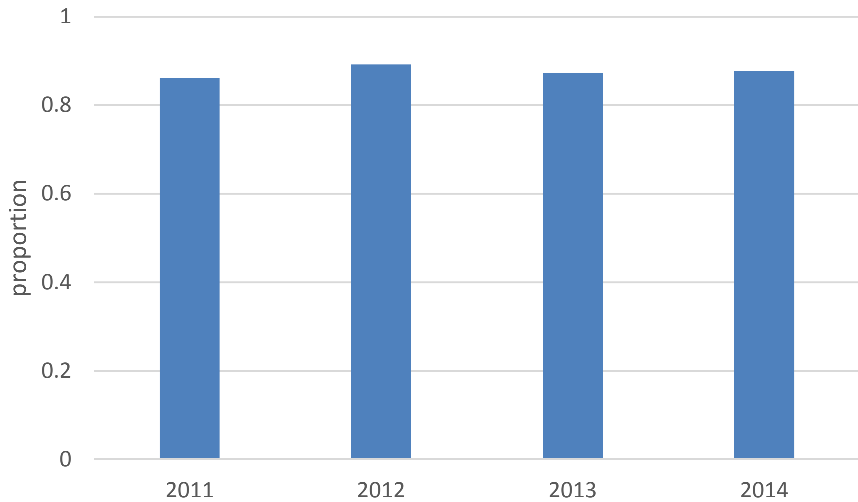

Figure 5. Proportion of red snapper observed on headboats each year that were hooked in the mouth or jaw.

On charter boat trips sampled in the NE region, non-offset circle hooks were the most frequently observed hook type in both years, and this gear also had the lowest incidence of deep hooking. Like the headboat fishery, J hooks are most prevalent on charter trips in the SE region, where circle hooks are not required. Assuming J hooks were used more frequently prior to 2011 in the NE charter fishery, there is a potential net conservation benefit from a shift to non-offset circle hooks in this segment of the recreational fishery.

Condition of Red Snapper Discards in Florida

Immediate mortality percentages for red snapper observed from for-hire vessels in the Gulf of Mexico adjacent to Florida are reported to be low (<1%, SEDAR41-RD16). On the Atlantic coast of Florida, no dead discards were recorded by fishery observers on for-hire vessels (all discards observed were released alive).

Live red snapper discards observed from the Atlantic coast of Florida were assigned to one of three release condition categories used to model relative survival of red snapper discards in the Gulf of Mexico (described in Table 8 and SEDAR41-RD16). The majority of red snapper discards observed from headboats were captured from depths of 30 meters or less; whereas, a higher portion of red snapper observed from charter boats were captured in depths of 31-40 meters and 41-50 meters (Figure 6). In both fisheries, the majority (67.4%) of red snapper were vented prior to release and did not exhibit obvious impairments (Figure 6). Among fish that were classified as impaired (16.3% of all fish observed), the majority were due to hook injury rather than swimming impairments associated with barotrauma and other stressors.

In the Gulf, survival percentages for fish released in each condition category were estimated from a model that was derived from gag grouper discarded during for-hire recreational trips and marked with conventional tags prior to release (Sauls 2014). The same model was also applied to red snapper that were tagged prior to discarding in the Gulf of Mexico (SEDAR41-DW16, percentages provided in Table 9). When these percentages are applied to red snapper observed on the Atlantic coast of Florida, the overall portion of discards that suffer mortality is estimated to be approximately 27-28% for charter boats and headboats, respectively (Table 10). This result is comparable to overall discard mortality estimates in the Gulf (Table 9).

Table 8. Description of live release condition categories for reef fishes observed during recreational hook-and-line fishing (SEDAR41-RD16).

Condition category	Description
1. Not impaired, not vented	Fish immediately submerged without the assistance of venting and did not suffer internal hook injuries or visible injury to the gills.
2. Not impaired, vented	Fish was vented first and submerged immediately, and did not suffer internal hook injuries or visible injury to the gills.
3. Impaired	Fish was either initially disoriented before it submerged or remained floating at the surface (regardless of whether it was vented), suffered internal hook injuries, suffered visible injury to the gills, or any combination of the three impairments.

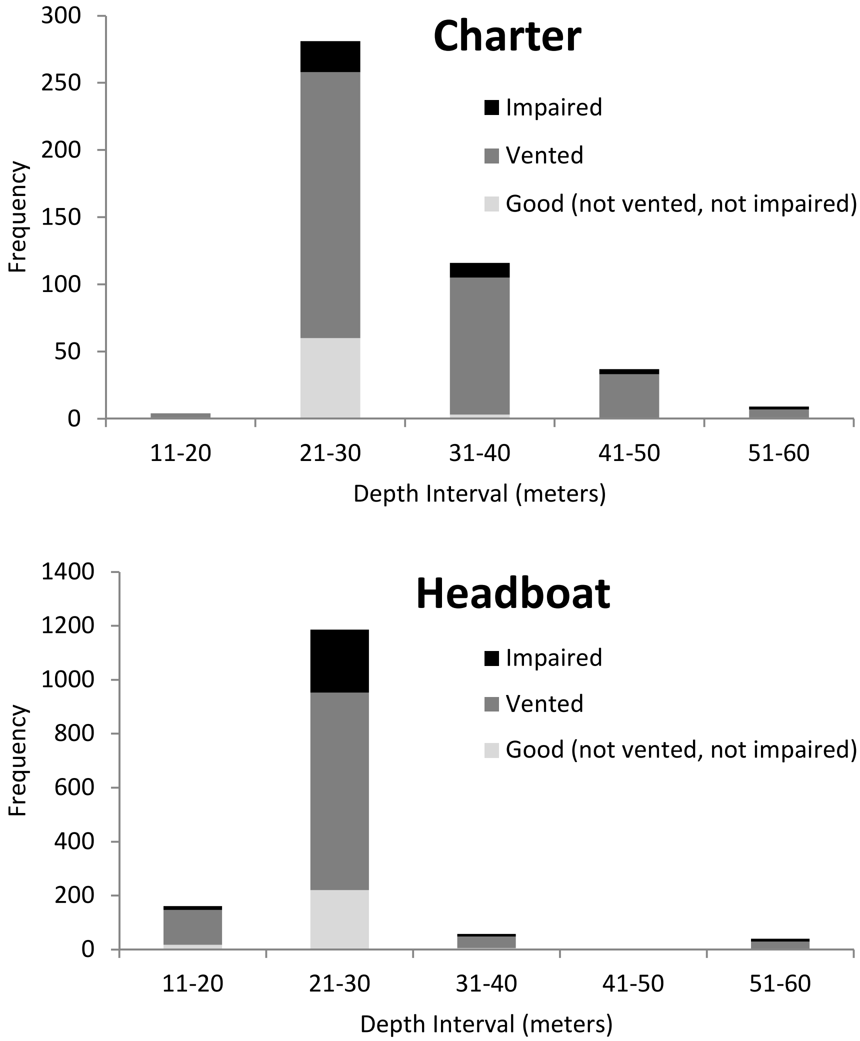

Figure 6. Release conditions for red snapper observed from charter boats (top) and headboats (bottom), by depth of capture.

Table 9. Proportion of live discarded red snapper caught with recreational hook-and-line gear in the eastern Gulf of Mexico estimated to survive catch-and-release, by release condition category (SEDAR41-RD16).

Release Condition Category	**Estimated Survival Portion**	**Overall estimated discard mortality**
1, not impaired, not vented	0.925 (range 0.85, 1.0)	Point estimate range 0.207 to 0.257
2, not impaired, vented	0.724 (95% CI 0.652, 0.804)	
3, impaired	0.495 (95% CI 0.391, 0.599)	

Table 10. Numbers of red snapper discards observed off the Atlantic coast of Florida by release condition category, estimated number of discard mortalities (based on estimated percent survival in Table 9), and overall proportion estimated to suffer mortality.

Vessel Type	**Release Condition Category**	**Discards observed**	**Estimated mortalities**	**Estimated mortality proportion**
Headboat	1, not impaired, not vented	237	17.8 (0, 35.6)	
	2, not impaired, vented	1,103	304.4 (216.2, 383.8)	
	3, impaired	327	165.1 (131.1, 199.1)	
	Total	1,667	487.3 (347.3, 618.5)	0.292 (0.208, 0.360)
Charter	1, not impaired, not vented	81	6.1 (0, 12.2)	
	2, not impaired, vented	610	168.4 (119.6, 212.3)	
	3, impaired	92	46.5 (36.9, 56.0)	
	Total	783	221.0 (156.5, 280.5)	0.282 (0.200, 0.358)

Evaluation of Abundance Indices:
SERFS Chevron Traps Red Snapper (Working Paper #06)

DESCRIPTION OF THE DATA SOURCE

1. Fishery Independent Indices

	Not Applicable	Absent	Incomplete	Complete
A. Describe the survey design (e.g. fixed sampling sites, random stratified sampling), location, seasons/months and years of sampling.				✓
B. Describe sampling methodology (e.g. gear, vessel, soak time etc.)				✓
C. Describe any changes in sampling methodology (e.g. gear, vessel, sample design etc.)				✓
D. Describe the variables reported in the data set (e.g. location, time, temperature, catch, effort etc.).				✓
E. What species or species assemblages are targeted by this survey (e.g. red snapper, reef fish, pelagic).				✓
F. Describe the size/age range that the index applies to. Include supporting figures (e.g. size comp) if available.				✓

2. Fishery Dependent Indices

	Not Applicable	Absent	Incomplete	Complete
A. Describe the data source and type of fishery (e.g. commercial handline, commercial longline, recreational hook and line etc.).				
B. Describe any changes to reporting requirements, variables reported, etc.				
C. Describe the variables reported in the data set (e.g. location, time, temperature, catch, effort etc.).				
D Describe the size/age range that the index applies to. Include supporting figures (e.g. size comp) if available.				

METHODS

1. Data Reduction and Exclusions

	Not Applicable	Absent	Incomplete	Complete
A. Describe any data exclusions (e.g. gears, fishing modes, sampling areas etc.). Report the number of records removed and justify removal.				✓
B. Describe data reduction techniques (if any) used to address targeting (e.g. Stephens and MacCall, 2004; gear configuration, species assemblage etc).	✓			
C. Discuss procedures used to identify outliers. How many were identified? Were they excluded?	✓			

Working Group Comments:

Survey did not consistently cover the center of distribution for Red Snapper in the South Atlantic (Georgia and northern Florida). Survey best covered the center from 2010 to 2013. Percent positives also were less than 5% prior to these years. Decision was made to split the index to 2010-2013 and 2009 and earlier. The percent positives in 1990-2009 were too low to develop an index, consistent with the decision made in SEDAR 24.

2. Management Regulations (for FD Indices)

	Not Applicable	Absent	Incomplete	Complete
A. Provide (or cite) history of management regulations (e.g. bag limits, size limits, trip limits, closures etc.).				
B. Describe the effects (if any) of management regulations on CPUE				
C. Discuss methods used (if any) to minimize the effects of management measures on the CPUE series.				

3. Describe Analysis Dataset (after exclusions and other treatments)

	Not Applicable	Absent	Incomplete	Complete
A. Provide tables and/or figures of number of observations by factors (including year, area, etc.) and interaction terms.				✓
B. Include tables and/or figures of number of positive observations by factors and interaction terms.				✓
C. Include tables and/or figures of the proportion positive observations by factors and interaction terms.				✓
D. Include tables and/or figures of average (unstandardized) CPUE by factors and interaction terms.				✓
E. Include annual maps of locations of survey sites (or fishing trips) and associated catch rates ***OR*** supply the raw data needed to construct these maps (Observation, Year, Latitude, Longitude (or statistical grid, area), Catch, Effort).				✓
F. Describe the effort variable and the units. If more than one effort variable is present in the dataset, justify selection.				✓
G. What are the units of catch (e.g. numbers or biomass, whole weight, gutted weight, kilograms, pounds).				✓

4. Model Standardization

	Not Applicable	Absent	Incomplete	Complete
A. Describe model structure (e.g. delta-lognormal)				✓
B. Describe construction of GLM components (e.g. forward selection from null etc.)				✓
C. Describe inclusion criteria for factors and interactions terms.				✓
D. Were YEAR*FACTOR interactions included in the model? If so, how (e.g. fixed effect, random effect)? Were random effects tested for significance using a likelihood ratio test?		✓		
E. Provide a table summarizing the construction of the GLM components.				✓
F. Summarize model statistics of the mixed model formulation(s) (e.g. log likelihood, AIC, BIC etc.)				✓
G. Report convergence statistics.				✓

Working Group Comments:

Initial model was a zero-inflated negative binomial model using polynomials to describe the effects of variables on catch rates. We investigated reducing the highest order that the polynomials could take and also considered including all lower order polynomials when a high order was selected by Bayesian Information Criterion. Since this approach has not been fully peer-reviewed, the decision was made to bin covariates based on preliminary generalized additive model fits. Inclusion of covariates in the sub-models was done by forward selection with Akaike's Information Criterion.

MODEL DIAGNOSTICS

Comment: Other model structures are possible and acceptable. Please provide appropriate diagnostics to the CPUE indices working group.

1. Binomial Component

Item	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:
A. Include plots of the chi-square residuals by factor.	✓				
B. Include plots of predicted and observed proportion of positive trips by year and factor (e.g. year*area)				✓	
C. Report overdispersion parameter and other fit statistics (e.g. chi-square / degrees of freedom).				✓	

2. Lognormal/Gamma Component

Item	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:
A. Include histogram of log(CPUE) or a histogram of the residuals of the model on CPUE. Overlay the expected distribution.	✓				
B. Include plots describing error distribution (e.g. Studentized residuals vs. linear predictor.	✓				
C. Include QQ-plot – (e.g. Student deviance residuals vs. theoretical quantiles), Overlay expected distribution.	✓				
D. Include diagnostic plot for variance function (e.g. square root of std residuals vs. fitted values). Overlay expected distribution.	✓				
E. Include diagnostic plot for link function (e.g. linear response variable vs. linear predictor). Overlay expected distribution.	✓				
F. Include plots of the residuals by factor	✓				

3. Poisson Component

Item	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:
A. Report overdispersion parameter and other fit statistics (e.g. chi-square / degrees of freedom).				✓	
B. Include plots describing error distribution (e.g. Studentized residuals vs. linear predictor.				✓	
C. Include QQ-plot – (e.g. Student deviance residuals vs. theoretical quantiles), Overlay expected distribution.				✓	
D. Include diagnostic plot for variance function (e.g. square root of std residuals vs. fitted values). Overlay expected distribution.				✓	
E. Include diagnostic plot for link function (e.g. linear response variable vs. linear predictor). Overlay expected distribution.	✓				***The feasibility of this diagnostic is still under review.***

4. Zero-inflated model

Item	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:
A. Include ROC curve to quantify goodness of fit.		✓			
B. Include plots describing error distribution (e.g. Studentized residuals vs. linear predictor).				✓	
C. Include QQ-plot (e.g. Student dev. residuals vs. theoretical quantiles), Overlay expected distribution.				✓	

MODEL DIAGNOSTICS (CONT.)

	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:

D. Include diagnostic plot for variance function (e.g. square root of std residuals vs. fitted values). Overlay expected distribution.				✓
E. Include diagnostic plot for link function (e.g. linear response variable vs. linear predictor). Overlay expected distribution.				✓

MODEL RESULTS

A. Tables of Nominal CPUE, Standardized CPUE, Observations, Positive Observations, Proportion Positive Observations and Coefficients of Variation (CVs). Other statistics may also be appropriate to report				✓
B. Figure of Nominal and Standardized Indices with measure of variance (i.e. CVs).				✓

IF MULTIPLE MODEL STRUCTURES WERE CONSIDERED:

(***Note: this is always recommended but required when model diagnostics are poor***.)

1. Plot of resulting indices and estimates of variance	✓			
2. Table of model statistics (e.g. AIC criteria)	✓

Revision				

The revision deadline is negotiated by the author, the SEDAR coordinator and the CPUE rapporteur. The author ***DOES NOT*** *commit to any* ***LEGAL OBLIGATION*** *by agreeing to submit a manuscript before this deadline. The maximum penalty for failure to submit a revised document prior to the submission deadline is rejection of the CPUE series.*

Justification of Working Group Recommendation

The SERFS chevron trap index is the only fishery-independent survey that can be used to develop a relative abundance index of Red Snapper that collects associated biological information (e.g. age/length comps) that can be used to inform selectivity of the gear. That being said, during SEDAR 24 the SERFS chevron trap index was not recommended for use due to the low percent positive rate of Red Snapper in the traps, the perceived inability of the trap to capture Red Snapper (i.e. low detectability, despite reports that chevron traps were capable of capturing Red Snapper in the Gulf of Mexico), and the limited sampling of the survey in the center of Red Snapper abundance off Georgia and northern Florida. While nothing could rectify the lack of positive occurrences in early years (1990-2009), the other two concerns were alleviated for the years 2010-2013 for SEDAR 41. During these years ample sampling occurred throughout the region and the percent positive occurrences were acceptable. Although the sampling distribution of the survey with regards to specific covariates (e.g. bottom temperature, depth, latitude, etc.) varied from year to year, the zero-inflation standardization approach effectively removes the effects of this variability from relative abundance trends. Finally, being a fishery-independent survey, standardized sampling techniques have been used and the survey has been immune to regulation changes. These observations generally make relative abundance trends suggested by fishery-independent surveys superior to parallel fishery-dependent abundance trends, especially as stricter management regulations are placed on the fishery.

Evaluation of Abundance Indices:
SERFS Video Index (SEDAR41-DW04)

DESCRIPTION OF THE DATA SOURCE

	Not Applicable	Absent	Incomplete	Complete
1. Fishery Independent Indices				
A. Describe the survey design (e.g. fixed sampling sites, random stratified sampling), location, seasons/months and years of sampling.				✓
B. Describe sampling methodology (e.g. gear, vessel, soak time etc.)				✓
C. Describe any changes in sampling methodology (e.g. gear, vessel, sample design etc.)				✓
D. Describe the variables reported in the data set (e.g. location, time, temperature, catch, effort etc.).				✓
E. What species or species assemblages are targeted by this survey (e.g. red snapper, reef fish, pelagic).				✓
F. Describe the size/age range that the index applies to. Include supporting figures (e.g. size comp) if available.				✓
2. Fishery Dependent Indices				
A. Describe the data source and type of fishery (e.g. commercial handline, commercial longline, recreational hook and line etc.).	✓			
B. Describe any changes to reporting requirements, variables reported, etc.	✓			
C. Describe the variables reported in the data set (e.g. location, time, temperature, catch, effort etc.).	✓			
D Describe the size/age range that the index applies to. Include supporting figures (e.g. size comp) if available.	✓			

METHODS

	Not Applicable	Absent	Incomplete	Complete
1. Data Reduction and Exclusions				
A. Describe any data exclusions (e.g. gears, fishing modes, sampling areas etc.). Report the number of records removed and justify removal.				✓
B. Describe data reduction techniques (if any) used to address targeting (e.g. Stephens and MacCall, 2004; gear configuration, species assemblage etc).	✓			
C. Discuss procedures used to identify outliers. How many were identified? Were they excluded?	✓			

Working Group Comments:

Working Group Comments:

2. Management Regulations (for FD Indices)

Item	Not Applicable	Absent	Incomplete	Complete
A. Provide (or cite) history of management regulations (e.g. bag limits, size limits, trip limits, closures etc.).	✓			
B. Describe the effects (if any) of management regulations on CPUE	✓			
C. Discuss methods used (if any) to minimize the effects of management measures on the CPUE series.	✓			

3. Describe Analysis Dataset (after exclusions and other treatments)

Item	Not Applicable	Absent	Incomplete	Complete
A. Provide tables and/or figures of number of observations by factors (including year, area, etc.) and interaction terms.				✓
B. Include tables and/or figures of number of positive observations by factors and interaction terms.				✓
C. Include tables and/or figures of the proportion positive observations by factors and interaction terms.	✓			
D. Include tables and/or figures of average (unstandardized) CPUE by factors and interaction terms.	✓			
E. Include annual maps of locations of survey sites (or fishing trips) and associated catch rates ***OR*** supply the raw data needed to construct these maps (Observation, Year, Latitude, Longitude (or statistical grid, area), Catch, Effort).				✓
F. Describe the effort variable and the units. If more than one effort variable is present in the dataset, justify selection.				✓
G. What are the units of catch (e.g. numbers or biomass, whole weight, gutted weight, kilograms, pounds).				✓

4. Model Standardization

Item	Not Applicable	Absent	Incomplete	Complete
A. Describe model structure (e.g. delta-lognormal)				✓
B. Describe construction of GLM components (e.g. forward selection from null etc.)	✓			
C. Describe inclusion criteria for factors and interactions terms.				✓
D. Were YEAR*FACTOR interactions included in the model? If so, how (e.g. fixed effect, random effect)? Were random effects tested for significance using a likelihood ratio test?	✓			
E. Provide a table summarizing the construction of the GLM components.	✓			
F. Summarize model statistics of the mixed model formulation(s) (e.g. log likelihood, AIC, BIC etc.)				✓
G. Report convergence statistics.				✓

MODEL DIAGNOSTICS

Comment: Other model structures are possible and acceptable. Please provide appropriate diagnostics to the CPUE indices working group.

Item	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:

C. Report overdispersion parameter and other fit statistics (e.g. chi-square / degrees of freedom).				✓	

2. Lognormal/Gamma Component

Item	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:
A. Include histogram of log(CPUE) or a histogram of the residuals of the model on CPUE. Overlay the expected distribution.				✓	
B. Include plots describing error distribution (e.g. Studentized residuals vs. linear predictor.				✓	
C. Include QQ-plot – (e.g. Student deviance residuals vs. theoretical quantiles), Overlay expected distribution.				✓	
D. Include diagnostic plot for variance function (e.g. square root of std residuals vs. fitted values). Overlay expected distribution.	✓				
E. Include diagnostic plot for link function (e.g. linear response variable vs. linear predictor). Overlay expected distribution.	✓				
F. Include plots of the residuals by factor				✓	

3. Poisson Component

Item	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:
A. Report overdispersion parameter and other fit statistics (e.g. chi-square / degrees of freedom).	✓				
B. Include plots describing error distribution (e.g. Studentized residuals vs. linear predictor.	✓				
C. Include QQ-plot – (e.g. Student deviance residuals vs. theoretical quantiles), Overlay expected distribution.	✓				
D. Include diagnostic plot for variance function (e.g. square root of std residuals vs. fitted values). Overlay expected distribution.	✓				
E. Include diagnostic plot for link function (e.g. linear response variable vs. linear predictor). Overlay expected distribution.	✓				***The feasibility of this diagnostic is still under review.***

4. Zero-inflated model

Item	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:
A. Include ROC curve to quantify goodness of fit.	✓				
B. Include plots describing error distribution (e.g. Studentized residuals vs. linear predictor).	✓				
C. Include QQ-plot (e.g. Student dev. residuals vs. theoretical quantiles), Overlay expected distribution.	✓				

MODEL DIAGNOSTICS (CONT.)

	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:

D. Include diagnostic plot for variance function (e.g. square root of std residuals vs. fitted values). Overlay expected distribution.	✓			
E. Include diagnostic plot for link function (e.g. linear response variable vs. linear predictor). Overlay expected distribution.	✓			

MODEL RESULTS

A. Tables of Nominal CPUE, Standardized CPUE, Observations, Positive Observations, Proportion Positive Observations and Coefficients of Variation (CVs). Other statistics may also be appropriate to report				✓
B. Figure of Nominal and Standardized Indices with measure of variance (i.e. CVs).				✓

IF MULTIPLE MODEL STRUCTURES WERE CONSIDERED:

(***Note: this is always recommended but required when model diagnostics are poor***.)

1. Plot of resulting indices and estimates of variance	✓			
2. Table of model statistics (e.g. AIC criteria)	✓			

	Date Received	***Workshop Recommendation***	***Revision Deadline ******	***Author and Rapporteur Signatures***
First Submission		recommend for use		
Revision				

The revision deadline is negotiated by the author, the SEDAR coordinator and the CPUE rapporteur. The author ***DOES NOT*** *commit to any* ***LEGAL OBLIGATION*** *by agreeing to submit a manuscript before this deadline. The maximum penalty for failure to submit a revised document prior to the submission deadline is rejection of the CPUE series.*

Justification of Working Group Recommendation

Evaluation of Abundance Indices of Red snapper: Headboat at-sea observer 2010-2013, SEDAR41-DW14

DESCRIPTION OF THE DATA SOURCE

Working Group Comments:

1. Fishery Independent Indices

	Not Applicable	Absent	Incomplete	Complete
A. Describe the survey design (e.g. fixed sampling sites, random stratified sampling), location, seasons/months and years of sampling.	✓			
B. Describe sampling methodology (e.g. gear, vessel, soak time etc.)	✓			
C. Describe any changes in sampling methodology (e.g. gear, vessel, sample design etc.)	✓			
D. Describe the variables reported in the data set (e.g. location, time, temperature, catch, effort etc.).	✓			
E. What species or species assemblages are targeted by this survey (e.g. red snapper, reef fish, pelagic).	✓			
F. Describe the size/age range that the index applies to. Include supporting figures (e.g. size comp) if available.	✓			

2. Fishery Dependent Indices

	Not Applicable	Absent	Incomplete	Complete
A. Describe the data source and type of fishery (e.g. commercial handline, commercial longline, recreational hook and line etc.).				✓
B. Describe any changes to reporting requirements, variables reported, etc.				✓
C. Describe the variables reported in the data set (e.g. location, time, temperature, catch, effort etc.).				✓
D Describe the size/age range that the index applies to. Include supporting figures (e.g. size comp) if available.				✓

METHODS

1. Data Reduction and Exclusions

	Not Applicable	Absent	Incomplete	Complete
A. Describe any data exclusions (e.g. gears, fishing modes, sampling areas etc.). Report the number of records removed and justify removal.				✓
B. Describe data reduction techniques (if any) used to address targeting (e.g. Stephens and MacCall, 2004; gear configuration, species assemblage etc).				✓
C. Discuss procedures used to identify outliers. How many were identified? Were they excluded?				✓

2. Management Regulations (for FD Indices)

	Not Applicable	Absent	Incomplete	Complete
A. Provide (or cite) history of management regulations (e.g. bag limits, size limits, trip limits, closures etc.).				✓
B. Describe the effects (if any) of management regulations on CPUE				✓
C. Discuss methods used (if any) to minimize the effects of management measures on the CPUE series.				✓

Working Group Comments:

3. Describe Analysis Dataset (after exclusions and other treatments)

	Not Applicable	Absent	Incomplete	Complete
A. Provide tables and/or figures of number of observations by factors (including year, area, etc.) and interaction terms.				✓
B. Include tables and/or figures of number of positive observations by factors and interaction terms.				✓
C. Include tables and/or figures of the proportion positive observations by factors and interaction terms.				✓
D. Include tables and/or figures of average (unstandardized) CPUE by factors and interaction terms.				✓
E. Include annual maps of locations of survey sites (or fishing trips) and associated catch rates ***OR*** supply the raw data needed to construct these maps (Observation, Year, Latitude, Longitude (or statistical grid, area), Catch, Effort).				✓
F. Describe the effort variable and the units. If more than one effort variable is present in the dataset, justify selection.				✓
G. What are the units of catch (e.g. numbers or biomass, whole weight, gutted weight, kilograms, pounds).				✓

4. Model Standardization

	Not Applicable	Absent	Incomplete	Complete
A. Describe model structure (e.g. delta-lognormal)				✓
B. Describe construction of GLM components (e.g. forward selection from null etc.)				✓
C. Describe inclusion criteria for factors and interactions terms.				✓
D. Were YEAR*FACTOR interactions included in the model? If so, how (e.g. fixed effect, random effect)? Were random effects tested for significance using a likelihood ratio test?		✓		
E. Provide a table summarizing the construction of the GLM components.		✓		
F. Summarize model statistics of the mixed model formulation(s) (e.g. log likelihood, AIC, BIC etc.)				✓
G. Report convergence statistics.				✓

MODEL DIAGNOSTICS

Comment: Other model structures are possible and acceptable. Please provide appropriate diagnostics to the CPUE indices working group.

	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:
1. Binomial Component					
A. Include plots of the chi-square residuals by factor.				✓	
B. Include plots of predicted and observed proportion of positive trips by year and factor (e.g. year*area)				✓	
C. Report overdispersion parameter and other fit statistics (e.g. chi-square / degrees of freedom).				✓	
2. Lognormal/Gamma Component					
A. Include histogram of log(CPUE) or a histogram of the residuals of the model on CPUE. Overlay the expected distribution.				✓	
B. Include plots describing error distribution (e.g. Studentized residuals vs. linear predictor.				✓	
C. Include QQ-plot – (e.g. Student deviance residuals vs. theoretical quantiles), Overlay expected distribution.				✓

Revision				

The revision deadline is negotiated by the author, the SEDAR coordinator and the CPUE rapporteur. The author ***DOES NOT*** *commit to any* ***LEGAL OBLIGATION*** *by agreeing to submit a manuscript before this deadline. The maximum penalty for failure to submit a revised document prior to the submission deadline is rejection of the CPUE series.*

Justification of Working Group Recommendation

Due to the limited geographic scope of the data set the working group decided not to use the data set for the stock assessment. However, the working group did use the data set to corroborate the South Carolina head-boat data being used.

Evaluation of Abundance Indices: MRFSS/MRIP (Working Paper # NA)

DESCRIPTION OF THE DATA SOURCE

	Not Applicable	Absent	Incomplete	Complete
1. Fishery Independent Indices				
A. Describe the survey design (e.g. fixed sampling sites, random stratified sampling), location, seasons/months and years of sampling.	✓

First Submission	1 Aug 2014	Not recommended		
Revision				

The revision deadline is negotiated by the author, the SEDAR coordinator and the CPUE rapporteur. The author ***DOES NOT*** *commit to any* ***LEGAL OBLIGATION*** *by agreeing to submit a manuscript before this deadline. The maximum penalty for failure to submit a revised document prior to the submission deadline is rejection of the CPUE series.*

Justification of Working Group Recommendation

- Nominal index only, not standardized
- Fishery dependent (i.e., potentially affected by regulations, targeting, hyperdepletion, hyperstability)
- Catchability may vary over time or with abundance
- Potential bias in trips intercepted
- High variability
- Effective effort is difficult to identify

Evaluation of Abundance Indices:
SERFS Chevron Traps Gray Triggerfish (Working Paper #05)

DESCRIPTION OF THE DATA SOURCE

1. Fishery Independent Indices

	Not Applicable	Absent	Incomplete	Complete
A. Describe the survey design (e.g. fixed sampling sites, random stratified sampling), location, seasons/months and years of sampling.				✓
B. Describe sampling methodology (e.g. gear, vessel, soak time etc.)				✓
C. Describe any changes in sampling methodology (e.g. gear, vessel, sample design etc.)				✓
D. Describe the variables reported in the data set (e.g. location, time, temperature, catch, effort etc.).				✓
E. What species or species assemblages are targeted by this survey (e.g. red snapper, reef fish, pelagic).				✓
F. Describe the size/age range that the index applies to. Include supporting figures (e.g. size comp) if available.				✓

2. Fishery Dependent Indices

	Not Applicable	Absent	Incomplete	Complete
A. Describe the data source and type of fishery (e.g. commercial handline, commercial longline, recreational hook and line etc.).				
B. Describe any changes to reporting requirements, variables reported, etc.				
C. Describe the variables reported in the data set (e.g. location, time, temperature, catch, effort etc.).				
D Describe the size/age range that the index applies to. Include supporting figures (e.g. size comp) if available.				

METHODS

1. Data Reduction and Exclusions

	Not Applicable	Absent	Incomplete	Complete
A. Describe any data exclusions (e.g. gears, fishing modes, sampling areas etc.). Report the number of records removed and justify removal.				✓
B. Describe data reduction techniques (if any) used to address targeting (e.g. Stephens and MacCall, 2004; gear configuration, species assemblage etc).	✓			
C. Discuss procedures used to identify outliers. How many were identified? Were they excluded?	✓			

Working Group Comments:

Full time series covered the center of distribution of Gray Triggerfish and had sufficient percent positives for index development.

2. Management Regulations (for FD Indices)

	Not Applicable	Absent	Incomplete	Complete
A. Provide (or cite) history of management regulations (e.g. bag limits, size limits, trip limits, closures etc.).				
B. Describe the effects (if any) of management regulations on CPUE				
C. Discuss methods used (if any) to minimize the effects of management measures on the CPUE series.				

3. Describe Analysis Dataset (after exclusions and other treatments)

	Not Applicable	Absent	Incomplete	Complete
A. Provide tables and/or figures of number of observations by factors (including year, area, etc.) and interaction terms.				✓
B. Include tables and/or figures of number of positive observations by factors and interaction terms.				✓
C. Include tables and/or figures of the proportion positive observations by factors and interaction terms.				✓
D. Include tables and/or figures of average (unstandardized) CPUE by factors and interaction terms.				✓
E. Include annual maps of locations of survey sites (or fishing trips) and associated catch rates ***OR*** supply the raw data needed to construct these maps (Observation, Year, Latitude, Longitude (or statistical grid, area), Catch, Effort).				✓
F. Describe the effort variable and the units. If more than one effort variable is present in the dataset, justify selection.				✓
G. What are the units of catch (e.g. numbers or biomass, whole weight, gutted weight, kilograms, pounds).				✓

4. Model Standardization

	Not Applicable	Absent	Incomplete	Complete
A. Describe model structure (e.g. delta-lognormal)				✓
B. Describe construction of GLM components (e.g. forward selection from null etc.)				✓
C. Describe inclusion criteria for factors and interactions terms.				✓
D. Were YEAR*FACTOR interactions included in the model? If so, how (e.g. fixed effect, random effect)? Were random effects tested for significance using a likelihood ratio test?		✓		
E. Provide a table summarizing the construction of the GLM components.				✓
F. Summarize model statistics of the mixed model formulation(s) (e.g. log likelihood, AIC, BIC etc.)				✓
G. Report convergence statistics.				✓

Working Group Comments:

Initial model was a zero-inflated negative binomial model using polynomials to describe the effects of variables on catch rates. We investigated reducing the highest order that the polynomials could take and also considered including all lower order polynomials when a high order was selected by Bayesian Information Criterion. Since this approach has not been fully peer-reviewed, the decision was made to bin covariates based on preliminary generalized additive model fits. Inclusion of covariates in the sub-models was done by forward selection with Akaike's Information Criterion.

MODEL DIAGNOSTICS

Comment: Other model structures are possible and acceptable. Please provide appropriate diagnostics to the CPUE indices working group.

1. Binomial Component

Item	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:
A. Include plots of the chi-square residuals by factor.	✓				
B. Include plots of predicted and observed proportion of positive trips by year and factor (e.g. year*area)				✓	
C. Report overdispersion parameter and other fit statistics (e.g. chi-square / degrees of freedom).				✓	

2. Lognormal/Gamma Component

Item	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:
A. Include histogram of log(CPUE) or a histogram of the residuals of the model on CPUE. Overlay the expected distribution.	✓				
B. Include plots describing error distribution (e.g. Studentized residuals vs. linear predictor.	✓				
C. Include QQ-plot – (e.g. Student deviance residuals vs. theoretical quantiles), Overlay expected distribution.	✓				
D. Include diagnostic plot for variance function (e.g. square root of std residuals vs. fitted values). Overlay expected distribution.	✓				
E. Include diagnostic plot for link function (e.g. linear response variable vs. linear predictor). Overlay expected distribution.	✓				
F. Include plots of the residuals by factor	✓				

3. Poisson Component

Item	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:
A. Report overdispersion parameter and other fit statistics (e.g. chi-square / degrees of freedom).				✓	
B. Include plots describing error distribution (e.g. Studentized residuals vs. linear predictor.				✓	
C. Include QQ-plot – (e.g. Student deviance residuals vs. theoretical quantiles), Overlay expected distribution.				✓	
D. Include diagnostic plot for variance function (e.g. square root of std residuals vs. fitted values). Overlay expected distribution.				✓	
E. Include diagnostic plot for link function (e.g. linear response variable vs. linear predictor). Overlay expected distribution.	✓				***The feasibility of this diagnostic is still under review.***

4. Zero-inflated model

Item	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:
A. Include ROC curve to quantify goodness of fit.		✓			
B. Include plots describing error distribution (e.g. Studentized residuals vs. linear predictor).				✓	
C. Include QQ-plot (e.g. Student dev. residuals vs. theoretical quantiles), Overlay expected distribution.				✓	

MODEL DIAGNOSTICS (CONT.)

	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:

D. Include diagnostic plot for variance function (e.g. square root of std residuals vs. fitted values). Overlay expected distribution.				✓
E. Include diagnostic plot for link function (e.g. linear response variable vs. linear predictor). Overlay expected distribution.				✓

MODEL RESULTS

A. Tables of Nominal CPUE, Standardized CPUE, Observations, Positive Observations, Proportion Positive Observations and Coefficients of Variation (CVs). Other statistics may also be appropriate to report				✓
B. Figure of Nominal and Standardized Indices with measure of variance (i.e. CVs).				✓

IF MULTIPLE MODEL STRUCTURES WERE CONSIDERED:

(***Note: this is always recommended but required when model diagnostics are poor***.)

1. Plot of resulting indices and estimates of variance	✓			
2. Table of model statistics (e.g. AIC criteria)	✓

Justification of Working Group Recommendation

The SERFS chevron trap index represents the longest time series of fishery-independent data available for Gray Triggerfish in the region, beginning in 1990. The survey exhibited ample geographical coverage throughout this time series and there was little concern that the survey missed significant areas of the range of Gray Triggerfish in the region. Being one of the most abundant species captured in the chevron trap survey, there is ample supporting biological data (e.g. age/length comps) that can be used to inform the selectivity of the gear. Although the sampling distribution of the survey with regards to specific covariates (e.g. bottom temperature, depth, latitude, etc.) varied from year to year, the zero-inflation standardization approach effectively removes the effects of this variability from relative abundance trends. Finally, being a fishery-independent survey, standardized sampling techniques have been used and the survey has been immune to regulation changes. These observations generally make relative abundance trends suggested by fishery-independent surveys superior to parallel fishery-dependent abundance trends, especially as stricter management regulations are placed on the fishery.

Working Group Comments:

DESCRIPTION OF THE DATA SOURCE

1. Fishery Independent Indices

	Not Applicable	Absent	Incomplete	Complete
A. Describe the survey design (e.g. fixed sampling sites, random stratified sampling), location, seasons/months and years of sampling.	✓			
B. Describe sampling methodology (e.g. gear, vessel, soak time etc.)	✓			
C. Describe any changes in sampling methodology (e.g. gear, vessel, sample design etc.)	✓			
D. Describe the variables reported in the data set (e.g. location, time, temperature, catch, effort etc.).	✓			
E. What species or species assemblages are targeted by this survey (e.g. red snapper, reef fish, pelagic).	✓			
F. Describe the size/age range that the index applies to. Include supporting figures (e.g. size comp) if available.	✓			

2. Fishery Dependent Indices

	Not Applicable	Absent	Incomplete	Complete
A. Describe the data source and type of fishery (e.g. commercial handline, commercial longline, recreational hook and line etc.).				✓
B. Describe any changes to reporting requirements, variables reported, etc.				✓
C. Describe the variables reported in the data set (e.g. location, time, temperature, catch, effort etc.).				✓
D Describe the size/age range that the index applies to. Include supporting figures (e.g. size comp) if available.				✓

METHODS

1. Data Reduction and Exclusions

	Not Applicable	Absent	Incomplete	Complete
A. Describe any data exclusions (e.g. gears, fishing modes, sampling areas etc.). Report the number of records removed and justify removal.				✓
B. Describe data reduction techniques (if any) used to address targeting (e.g. Stephens and MacCall, 2004; gear configuration, species assemblage etc).				✓
C. Discuss procedures used to identify outliers. How many were identified? Were they excluded?				✓

Working Group Comments:

2. Management Regulations (for FD Indices)

	Not Applicable	Absent	Incomplete	Complete
A. Provide (or cite) history of management regulations (e.g. bag limits, size limits, trip limits, closures etc.).				✓
B. Describe the effects (if any) of management regulations on CPUE				✓
C. Discuss methods used (if any) to minimize the effects of management measures on the CPUE series.				✓

3. Describe Analysis Dataset (after exclusions and other treatments)

	Not Applicable	Absent	Incomplete	Complete
A. Provide tables and/or figures of number of observations by factors (including year, area, etc.) and interaction terms.				✓
B. Include tables and/or figures of number of positive observations by factors and interaction terms.				✓
C. Include tables and/or figures of the proportion positive observations by factors and interaction terms.				✓
D. Include tables and/or figures of average (unstandardized) CPUE by factors and interaction terms.				✓
E. Include annual maps of locations of survey sites (or fishing trips) and associated catch rates ***OR*** supply the raw data needed to construct these maps (Observation, Year, Latitude, Longitude (or statistical grid, area), Catch, Effort).				✓
F. Describe the effort variable and the units. If more than one effort variable is present in the dataset, justify selection.				✓
G. What are the units of catch (e.g. numbers or biomass, whole weight, gutted weight, kilograms, pounds).				✓

4. Model Standardization

	Not Applicable	Absent	Incomplete	Complete
A. Describe model structure (e.g. delta-lognormal)				✓
B. Describe construction of GLM components (e.g. forward selection from null etc.)				✓
C. Describe inclusion criteria for factors and interactions terms.				✓
D. Were YEAR*FACTOR interactions included in the model? If so, how (e.g. fixed effect, random effect)? Were random effects tested for significance using a likelihood ratio test?	✓			
E. Provide a table summarizing the construction of the GLM components.				✓
F. Summarize model statistics of the mixed model formulation(s) (e.g. log likelihood, AIC, BIC etc.)				✓
G. Report convergence statistics.	✓			

MODEL DIAGNOSTICS

Comment: Other model structures are possible and acceptable. Please provide appropriate diagnostics to the CPUE indices working group.

	Not Applicable	Absent	Incomplete	Complete	Working Group Comments:
1. Binomial Component

Southeast Fisheries Science Center
101 Pivers Island Road, Beaufort, NC 28516

Abstract

Standardized video counts of red snapper were generated from video cameras deployed by the Southeast Reef Fish Survey from 2010 – 2014. Samples between Cape Hatteras, North Carolina, and St. Lucie Inlet, Florida, were included in the analyses. The index is meant to describe population trends for red snapper in the region. To obtain an index of video counts, a zero-inflated negative binomial model was used to standardize video count data by a variety of predictor variables, differences across years in sampling effort (with respect to the predictor variables investigated) were accounted for, and a camera calibration calculation was used to calibrate counts of red snapper between two different cameras that were used during monitoring.

Background

The Marine Resources Monitoring, Assessment, and Prediction (MARMAP) program has conducted most of the historical fishery-independent sampling in the U.S. South Atlantic (North Carolina to Florida). MARMAP has used a variety of gears over time, but chevron traps are one of the primary gears used to monitor reef fish species and have been deployed since the late 1980s. In 2009, MARMAP began receiving additional funding to monitor reef fish from the SEAMAP-SA program. In 2010, the SouthEast Fishery-Independent Survey (SEFIS) was initiated by NMFS to work collaboratively with MARMAP/SEAMAP-SA using identical methods to collect additional fishery-independent samples in the region. Together, these three programs are now called the Southeast Reef Fish Survey (SERFS).

The SERFS survey currently samples between Cape Hatteras, North Carolina, and St. Lucie Inlet, Florida. This survey targets hardbottom habitats between approximately 15 and 100 meters deep. SERFS began affixing high-definition video cameras to chevron traps on a limited basis in 2010 (Georgia and Florida only), but since 2011 has attached cameras to all chevron traps as part of their normal monitoring efforts. All five years of data are included here, as recommended by Bacheler and Carmichael (2014; SEDAR41-RD23).

Hard-bottom sampling stations were selected for sampling in one of three ways. First, most sites were randomly selected from the SERFS sampling frame that consisted of approximately 3,000 sampling stations on or very near hard bottom habitat. Second, some stations in the sampling frame were sampled opportunistically even though they were not randomly selected for sampling in a given year. Third, new hard-bottom stations were added during the study period through the use of information from various sources including fishermen, charts, and historical surveys. These new locations were investigated using a vessel echosounder or drop cameras and sampled if hard bottom was detected. Only those new stations landing on hardbottom habitat were included in the analyses. All sampling for this study occurred during daylight hours between April and October on the R/V *Savannah*, R/V *Palmetto*, NOAA Ship *Nancy Foster*, or the NOAA Ship *Pisces* using identical methodologies as described below.

Samples were intentionally spread out spatially on each cruise (see Figure 2 in Bacheler and Carmichael 2014).

Chevron fish traps with attached video cameras were deployed at each station sampled in our study (Figure 1). Chevron traps were constructed from plastic-coated, galvanized 2-mm diameter wire (mesh size = 3.4 cm2) and measured 1.7 m × 1.5 m × 0.6 m, with a total volume of 0.91 m^3. Trap mouth openings were shaped like a teardrop and measured approximately 18 cm wide and 45 cm high. Each trap was baited with 24 menhaden (*Brevoortia* spp.). Traps were typically deployed in groups of six, and each trap in a set was deployed at least 200 m from all other traps to provide some measure of independence between traps. A soak time of 90 minutes was targeted for each trap deployed.

GoPro Hero (2010) or Canon Vixia HFS-200 high-definition video cameras in Gates underwater housings (2011 – 2014) were attached to chevron traps. A second high-definition GoPro Hero video or Nikon Coolpix S210/S220 still camera was attached over the nose of most traps in an underwater housing, and was used to quantify microhabitat features in the opposite direction. Cameras were turned on and set to record before traps were deployed, and were turned off after trap retrieval. Trap-video samples were excluded from our analysis if videos were unreadable for any reason (e.g., too dark, camera out of focus, files corrupt) or the traps did not fish properly (e.g., bouncing or dragging due to waves or current, trap mouth was obstructed).

For each fish trap deployed with a camera, video reading time was limited to an interval of 20 total minutes, commencing 10 minutes after the trap landed on the bottom to allow time for the trap to settle. One-second snapshots were read every 30 seconds for the 20-minute time interval, totaling 41 snapshots read for each video sample. SERFS employs video readers to count fish on videos. There was an extensive training period for each video reader, and all videos from new readers are re-read by fish video reading experts until they are very high quality. After that point, 10% or 15 videos (whichever is larger) are re-read annually by fish video reading experts. Video readers also quantify microhabitat features (percent of bottom that is hardbottom, maximum substrate relief, substrate size, coverage of attached biota, predominant biotic type, and maximum biotic height), in order to standardize for habitat types sampled over time. Water clarity was also scored for each sample as poor, fair, or good. If bottom substrate could not be seen, then water clarity was considered poor, and if bottom habitat could be seen but the horizon was not visible, water clarity was considered fair. If the horizon could be seen in the distance, water clarity was considered to be good. Including water clarity in index models allowed for a standardization of fish counts based on variable water clarities over time and across the study area. A CTD cast was also taken for each simultaneously deployed group of traps, within 2 m of the bottom, and water temperature from these CTD casts was available for standardization models.

Camera calibration

GoPro cameras were used for fish counts in 2010, while Canon cameras were used in 2011 – 2014. To calibrate fish counts between these two cameras, side-by-side Canon-GoPro videos were taken during the summer of 2013 and read for red snapper. Additionally, a lab experiment was conducted to quantify differences in field of view between the two cameras. Results indicated the Canon cameras saw 51% of the field of video of GoPro cameras, but the quality of GoPro videos was perhaps slightly lower than that of Canon videos. A total of 15 calibration videos were read that included red snapper. Based on a regression analysis applied to the calibration video results, there were 53% (1 minus the regression slope parameter) fewer red snapper seen on Canon cameras compared to GoPro cameras, which is almost exactly what one would predict based on the reduction of field of view on Canon cameras compared to GoPro cameras (see Figures 7-9 in Bacheler and Carmichael 2014). Therefore, it was recommended that the 2010 relative abundance data point be reduced by 53% to account for differences in viewing areas among the cameras.

Data and Treatment

Data subsetting

Overall, there were 4923 survey videos with *L. campechanus* data during the 5 year sampling period (2010-2014). We removed data points in which the survey video was considered unreadable by an analyst, or if the survey point was located at a depth greater than 100 meters, due to very limited samples in waters deeper than 100 m. Additionally, survey video for which less than 41 video frames were read was removed from the full data set. Standardizing the number of readable frames was essential due to our use of *SumCount* as a response variable (see below). We also identified any video sample in which corresponding predictor variables were missing and removed them from the final data set.

Of the total 4923 video samples considered for inclusion in our modeling analysis, 514 were removed based on the data subsetting procedure described above, leaving 4409 samples in the *L. campechanus* analyses for 2010 – 2014 (Figure 2).

Standardization

Response Variable

For the video index of *L. campechanus*, we modeled the *SumCount*, or total number of red snapper observed across all readable video frames for each sample. There are a number of viable candidate response variables applicable for the estimation of abundance from video surveys, the relative merits of which were discussed at length during the video index development workshop (Bacheler and Carmichael 2014). The panel recommended the use of *SumCount* as a response variable suitable for a zero-inflated modeling approach (we employed a zero-inflated model in our analysis). The use of *SumCount* requires that an equal number of video frames be considered for each data point considered in the model estimation. As a result, only samples with 41 readable frames (the maximum number) were included in our analysis (~99% of all samples).

Explanatory Variables

We considered 9 explanatory variables in our model analysis, which included year, season, depth, latitude, water temperature, turbidity, and current direction, all of which were recommended during the video index development workshop (Bacheler and Carmichael 2014). The workshop panel also suggested including habitat variables, for which we included biotic density and substrate composition.

YEAR (*y*) – Year was included because standardized catch rates by year are the objective of this analysis. We modeled data from 2010-2014, data from 2010 was spatially limited due to reduced video deployment during this initial year. Due to the high spatial overlap between the sampled region and the spatial occupancy of *L. campechanus,* data from 2010 were included in this analysis. This decision was supported by recommendations from the video index development panel (Bacheler and Carmichael 2014). Annual summaries of data points considered are outlined in Table 2.

SEASON (*t*) – a temporal parameter based on the Julian day the sample was collected (Figure 3). The season parameter was treated as an octile factor based on the recommendations of the video index development workshop.

DEPTH (*d*) – Water depth is a key component effecting the distribution of *L. campechanus*, we considered all data points in waters shallower than 100m. Data points were excluded from deeper waters generally due to limited samples and rare occurrence (Figure 3). Annual depth distribution for survey data are outlined in Table 2. The depth parameter was treated as a quantile factor based on the recommendations of the video index development workshop.

LATITUDE (*lat*) – The latitude of video samples were included as a spatial parameter in the model (Figure 3). Based on recommendations made by the video index development workshop, latitude was treated as a factor in the model and divided into 8 levels based on octiles.

TEMPERATURE (*temp*) – Bottom water temperature was collected from each group of traps and incorporated as a predictor variable. Bottom water temperature ranged from 12 – 29 degrees Celsius (Figure 3). For the standardization model temperature was treated as a factor with 4 levels based on quantiles.

TURBIDITY (*wc*) – Due to the effect of turbidity on both species distributions and on the ability of an analyst to process video survey samples, we included water clarity (*wc*) in our standardization model. Turbidity information was recorded during video analysis based on the ability of an analyst to perceive the horizon and surrounding habitat and was scored at 3 levels (0 – Horizon visible, 1 – Horizon not visible but habitat is still visible, 2 – Both horizon and habitat are not visible).

CURRENT DIRECTION (*cd*) – A categorical variable estimating current direction based on the video point of view. Current direction data was included to better account for variability in detection due to the current moving fish away or towards the camera. This variable is collected during video processing and scored natively as a 4 level categorical variable (Towards, Away, Left to Right, and Right to Left). It was incorporated into the model as “Towards”, “Away”, and “Sideways”.

BIOTIC DENSITY (*bd*) – An estimation of the percent cover of attached biota visible during any video. The estimation is made based on percentage cover and ranged from 0 – 98%. For our analysis, *bd* was treated as a categorical variable with 4 levels: none (0%), low (1-9%), moderate (10-39%), and high (>40%).

SUBSTRATE COMPOSITION (*sc*) – An estimate of the total percent of substrate that is consolidated sediments. Consolidated sediment is defined as rocks or boulders the size of a fist or larger, or hard pavement habitats. For our analysis, substrate composition was treated as a categorical variable with 4 levels: none (0%), low (1-9%), moderate (10-39%), and high (>40%).

Zero-Inflated Model

The recommendation of the video index workshop was to apply a zero-inflated modeling approach to develop a fishery-independent video index for *L. campechanus* in the South Atlantic. Zero-inflated models are valuable tools for modeling distributions that do not fit a standard error distribution due to an excessive number of zeroes. These data distributions are often referred to as “zero-inflated” and are a common condition of count based ecological data. Zero inflation is considered a special case of over dispersion that is not readily addressed using traditional transformation procedures (Hall 2000). Due to the high proportion of zero counts found in our data set (Figure 4), we used a zero inflated mixed model approach that models the occurrence of zero values using two different processes, a binomial process and a count process (Zuur et al. 2009). The benefit and utility of this approach was discussed at length during the video index workshop (Bacheler and Carmichael 2014) and was the final recommendation of the panel.

Initially, both a zero-inflated Poisson (ZIP) and a zero-inflated negative binomial (ZINB) formulation were considered and each model included all nine of the predictor variables.

(1) $$SumCount = y + wc + cd + sc + bd + d + t + lat + temp \,|\, y + wc + cd + sc + bd + d + t + lat + temp$$

We compared the variance structure of each model formulation using a likelihood ratio test (Zuur et al 2009), to determine the most appropriate model formulation for the development of a video index for red snapper. A likelihood ratio test (Table 1) showed strong support for application of a ZINB formulation, as did a comparison of model fit for both the ZIP and ZINB formulations (Figure 5), which resulted in the decision to use a ZINB approach. The results concurred with expectations based on the level of zero-inflation and over dispersion within the original red snapper data and with the recommendations of the video index development panel (Bacheler and Carmichael 2014).

A backwards step-wise model selection procedure was used to exclude unnecessary model parameters from the full model (1) formulation. The optimum red snapper model formulation (2) was determined using a combination of AIC and likelihood ratio tests (Zuur et al. 2009). Water clarity (*wc*) was excluded from the negative binomial component of the model and both water clarity (*wc*) and season (*t*) were excluded from the binomial component of the model (Table 3).

(2) $$SumCount = y + cd + sc + bd + d + t + lat + temp \,|\, y + cd + sc + bd + d + lat + temp$$

Model diagnostics showed no discernable pattern of association between Pearson’s residuals and fitted values or the fitted values and the original data (Figure 6). Additionally, an examination of model residuals for the spatio-temporal (Figure 7) and environmental model parameters (Figure 8) showed no clear patterns of association, indicating correspondence to underlying model assumptions (Zuur et al. 2009). Finally, a comparison of predicted values against the original data distribution (Figure 9) shows how our model fits the original data.

All data manipulation and analysis was conducted using R version 3.1.2 (R Core Team 2014). Modeling was executed using the *zeroinfl* function in the *pscl* package (Jackman 2008), available from the Comprehensive R Archive Network (CRAN).

Results

The relative nominal CPUE for *L. campechanus* was 2.609 in 2010, 0.433 in 2011, 0.567 in 2012, 0.639 in 2013, and 0.752 in 2014 (Table 4). After standardizing the original data set by each of the predictor variables included in the final model, we obtained a CPUE estimate of 2.913 in 2010, 0.379 in 2011, 0.503 in 2012, 0.537 in 2013, and 0.880 in 2014. When also accounting for unequal sampling across years (with respect to the predictor variables included in the final model), we obtained a CPUE estimate of 2.016 in 2010, 0.467 in 2011, 0.831 in 2012, 0.626 in 2013, and 1.060 in 2014. When we applied the camera calibration calculation for 2010 to these standardized annual values, we obtained a CPUE estimate of 1.206 in 2010, 0.592 in 2011, 1.056 in 2012, 0.798 in 2013, and 1.348 in 2014 (Table 4).

Only the 2011 relative nominal value falls within the 2.5% and 97.5% confidence intervals of the standardized index (Figure 10). The nominal value for 2010 was considerably higher than the standardized index value for 2010 while the nominal values for 2011, 2012, 2013, and 2014 were all considerably lower than their standardized index values, which was expected due to the integration of the camera calibration calculation into the standardized index. The standardized video index indicates that while there is a considerable amount of fluctuation in relative annual abundance from year to year, red snapper relative abundance has been generally stable across the survey years (Figure 10). However, due to the short temporal extent of this index (5 years), limited inferences can be made concerning long term patterns of *L. campechanus* relative abundance.

SEDAR41-DW51
MARMAP Technical Report # 2015-009

This work represents partial fulfillment of the Marine Resources Monitoring, Assessment, and Prediction (MARMAP) program contract (NA11NMF4540174) sponsored by the National Marine Fisheries Service (Southeast Fisheries Science Center) and the South Carolina Department of Natural Resources.

Background

Though widely used for a host of other species, researchers involved in previous assessments of Red Snapper in the South Atlantic region have not used the fishery-independent chevron trap relative abundance index. A primary reason for this is that Red Snapper catches (and number of positive traps) were generally low in the MARMAP (Marine Resources Monitoring, Assessment & Prediction Program) chevron trap reef fish survey prior to 2010. SEDAR 24 panelists cited two primary reasons for the exclusion of the survey from the final assessment model, 1) the large spatial variability in abundance and sampling locations and 2) the low catches and high variability in the data. At the time, panelists did not know why catches of Red Snapper in the chevron trap survey were so low. Three (among others) possible explanations for the low catches were 1) because the chevron trap was a poor gear to index the relative abundance of Red Snapper, 2) the traditional areas sampled by the chevron trap index were not in core Red Snapper habitat, and hence may not track overall regional abundance, and 3) that the low catches in the chevron trap survey were truly indicative of regional Red Snapper abundance, with abundances being extremely low in totality throughout the survey area. The final assessment model derived from SEDAR 24, based on a host of other data sources, concluded that indeed Red Snapper regional abundance was at low levels throughout the history of the traditional MARMAP chevron trap survey (1990-2009; Figure 1).

Since (or in some cases during the terminal year of) SEDAR 24 there have been a host of management changes aimed at increasing Red Snapper abundance throughout the region. Most notable of these was the prohibition of harvest and possession of Red Snapper that began in early 2010 that continues today, with the exception of some very limited harvest in 2012-2014 as part of the Red Snapper “mini-seasons”.

There have also been some significant changes made to the SERFS chevron trap survey since SEDAR 24 due to the availability of additional fishery-independent funds to study reef fish in the region. The first new funding source, the Reef Fish Complement project funded by the Southeast Area Monitoring and Assessment Program, South Atlantic region (SEAMAP-SA), initially allocated funds in 2008, with a first field season in 2009. The second new funding source, the creation of the Southeast Fishery Independent Survey (SEFIS), had a first field season in 2010. This infusion of resources into the traditional MARMAP chevron trap survey has allowed for a large expansion in the geographical coverage of the survey, particularly off Florida (Table 1, Figure 2 and Figure 3) and an increase in the annual sample size of the chevron trap survey. The combined efforts of MARMAP, SEAMAP-SA Reef Fish Complement, and SEFIS to conduct fishery-independent monitoring in the US South Atlantic region are now referred to as the Southeast Reef Fish Survey (SERFS).

Objective

This report presents a summary of an investigation to determine what the net effect of the changes in management regulations pertaining to Red Snapper (and other species in this mixed species fishery) and the changes in the SERFS chevron trap survey has on the utility of the SERFS chevron trap survey in the SEDAR 41 assessment model. Specifically, this report investigates two primary questions:

1) Does the recent increase in capture rate (and relative abundance) of Red Snapper in the survey reflect shifts in spatial sampling distribution of the survey or changes in relative abundance?
2) What does the increase in capture rate since 2010 mean for the utility of the historical (1990-2009) chevron trap data?
    a) Does the historical data accurately represent historical relative abundance in the region?

The investigation focuses on comparing relative abundance trends of Red Snapper derived from valid samples taken from known live-bottom and/or hard-bottom chevron trap stations identified prior to 2010 (MARMAP Universe) to relative abundance trends of Red Snapper derived from valid samples taken from all stations currently identified as part of the SERFS chevron trap universe of known live-bottom and/or hard-bottom habitats (SERFS Universe). Primarily, these two chevron trap universes differ in the number of known live-bottom and/or hard-bottom stations identified (Figure 4) and the geographic distribution of the identified stations (Table 1, Figure 2 and Figure 3; pay particular attention to the distribution in 2009 vs. 2014). As such, the MARMAP Universe dataset can be thought of as a subset of all available data from any given year, representing only data derived from traditional MARMAP chevron trap stations.

A secondary objective is to evaluate the performance of models modeling continuous covariates (e.g. depth or latitude) as polynomials vs. the traditional approach of binning continuous covariates into discrete bins and subsequently modeling them as discrete covariates in index standardization models.

Methods

Survey Design and Gear
(see Smart et al. 2015 for full description)

Sampling area
- Cape Hatteras, NC, to St. Lucie Inlet, Fl (Figure 5)
    - General expansion of geographic coverage through time
- Sampling depths range from 13 to 218 m
    - Generally less than 100 m

Sampling season
- May through September
    - Limited earlier and later sampling in some years

Survey Design
- Simple random sample survey design
    - Annually, randomly select stations from a chevron trap universe of confirmed live-bottom and/or hard-bottom habitat stations
    - No two stations are randomly selected that are closer than 200 m from each other
        - Minimum distance is typically closer to 400 m

- Traps deployed on suspected live-bottom and/or hard-bottom in a given year (reconnaissance) are evaluated based on catch and/or video or photographic evidence of bottom type for inclusion in the universe in subsequent years
  - If added to the known habitat universe, data from the reconnaissance deployment is included in CPUE analysis

Sampling Gear – Chevron Traps
(see Collins 1990 and MARMAP 2009 for descriptions that are more complete)

- Arrowhead shaped, with a total interior volume of 0.91 m^3
- Constructed of 35 x 35 mm square mesh plastic-coated wire with a single entrance funnel ("horse neck")
- Baited with a combination of whole or cut clupeids (*Brevoortia* or *Alosa* spp., family Clupeidae), with *Brevoortia* spp. most often used
  - Four whole clupeids on each of four stringers suspended within the trap
  - Approximately 8 clupeids placed loose in the trap
- Soak time of approximately 90 minutes

Oceanographic Data
- Hydrographic data collected via CTD during soaking of a "set" (typically 6 traps, but may be less) of chevron traps deployed at the same time
  - Bottom temperature (^{o}C) is defined as the temperature of the deepest recording within 5 m of the bottom

Data Filtering/Inclusion
Chevron trap data were limited to:
- Projects conducting monitoring efforts (project IDs: P05, T59, T60; data sources: MARMAP, SEAMAP-SA, SEFIS)
- Reef fish monitoring samples (Data source ≠ "Tag-MARMAP")
  - "Tag-MARMAP" denotes special historic MARMAP cruises that were used to tag various species of fish, with all species captured not being counted and measured
- Traps that fished properly (catch IDs: 0-2, 8, 9, 90-92)
- Traps on live-bottom and/or hard-bottom habitat (station types: Random, NonRandom, ReconConv, Null)
- Traps with soak times that were neither extremely short nor long which often indicates an issue with the deployment not captured elsewhere (included 45-150 minutes)
- For Red Snapper specifically, only the depths at which Red Snapper have ever been captured by any of the monitoring programs (included 15-75 m)
- Excluded any chevron trap samples missing covariate information

Index Model Structure
- Response variable – Catch/Trap
- Offset term – natural log of soak time ($\ln(soak\ time)$)

- Dependent variables
  - Year
  - Covariates
    - Depth, latitude (^oN), bottom temperature (^oC), and day of year
- Model structure – zero-inflated negative binomial GLM (ZINB)
  - Other model structures considered: Poisson GLM, negative binomial GLM, and zero-inflated Poisson GLM (ZIP)
    - ZINB favored over other model structures in all analyses
- Annual year effect coefficients of variation (CVs) computed using bootstrapping
- Software used
  - R (Version 3.1.0; R Development Core Team 2014)
  - Function zeroinfl in package *pscl* (Jackman 2011; Zeileis et al. 2008)
  - Function gam in package *mgcv* (wood 2011; Wood 2006; Wood 2004; Wood 2003; Wood 2000)

Models and Data

<u>Data</u>

- Time periods (see Figure 5 for annual geographic distribution of SERFS chevron trap sampling)
  - 1990-2014
    - The full SERFS chevron trap survey time-series over which a standardized approach to chevron trap sampling was used
  - 2010-2014
    - Restricted SERFS chevron trap survey time-series during which the annual percent positive rate in each year was greater than 5% and geographic coverage of sampling was increased off the coast of FL
    - Time period during which sampling effort in the region was greatly increased due to the addition of SEAMAP-SA Reef Fish Complement and SEFIS funds
- Data sets (see Table 2 for annual sample size, percent positive rate, and number of Red Snapper captured; see Table 3 for a comparison of several summary metrics comparing the two data sets)
  - Data set derived from stations present in the current SERFS chevron trap station universe of known live-bottom and/or hard-bottom habitats
    - SERFS Universe data set (see Figure 5 for annual geographic distribution of realized sampling from the SERFS Universe)
  - Data set derived from stations sampled annually that were present in the MARMAP chevron trap station universe of known live-bottom and/or hard bottom habitats at the beginning of the 2010 sampling season
    - MARMAP Universe data set (see Figure 6 for annual geographic distribution of realized sampling from the MARMAP Universe during the period 2010-2014)

(Note: there is no difference in annual geographic sampling distribution based on the two data sets during the period 1990-2009)

- Covariate treatment

- Polynomial treatment
  - The covariates were each modeled as polynomials in the ZINB standardization model (used function poly in package *stats* (R Core Team 2014); with option raw = TRUE)
    - For each covariate, coefficients were estimated for each raw polynomial from degree 1 to maximum polynomial order
  - Maximum allowed polynomial order for each covariate was based on preliminary generalized additive models (GAMs)
    - Used function gam in package *mgcv* (Wood 2011; Wood 2006; Wood 2004; Wood 2003; Wood 2000)
      - Used Restricted Maximum Likelihood (REML) estimation for smoothing parameter estimation
      - Investigated use of several different spline options (see gam function help in R for available options and descriptions)
        - Chose maximum polynomial order based on the effective degrees of freedom estimate (rounded to the nearest whole number) for the covariate in question using the spline type that provided the lowest REML estimate
    - Modeled Red Snapper abundance versus all covariates
      - Used to inform maximum polynomial order for the count sub-model of the ZIP and ZINB models
      - Used to inform maximum polynomial order for the Poisson GLM and negative binomial GLM models
    - Modeled Red Snapper presence/absence versus all covariates
      - Used to inform maximum polynomial order for the zero-inflation sub-model of the ZIP and ZINB models
  - Model selection based on Bayesian information criterion (BIC; Schwarz 1978) to increase the penalty associated with adding parameters to the model
    - ZIP and ZINB Models (2 step process, optimizing one sub-model during each step; needed because of computational demand)
      - Remove all covariates from the zero-inflation sub-model (i.e., intercept only zero-inflation sub-model) and optimize count sub-model for all covariates
      - Fixing count sub-model to the optimum values found during step 1, optimize the covariate structure of the zero-inflation sub-model
- Discrete treatment
  - Binned each covariate according to decisions made during the SEDAR 41 Data Workshop held in 2014 (Table 4)
  - Model selection based on BIC, optimizing both sub-models of ZIP and ZINB models simultaneously

Models

(see Figure 7 for model hierarchy)

Results

Model Structure, Stability and Performance
(see Table 5 for model structure of each of the best-fit models)

- BIC estimates of model pairs (same data set, different covariate treatment) indicate models using continuous covariates fit with polynomials provide better fit that discrete covariate models (Table 5)
- Despite containing more parameters (Table 5), models using continuous covariates fit with polynomials exhibit higher convergence rates and do a superior job fitting observed catch frequency distribution (Table 6)
- Models based on the SERFS Universe data set produced lower CV estimates than those based on the MARMAP Universe data set (Table 6 and Figure 8)
    - Driven by the larger sample size and higher percent positive rate of Red Snapper in SERFS Universe data set

Covariate Effects
(see Figure 9, Figure 10, and Figure 11)

- Given the same method of modeling covariates (polynomial vs. discrete), predicted covariate effects are similar across models
    - Continuous covariates modeled as polynomials
        - Day of Year – covariate is not retained when using the SERFS Universe data set and short time-series
            - Only very slight negative effect of day of year in the full time series SERFS Universe data set model
            - Models based on the MARMAP Universe data set predict a negative exponential effect of day of year on Red Snapper catch
                - Covariate effect is reduced in the full time-series model compared to the restricted time-series model
        - Depth – effect depends on what data set is used
            - SERFS Universe data set – dome shaped relationship of catch at depth, with maximum catch being at 30-50 m of depth
                - More non-linearity of this depth effect is apparent when using the full time-series
            - MARMAP Universe data set – still see a peak in catch at around 30-50 m of depth, though it also predicts high catch of Red Snapper at deep (> 60 m) depths
                - Peak at 30-50 m of depth is shifted deeper when the full time-series of data is used
                - Increase at deep depth is driven by low sample size at these depths to inform covariate effect
        - Latitude – predicted highest catch of Red Snapper at latitudes <30^{o}N, with smaller increases in catch at approximately 32^{o}N and >34^{o}N
            - Most models are remarkably similar in their predicted effect of latitude over the range 28-34.5^{o}N

            - MARMAP Universe data set models have less data informing covariate effect at extreme latitudes, thus predicted effect differs marginally at extremes when compared to models based on SERFS Universe
        - Temperature – models based on both data sets produce very similar predicted effects of temperature, regardless of survey start data
            - Catch of Red Snapper is predicted to increase exponentially as temperature increases through the range of temperatures observed
    - Discrete covariates
        - Day of Year – covariate is not retained in any of the final models
        - Depth – All models predict higher than average catches at 30-44 m depths
            - Predicted effect of depth on catch is smaller when using the MARMAP Universe data set
            - Similar to above, MARMAP Universe data set predicts above average catch rates of Red Snapper at deep (≥ 60 m) depths
        - Latitude – All models predict higher than average catch at <30°N, with lowest catches between 32.5 and 34°N
            - Predicted effect of latitude on catch is smaller when using the MARMAP Universe data set
        - Bottom temperature – covariate is only retained in the full time-series models
            - When retained, the predicted effect of bottom temperature differs depending on the data set used
                - SERFS Universe data set – generally increases over the range of temperatures observed
                - MARMAP Universe data set – catch peaks at temperatures of 15-26.9°C, decreasing at lower and higher temperatures
- Predicted effect of covariates are generally more coarse when modeling the covariates as discrete covariates than suggested when model covariates as continuous variables using polynomials
- Predicted covariate effects are generally more extreme (see y-axis scale of Figure 9) when covariates are modeled as polynomials instead of as discrete variables

2010 – 2014 Time Series Models

Initially, the goal was to focus on only the four relative abundance index models constructed using the data available from 2010-2014. By excluding the data from 1990-2009, one can focus on the impact that each individual data set (SERFS Universe vs. MARMAP Universe) had on the predicted relative abundance trends. This allows one to investigate whether the recent increase in capture rate (and relative abundance) of Red Snapper in the survey reflect shifts in spatial sampling distribution of the survey or changes in relative abundance? Under the null hypothesis of no change in the predicted relative abundance trend of Red Snapper as a function of data set, one would expect a significant positive correlation among indices, regardless of data set used. This indicates whether the traditional MARMAP chevron trap survey stations, as randomly sampled from 2010 to 2014, can adequately characterize the recent abundance trends of Red Snapper in the region, assuming the abundance trend observed using all the data (SERFS Universe) is the "true" abundance trend.

<u>Relative Abundance and Index Correlation</u>

(see Table 7 and Figure 12)

- Relative abundance trend is similar across all four models (generally increasing throughout the time series)
  - Exception is the model using the MARMAP Universe data set and treating covariates as discrete variables (exhibits least correlation with other models)
    - Indicates increasing trend in relative abundance from 2012-2013 while all other models suggest decreasing trend
    - Indicates higher terminal year relative abundance and lower relative abundance in 2012 compared to other models
- All models are correlated at >90% confidence level
  - Models using continuous covariates modeled as polynomials correlated at >95% confidence level
  - Model using SERFS Universe data set and discrete covariates is correlated with the two models modeling the continuous covariates using polynomials at >95% confidence level

<u>Summary</u>

- Indices produce similar relative abundance trends
  - Regardless of data set used
    - Suggest traditional MARMAP stations (representing traditional MARMAP annual spatial distribution of samples) adequately characterize changes in relative abundance of Red Snapper throughout the region
  - Regardless of covariate treatment methodology in standardization model
- Continuous covariate models…
  - More stable despite estimating more parameters
  - Better capture "catch patterns" of Red Snapper in the region
- Models using the SERFS Universe data set produce lower coefficient of variation estimates (Figure 8)

1990 – 2014 Time Series Models

Now the goal is to focus on comparing the short time-series models presented above to relative abundance indices of a similar structure based on the full chevron trap survey time-series (1990-2014; Figure 7) to answer the question does the historical data accurately represent historical relative abundance in the region. If one concludes, based on the above analysis, that the traditional MARMAP chevron trap stations identified prior to 2010 do an adequate job characterizing regional Red Snapper abundance during the period 2010-2014, one can then assume that they would adequately characterize Red Snapper relative abundance in the region over the period 1990-2009. Given this assumption, under the null hypothesis that the historical data does accurately characterize regional Red Snapper abundance, we would expect a high degree of positive correlation in the predicted abundance trends of the full time-series models to the short time-series models. To simplify interpretation, in the correlation analysis I will only compare the four long time-series models presented here to the two "best" short time-series models, those being the two using the SERFS Universe data set (differ in covariate treatment only).

<u>Relative Abundance and Index Correlation</u>

(see Table 8, Figure 13 and Figure 14)

- Relative abundance trend is similar across all models considered
    - All models suggest increasing trend in relative abundance from 2010-2014
        - Excellent agreement in relative abundance trends among models using same data set and covariate treatment approach, but different start years (Figure 14)
    - All full time-series models exhibit good agreement regarding relative abundance over the period 1990-2009
- All models compared are correlated at >90% confidence level (Table 8)
    - All full time-series models are correlated at >99.9% confidence level
    - Most (7 of 8) full time-series models are correlated with the SERFS Universe data restricted time-series models at >95% confidence level
        - Exception is the full time-series model using MARMAP Universe data set and discrete covariates is correlated with the restricted time-series model using the SERFS Universe data set and discrete covariates at only >90% confidence level

<u>Summary</u>

- High degree of positive correlation among all models investigated
    - All models developed using the current station universe (SERFS Universe data set), and hence most data to inform covariate effects, correlated at >95% confidence level
        - Regardless of covariate treatment
        - Suggest they are modeling the same "signal," after accounting for covariate effects, regarding Red Snapper relative abundance
            - Standardization model appears to be working appropriately and as expected by removing the effect of annual variability in sampling distribution with regards to important environmental variables from observed relative abundance
- Indices produce similar relative abundance trends
    - Regardless of data set used
        - Suggest traditional MARMAP chevron trap stations (representing traditional MARMAP annual spatial distribution of samples) adequately characterize changes in relative abundance of Red Snapper throughout the region
    - Regardless of covariate treatment methodology in standardization model
- Continuous covariate models…
    - More stable despite estimating more parameters
    - Better capture "catch patterns" of Red Snapper in the region
- Model stability greater for full time-series models compared to same configuration restricted time-series models
    - Continuous covariate models are more stable despite estimating more parameters
- Continuous covariate models better capture "catch patterns" of Red Snapper in the region
    - Full time-series models do better job than other models
- Time series average CV estimates for full time-series models are larger than restricted time-series counterparts
    - Product of smaller sample sizes in earlier years

   - Produce similar CV estimates as their restricted time-series counterparts during the period 2010-2014
- Within model structure (covariates modeled as polynomials vs. discrete variables), CV estimates are similar when using full vs. restricted time-series

Comparison to SEDAR 24 Indices

(see Figure 15)

- All indices seem to be in general agreement regarding the overall time-series pattern
   - Decreasing relative abundance pattern from late 1970s through early- and mid-1990s
   - Low relative abundance through late 1990s
   - Brief increase in relative abundance in early 2000s prior to another decrease in relative abundance
   - Consistent increase in relative abundance since the late 2000s

Conclusions

- Strong evidence that, after accounting for annual shifts in sampling distribution with regard to several covariates, that data derived solely from historical MARMAP chevron trap stations can adequately track annual Red Snapper relative abundance
   - If wasn't the case, wouldn't expect the high degree of correlation exhibited between indices developed using data only from historical chevron trap stations (MARMAP Universe data set) and those using the current chevron trap data set (SERFS Universe data set)
   - Further, models developed from different data sets are predicting similar effects of covariates on Red Snapper relative abundance
- As expected, CV estimates for the years 1990-2009 are somewhat larger than those estimated for 2010-2014
   - This is a product of annual sample size of the chevron trap survey, with the net effect of increasing sampling intensity in the recent time period being to decrease uncertainty around relative abundance trends
- Models that allow covariates that are originally measured on a continuous scale to be modeled as continuous variables, with a possibly non-linear effect on the response variable, perform better than analogous models that convert the continuous covariates to discrete variables

Pre-Data Workshop Recommendation

- Use the full time-series relative abundance index using data from all valid stations sampled via chevron traps (SERFS Universe data set) and modeling covariates as continuous variables using polynomials in the assessment model
   - Extends the fishery-independent chevron trap index back an additional 20 years
      - Bridges the gap between the termination of most of the fishery-dependent surveys used in SEDAR 24 and the other fishery-independent index developed using videos that begins in 2010

- Brings the available length comp and age comp data associated with the index into the assessment model for consideration, which can be important for informing year class strength

Tables

Table 1: Annual distribution of stations in the chevron trap universe (known live-bottom/hard-bottom stations available for selection via random sampling annually) according to latitude and depth strata. Strata are defined based on multivariate partitioning based on changes in chevron trap catch species composition. Each column represents the number of stations in the universe found in each stratum in a given year.

	Survey Strata											
	Southern Latitudes (<29.71°N)				Mid Latitudes (29.71-32.60°N)				Northern Latitudes (≥32.61°N)			
Year	Inner Shelf (<30 m)	Mid Shelf (30-42 m)	Outer Shelf (43-63 m)	Slope (≥64 m)	Inner Shelf (<30 m)	Mid Shelf (30-42 m)	Outer Shelf (43-63 m)	Slope (≥64 m)	Inner Shelf (<30 m)	Mid Shelf (30-42 m)	Outer Shelf (43-63 m)	Slope (≥64 m)

Table 4: Covariate bin structure as defined during the SEDAR 41 Data Workshop held in 2014.

	Covariate			
Bin	**Depth (m)**	**Latitude (oN)**	**Bottom Temperature (oC)**	**Day of Year**
1	< 30	< 28.00	< 15.0	< 150
2	30 – 44	28.00 – 29.99	15.0 – 26.9	150 – 199
3	45 – 59	30.00 – 32.49	≥ 27.0	200 – 249
4	≥ 60	32.50 – 33.99	–	≥ 250
5	–	≥ 34.00	–	–

Table 5: Model structures of each of the best-fit models. Numbers represent the maximum polynomial order for individual covariates. ✓ indicates discrete covariate retained in model. Count = indicates the count sub-model of the ZINB. ZI = zero-inflation sub-model of the ZINB. Lower BIC among pairs of models (1 per column) not separated by line (dashed or solid) indicates most parsimonious model.

Figures

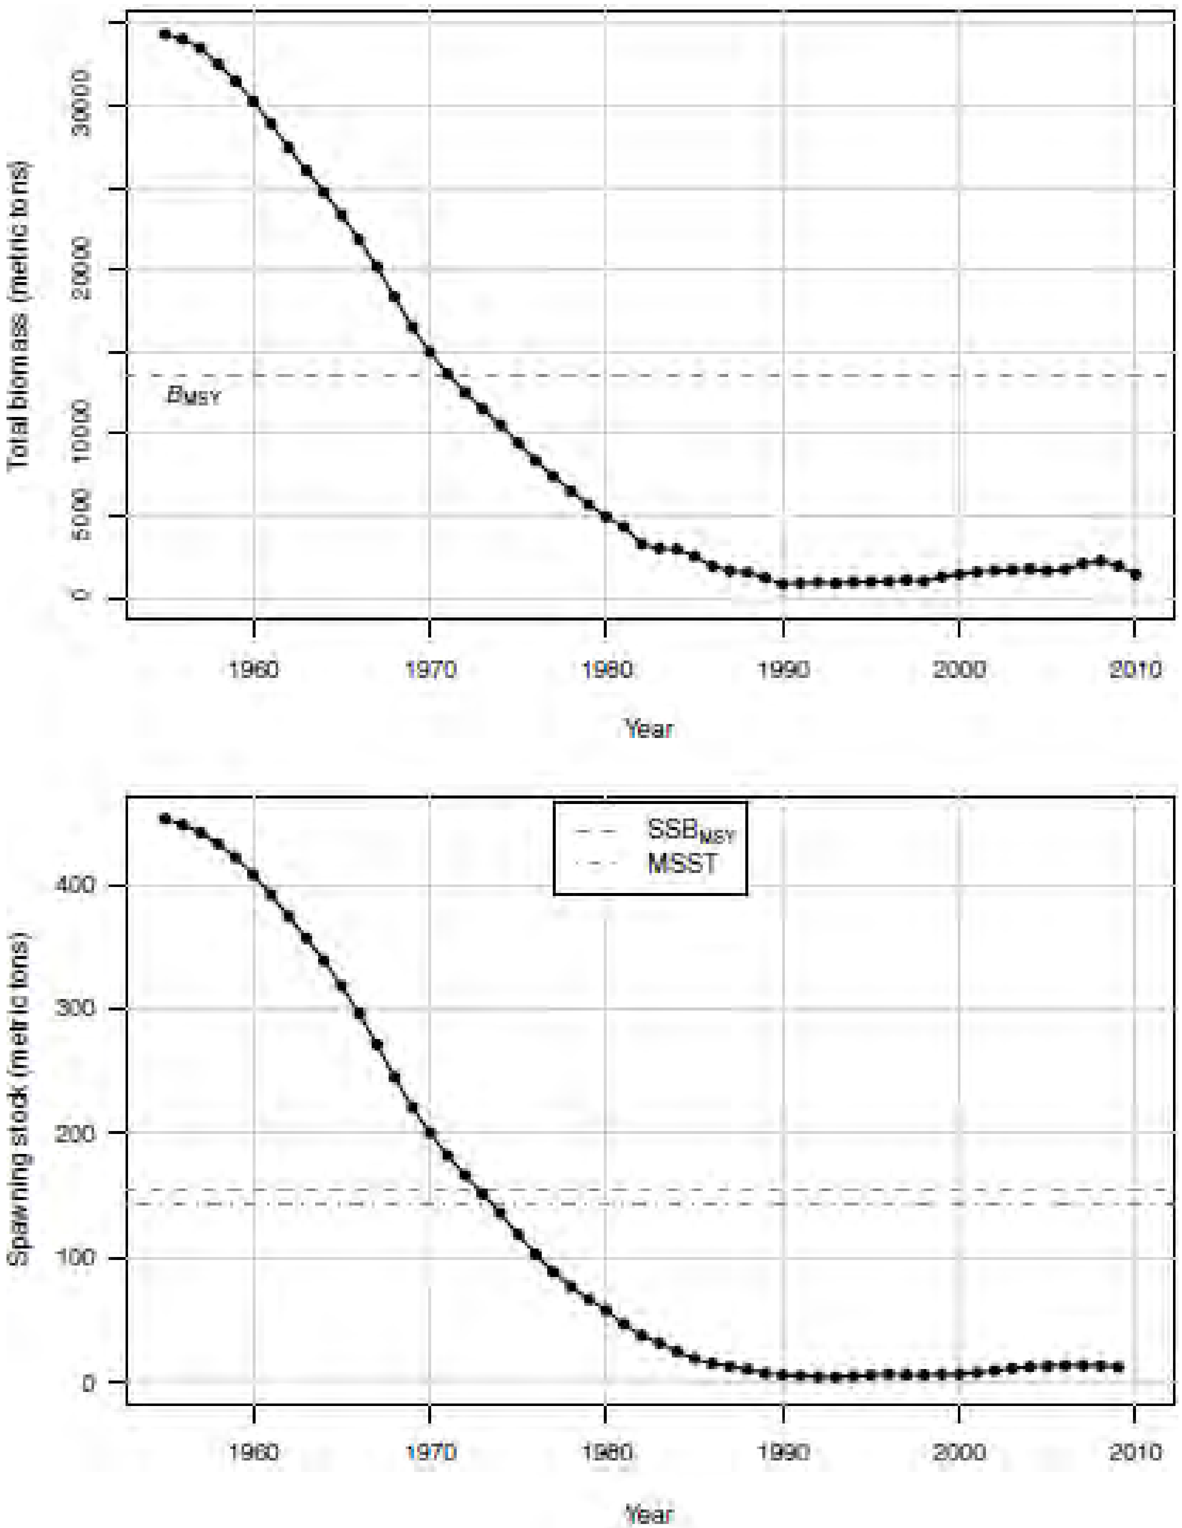

Figure 1: Predicted total biomass (top panel) and spawning stock biomass (bottom panel) of Red Snapper derived from final SEDAR 24 stock assessment (SEDAR 24).

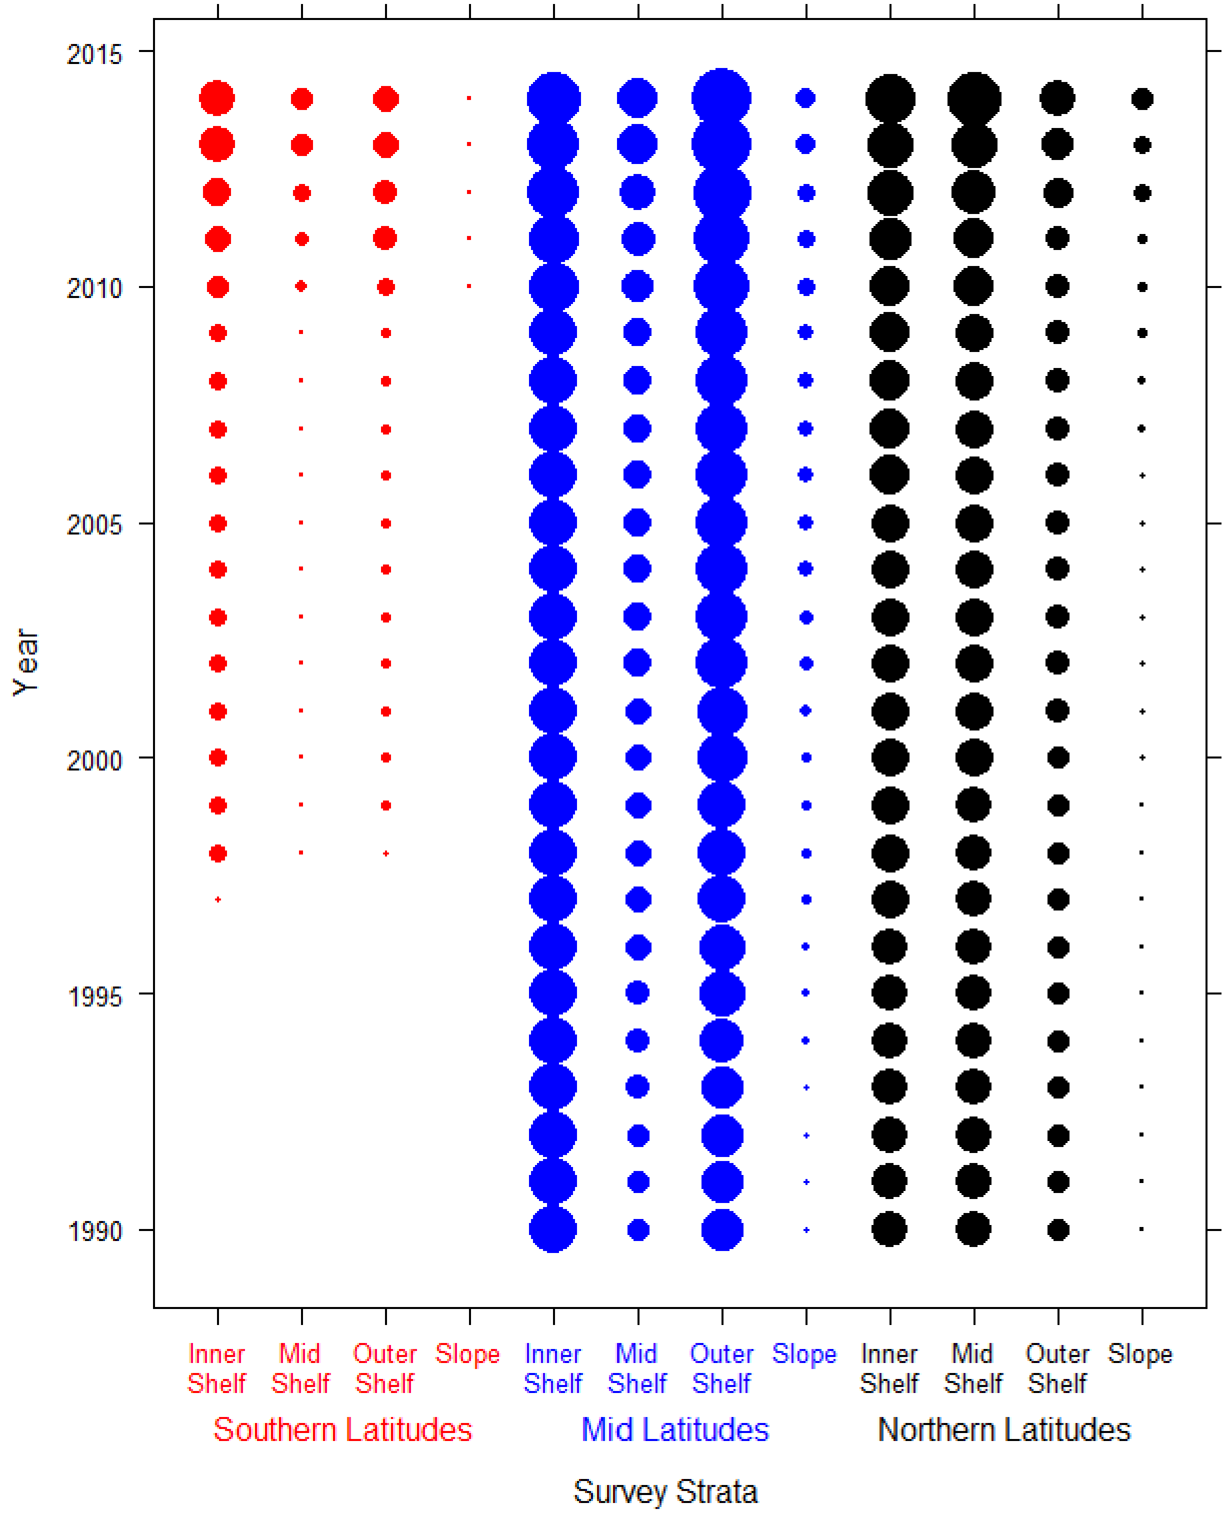

Figure 2: Distribution of SERFS chevron trap stations according to latitude and depth strata. Area of each circle is proportion to the total number of stations found in the strata.

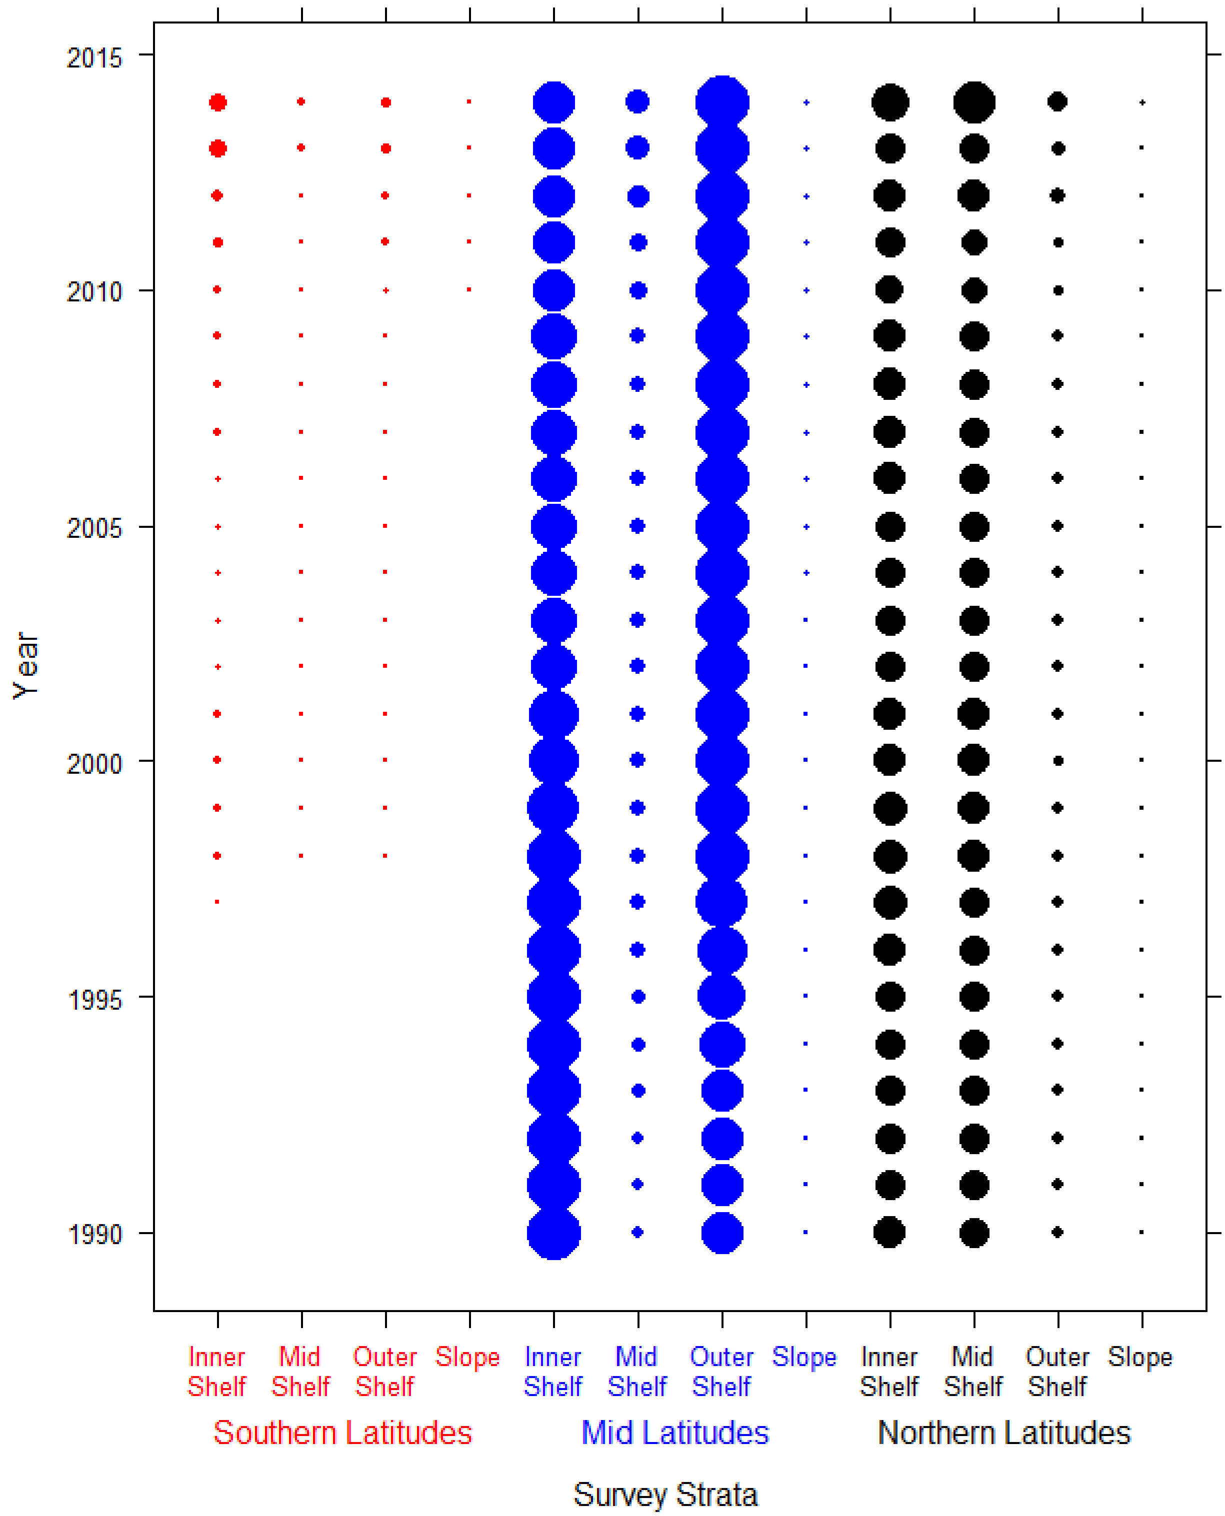

Figure 3: Distribution of SERFS chevron trap universe stations according to latitude and depth strata. Size of each circle in each year is proportional to the strata possessing the maximum number of stations in that year.

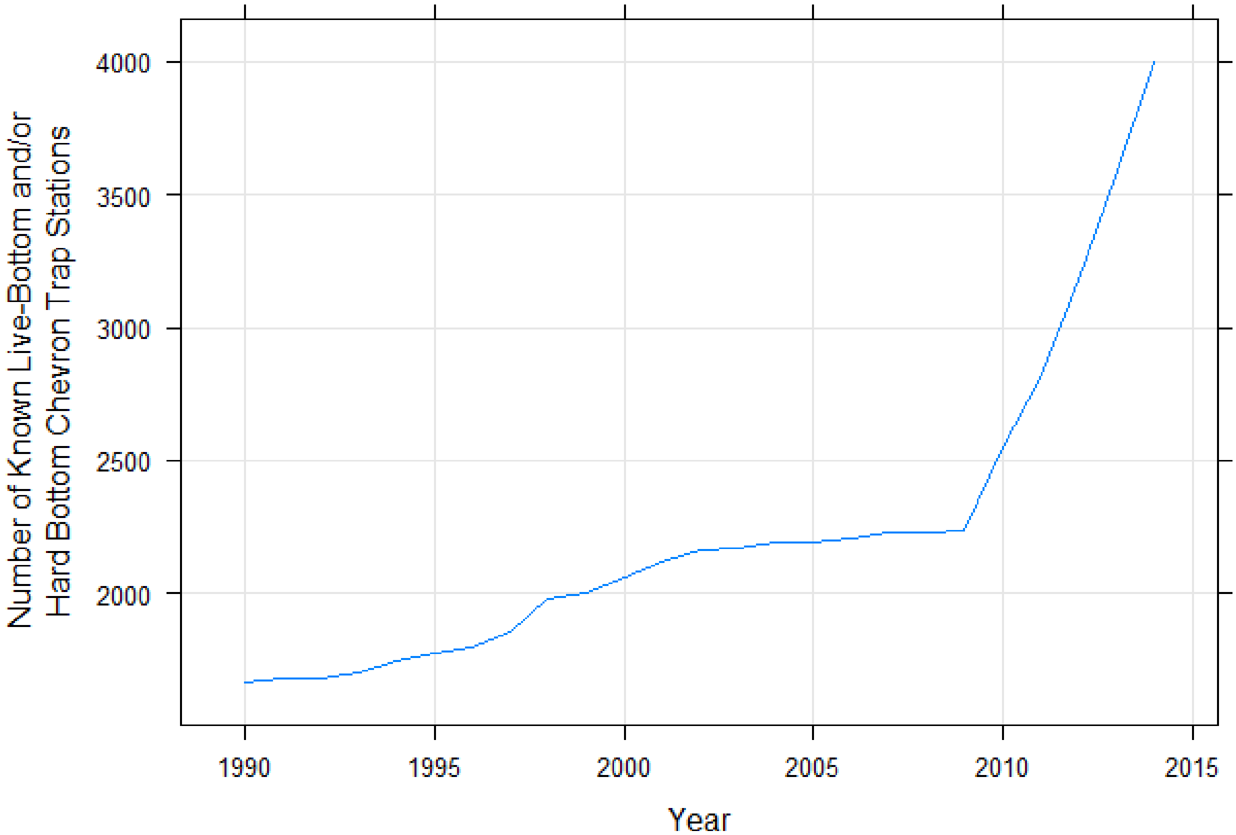

Figure 4: Time series of the number of stations composing the chevron trap station universe (locations with known live-bottom and/or hard-bottom habitat suitable for sampling via chevron traps). The drastic increase in known live-bottom and/or hard bottom stations since 2009 is driven primarily by the geographic expansion in the survey made possible due to the addition of funds via the SEAMAP-SA Reef Fish Complement and SEFIS programs. The chevron trap universe in 2009 represents the traditional MARMAP chevron trap universe, representing the geographic distribution of stations available for random sampling by the SERFS program during all years of the chevron trap index. The chevron trap universe in 2014 represents the current universe of known live-bottom and/or hard-bottom habitat identified by the SERFS program, with many of these new stations being found off the coast of Florida.

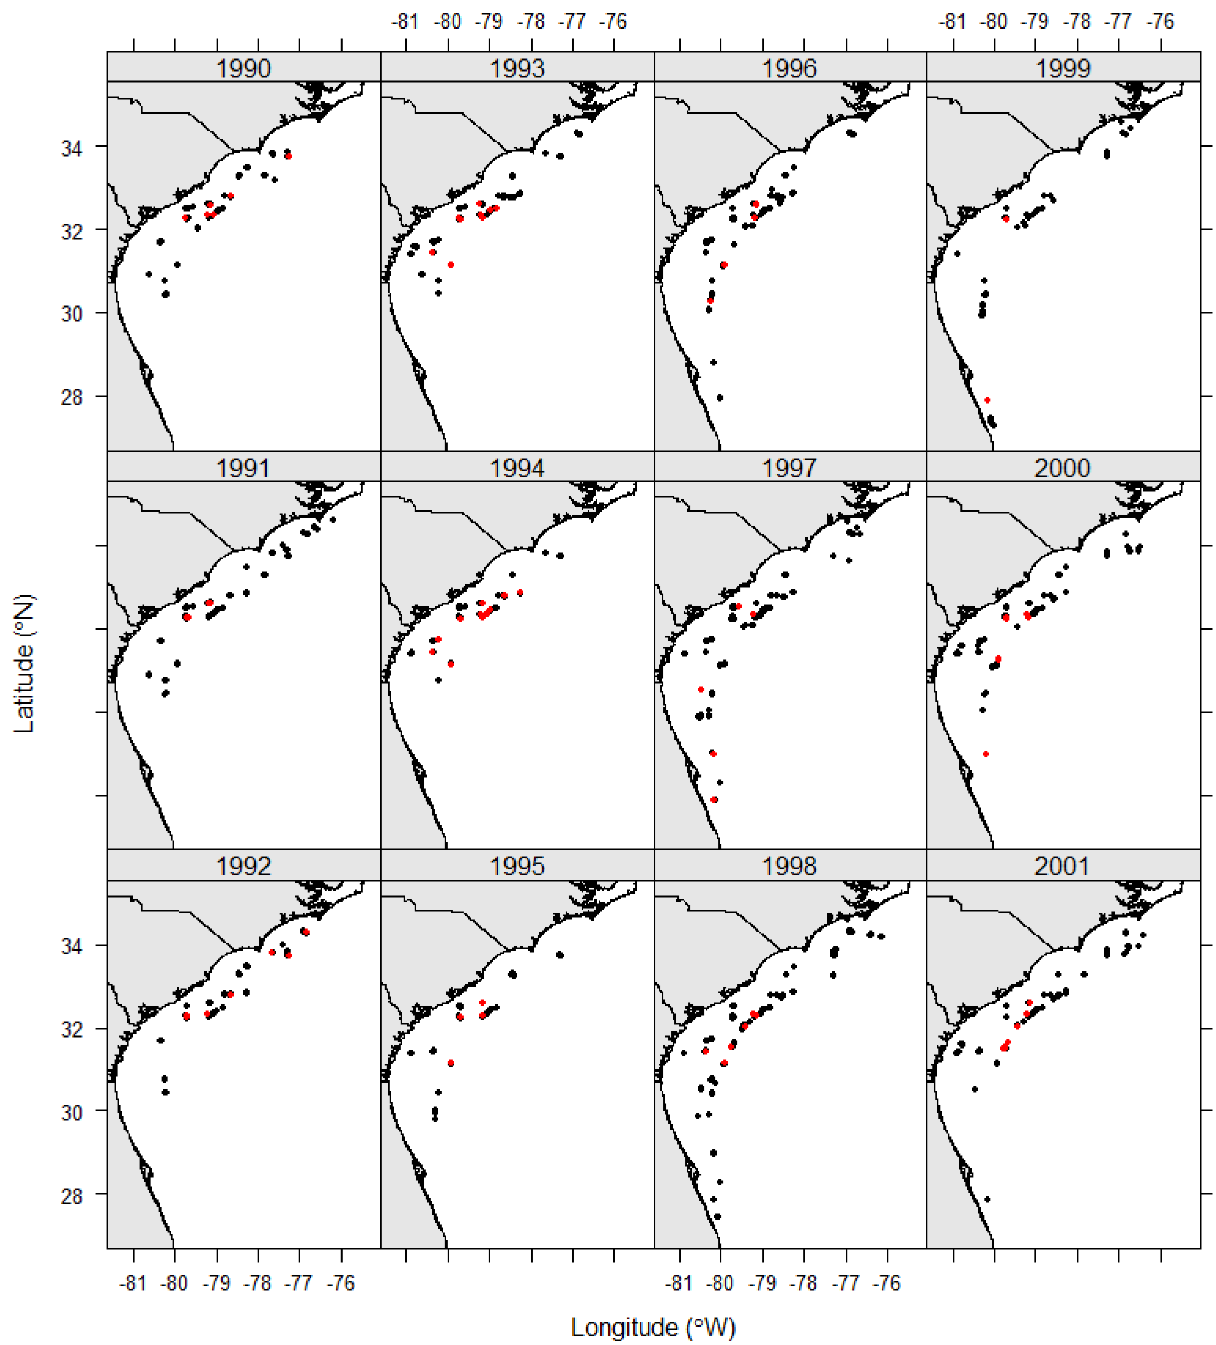

Figure 5: Annual sampling distribution of the SERFS chevron trap survey from 1990-2014 using the SERFS Universe (all valid chevron trap samples from a given year). Black dots represent samples absent of Red Snapper. Red dots represent samples where Red Snapper were captured.

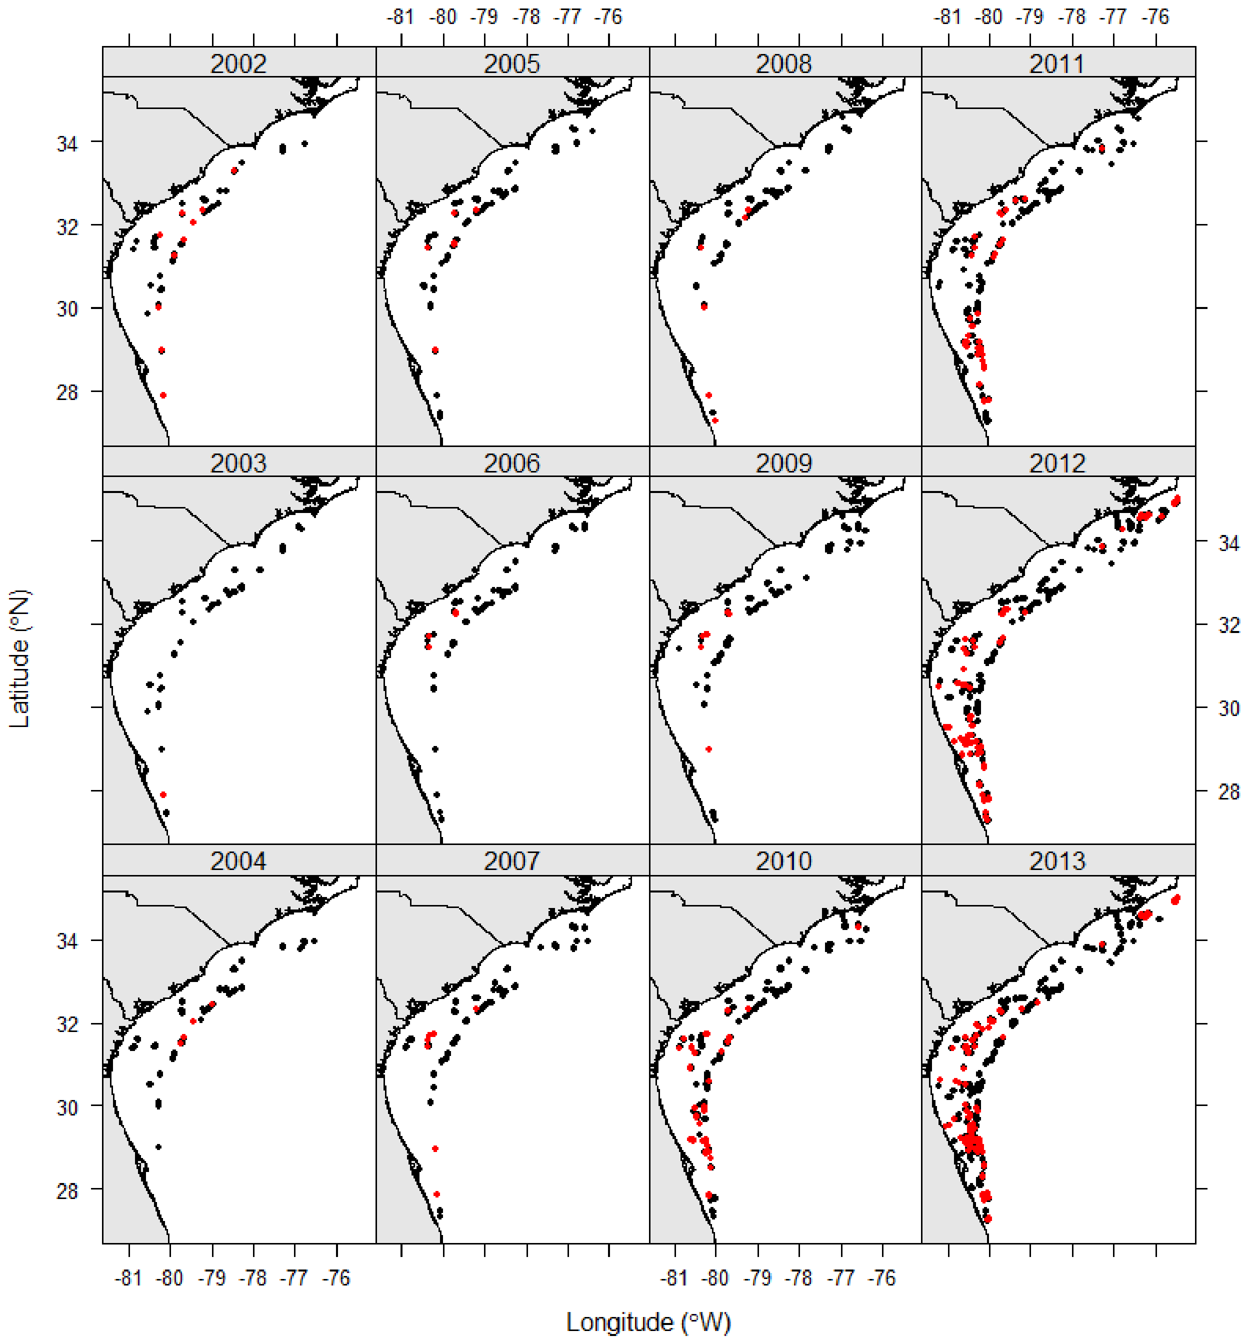

Figure 5: continued

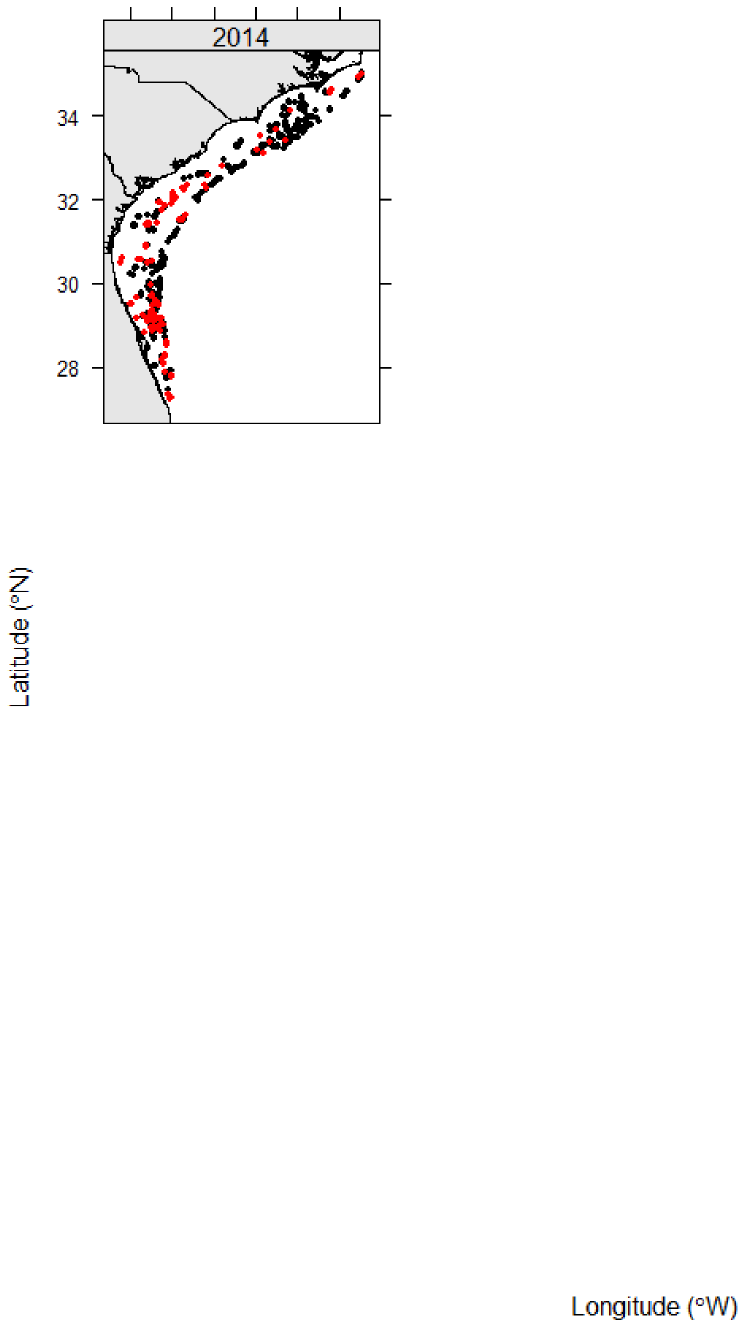

Figure 5: continued

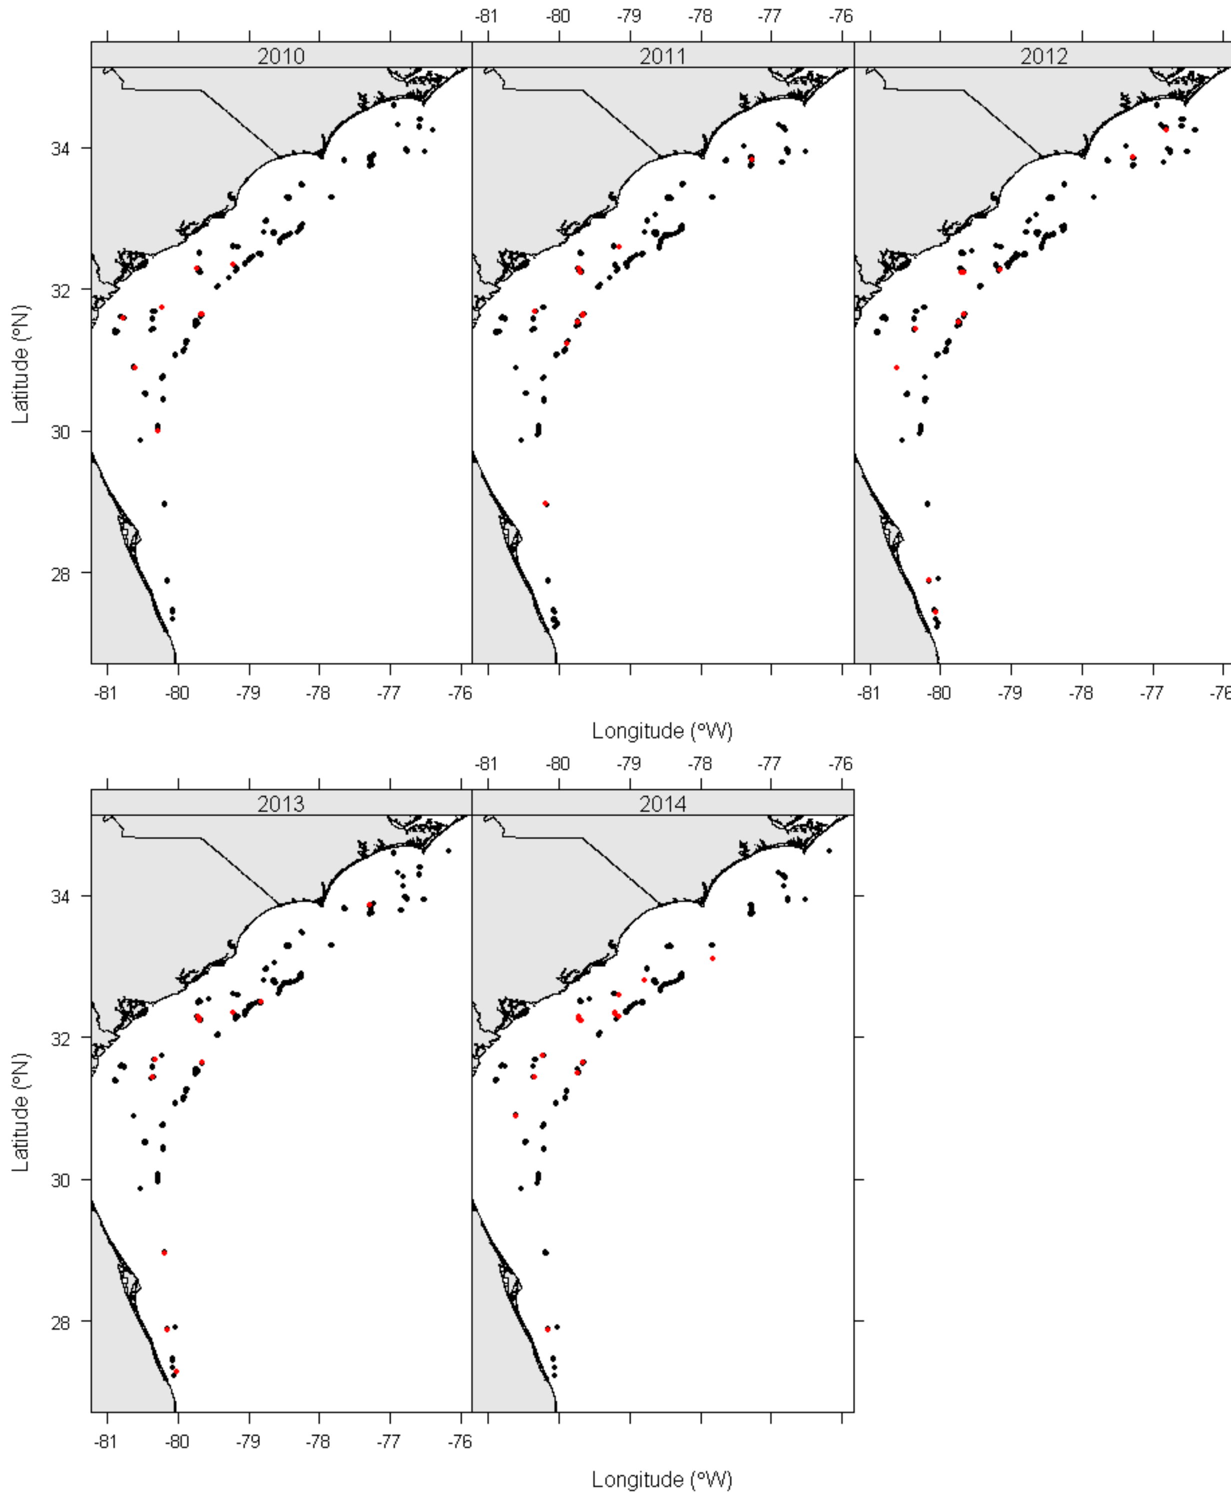

Figure 6: Annual sampling distribution of the SERFS chevron trap survey from 2010-2014 based only on those stations contained within the MARMAP chevron trap station universe at the beginning of the 2010 sampling season (identified as known live-bottom and/or hard-bottom habitat prior to 2010).

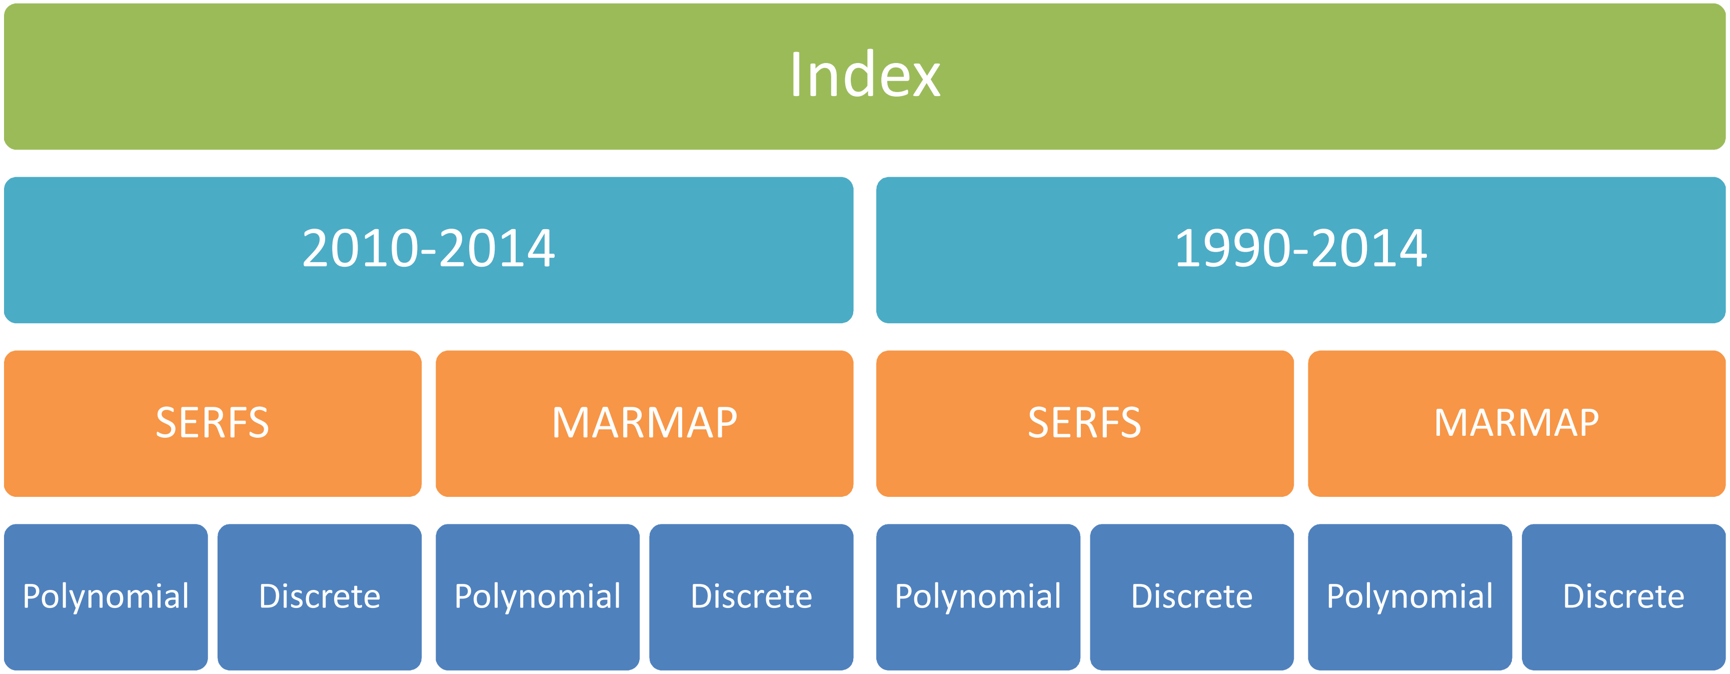

Figure 7: Hierarchical depiction of the eight relative abundance indices considered.

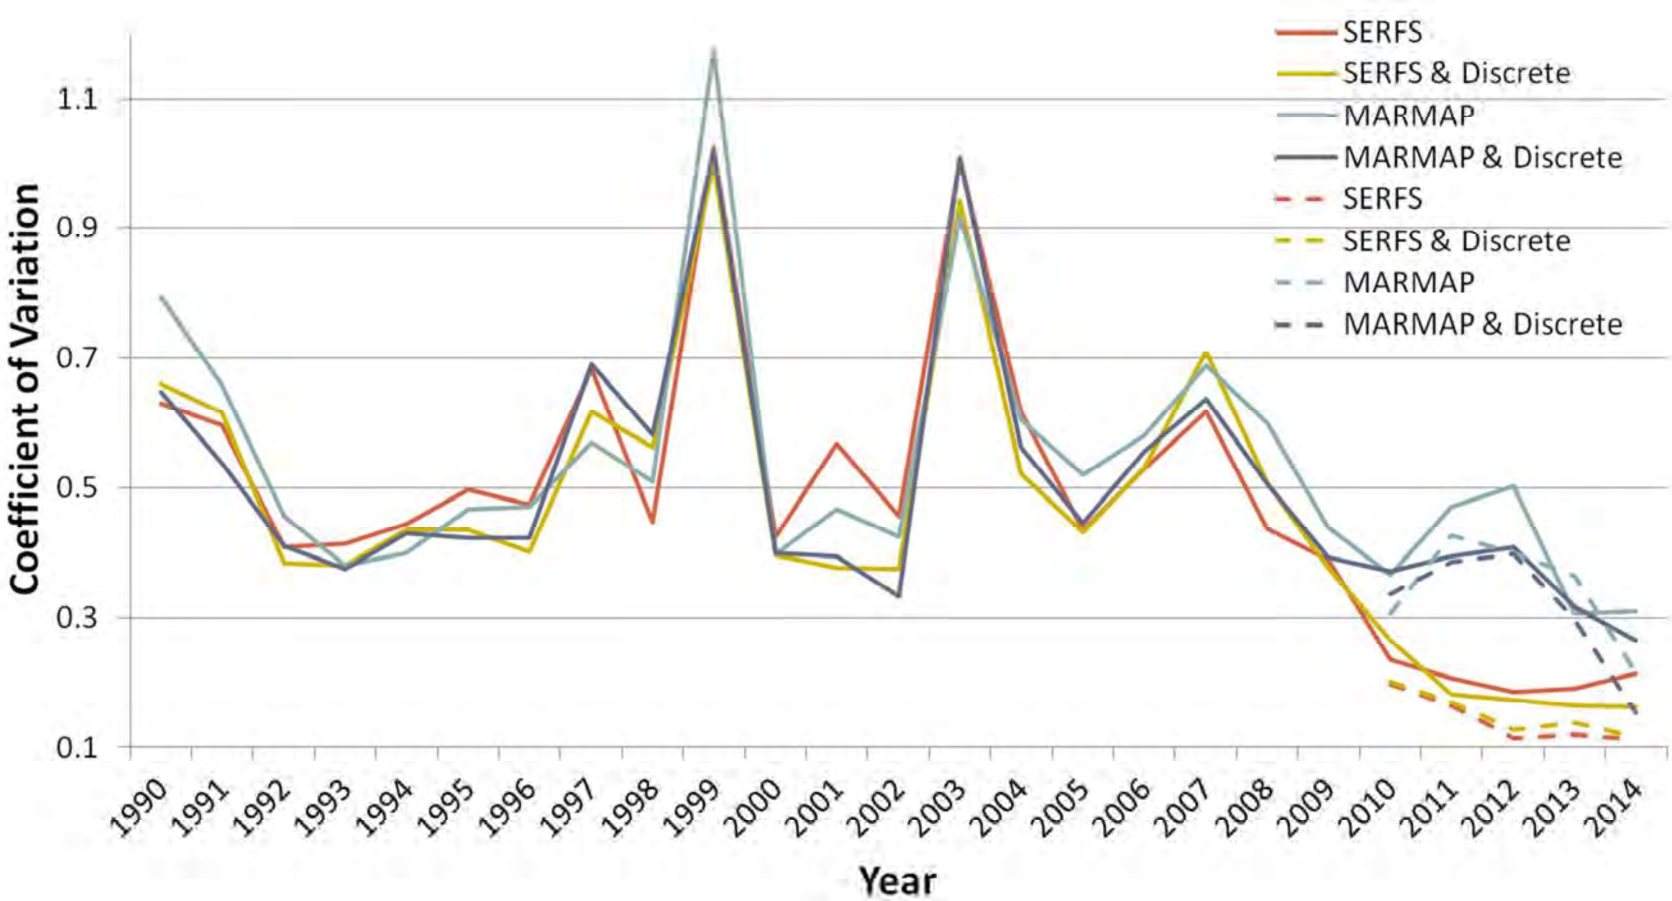

Figure 8: Annual coefficient of variation estimates from each of the eight models considered. Dashed lines represent models based on the restricted time series (2010-2014). Discrete in the legend refers to models using discrete covariates in the model (if missing indicates used covariates modeled as polynomials). SERFS and MARMAP refer to the data set used in the analysis, the SERFS Universe data set and MARMAP universe data set, respectively.

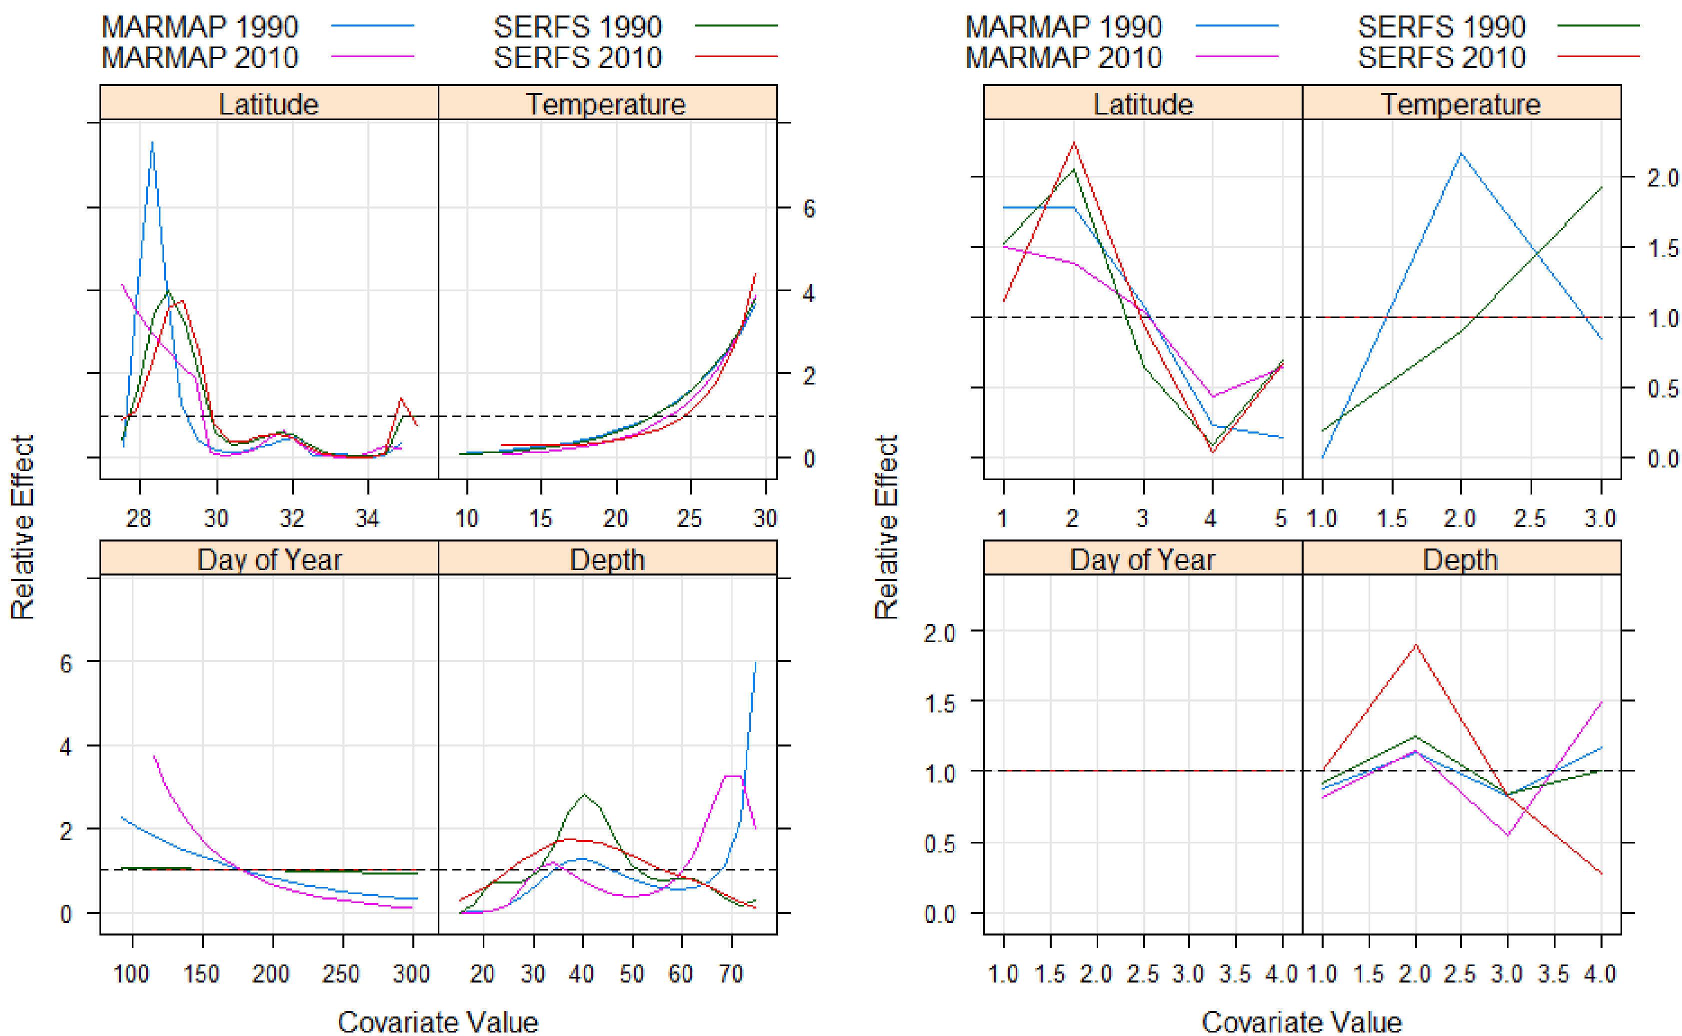

Figure 9: Predicted covariate effects from each of the eight models. Left side presents the covariate effects using continuous covariates modeled as polynomials. Right side presents the covariate effects using discrete covariates, with x-axis numbers representing bin number (refer to Table 4

	2010-2014	5	1
Avg. Proportion Positive	1990-2009	–	0.023
	2010-2014	0.1	0.036
Avg. Fish/Year	1990-2009	–	18
	2010-2014	317	22
Avg. Fish/Positive Trap	1990-2009	–	2.4
	2010-2014	3	1.7
Nominal Catch/Trap	1990-2009	–	0.0564
	2010-2014	0.3088	0.0599

Table 4). MARMAP and SERFS refer to the use of the MARMAP Universe data set and SERFS Universe data set in the model, respectively. 1990 and 2010 represent the start year of the model in question.

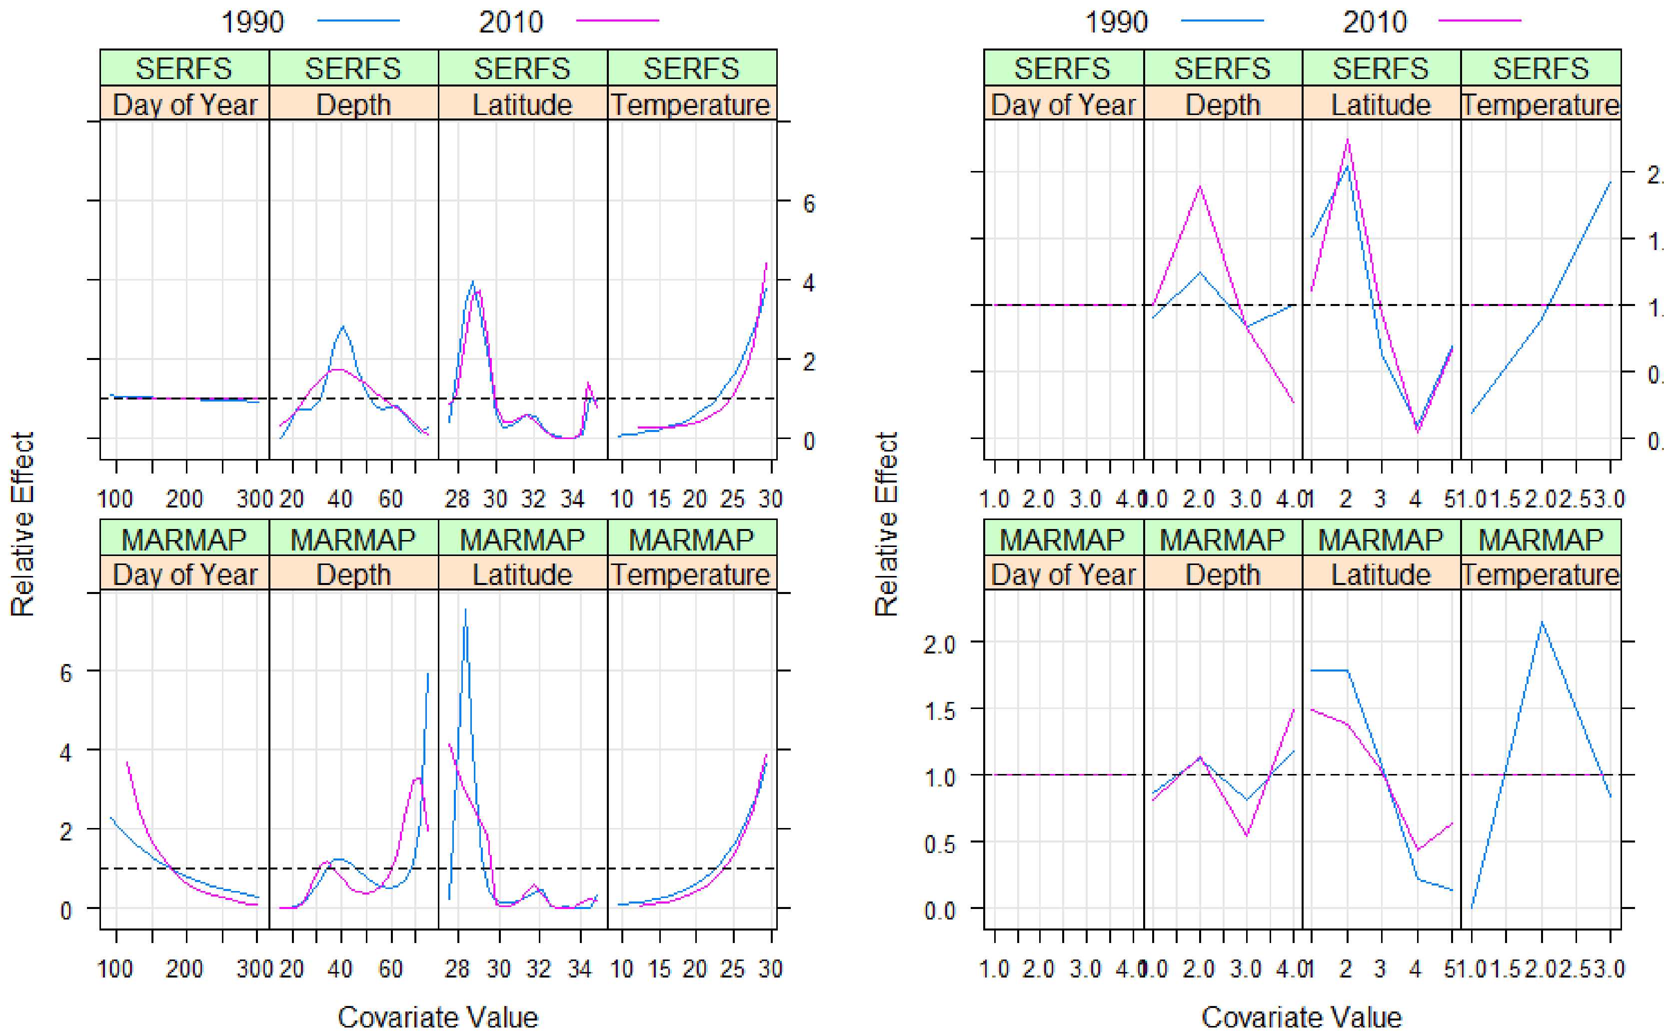

Figure 10: Same data presented in Figure 9, here comparing models with different start years within a given data set.

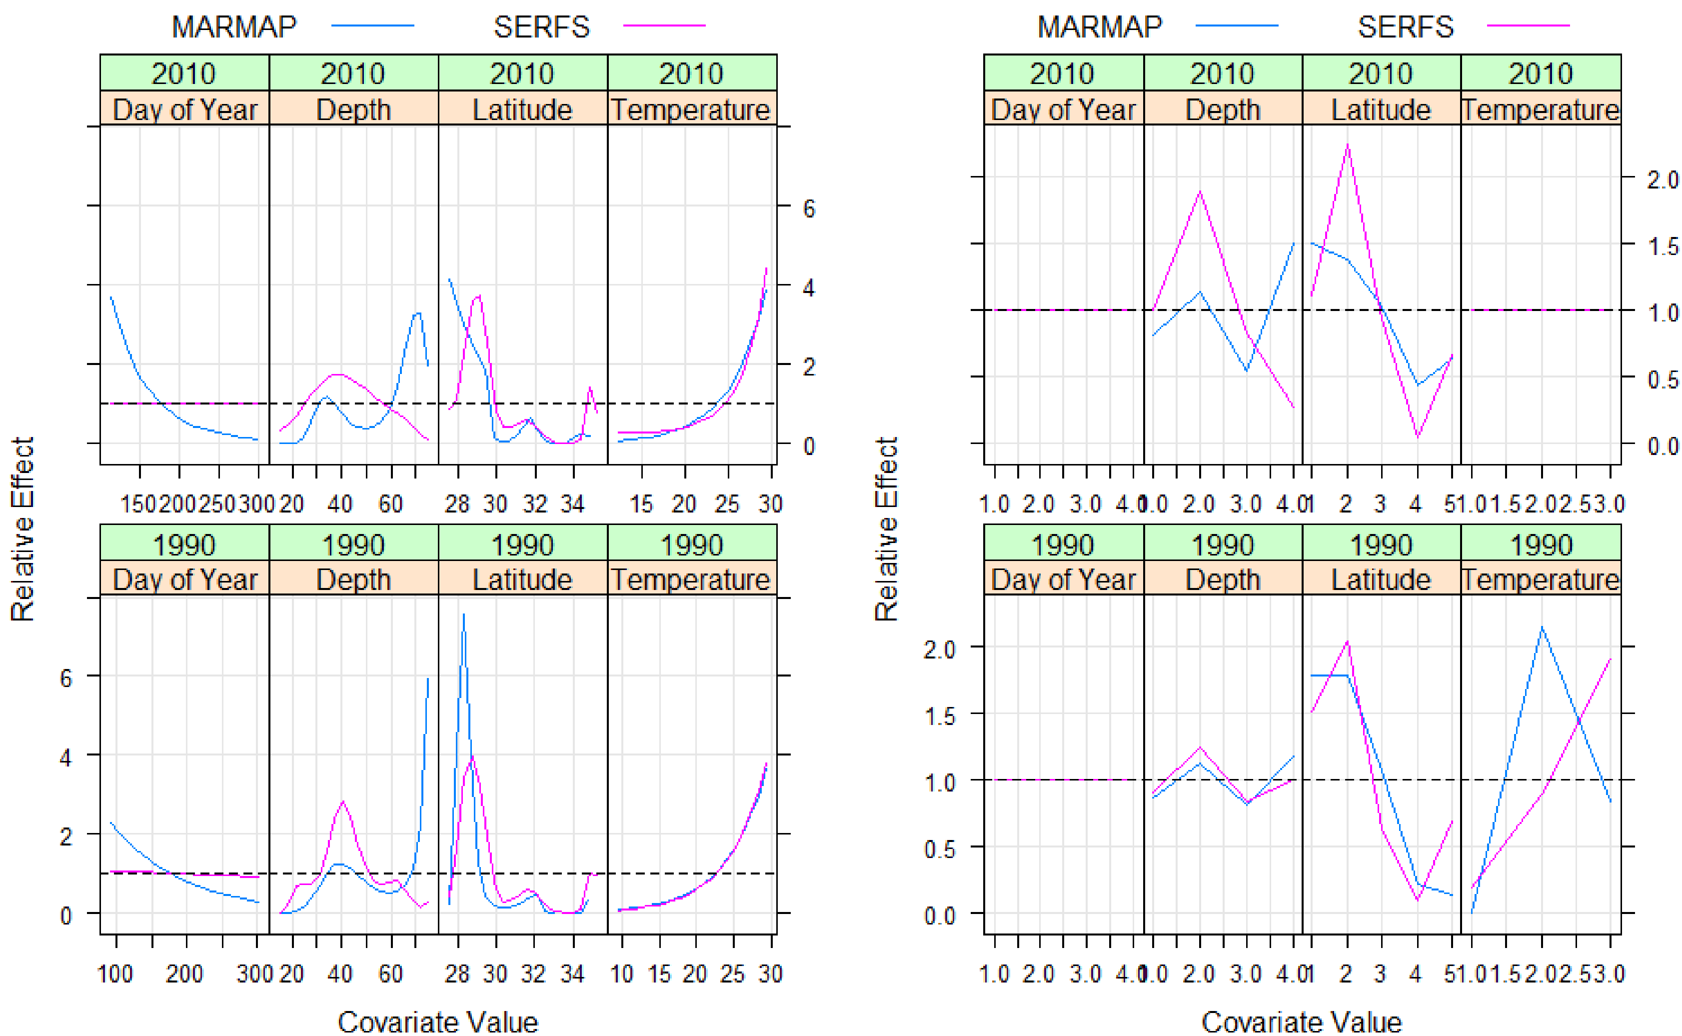

Figure 11: Same data presented in Figure 9, here comparing models using different data sets within a given survey start year.

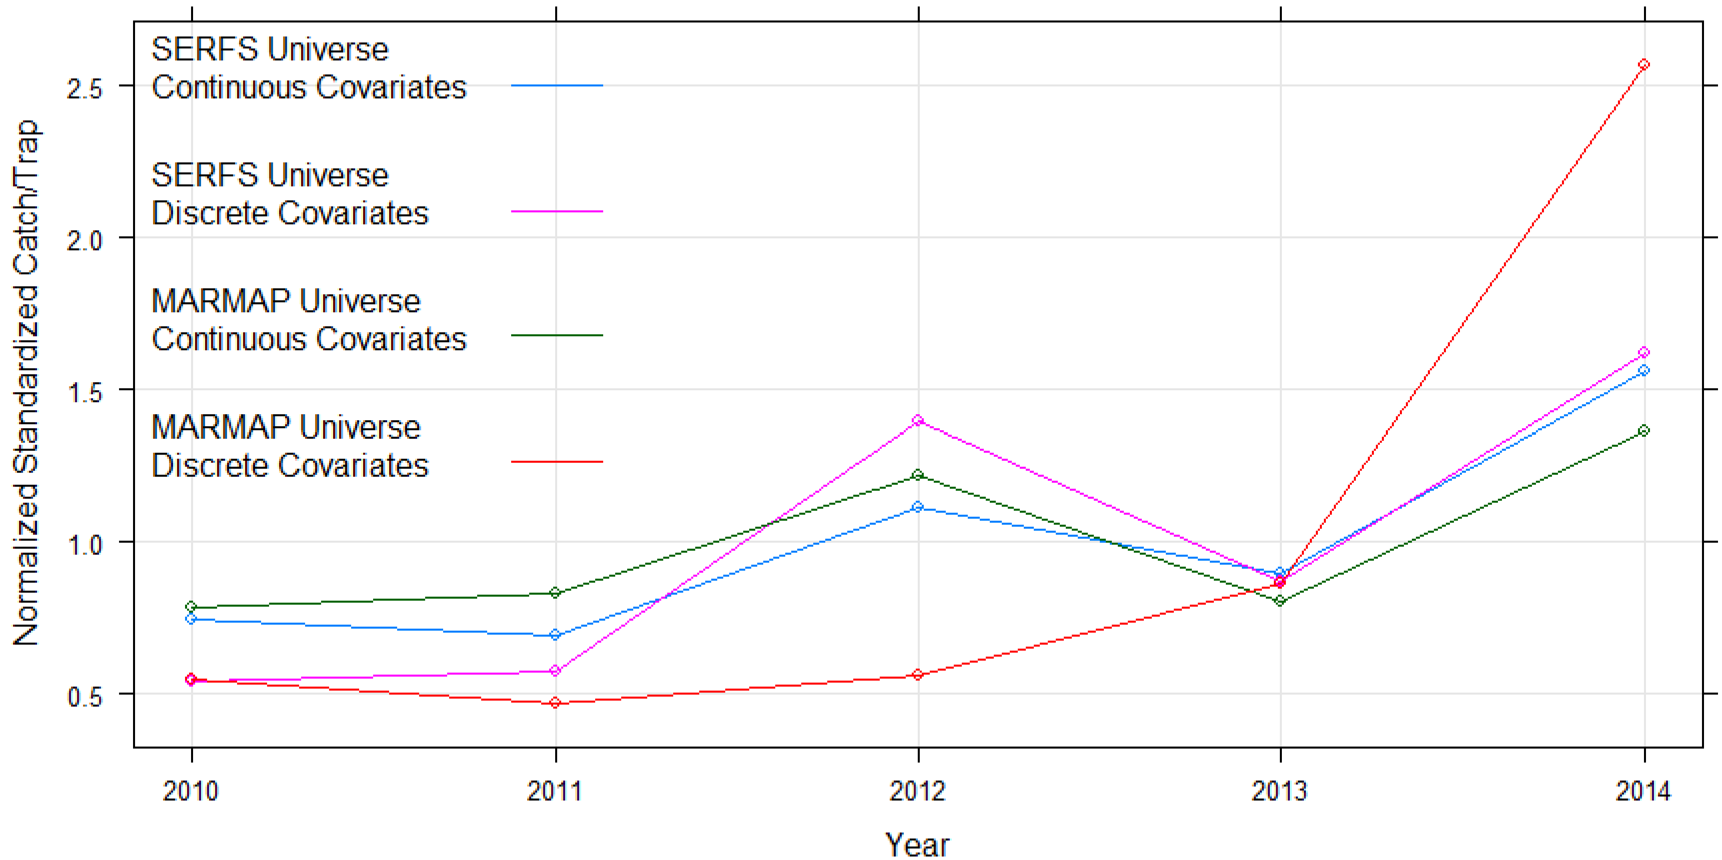

Figure 12: Relative abundance index for Red Snapper based on four different index models using only data from 2010-2014. Continuous covariates refer to models using polynomials.

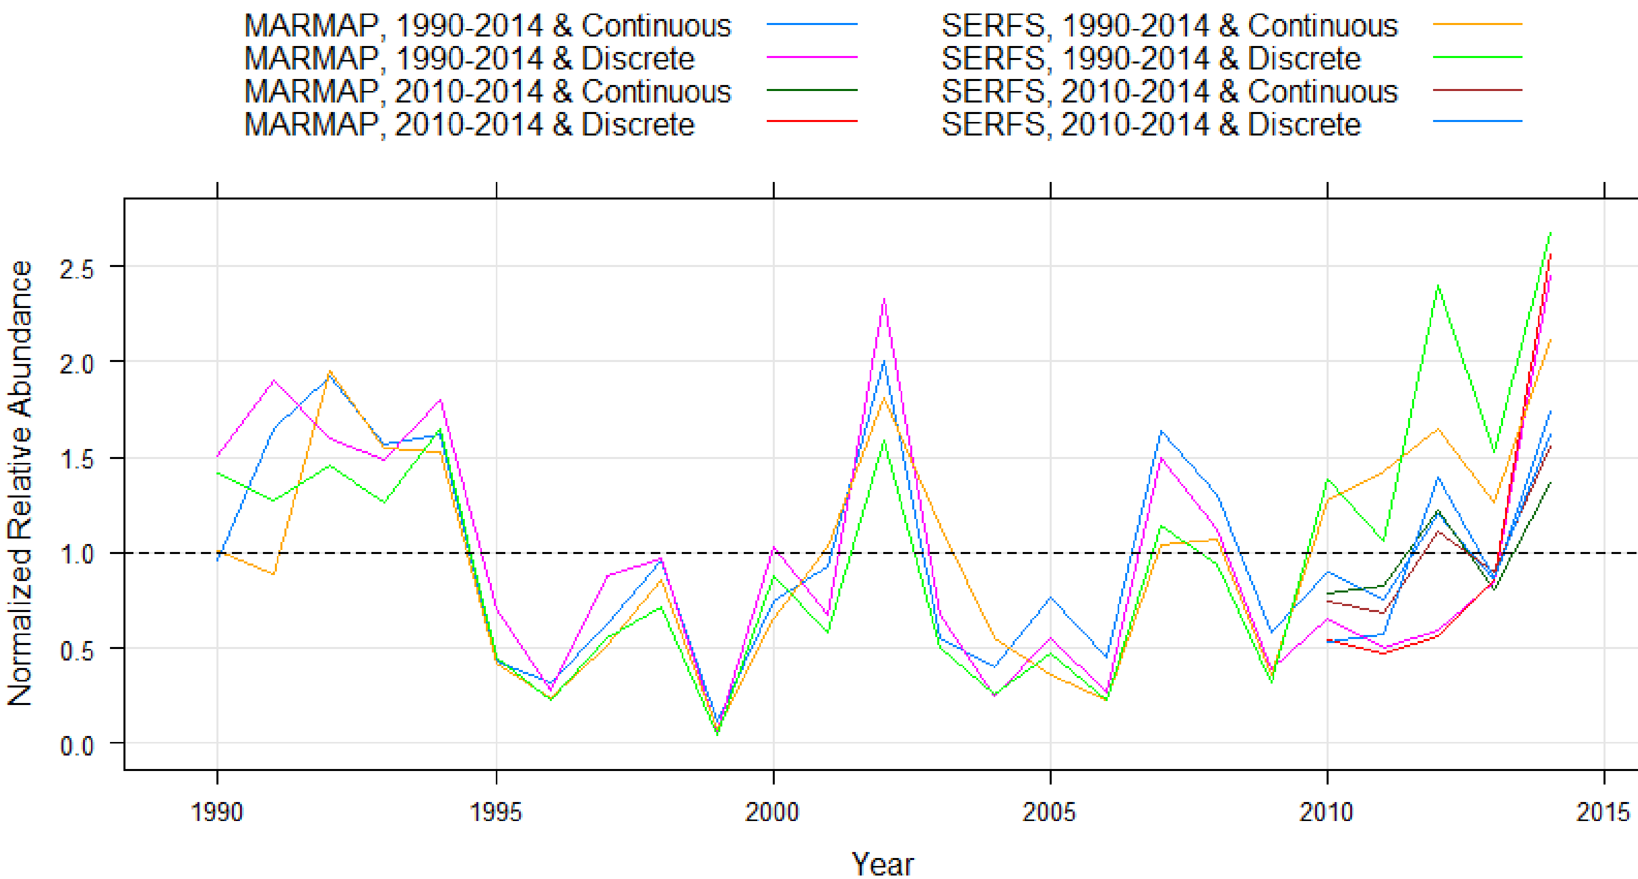

Figure 13: Relative abundance index for Red Snapper based on eight different index models (see Figure 7). Continuous identifies those models using polynomials to model covariates.

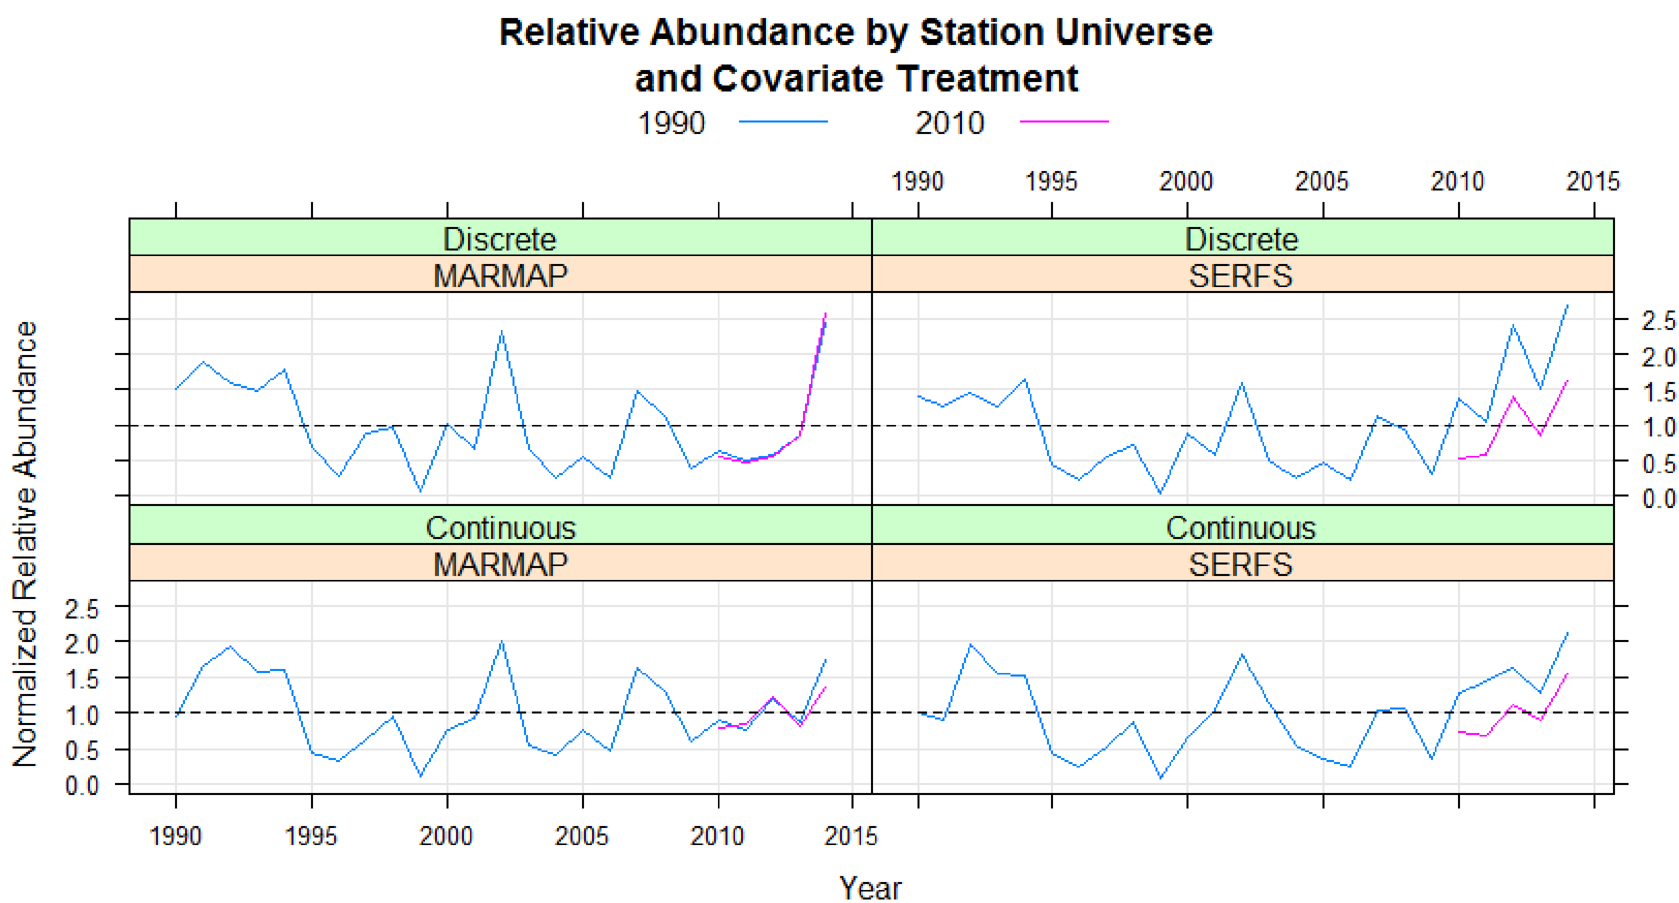

Figure 14: Same data as presented in Figure 13, here comparing pairs of models using the same data set and covariate treatment technique, but different start years.

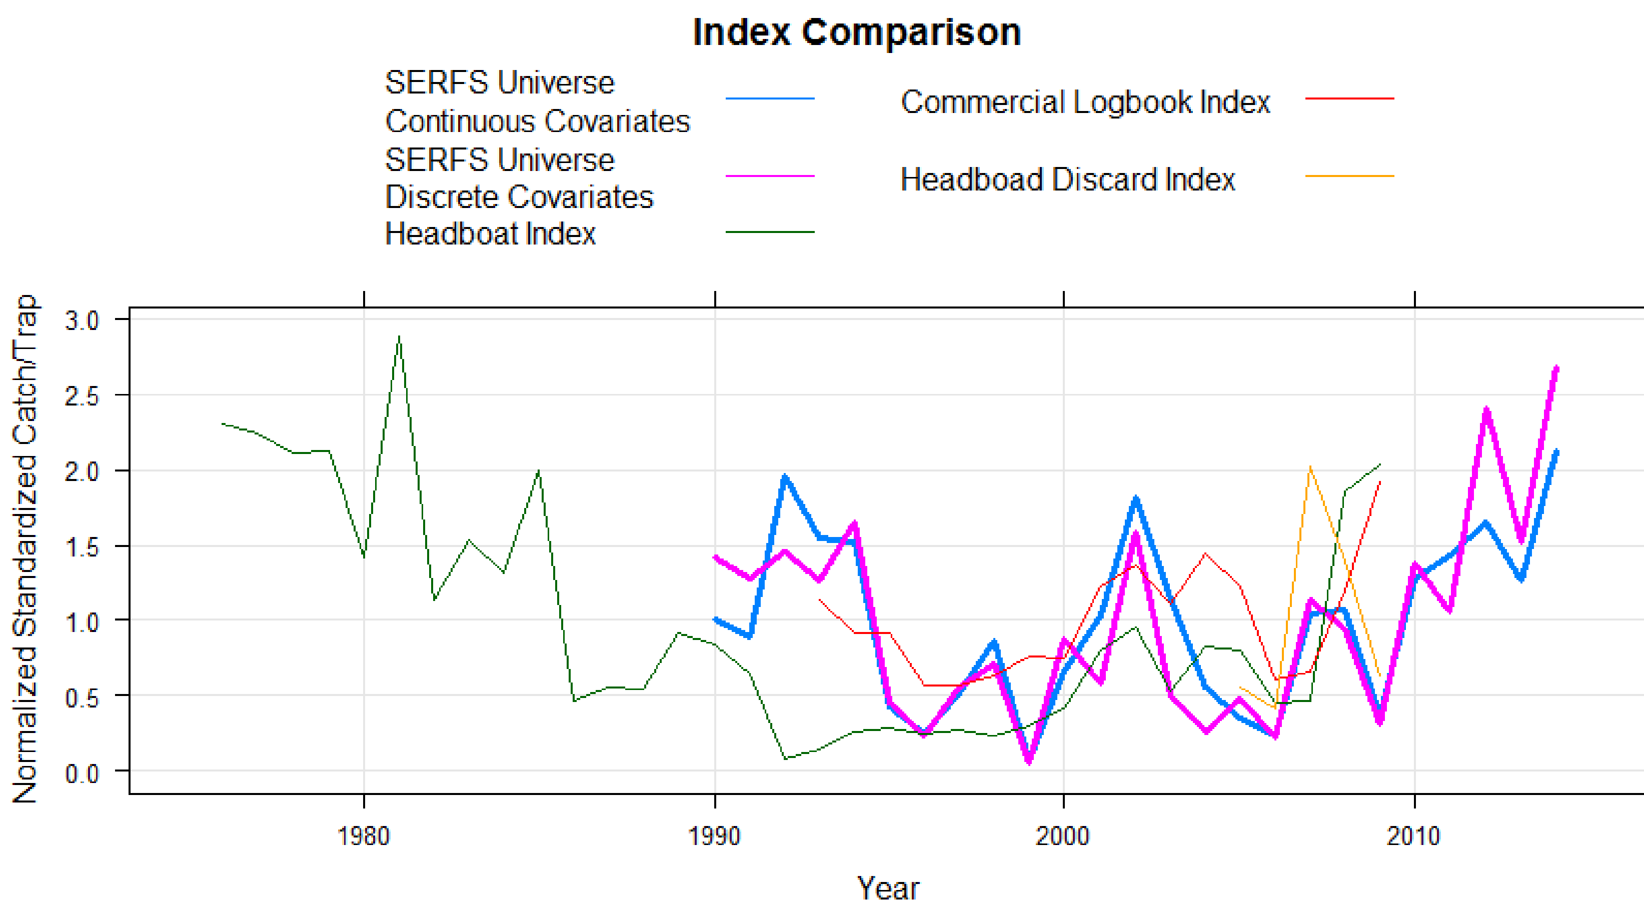

Figure 15: Comparison of the two full time-series indices using the SERFS Universe data set to the three fishery-dependent relative abundance indices of Red Snapper produced for SEDAR 24.

ABC determination methods by Center - email communications

PIFSC:

Standard P* approach

AFSC:

Tier 1: Geometric mean of F_MSY*fishable biomass
Tier 3: F40*fish_sel*natage*wt_age
Tier 4: F40*survey biomass
Tier 5: Recent survey biomass or average * 0.75* M (this is just an assumption of q=1)
Tier 6: Average catch over some fixed period * 0.75

NWFSC:

On the US continental Pacific coast, the council predominantly uses assessment based OFLs (with SSC final determination depending on stock assessment output/rigor/available data) and ABCs (with Council final determination depending on risk level). The one that I'm aware of that is different is Pacific Sardine. Here they use an environmentally driven (SST) formulation to specify Emsy, which is then related to specifying the OFL and ABC. You can find the assessment here (http://www.pcouncil.org/wp-content/uploads/2017/05/Appendix-C-2017-sardine-assessment-NOAA-TM-NMFS-SWFSC-576.pdf), and a brief description of this approach is in the executive summary (pages 13-14). I pasted below a few summary points from that document.

NEFSC:

You are correct that the Georges Bank yellowtail flounder assessment uses survey biomass expanded to population biomass through a catchability estimate along with an exploitation rate to derive the ABC (see https://www.nefsc.noaa.gov/saw/trac/ for the latest assessment). This approach is also used for Gulf of Maine winter flounder and Witch flounder (see https://www.nefsc.noaa.gov/publications/crd/crd1717/ for the latest updates and https://www.nefsc.noaa.gov/publications/crd/crd1117/ and https://www.nefsc.noaa.gov/publications/crd/crd1703/ for the most recent benchmarks).

We also have a survey smoothing approach that modifies recent catch according to changes in the survey. This approach has been used for both Georges Bank cod (https://www.nefsc.noaa.gov/publications/crd/crd1717/), Eastern Georges Bank cod (https://www.nefsc.noaa.gov/saw/trac/), and Monkfish (https://www.nefsc.noaa.gov/publications/crd/crd1609/crd1609.pdf), although in slightly different forms. The approach is currently under consideration by the NEFMC SSC for application to Southern New England Mid-Atlantic yellowtail flounder (no citeable reference, but see attached WP for details of the approach).

The Windowpane flounder stocks use AIM (An Index Method) to set ABC (https://www.nefsc.noaa.gov/publications/crd/crd1717/). Ocean Pout uses the survey and catch history to set ABC (https://www.nefsc.noaa.gov/publications/crd/crd1717/). The seven stocks in the Skate complex use the surveys in a different way to set the ABCs (https://www.nefsc.noaa.gov/publications/crd/crd0902/). We also have a truly data-poor assessment for deep sea red crab that only has two video surveys separated by 40 years along with catch information (https://www.nefsc.noaa.gov/publications/crd/crd0902/).

Another different approach is found in the surfclam assessment that uses SS for trend but doesn't believe the absolute magnitude of the estimates (https://www.nefsc.noaa.gov/publications/crd/crd1705/).

Methods used at other Centers:

PIFSC: Standard P* approach

i. Has the method been vetted through the SAFMC SSC?
    1. Yes and is used by the SSC for ABC determination
ii. What are the pros and cons of each method?
    1. Pros: Includes scientific uncertainty and a risk tolerance for management
    2. Cons: Doesn't include structural uncertainty
iii. Are the data for red snapper sufficient for the method?
    1. Yes and this has already been completed for red snapper

AFSC: Look at p.5 of document called "species profiles"
Tier 1: **Harmonic** mean of pdf of F_MSY*fishable biomass (fishable biomass is projected 1 year forward)
Tier 2: Point estimate of F_MSY*fishable biomass*F40/f35 (fishable biomass is projected 1 year foward) -- Tier 2 hasn't been used.
Tier 3: F40*fish_sel*natage*wt_age (natage is projected 1 year forward)
Tier 4: F40*survey biomass
Tier 5: Recent survey biomass or average * 0.75* M (this is just an assumption of q=1)
Tier 6: Average or maximum catch over some fixed period * 0.75

i. Has the method been vetted through the SAFMC SSC?
    1. Most of these, if not all, have been vetted through the SAFMC SSC in some form. The Average Catch approach is used for some stocks by the SAFMC SSC. SPR based approaches (F30, F35, and F40) have been discussed by the SAFMC SSC.
ii. What are the pros and cons of each method?
    1. Pros: Well studied and used to effectively manage some stocks. Leverages all of the data available for a species given the tiered nature of the harvest control rule.
    2. Cons: Data not available in the SA for some of the options.
iii. Are the data for red snapper sufficient for the method?
    1. Yes. Using average catch would not use all of the data available for red snapper (under utilization of data).

NWFSC: On the US continental Pacific coast, the council predominantly uses assessment based OFLs (with SSC final determination depending on stock assessment output/rigor/available data) and ABCs (with Council final determination depending on risk level). The one that I'm aware of that is different is Pacific Sardine. Here they use an environmentally driven (SST) formulation to specify Emsy, which is then related to specifying the OFL and ABC. You can find the assessment here (http://www.pcouncil.org/wp-content/uploads/2017/05/Appendix-C-2017-sardine-assessment-NOAA-TM-NMFS-SWFSC-576.pdf), and a brief description of this approach is in the executive summary (pages 13-14). I pasted below a few summary points from that document.

- i. Has the method been vetted through the SAFMC SSC?
    1. No, use of environmental metrics to help determine ABCs (as implemented through a harvest control rule) have not been vetted by the SAFMC SSC.
- ii. What are the pros and cons of each method?
    1. Pros: Includes environmental components and uncertainty into the determination of an ABC.
    2. Cons: Requires identification of an environmental factor linked to a species population dynamics.
- iii. Are the data for red snapper sufficient for the method?
    1. No, no specific link between red snapper and an environmental factor has been identified. Thus, this methods cannot be used.

NEFSC: You are correct that the Georges Bank yellowtail flounder assessment uses survey biomass expanded to population biomass through a catchability estimate along with an exploitation rate to derive the ABC (see https://www.nefsc.noaa.gov/saw/trac/ for the latest assessment). This approach is also used for Gulf of Maine winter flounder and Witch flounder (see https://www.nefsc.noaa.gov/publications/crd/crd1717/ for the latest updates and https://www.nefsc.noaa.gov/publications/crd/crd1117/ and https://www.nefsc.noaa.gov/publications/crd/crd1703/ for the most recent benchmarks).

The basic model of abundance would be based on empirical measures of abundance and assumed parameters as follows □ = (□□/ □□□)(□□ /□) Where N is the estimated total population , It is the index of abundance expressed as numbers or weight per tow, Ad is the total area within the sampling domain, a is the average area swept per tow, pd is the fraction of the total area within the population domain, (i.e., pd=Ad/A where A is the total area where the stock resides), and e is the efficiency of the gear, expressed as probability of capture given encounter. (From document called "Center methods…"

- iv. Has the method been vetted through the SAFMC SSC?
    1. No, use of absolute biomass metrics to help determine ABCs has not been vetted by the SAFMC SSC.
- v. What are the pros and cons of each method?
    1. Pros: "Direct" estimate of population size.

2. Cons: Requires estimation of a known catchability, which we do not have the ability to estimate. Requires an estimate of the total population that is contained within the survey sampling frame, which we do not have an estimate of. Requires an index with a long time series and contrast.

vi. Are the data for red snapper sufficient for the method?

1. No, we do not have a broad index with estimated catchability and a long time series.

We also have a survey smoothing approach that modifies recent catch according to changes in the survey. This approach has been used for both Georges Bank cod (https://www.nefsc.noaa.gov/publications/crd/crd1717/), Eastern Georges Bank cod (https://www.nefsc.noaa.gov/saw/trac/), and Monkfish (https://www.nefsc.noaa.gov/publications/crd/crd1609/crd1609.pdf), although in slightly different forms. The approach is currently under consideration by the NEFMC SSC for application to Southern New England Mid-Atlantic yellowtail flounder (no citeable reference, but see attached WP for details of the approach).

SEE reference on Google drive - Application of planBsmooth approach to groundfish stocks

vii. Has the method been vetted through the SAFMC SSC?

1. No, the method if using a smoothed, average biomass time series has not been vetted by the SAFMC SSC. [This is just an expansion of the method directly above this.]

viii. What are the pros and cons of each method?

1. Pros: "Direct" estimate of population size.
2. Cons: Requires estimation of a known catchability, which we do not have the ability to estimate. Requires an estimate of the total population that is contained within the survey sampling frame, which we do not have an estimate of. Requires an index with a long time series and contrast.

ix. Are the data for red snapper sufficient for the method?

1. No, we do not have a broad index with estimated catchability and a long time series.

x. Note - this was looked at to address severe retrospective patterns.

The Windowpane flounder stocks uses bottom trawl survey data and the AIM (An Index Method) package to set ABCs (https://www.nefsc.noaa.gov/publications/crd/crd1717/). A long time series of catch and FI survey data are used to identify trends in survey biomass catch/tow, relative F (catch/3-yr moving average catch/tow), and the replacement ratio (current relf/moving average refF). This approach involves either selecting MSY by calculating the median catch during a reference period in which fishing did not result in index declines and applying MSY/IBmsy = relF at MSY (IBmsy = kg/tow at MSY); or examining trends in replacement ratio and identifying a period where it is around 1, then applying the above equation to get MSY. Overfished = 3-yr moving average IB relative to Bthreshold = 50%IBmsy, Fmsy = relF at MSY or AIM-based replacement ratio=1. Requires an index of abundance and catch covering the same time period which includes a reference period of low exploitation. AIM's randomization test provides limited bootstrapped CIs and some stochastic projection runs can be generated.

i. Has the method been vetted through the SAFMC SSC?
   1. No, the SSC has not reviewed the use of AIM or any other survey-based relF approach to set ABCs in the South Atlantic.

Comment [1]: Is this true? I'm a newbie to the SSC.

Comment [2]: I think that this is true. We can run it by the work group, some of them have been on the committee for quite some time.

ii. What are the pros and cons of each method?
   1. Pros: Leverages long time series of reliable catch and an index of abundance spanning pre- and post high exploitation periods to identify sustainable fishery removal rates using very little data.
   2. Cons: Requires time series of reliable catch and an index of abundance spanning pre- and post high exploitation periods which may not exist for red snapper. Assumes catchability has not changed over the assessment period. Sensitive to smoothing decisions. Limited uncertainty and projection capabilities.

iii. Are the data for red snapper sufficient for the method?
   1. No, not unless a new long time series index of abundance can be generated from existing data sources. Index should span the early period prior to modern/high red snapper exploitation or at least cover a period during which the replacement ratio = 1.

Ocean Pout is similar to windowpane, but only uses the survey and catch history to set ABCs (https://www.nefsc.noaa.gov/publications/crd/crd1717/). It does not use AIM because of lack of a significant relationship between relative F and replacement ratio. This approach involves selecting MSY by calculating the median landings during a reference period in which fishing did not result in index declines and applying MSY/IBmsy = relF at MSY (IBmsy = kg/tow at MSY).

iv. Has the method been vetted through the SAFMC SSC?
   1. No, the SSC has not reviewed the use a AIM or any other survey-based relF approach to set ABCs in the South Atlantic.

v. What are the pros and cons of each method?
    1. Pros: Leverages long time series of reliable catch and an index of abundance spanning pre- and post high exploitation periods to identify sustainable fishery removal rates using very little data.
    2. Cons: Requires time series of reliable catch and an index of abundance spanning pre- and post high exploitation periods which may not exist for red snapper. Assumes catchability has not changed over the assessment period. Sensitive to smoothing decisions. No uncertainty or projection capabilities.

vi. Are the data for red snapper sufficient for the method?
    1. No, not unless a new long time series index of abundance can be generated from existing data sources. Index must span an early period prior to modern/high red snapper exploitation.

The seven stocks in the Skate complex use the surveys in a different way to set the ABCs (https://www.nefsc.noaa.gov/publications/crd/crd0902/). BMSY Proxy is the 75th percentile of the given survey time series (3-yr moving average), and half that value for Bthreshold. It was assumed that all species had at some time passed through BMSY at some point in the time series. The exception is barndoor skate for which the mean of the first four years of the autumn survey were used instead, given that biomass had been extremely low during most of the time series. The thresholds for fishing mortality are based on annual percentage declines of the three-year average of the NEFSC trawl survey time series chosen for the biomass reference points. The percentages are specified for each species individually based on historical variation within the survey. Overfishing is occurring when the three-year moving average of the given survey biomass index declines by more than the average CV of the time series.

vii. Has the method been vetted through the SAFMC SSC?
    1. No?

viii. What are the pros and cons of each method?
    1. Pros: Only survey index of abundance and biological knowledge of the species needed.
    2. Cons: Requires time series of reliable catch and an index of abundance that covers a time period during which Bmsy was achieved.

ix. Are the data for red snapper sufficient for the method?

1. No, not unless a new long time series index of abundance can be generated from existing data sources. Time series must span time period during which Bmsy was achieved.

We also have a truly data-poor assessment for deep sea red crab that only has two video surveys separated by 40 years along with catch information (https://www.nefsc.noaa.gov/publications/crd/crd0902/). Based on the FMP, the red crab stock will be considered to be in an overfished condition if one of the following three conditions is met:

Condition 1 -- The current biomass of red crab is below ½ BMSY in the New England Council's management area (excluding the Gulf of Maine). Bmsy based on Schaefer surplus production model for male crabs.

Condition 2 -- The annual fleet average CPUE, measured as marketable crabs landed per trap haul, continues to decline below a baseline level for three or more consecutive years.

Condition 3 -- The annual fleet average CPUE, measured as marketable crabs landed per trap haul, falls below a minimum threshold level in any single year. Similarly two potential approaches or proxies for identifying overfishing are described: Proxy #1: F / FMSY -- It is common for data sparse stocks to estimate trends in fishing mortality as an exploitation ratio, i.e., landings or catch divided by an index of abundance, usually from a survey. As a proxy for FMSY, Councils in the past have selected an exploitation level that existed during a time with no trend in biomass at an intermediate biomass level. Proxy #2: Landings / MSY – In the absence of other information, overfishing can be defined as catches in excess of an estimate of MSY. Although crude, provides an indication of current fishing effort relative to MSY conditions.

The FMP describes a default control rule that could be used by managers, although this has proved impractical due to lack of biomass, exploitation, natural mortality and reference point estimates.

x. Has the method been vetted through the SAFMC SSC?
    1. Some aspects have, others not. Certainly not this complete package.

xi. What are the pros and cons of each method?
    1. Pros: Uses surveys with gap (surveys combined across time gap as would likely need to be done in SA). Some status setting conditions involve use of fishery CPUE instead of survey CPUE.
    2. Cons: SPM-based MSY available but not accepted as primary model for management, right?

xii. Are the data for red snapper sufficient for the method?

1. Perhaps...would depend on which surveys were selected for consideration. Do we have a reliable logbook index?

Another different approach is found in the surfclam assessment that uses SS for trend but doesn't believe the absolute magnitude of the estimates (https://www.nefsc.noaa.gov/publications/crd/crd1705/). The OFL was determined to be not estimable, so The recommended ABC was based on a recent catch that has been sustained by the stock historically and shown to show no harm. This ABC is recommended for three years. *Survey data, including survey indices and swept area estimates of biomass (when available)*, catch records, and spatial distribution of the fishery will be examined as interim metrics.

xiii. Has the method been vetted through the SAFMC SSC?

1. In the form of average catch….yes, but this is a very unique stock with almost 0% chance of overfishing occurring (so not red snapper!). Also, doesn't use surveys directly to set the ABC, but only as rumble strips.

xiv. What are the pros and cons of each method?

1. Pros: easy to calculate
2. Cons: Doesn't use survey data. Need a stock as lightly exploited as surfclam to be so confident in this type of approach

xv. Are the data for red snapper sufficient for the method?

1. Yes, but not a survey-based method desired by Council.

Rcrit method for Atlantic halibut (document: Halibut-Assessment-Report-draft-12-01-17.pdf)

Builds off of GB cod index based method - reviewed by NE SSC

A method to determine if the differences seen over the duration of an index (Rcrit), specifically at the end of a time series, are significantly different. Method is outlined in reference document on page 13 of the pdf. If the change is significantly different, then an estimate of the catchability is needed to determine the scale or magnitude of the change. (from pdf p.16 of reference document - "While Rcrit provides a way of quantifying the rate of change in population size, it cannot distinguish the change in scale. For example a population that increase 3 fold during some period could increase from 2% to 6% of the virgin stock size for from 20 to 60%."). Thus, in order to use the Rcrit method an index that has a long time series and continues until the end of the time series is needed, as well as an estimate of catchability to determine the scale of the change and historic fishing mortality rates.

Application of PlanBsmooth approach to groundfish stocks

Chris Legault (NEFSC)

Introduction

During the October 23-24, 2017 NEFMC SSC meeting to set OFL and ABC for 19 groundfish stocks, I provided results of the PlanBsmooth approach for some stocks verbally. After the meeting, PDT members Paul Nitschke and Jamie Cournane contacted me regarding details of the PlanBsmooth approach for the SNEMA Yellowtail Flounder stock. This stock had an ASAP model that was accepted by the review panel and used by the PDT to provide possible OFL and ABC values. However, during our deliberations the SSC decided to use the PlanBsmooth approach to set the OFL and ABC. When I prepared a full description of the approach for the PDT, I realized that I had inadvertently used the wrong years to define the recent catch. I had used 2015-2017 instead of 2014-2016. The amount of SNEMA YT catch in 2017 was much less than 2014, causing a large change in the OFL and ABC. During my review of the application across all 19 groundfish stocks I also realized that some surveys that were in the database I drew from were not used in the assessment. This document provides details of the PlanBsmooth application for all 19 groundfish stocks so that the SSC is more informed about the approach during its upcoming conference call.

Data

Catch data from the PDT report for years 2014 through 2017 and the two three year means (2014-2016 and 2015-2017) are provided by stock in Table 1. The ordering of the stocks follows the order in the PDT presentation. Note that only three stocks have a higher mean catch during 2015-2017 compared to 2014-2016 (wolffish, gomhaddock, and gbhaddock). During the SSC meeting, I reported OFL and ABC values using the 2015-2017 mean catch instead of the 2014-2016 mean catch for gbwinter (OFL, ABC = 550, 412 mt), snemawinter (681, 510), snemayt (69, 52), ccgomyt (452, 339), and plaice (1461, 1096). These reported values are incorrect due to using the wrong time period for the three year recent catch.

While examining the SNEMA Yellowtail Flounder stock in more detail, I realized there were both stocks with missing surveys in our ADIOS database as well as stocks with extra surveys in our ADIOS database (Table 2). The values I reported during the SSC meeting used all the surveys available in ADIOS (those listed as either U or AN in Table 2). This means the multipliers I used for snemawinter (multiplier = 0.995), snemayt (multiplier = 0.360), and witch (multiplier = 1.133, OFL, ABC = 669, 502) were incorrect and thus the OFL and ABC I reported during the meeting were incorrect.

Methods and Results

The PlanBsmooth approach estimates OFL as the recent change in the smoothed, averaged biomass index from surveys applied to the recent catch. The ABC is calculated as 0.75 * OFL. Thus, when surveys are declining, the OFL declines, while increasing surveys cause the OFL to increase. There are of course many details in how exactly the approach is applied. An R package for PlanBsmooth is available at https://github.com/cmlegault/PlanBsmooth.

As shown in Table 2, the PlanBsmooth approach cannot always use the same information used in an analytical assessment. This is due to data availability for this exercise (I drew from a database called ADIOS that does not contain all surveys). It is also due to incomplete time series, such as the NMFS winter survey. The default approach in PlanBsmooth is to not standardize the surveys before combining them. This means that incomplete surveys, especially ones with much higher or lower catch rates than the other surveys, will cause a discontinuity in the average survey time series that could influence the loess smooth well beyond the years where it is included. Surveys covering few years, such as the MENH surveys, are particularly problematic for this approach. The surveys that were available and used in the assessment (only those denoted "U" in Table 2) were used in the results presented in this document.

To compute the average biomass index, the surveys are first lagged ahead one year if they occurred during the fall (meaning a fall survey value in 2016 becomes 2017 for the analysis). The lagged fall and standard spring surveys are then combined using a simple arithmetic average to produce the average survey time series. Years with missing survey information for any of the used surveys become NA in this average survey time series. Thus, only years where all appropriately lagged surveys are available are included in the average biomass index.

The average biomass index time series is then smoothed. A loess smooth is applied to the recent 33 years (1985-2017) using a span of 0.3. If the average survey time period is less than 33 years, for example during a retrospective analysis, then the span is changed to 9.9/nyears so that the same amount of smoothing is applied despite the change in the number of years. The loess smooth of each average biomass index time series along with approximate 95% confidence intervals of the smooth are shown for each stock in the accompanying file GARM2017PlanBsmooth.pdf. The smooth for SNEMA YT is shown in Figure 1 with the caption providing a guide for how to interpret the figure for all the stocks.

Once the surveys are averaged and smoothed, the most recent three years are used to determine the directional change in the recent surveys. The natural logarithm is taken of the three recent loess smooth predicted values and a linear regression fit through these points. The estimated slope of this regression is transformed back to regular scale using the exponentiation function to create the Multiplier value labeled in Figure 1. The retransformed linear fit is shown in Figure 1 as a dashed red line. This Multiplier is used to calculate the OFL as OFL = recent mean catch * Multiplier. The ABC is then calculated as 0.75 * OFL.

The results of these OFL and ABC calculations for each stock are shown in Table 3. Note the shaded columns in Table 3 are for comparison only, they use the incorrect years 2015-2017 to compute the mean catch. The correct values use years 2014-2016 to compute the mean catch and are not shaded in Table 3.

Multipliers for the 19 groundfish stocks estimated by PlanBsmooth are compared in Figure 4. The two stocks that use PlanBsmooth correspond to the largest (gbcod = 1.5173) and smallest (snemayt = 0.3595) multipliers across all 19 stocks. The remaining 17 stocks have multipliers between 0.7 and 1.3 (meaning OFL changes by less than 30% from recent catch).

Biomass index Mohn's rho values for 18 groundfish stocks estimated by PlanBsmooth are compared in Figure 5. The two stocks that use PlanBsmooth correspond to the smallest (snemayt = -0.318) and 5th smallest (gbcod = -0.04) of the 18 stocks. All of the 18 stocks have minor retrospective patterns because the rho adjusted terminal value is within the 90% confidence intervals of the terminal year. The one stock not included in Figure 5 is Gulf of Maine Haddock. As seen in the included pdf file, the Mohn's rho value for this stock is -18.9, indicating something has gone wrong because Mohn's rho should not have a value less than -1. The reason for this result is that the 0 year peel (the original data) has a loess smooth predicted value that is negative for 2012. Thus, when the retrospective value is computed as (tip – term)/term for the 5 year peel (making 2012 the terminal values) the negative value for term causes the Mohn's rho calculation to produce a large negative value (-131.8). This could be fixed by taking the absolute value of the term in the denominator, but would result in a very large positive value and would be a deviation from the standard Mohn's rho calculation. Instead of trying to plot this stock with the rest, I decided to take it out of the plot and note the reason why here in the text. Dropping just the 5 year peel for this stock (meaning using only peels 1-4, 6, and 7), results in a Mohn's rho value of -0.047. This value is well within the range seen in the other groundfish stocks.

Discussion

The changes to SNEMA YT recent catch (mt) were major (193 to 371) while the changes to the multiplier were minor (0.360 to 0.3595) resulting in a major change to OFL (69 to 134 mt) and ABC (52 to 100 mt) for this stock. This result causes an even larger issue when comparing this new ABC with the OFL for 2018 from the model, 45 mt, because the PlanBsmooth ABC is now more than twice as large as the model OFL. I cannot speak for NMFS, but this comparison will certainly raise questions about whether the ABC can be approved, as noted by Mike Simpkins during the SSC meeting for the previously agreed ABC of 52 mt.

A sharp-eyed reader may notice in Figure 2 that peel 1 does not end in 2016 for SNEMA YT as would be expected. This is because the loess smooth for the 1 year peel estimates a negative biomass value for 2016. Since the natural logarithm of a negative number is undefined, the 2016 value is not included in the 1 year peel regression, meaning only year 2014 and 2015 are used in the regression for that peel when computing the multiplier. The ability of the loess smooth to estimate negative biomass values despite all the observations being positive can cause problems for the PlanBsmooth approach.

The PlanBsmooth approach has a number of decisions that could be made differently. For example, the year range to define recent catch, whether to standardize surveys before averaging, use of biomass or numbers as the catch per tow index for a survey, the time frame and span for the loess smoother, whether to apply the loess smooth in regular or log space, use of smoothing approaches other than loess, the number of years in the regression to estimate the multiplier, the conversion of the log-scale slope to a multiplier, and whether the recent catch times the multiplier is the OFL or ABC are all decisions that could be made differently. As mentioned by John Wiedenmann during the SSC meeting, we do not have a policy for how to apply these data-limited harvest control rules currently. Adopting one that was not examined during the review meeting for a particular stock puts the SSC in the position of creating the “assessment” (quotes used because we did not reject the accepted assessment for SNEMA YT) and also serving as the review body of that decision. In my opinion, it would be better if the SSC sub-group on harvest control rules for data-limited approaches could provide guidance regarding this situation that could be reviewed by the appropriate panel before being brought to the SSC for OFL and ABC setting.

I hope this document improves transparency of the PlanBsmooth approach and reduces questions during our upcoming SSC conference call. Feel free to email me or give me a call (office phone 508-495-2025) prior to the conference call if you have any questions.

Table 1. Catch (mt) by stock for years 2014 through 2017 and the arithmetic average of years 2014-2016 and 2015-2017.

		Year				Mean Catch	
IDnum	Stock	2014	2015	2016	2017	2014-2016	2015-2017

Table 2. Survey and stock combinations considered for this analysis. The letter “U” denotes the survey was used for the stock both in the assessment and the PlanBsmooth calculations. The letter “M” denotes the stock was missing from the PlanBsmooth calculations but was used in the stock assessment. The letters “AN” denote the survey was available in the ADIOS database but was not included in the PlanBsmooth approach because either the survey was incomplete in recent years (NMFS winter survey) or else the surveys were not used in the stock assessment (pout and witch). The Other surveys for snemawinter are the Rhode Island spring, Connecticut spring, two New Jersey, Massachusetts young of year, Connecticut young of year, and University of Rhode Island Graduate School of Oceanography surveys.

IDnum	Stock	NMFS fall	NMFS spring	NMFS winter	MADMF fall	MADMF spring	MENH fall	MENH spring	DFO	AS Sh

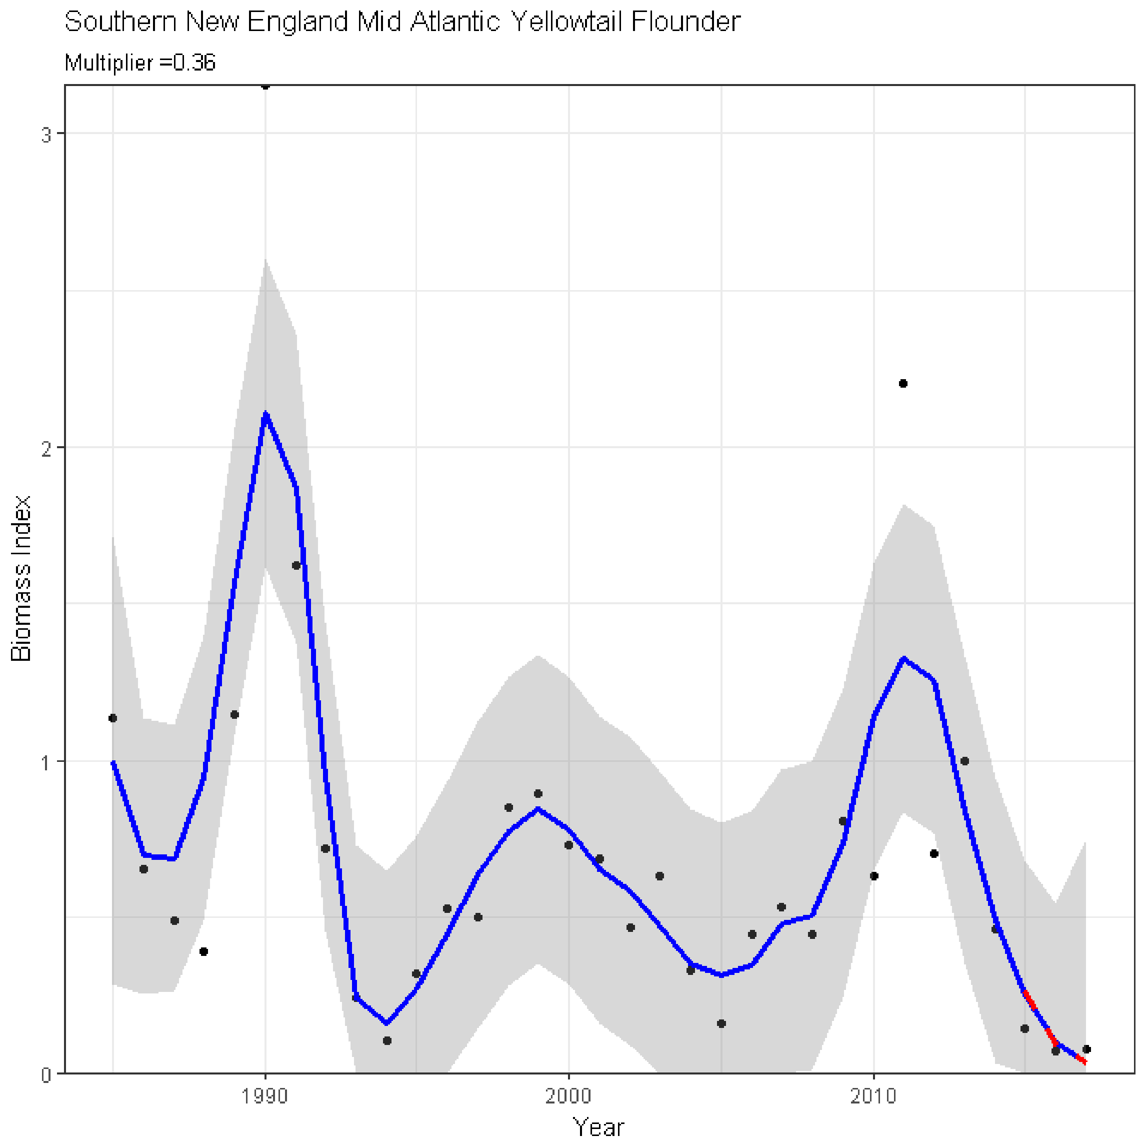

Figure 1. PlanBsmooth standard plot for Southern New England Mid-Atlantic Yellowtail Flounder. The dots denote the average survey values (arithmetic average of the NMFS fall survey lagged ahead one year and the NMFS spring survey). The blue line is the loess smooth. The gray area shows an approximate 95% confidence interval for the loess smooth. The red dashed line shows the retransformed log-linear fit to the most recent three years of the smoothed values. The Multiplier in the top left is the value used to generate the OFL as recent mean catch times the Multiplier.

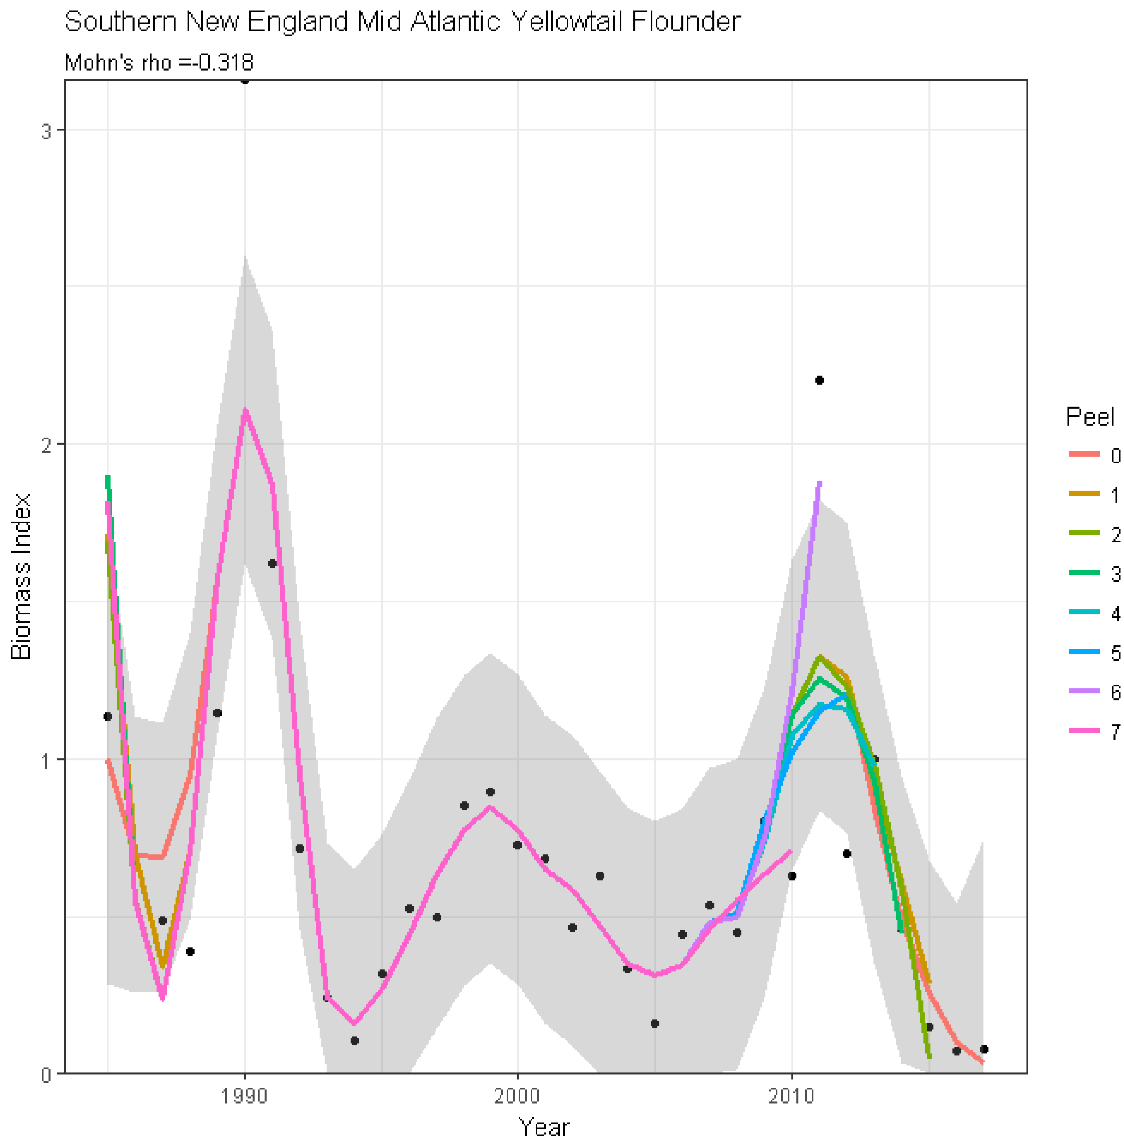

Figure 2. PlanBsmooth biomass index retrospective plot for Southern New England Mid-Atlantic Yellowtail Flounder. The dots show the average survey time series. The peel lines denote how many years from the terminal year have been removed when computing the loess smooth. The grey area shows an approximate 95% confidence interval for the loess smooth using peel 0 (the original data).

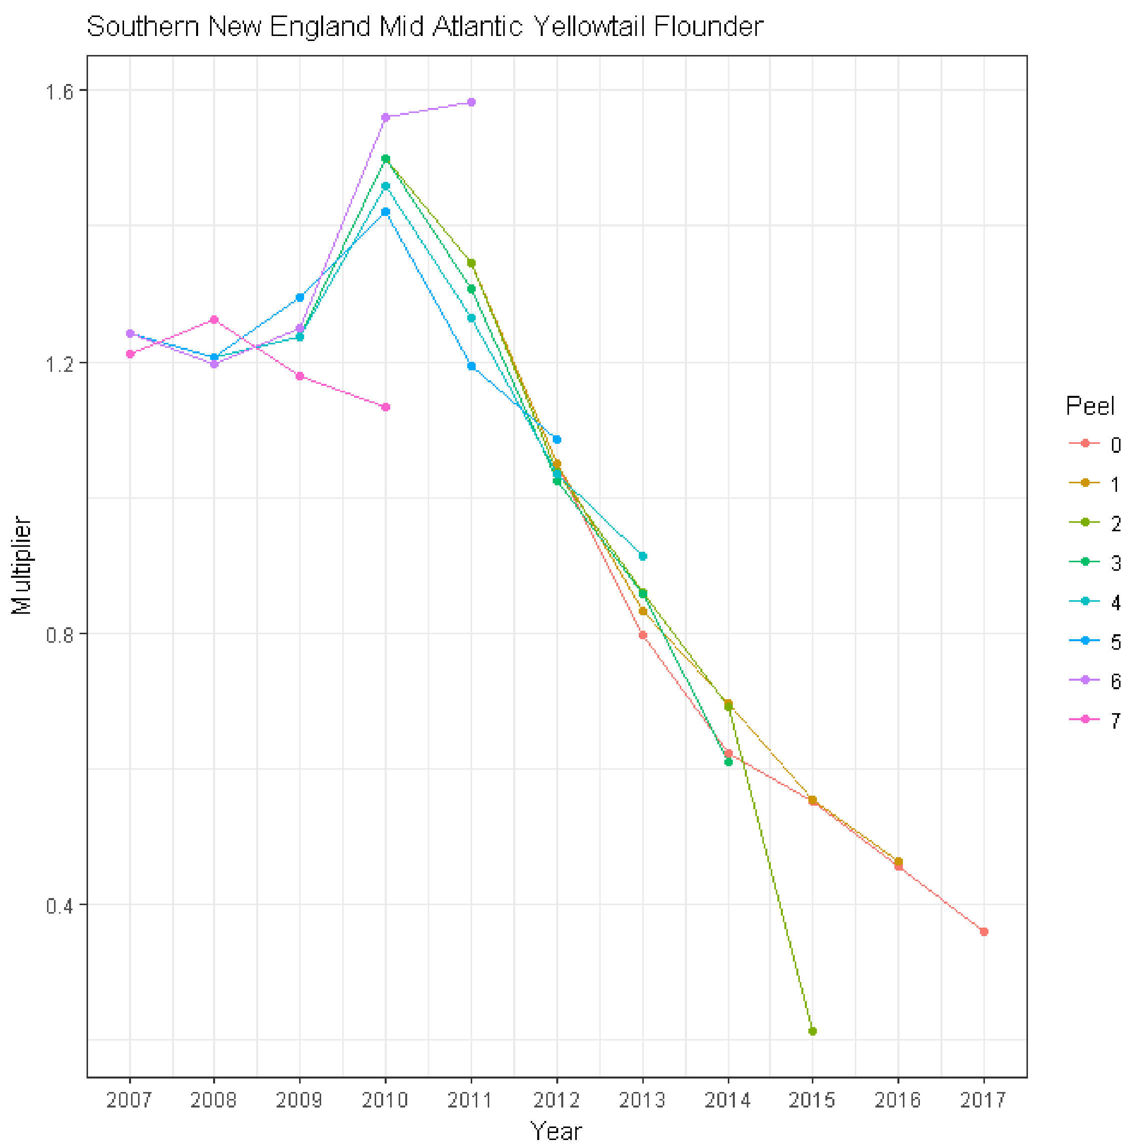

Figure 3. PlanBsmooth multiplier retrospective plot for Southern New England Mid-Atlantic Yellowtail Flounder. The log-linear regression is extended back in time using a three year moving window to estimate historical multipliers in addition to the standard terminal year multiplier. The peel indicates the number of years removed from the terminal year when computing the loess smooth.

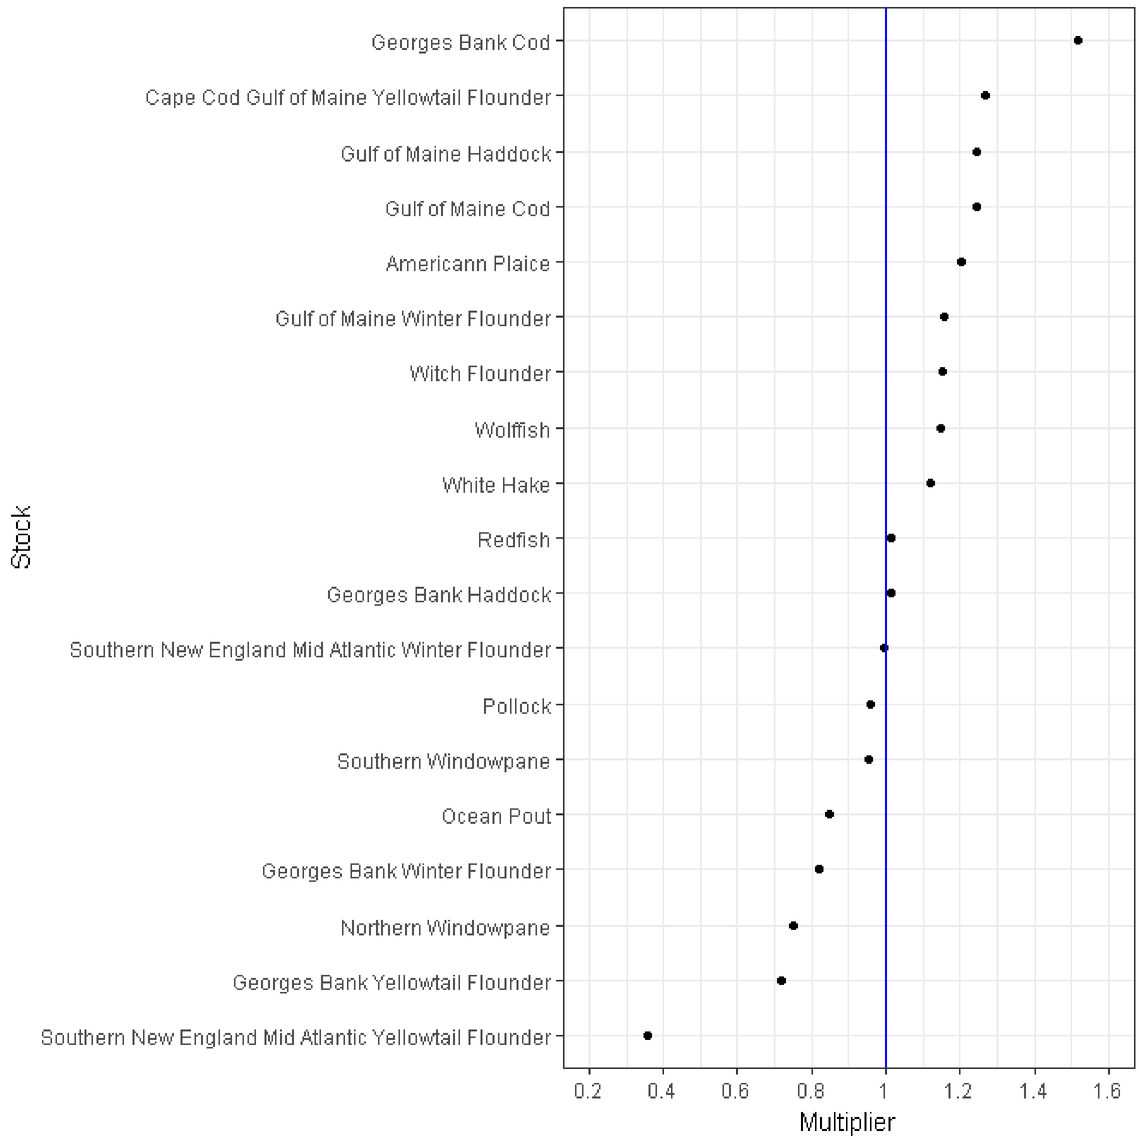

Figure 4. PlanBsmooth multipliers for the 19 groundfish stocks ordered from smallest to largest. The blue line denotes a multiplier of 1, meaning the OFL is equal to the recent mean catch.

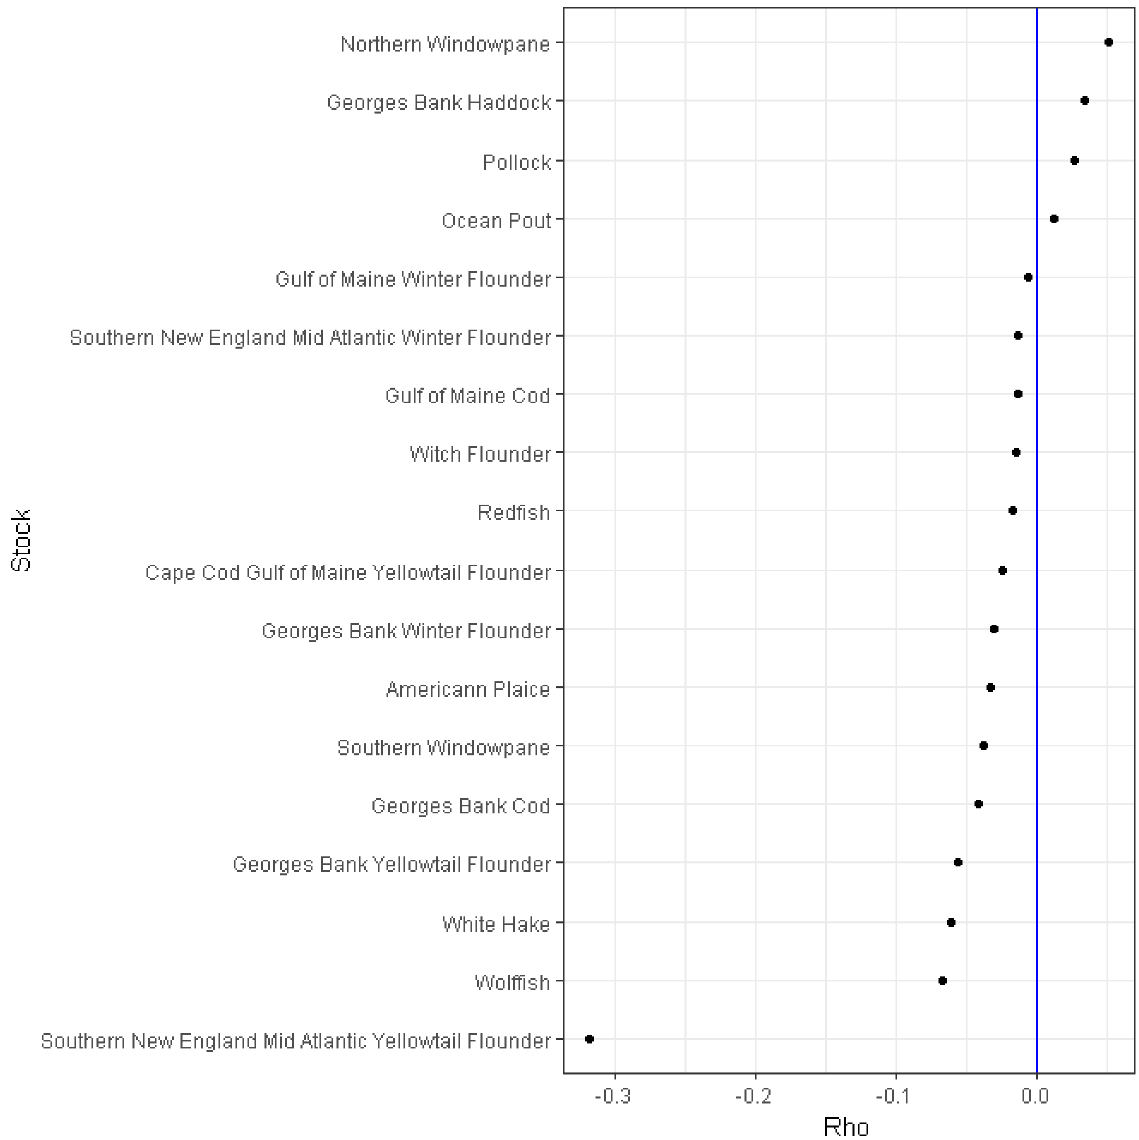

Figure 5. PlanBsmooth Mohn's rho values for 18 groundfish stocks ordered from smallest to largest. The GOM Haddock rho of -18.9 is not shown due to the negative 2012 prediction for the original data causing problems for this calculation (see Discussion section in text).

Plan B Assessment for Atlantic Halibut

Paul Rago

Webinar with NEFMC Science and Statistical Committee
December 14, 2017

Outline of this Presentation

- Follows the material in “Halibut Assessment for 2017”, Draft, December 1, 2017.
- Consideration of available data
- De-emphasizes the DCAC analyses
- Focuses on methodology used to project catch in 2018
  - Ratio methods and randomization tests to estimate magnitude and significance of changes in relative abundance.
  - Simulation tests of Ratio method
  - Proposed catch adjustment method based on rates of change in indices
  - Simulation tests of FSD method
  - Estimation of uncertainty of forecast
  - Application of method to DFO 3NOPs4VWX5Zc Atlantic halibut and IPHC Pacific halibut

The Plan B Dilemma

- Restrictions on introductions of new data and analytical models
- Rebuilding considerations
- No revisions of stock structure
- Accountability measures
- *How should catch be adjusted without measures of biomass and fishing mortality, and their respective reference points?*

Some Plan B Options

1. Use some function of recent catch
    1. Last year
    2. Some arbitrary average
    3. Some arbitrary scalar applied to some arbitrary average
2. Apply a method that relies entirely on the assumed state of the stock.
3. Apply a biologically based rate to a swept area estimate
4. Piggy back the US control rule on the management decisions applied to the adjoining Canadian stock
5. Develop an updating function that adjusts catches based on trends in one or more indices.

- First 4 options are either hard to justify or cause knife fights

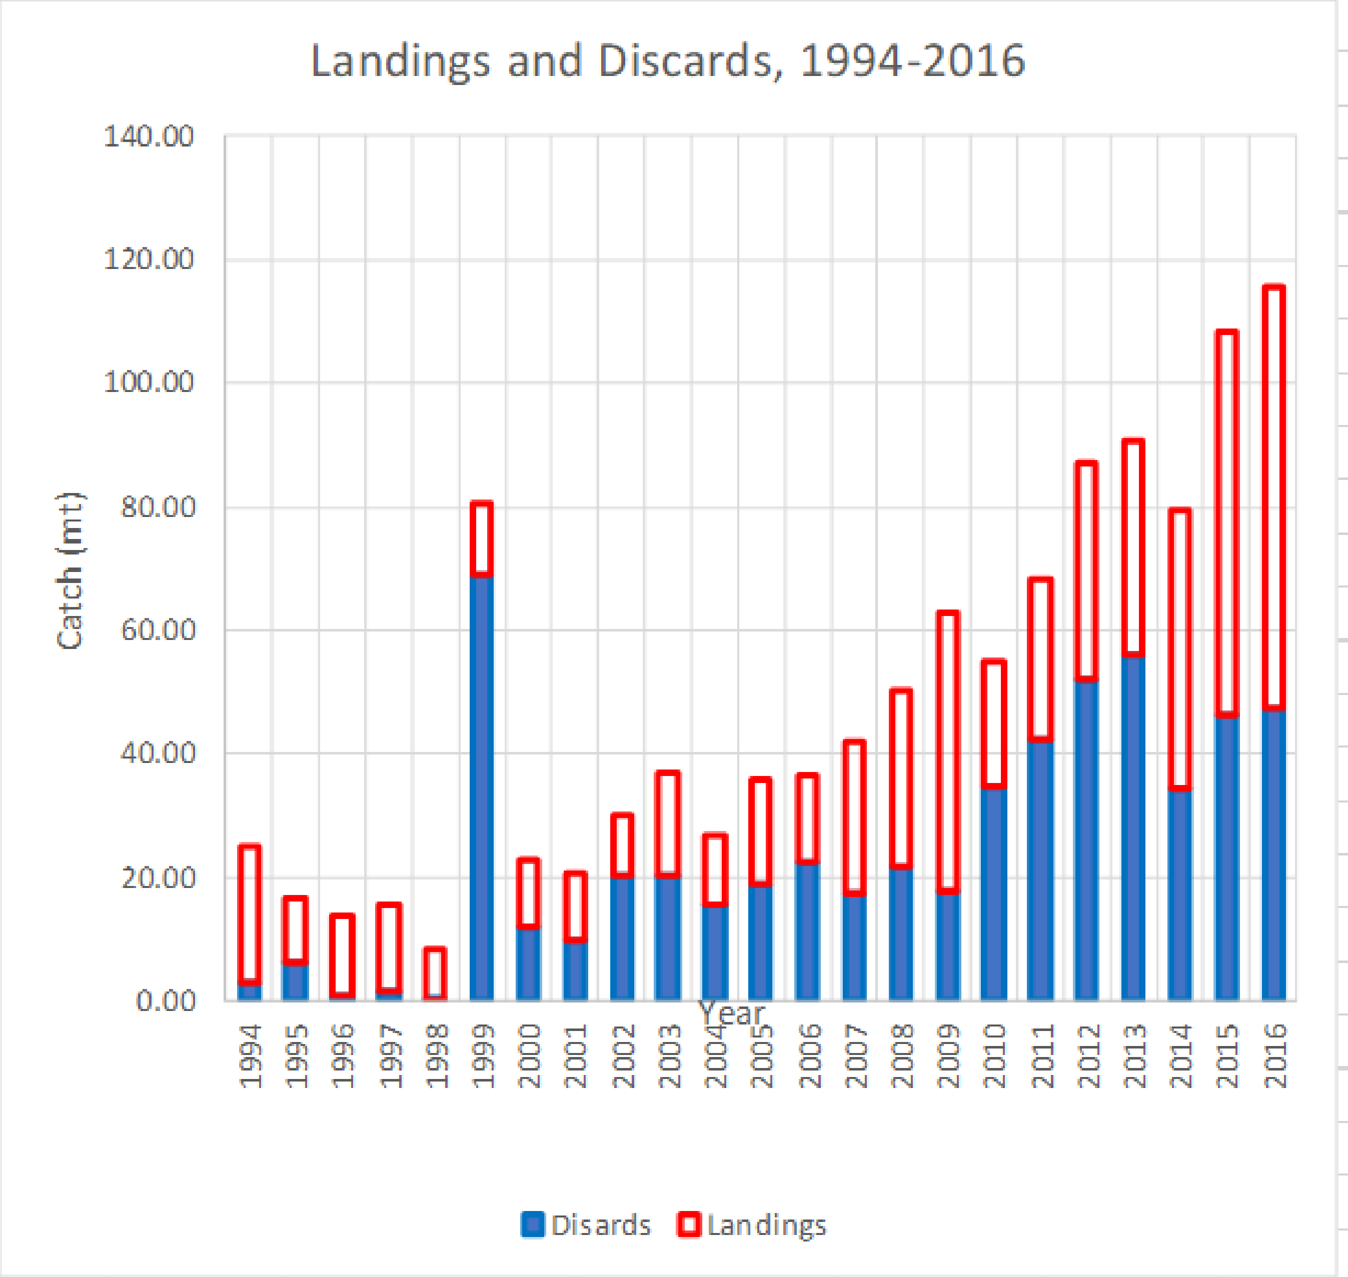
Perspectives

- Has the population changed in recent years?
- Is the change significant?
- Is the observed change supported by multiple indices?
- How does the proposed data poor method perform in simulation?
- Are there adverse effects for rebuilding, catches, and accountability measures?

Data Sources Considered (Table 1)

- Standard NEFSC survey update
- Landings and Discard update
- Abundance Indices
  - d/k ratio gill net
  - d/k ratio trawl
  - Maine Standardized CPUE—Hansell et al.
  - Maine Survey indices
  - Maine Commercial Indices from logbooks
- Comparisons with Canada

Year	Disards	Landings	Catch
1994	3.16	21.77	24.93
1995	6.34	10.54	16.88
1996	0.65	13.32	13.97
1997	1.64	14.01	15.65
1998	0.10	8.41	8.51
1999	69.08	11.51	80.59
2000	11.87	11.07	22.94
2001	9.68	10.82	20.50
2002	20.20	10.01	30.21
2003	20.15	16.68	36.83
2004	15.71	11.22	26.93
2005	18.89	16.81	35.70
2006	22.45	14.08	36.53
2007	17.27	24.61	41.88
2008	21.66	28.69	50.35
2009	17.85	45.05	62.90
2010	34.68	20.20	54.88
2011	42.34	25.79	68.13
2012	52.18	34.80	86.98
2013	56.16	34.67	90.83
2014	34.33	44.99	79.32
2015	46.28	62.00	108.28
2016	47.39	68.20	115.59



Trends in Utilization Ratio (Landings/Catch), 2002-2016

FIG 9 in Report

The Panoply of Data Poor Methods

- Methods that rely some arbitrary scalar adjustment to recent average catches with no rigorous analyses of population consequences.
  - ORCS
- Methods that rely on strong assumptions about current stock status
  - DCAC, DB-SRA etc.
- Methods that apply a biologically based harvest rate to a swept area estimate of abundance
  - Eg GOM winter flounder, GB yellowtail flounder, etc.
- Methods that adjust current catches based on measures of current trends or trends.
  - GB cod
  - MPA etc. Butterworth type, also Hillary, Apostolaki et al. etc.

DCAC = Plan C—served as a useful starting point

- Basic Equation
- $C_{sustainable} = \frac{\sum_{t=1}^{n} C_t}{n + \frac{Delta}{0.2\ M}}$ [3]
- $Delta = \frac{B_t - B_{t+n}}{B_{MSY}}$ [4]
- $C_t = C_{sustainable} \frac{B_t}{B_{MSY}}$ [5]
- Finding DELTA ?
  - Ratio Increase
  - Percentage increase with respect to current stock abundance

Rcrit and Randomization—is the observed trend in one or more indices significant?

- Definition:
- $R_{crit,j} = \frac{\sum_{t=T-m+1}^{T} \frac{I_{j.t}}{m}}{\sum_{t=1}^{n} I_{j,t} \frac{I_{j.t}}{n}}$ [6]
- Standardize the indices with respect to means (multiple indices)
- $R_{crit,.} = \frac{\sum_{j=1}^{J} \sum_{t=T-m+1}^{T} \frac{s(I_{j.t})}{m}}{\sum_{j=1}^{J} \sum_{t=1}^{n} \frac{s(I_{j,t})}{n}}$ [7]
- Create the sampling distribution of Rcrit.
- $R_{crit,k} = \frac{\sum_{j=1}^{J} \sum_{t=T-m+1}^{T} R_k\left(\frac{s(I_{j.t})}{m}\right)}{\sum_{j=1}^{J} \sum_{t=1}^{n} R_k\left(\frac{s(I_{j,t})}{n}\right)}$ [9]

Rcrit and Randomization (2)

- <u>Significance Level of Rcrit</u>
- $P(R_{crit,k} > Rcrit, obs) = \frac{\sum_k^{Nrand} g(R_{crit,k} \geq R_{crit,obs})}{N_{rand}}$ [10]

Rcrit Simulation tests

- Key factors to consider
  - True underlying rate of change
  - Observation error of the indices
  - Number of variables available

Results of Simulation Tests for Rcrit model

Table 2. Relative bias in estimates as function of true Rcrit, CV and number of indices considered.

Table xx. Summary of ratio test simulations for estimation of bias in mean and median of Rcrit as a function of the magnitude of true rate of change (Rcrit_true), the variation of the observation error (CV) and the number of relative abundance indices (Nvar). All simulations were based on a time series of length 10, and the ratio of the average of the last 3 to the first 3 observations for 2000 randomizations of each of 1000 stochastic realizations.

		Relative Bias in Estimated Rcrit vs True Rcrit

Table 3. Average Probability value of Rcrit estimates as function of true Rcrit, CV and number of indices considered.

Performance improves as CV decreases, as the number of indices increases and as the true underlying rate of increase increases.

lambda	Rcrit_true	CV	P0.005	P0.01	P0.025	P0.05	P0.1	P0.15	P0.2	P0.25

Table 7. Fraction of simulations with significance probabilities less than or equal to the value in the column header. Color coding is consistent across Tables 4-7.

Results in this table are for FIVE indices of relative abundance.

Rcrit *Applications*

- US—6 candidate indices
- DFO—3 indices AND SSB from an analytical model

Finding the best estimate of Rcrit for multiple indices?

- Often a difficult problem in stock assessments—lots of group discussion
- Therefore-- Consider all possible models
- Combination of all possible models of n indices taken m at a time summed over m=1,…, n
- Comb(6,6)+Comb(6,5)+Comb(6,4)+Comb(6,3)+Comb(6,2)+Comb(6,1)
- 1 + 6 + 15 + 20 + 15 + 6=63

- Can now compare alternative models and compute average Rcrit and Pvalue of Rcrit across all possible models.

50000 replicates

ratio 2014/2016 to 2002-2004

USA Data (2002-2016)

Replacement Yield Model (RYM)

- Used in past assessment but unstable results when updated in 2015 (concluded to be REBUILT in 2014)

$$B_t = B_{t-1} + R_{t-1} - C_{t-1} \; [1]$$

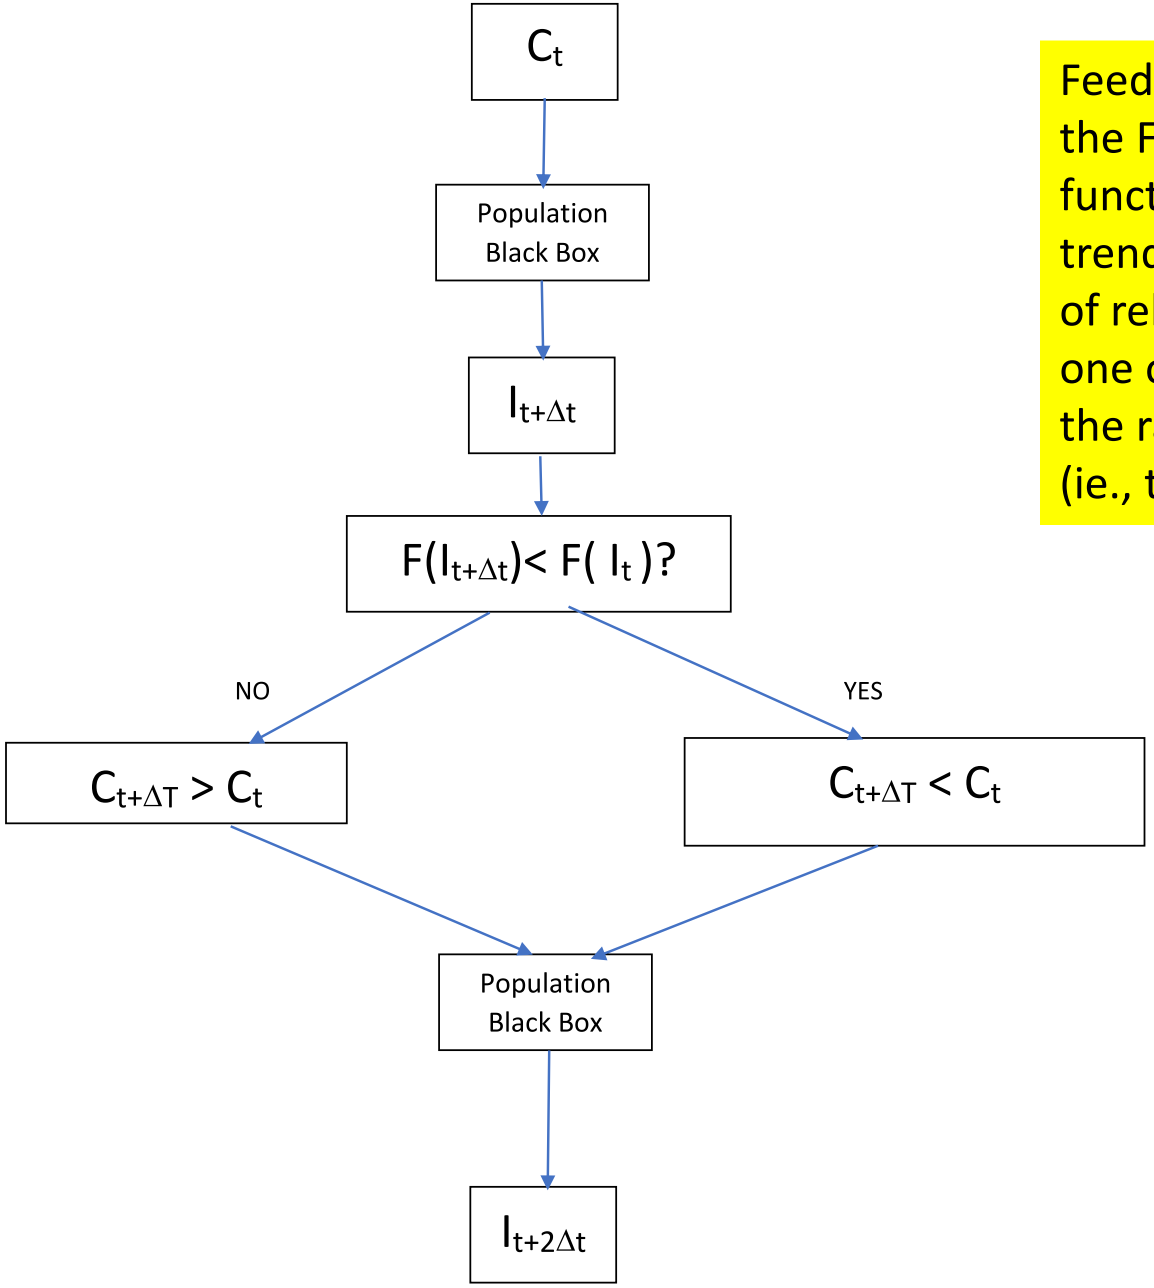
$$R_t = rB_t\left(1 - \frac{B_t}{K}\right) \quad [2]$$

- Basically a Surplus production model with constraints
  - Fixed r=2 F0.1
  - Fixed q=0.5 for fall survey
  - Assumptions about catch history
- Review panel “the updated assessment was not acceptable as a scientific basis for management advice. The updated assessment produced an unstable and unrealistic solution”

Revised model for stock dynamics

- Assume linear model BUT r and h vary with time
- $B_{t+1} = B_t + r_t B_t - h_t B_t$ [17]
- $C_t = h_t B_t$ [18]
- $\frac{C_{t+1}}{C_t} = \frac{h_{t+1} B_{t+1}}{h_t B_t}$ [22] $= C_{t+1} = \frac{h_{t+1}}{h_t} \frac{I_{t+1}}{I_t} C_t$ [24]
- $\frac{B_{t+1}}{B_t} = \frac{qI_{t+1}}{qI_t} = \frac{I_{t+1}}{I_t} = 1 + r_t - h_t$ [26]
- $\ln(I_{t+p}) = \left(p\, ln(1 + r - h) + \ln(I_t)\right)$ [29]
- $slope_t = \ln(1 + r_t - h_t)$

FIG 15 in Report



Feedback Process used in the FSD model. The F() function estimates the trend (ie., first derivative of relative abundance) in one or more indices AND the rate of change in trend (ie., the second derivative)

The magnitude of the change in C is determined by the values of the first and second derivatives and the gain parameters(Kp, Kd) applied.

Building the First and Second Derivative Model

- Recursive equation for updating catch
- $C_{t+1} \cong \frac{h_{t+1}}{h_t} e^{slope_t} C_t$ [31]
- This can be extended to multiple indices
- BUT also interested in ability to detect changes in the slope.
- Need to extend model
- $\beta(t, n) = slope(x_{t-n+1,} x_{t-n}, \dots . x_{t-1}, x_t)$
- $\Delta\beta(t, n) = \beta(t, n) - \beta(t-1, n)$ [34]

Controllability

- Do we want to take all of the increase in relative abundance and translate it to an equivalent increase in catch?
- Why not, it's only fair
  - Concerns about lag in signal—based on 5 year window of index observations
  - Possibly bad signal, observation error is high.
  - Longevity suggest that under harvest of halibut will be in the water next year to capture. Therefore can balance tradeoff.
  - Examples from control theory literature (eg. Thermostats) suggest potential instability in process if gain is set too high.
- Many MPA examples consider "slow up, fast down" policies
- One way to quantify is to consider rate of change in slope in terminal year, an approximation of the second derivative of abundance.
- Important because of potential changes in productivity over time (r(t)). Especially important if stock productivity is declining via slower growth or reduced recruitment

Weighting the slope and delta slope components

- Gain factors
  - Kp Gain on proportional rate of change
  - Kd Gain on derivative of change

- $C_{t+1} = e^{\left(K_p \beta(t,n) + K_d \Delta\beta(t,n)\right)} C_t$ [35]

- Equation 35 is the recursive updating equation for catch. Note that when Kp=Kd=0 this becomes a constant status quo catch model.

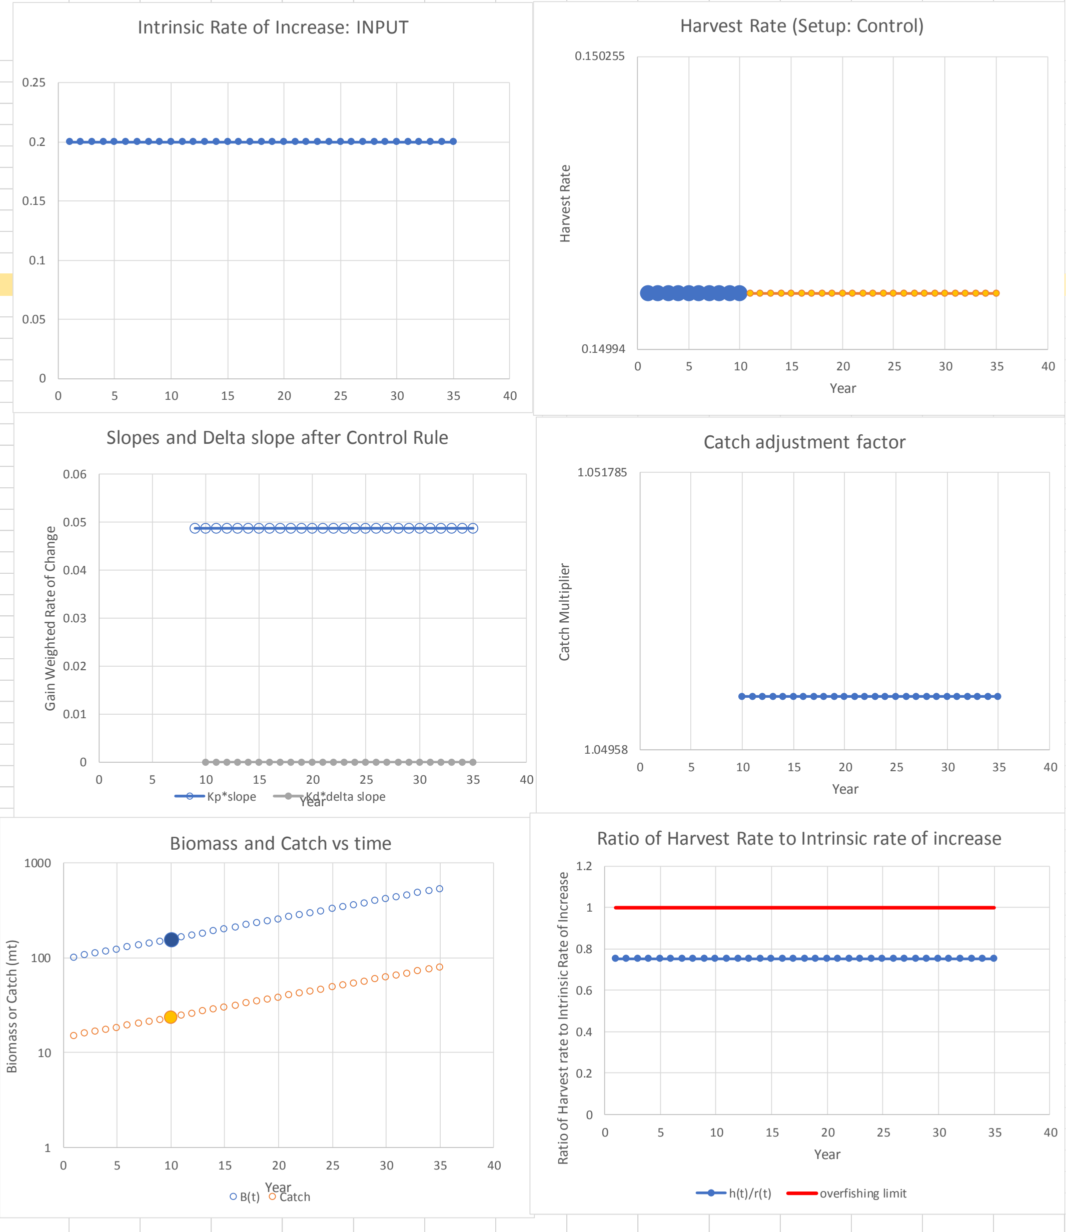
Simulation Tests on FSD model

- Observation error for the relative abundance indices ***CV={0.005,0.2}***
- Number of abundance indices available ***Nvar={2,6}***
- Number of years to consider for estimating average slope. ***Ntrend={3,5}***
- Effects of alternative values of Kp and Kd
- The underlying rate of population increase (r(t)) during the period before and after the control rule is applied.
- The pattern of harvesting (h(t)) prior to the application of the control rule.

What is expected behavior of population controlled by FSD?

- Depends on:
  - True rate of change in productivity
  - Initial conditions prior to implementation of controls
    - Harvest rates
    - Intrinsic rate of increase
  - Weighting factors applied to slope and Delta slope
  - Ability to track changes in relative abundance
- Any control system that relies on past information to forecast future conditions will have problems when
  - Lags in information—slope is based on n years, reflecting a balance between sensitivity and estimability –the Signal:Noise ratio.
  - The population biology changes—growth declines, recruitment fails etc (e.g., IPHC Pacific Halibut)
  - The fishery changes—fishing activity becomes more targeted resulting in stable CPUE while stock declines

Initial Harvest h(t) Scenario	Intrinsic rate of increase r(t) scenario	Number of years used for slope estimation	Kp Gain on Slope	KD Gain on slope derivative		Total Catch	CV of Catch	Max Cmult	Min Cmult	Fraction of Overfishing Events
1	1	5	1	0		1166	0.355	1.050	1.050	0.00



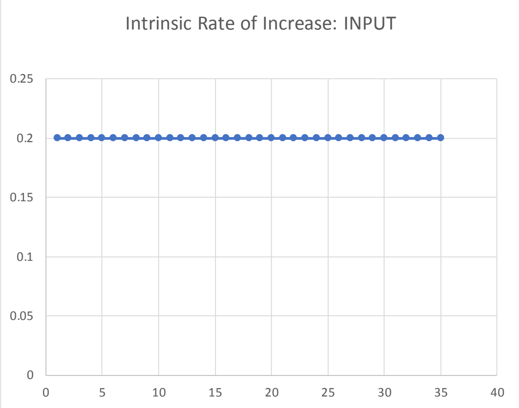
Example 1—the boring equilibrium:

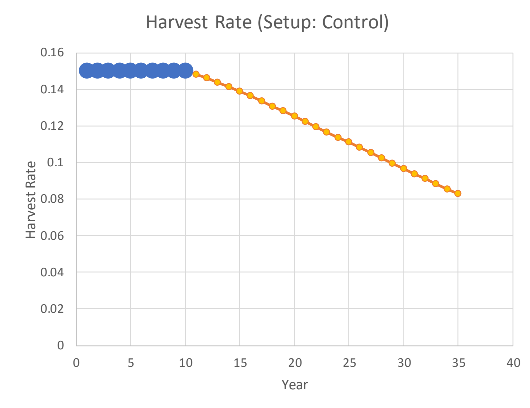
- Intrinsic rate of increase is constant =0.2
- Initial Harvest rate is below intrinsic rate during initial period h(t)=0.15
- Assume Kp=1.0 for proportional and Kd=0 for derivative controls

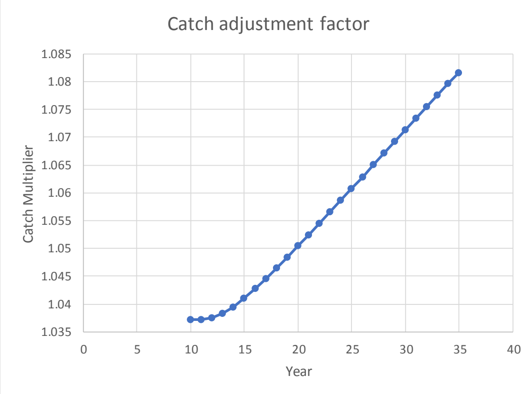
Key Results

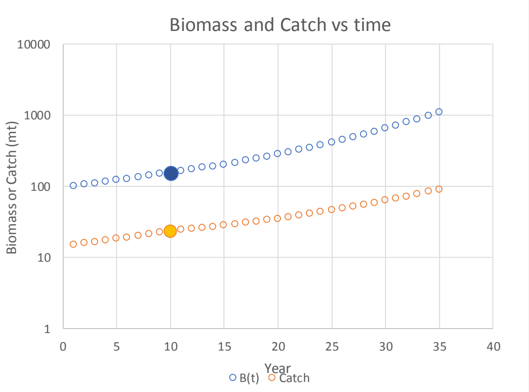
- High cumulative catch 1166 mt
- No Overfishing
- Multiplier is same over entire period= 1.05
- Stock size AND catch continuously increase.
- Rate of population growth during control period is same as in period of no direct control.

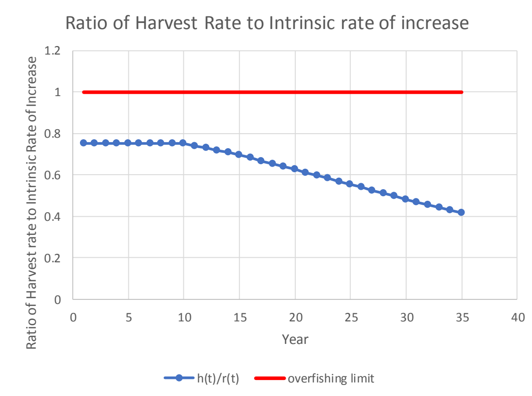
Initial Harvest h(t) Scenario	*Intrinsic rate of increase r(t) scenario*	*Number of years used for slope estimation*	*Kp Gain on Slope*	*KD Gain on slope derivative*		Total Catch	CV of Catch	Max Cmult	Min Cmult	Fraction of Overfishing Events
1	***1***	5	***0.75***	***0***		1157	0.42	1.082	1.037	0.00











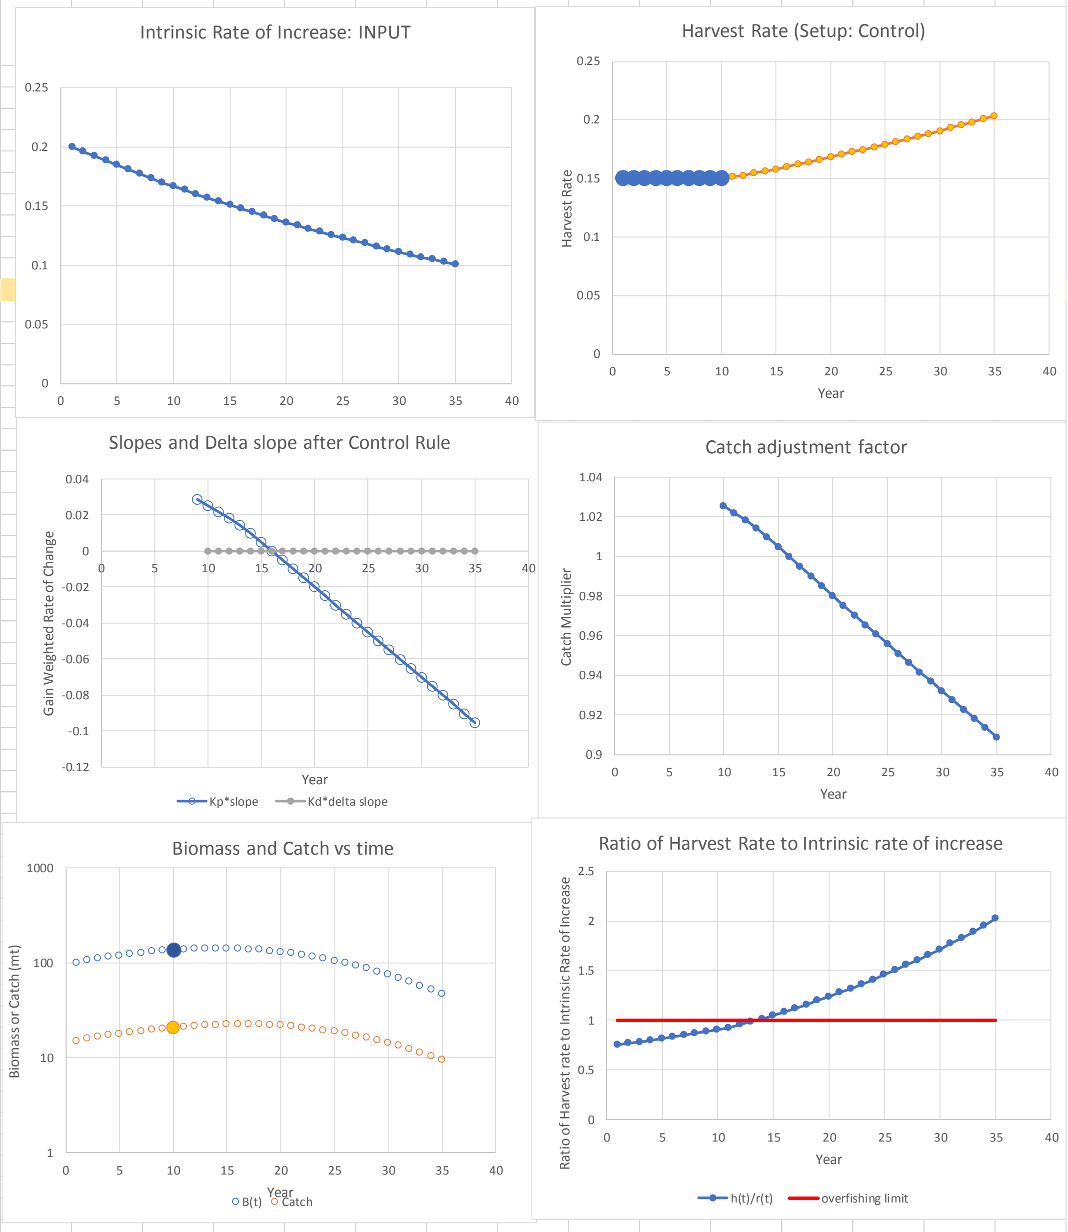
Example 2— Don't take it all policy:

- Intrinsic rate of increase is constant =0.2
- Initial Harvest rate is below intrinsic rate during initial period h(t)=0.15
- Assume Kp=0.75 for proportional and Kd=0 for derivative controls

Key Results

- High cumulative catch 1157 mt but much of this comes in the out years as population continues to increase
- No Overfishing AND Harvest Rate continues to decrease
- Multiplier increases over entire period= 1.05
- Stock size AND catch increases slightly.
- Rate of population growth increases continuously over the control period.

Initial Harvest h(t) Scenario	Intrinsic rate of increase r(t) scenario	Number of years used for slope estimation	Kp Gain on Slope	KD Gain on slope derivative		Total Catch	CV of Catch	Max Cmult	Min Cmult	Fraction of Overfishing Events
1	4	5	1	0		456.7	0.233	1.025	0.909	0.63



More challenging Control Problems: Stock productivity declines continuously

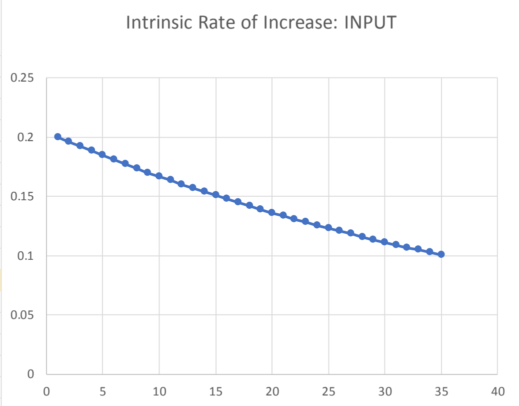
Example 3:

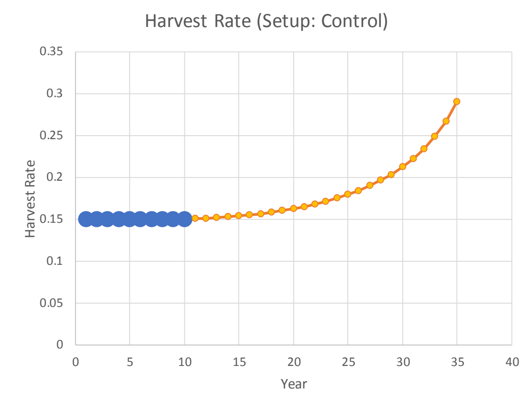
- Intrinsic rate of increase is DECLINING
- Initial Harvest rate is below intrinsic rate during initial period
- Set Kp=1 (take it all). Don't consider derivative. (Kd=0)

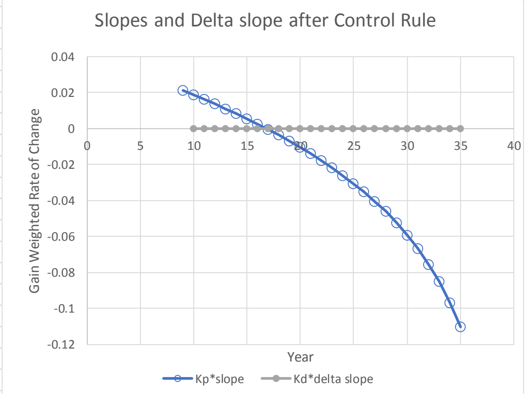
Key Results

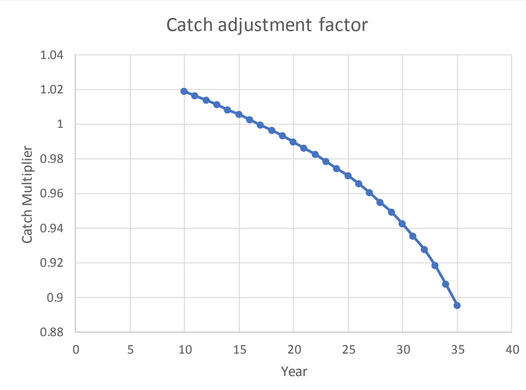
- Moderate cumulative catch 457 mt
- Overfishing commences about year 10. Frequency of overfishing years is 63%
- Minimum catch multiplier is 0.91 or 9% decrease
- Stock size gradually declines as do catches as the stock declines

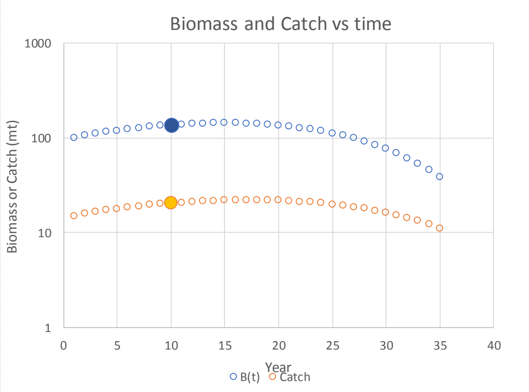
Initial Harvest h(t) Scenario	Intrinsic rate of increase r(t) scenario	Number of years used for slope estimation	Kp Gain on Slope	KD Gain on slope derivative		Total Catch	CV of Catch	Max Cmult	Min Cmult	Fraction of Overfishing Events
1	4	5	0.75	0		475.3	0.18	1.019	0.895	0.60

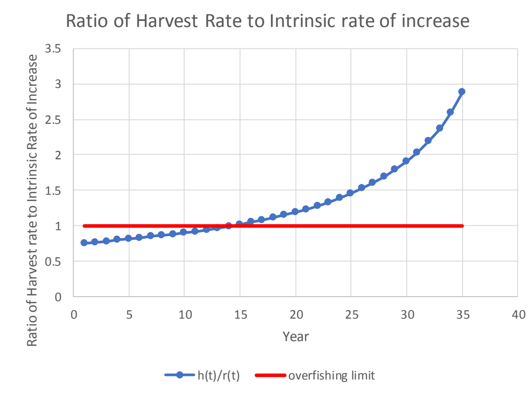












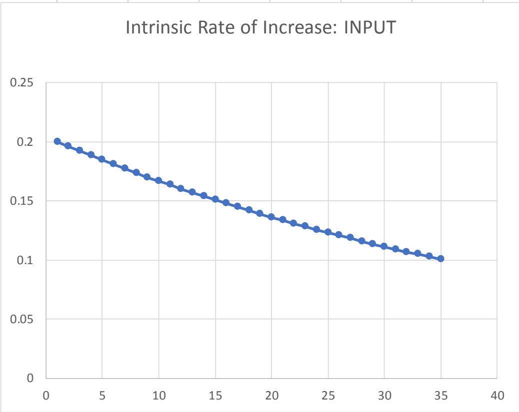
Example 4:

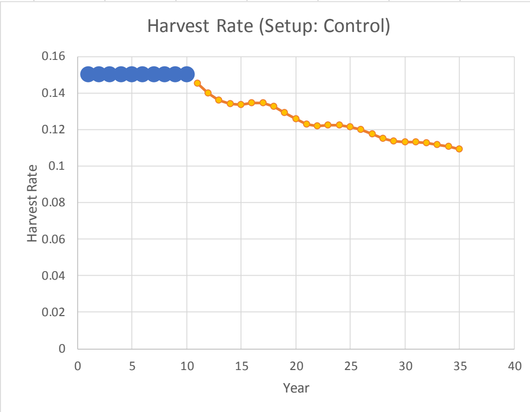
- Intrinsic rate of increase is DECLINING
- Initial Harvest rate is below intrinsic rate during initial period
- Set **Kp=0.75** (hold back). Don't consider derivative. (Kd=0)

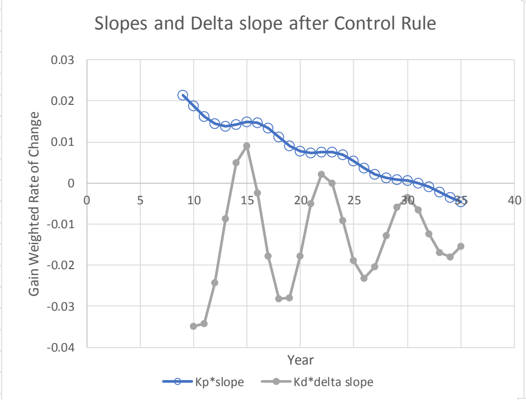
Key Results

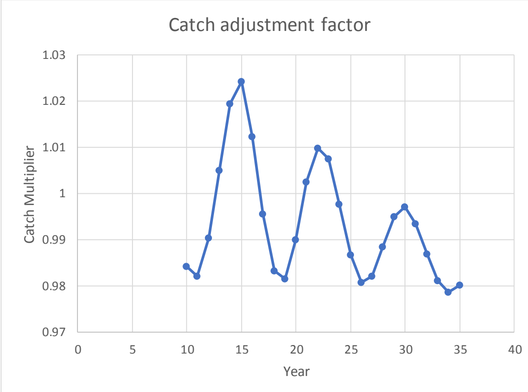
- Moderate cumulative catch 475 mt
- **Overfishing commences about year 15**. Frequency of overfishing years is 60%
- Minimum catch multiplier is 0.89 or 11% decrease
- Stock size gradually declines as do catches as the stock declines

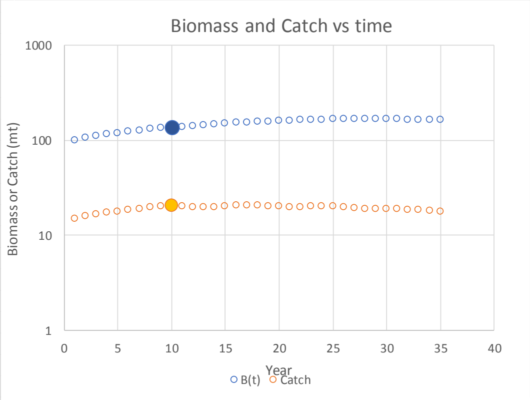
Initial Harvest h(t) Scenario	Intrinsic rate of increase r(t) scenario	Number of years used for slope estimation	Kp Gain on Slope	KD Gain on slope derivative		Total Catch	CV of Catch	Max Cmult	Min Cmult	Fraction of Overfishing Events
1	4	5	0.75	10		487.4	0.042	1.024	0.979	0.20

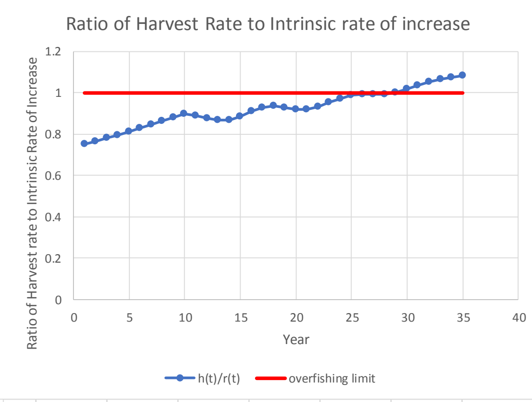












Using the gain on the second derivative Kd>0

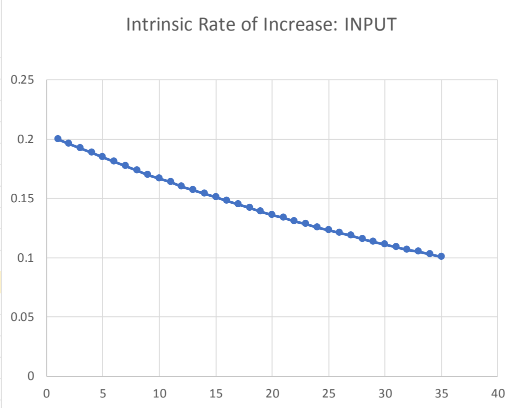
Example 5:

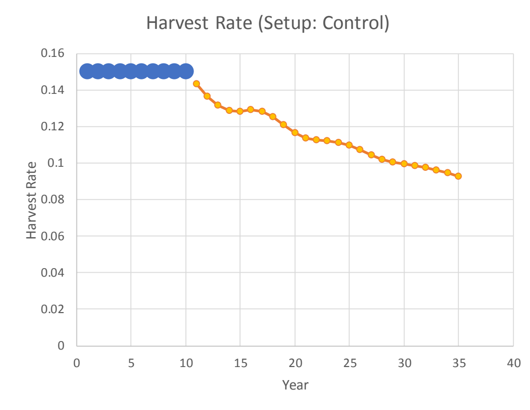
- Intrinsic rate of increase is DECLINING
- Initial Harvest rate is below intrinsic rate during initial period
- Differential weights on proportional and derivative controls:
  - Kp=0.75
  - Kd=10

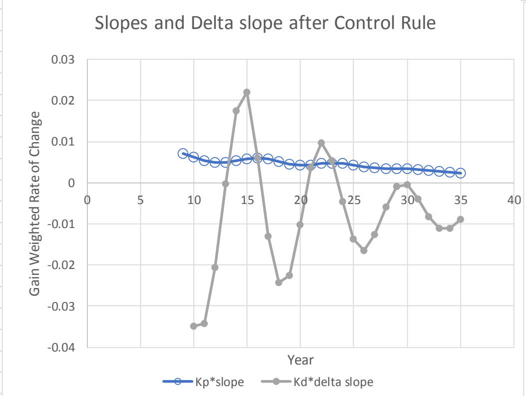
Key Results

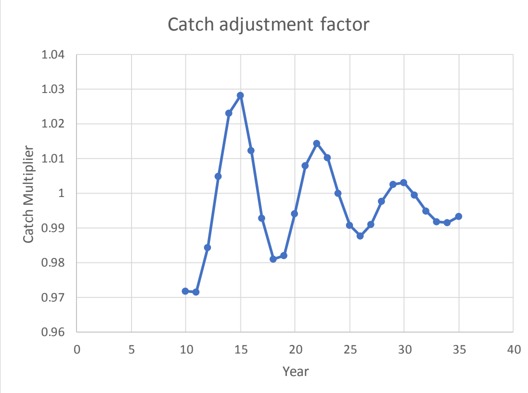
- Slightly higher cumulative catch 488 mt
- Overfishing commences about year 30. Frequency of overfishing years is 20%
- Minimum catch multiplier is 0.98 or 2% decrease
- Catch multiplier oscillates but within a narrow range.+/- 2%.
- Stock size remains stable despite decreasing trend in productivity as do catches

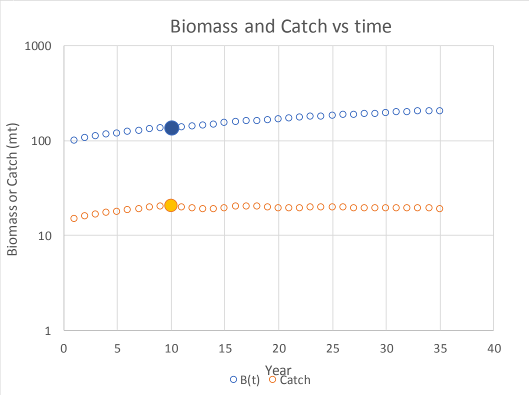
Initial Harvest h(t) Scenario	Intrinsic rate of increase r(t) scenario	Number of years used for slope estimation	Kp Gain on Slope	KD Gain on slope derivative		Total Catch	CV of Catch	Max Cmult	Min Cmult	Fraction of Overfishing Events
1	4	5	0.25	10		487.2	0.019	1.028	0.972	0.00

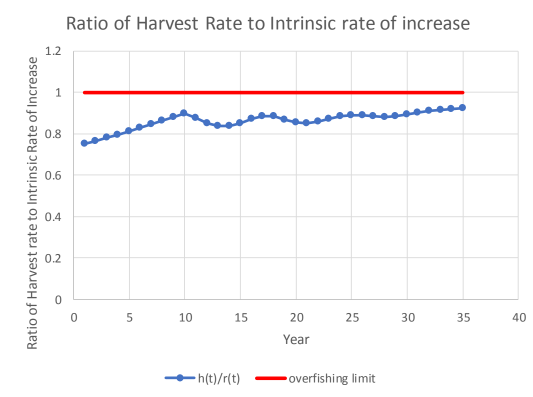












Fine tuning. Set Kp to a low value and rely more on gain on the second derivative Kd>0

Example 6:

- Intrinsic rate of increase is DECLINING
- Initial Harvest rate is below intrinsic rate during initial period
- Differential weights on proportional and derivative controls:
  - Kp=0.25 (less weight on proportional change)
  - Kd=10

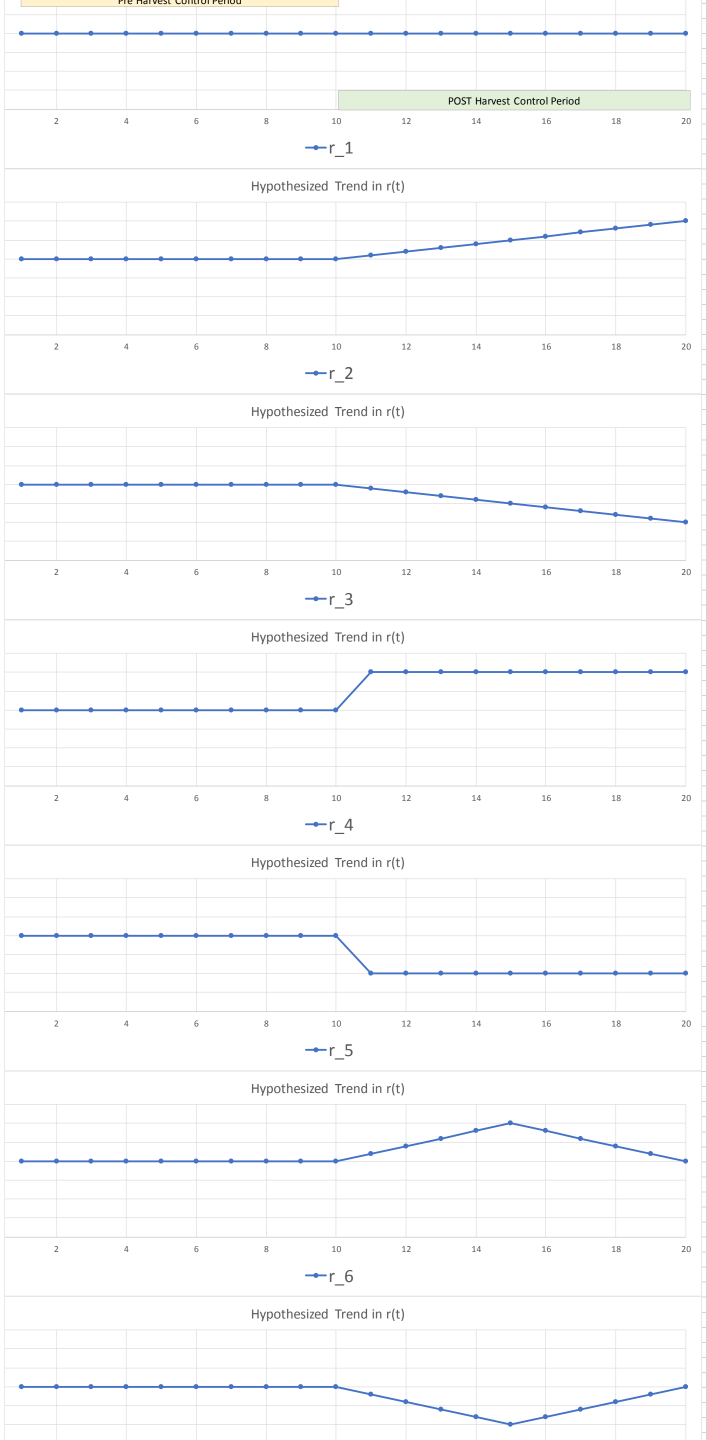
Key Results

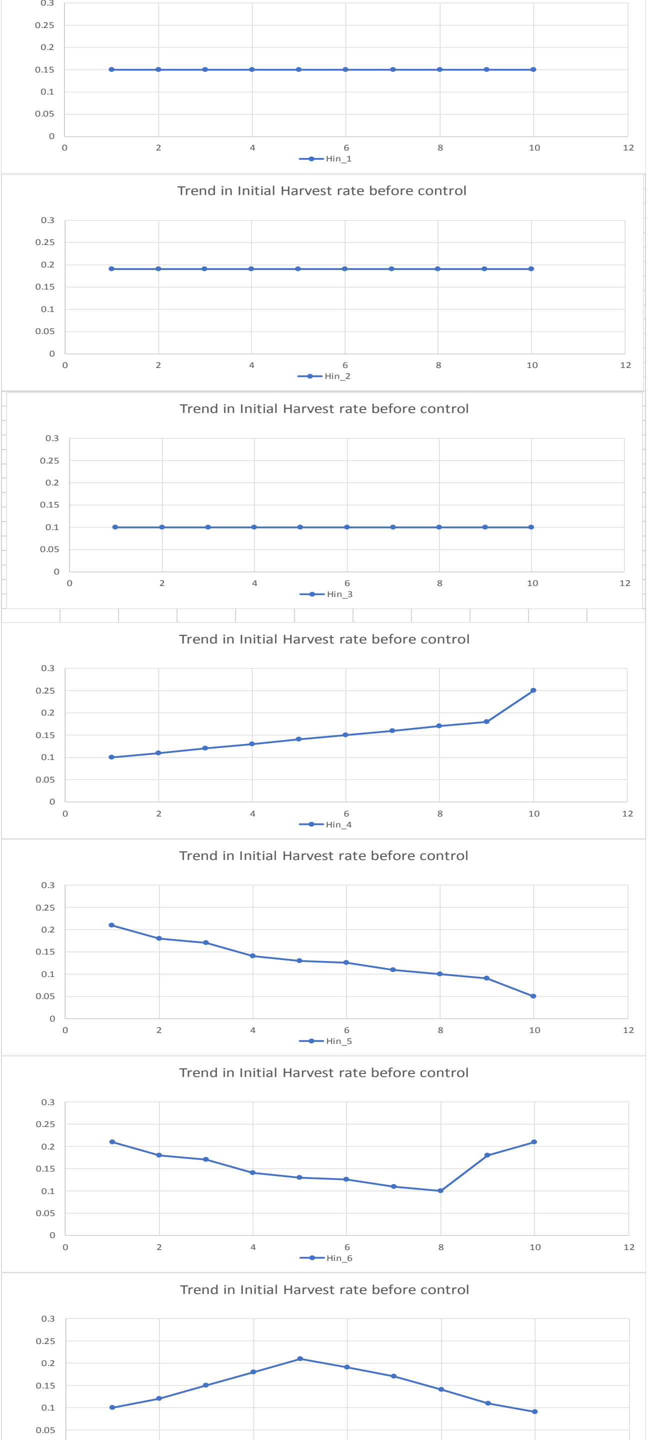
- About the same cumulative catch 487 mt
- NO overfishing over the entire period
- Minimum catch multiplier is 0.97 or 3% decrease
- Catch multiplier oscillates but within a narrow range.+/- 3%.
- Stock size remains stable despite decreasing trend in productivity as do catches

But of course, we don't know what the future holds and only have modest information about the initial conditions.

- So it is helpful to simulate various control strategies for different assumptions about the:
  - Intrinsic rate of increase
  - Harvest rate in the initial (pre-control) period
  - Variability of observations
  - Number of indices available
  - Number of years used to estimate slope
  - Alternative weighting factors for proportional and derivative gain (Kp, Kd)

Temporal Change in intrinsic rate of growth r(t). See Fig. 16





Temporal Change in initial harvest rate h(t) prior to implementation of the control rule governed by FSD.

See Fig. 17

FSD Simulation Results

- Consider effects of
  - Multiple set up conditions r(t) and h(t).
  - Multiple number of relative abundance indices
  - Varying levels of observation error
  - Varying number of years used to estimate slope.
  - Different gain factors applied to slope indices
- Need to consider multiple objectives as metrics for choosing a control strategy.
  - Average # of overfishing events
  - Average catch
  - CV of catch
  - Simulation failures—overshoots on catch
  - Net rate of population growth during the period where the FSD control is applied

1%	5%	10%	25%	50%	75%	90%	95%	99%
98.24	104.98	108.61	114.88	122.65	130.69	138.34	143.16	152.26

The bootstrap mean of projected catch is 123.10 mt with a CV equal to 0.095.

Range of Possible Catch Estimates

- Examine implications of different weightings of Kp and Kd gain factors.
- How much weight for the proportional gain—how much of the population rate of increase translates into an increase in Catch?
- How much weight for the rate of change in population increase (ie the second derivative)?
  - IF second derivative has same sign as first then veracity of the population trend supported.
  - If second derivative has a different sign, then population may be going through an inflection --*Caveat coerator "Let the manager beware"*
- *If both* Kp and Kd are set to zero, the update function reverts to 1.0—NO change in catch in following year.

Data table for 2018 Catch give range of Kp and Kd gain factors

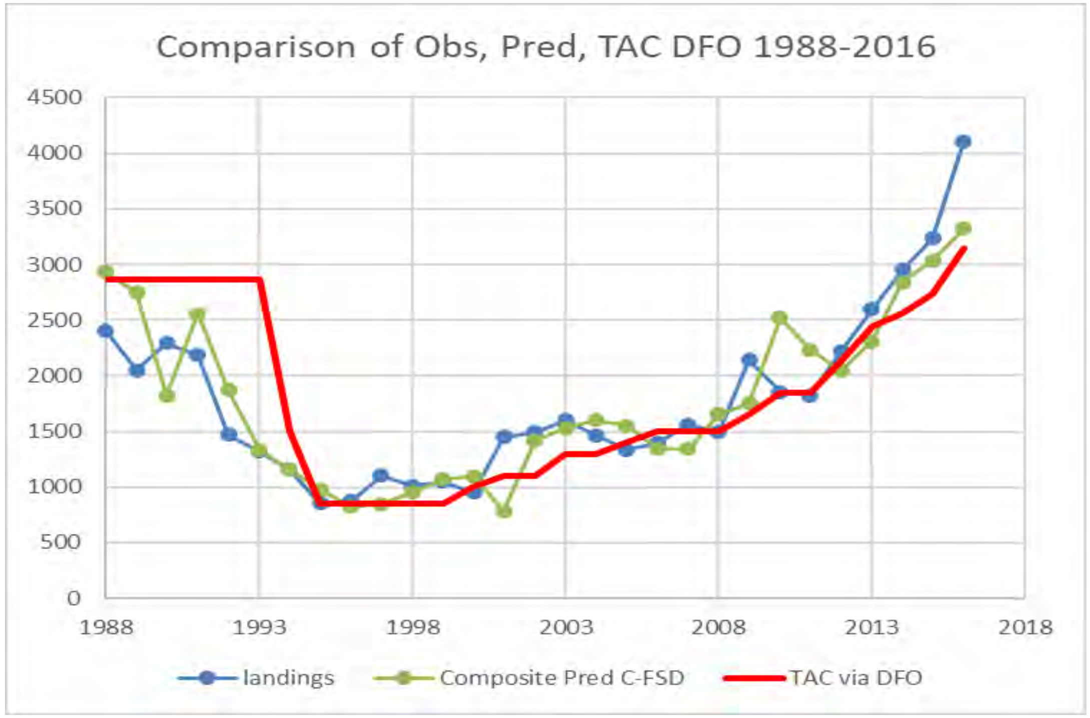
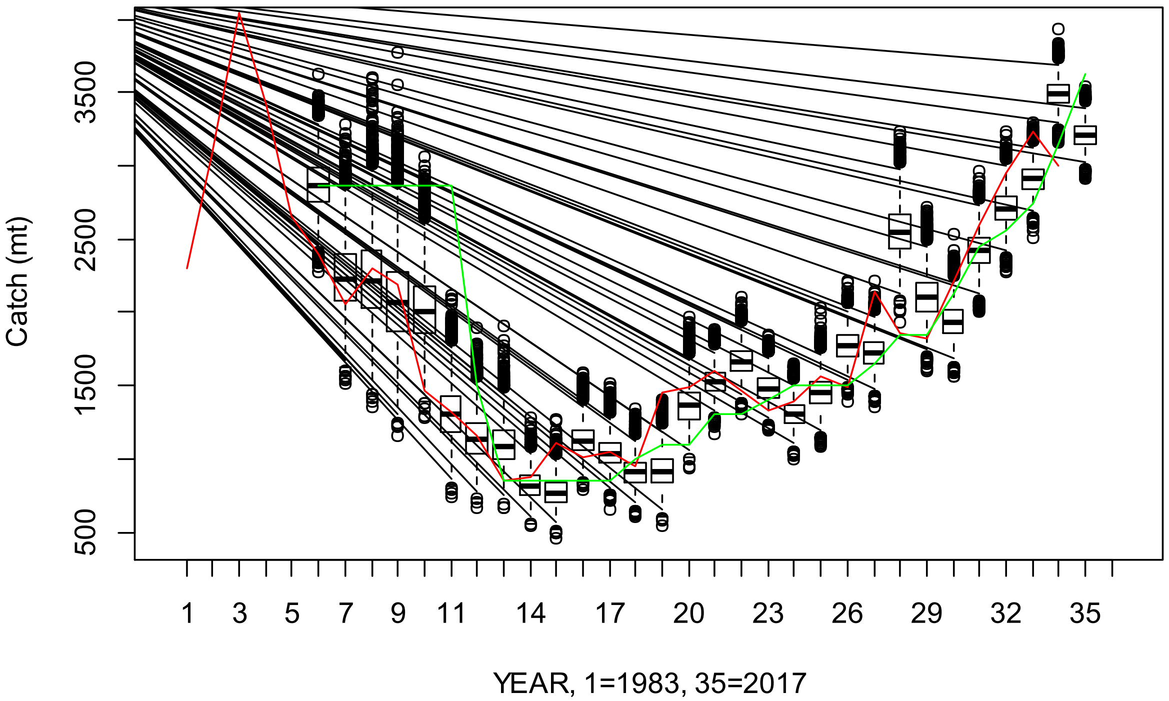
Application to DFO 3NOPs4WX5Zc halibut stock

- Utilized same abundance indices used in the statistical catch at age model used by DFO.
- Comparisons with TAC

Figure 23 in Report





Appendix 2. Figure 2.1 in Report

Application to IPHC Pacific Halibut

- Used same indices as used in IPHC assessment
- Assumed that observed catches were very close to TAC
- Residuals tend to be small in recent years, less than 10% of actual catch

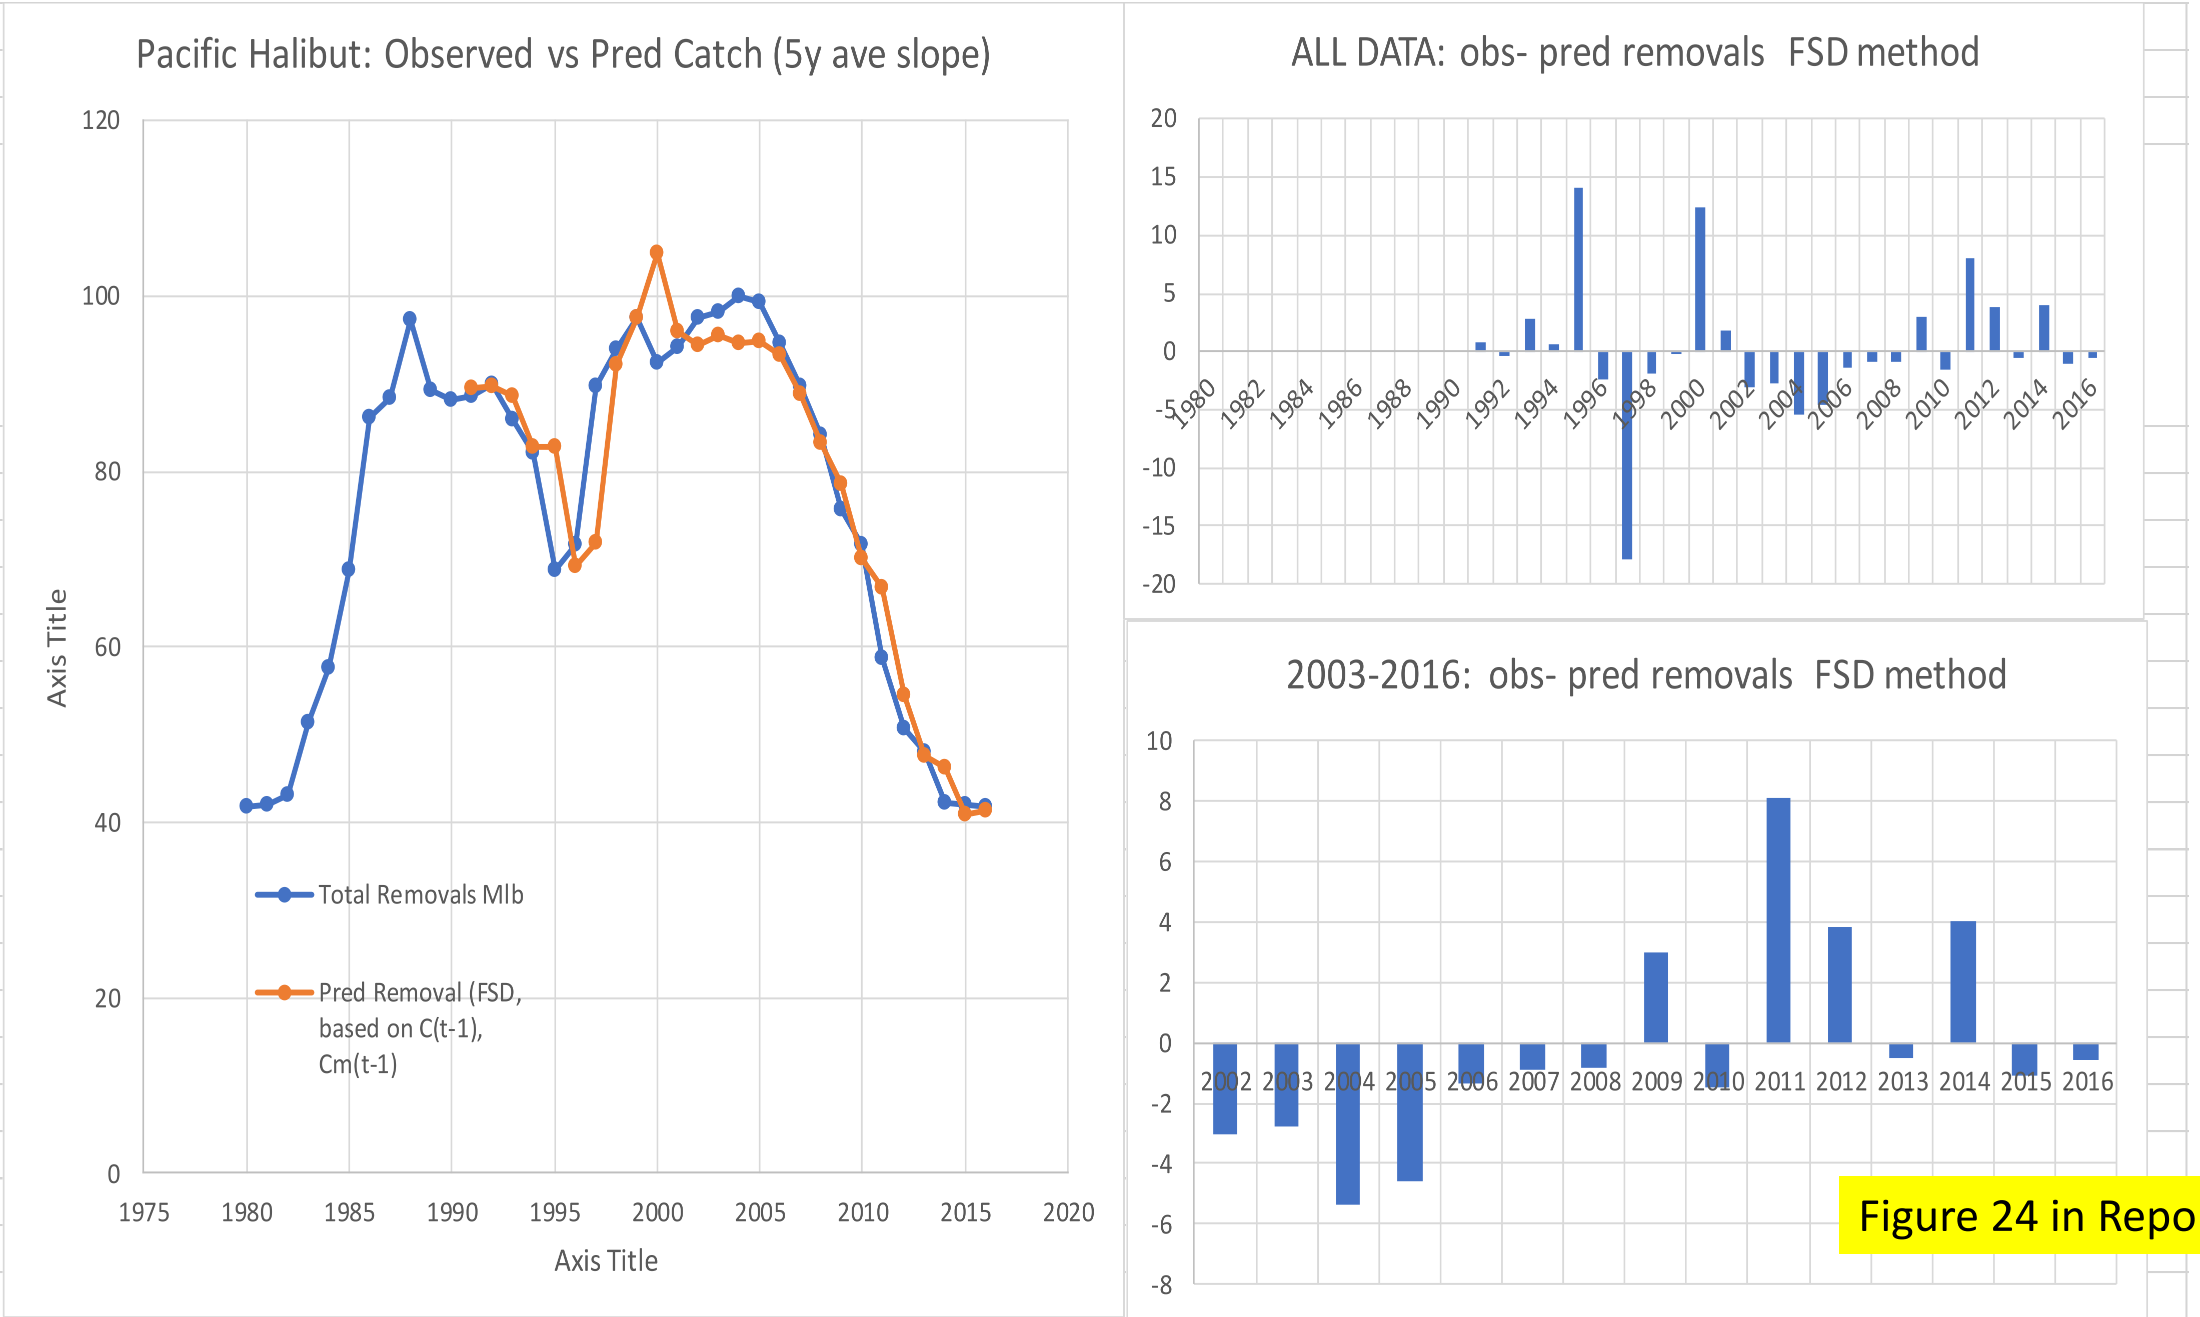


Figure 24 in Report

Add bootstrap for IPHC stock

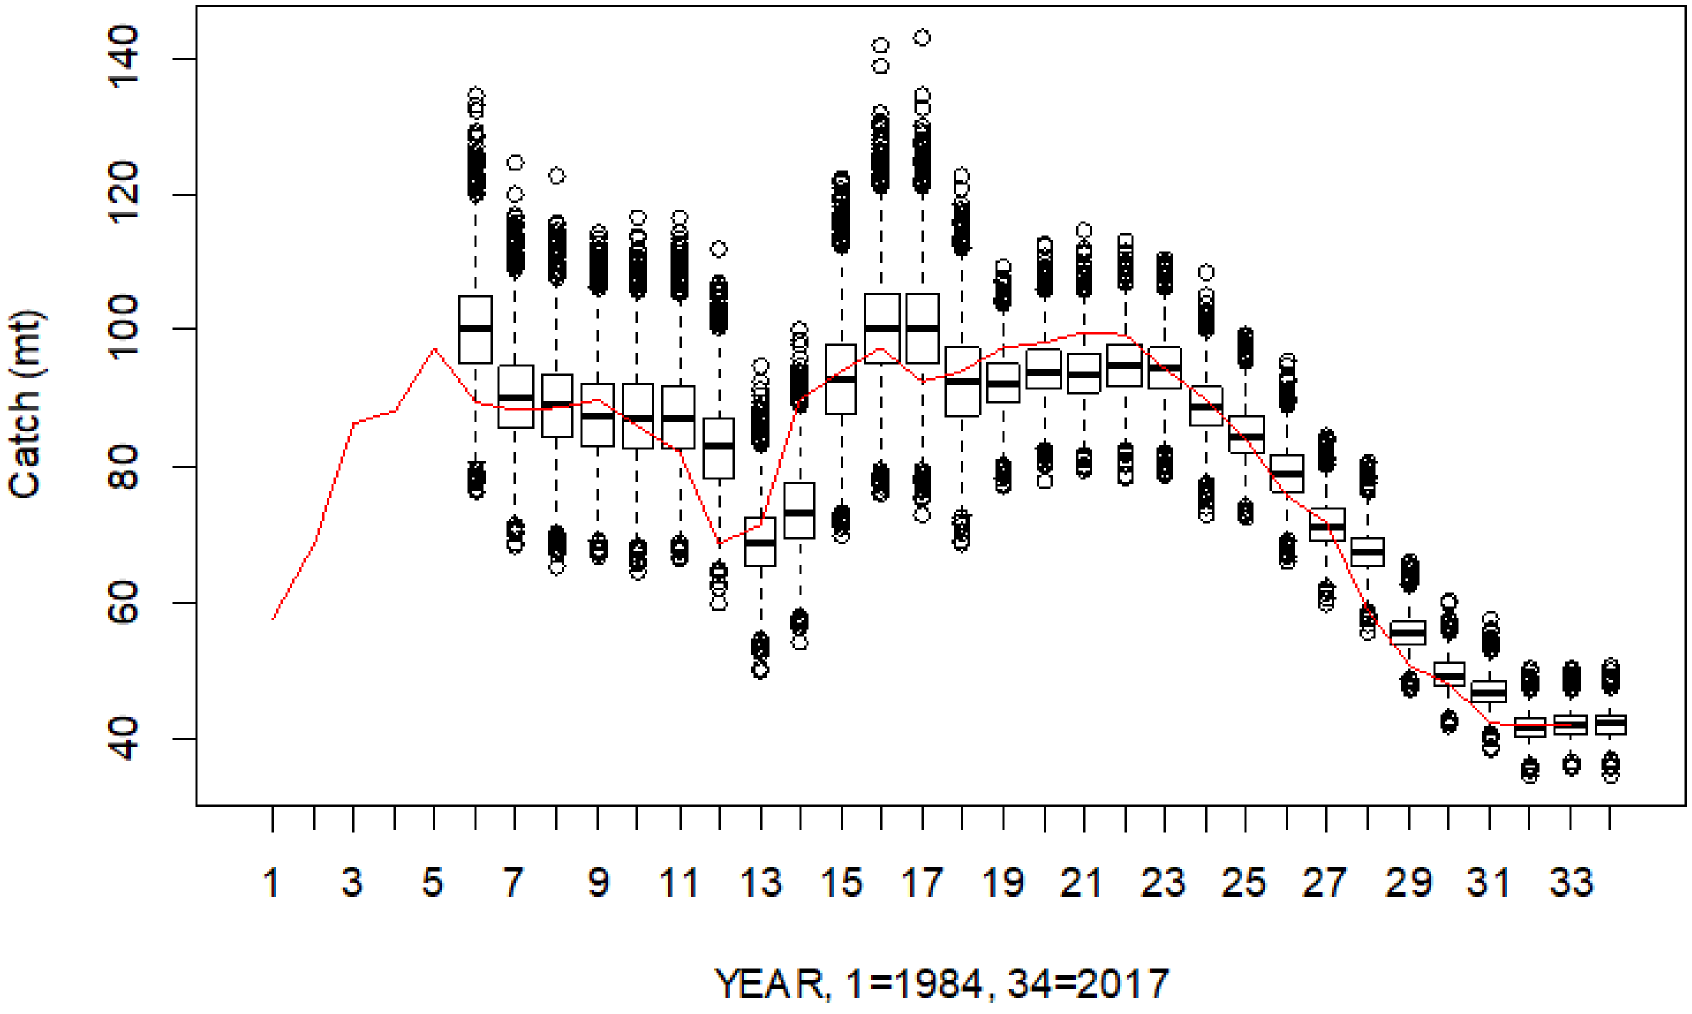

Figure 25 in Report

Odds and Ends—Discard Mortality and Alternative measure of relative abundance from Observed Trips

- Discard mortality
  - Concerns from harvesters and managers about effects of decreased mortality of captured halibut. See page 28-29 in report.
- d/k vs t/k revision
  - PDT suggested that ratio of total encounters to kept all (i.e., t/k)was a better measure of relative abundance that discards to kept all (i.e., d/k).
  - d/k ratio may be more influenced by regulations (min size, trip limits)

Effect of discard mortality on estimated discards and catch: 76% Trawl, 30% gill net, 10% hook

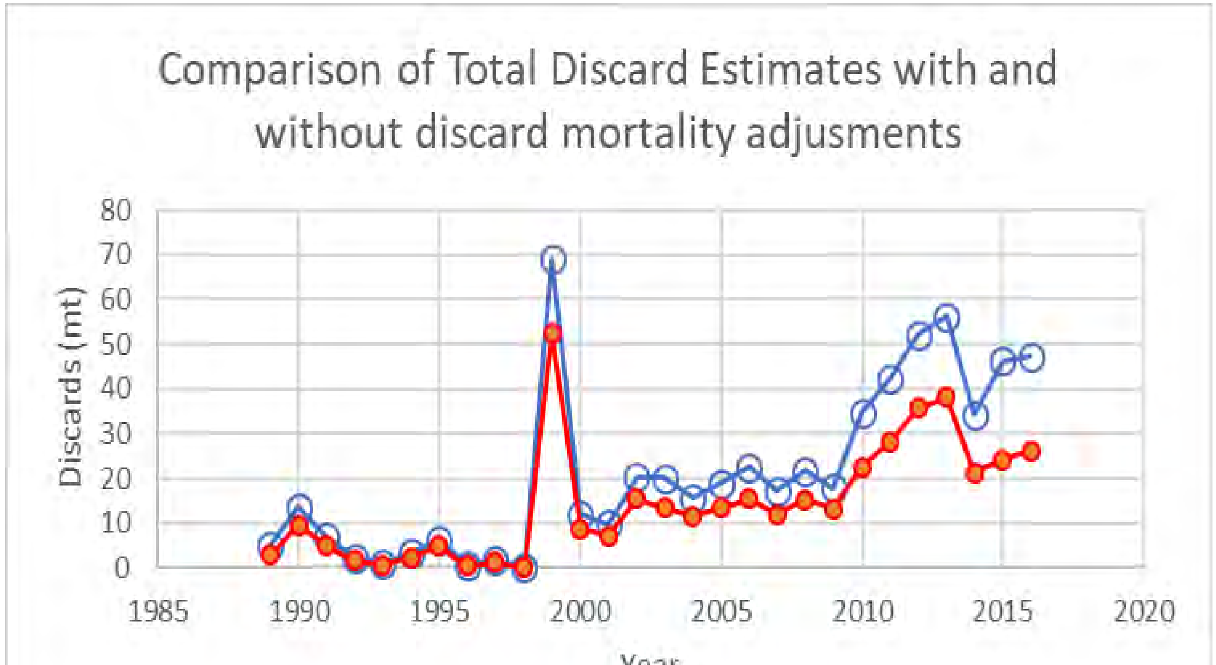

FIG 29

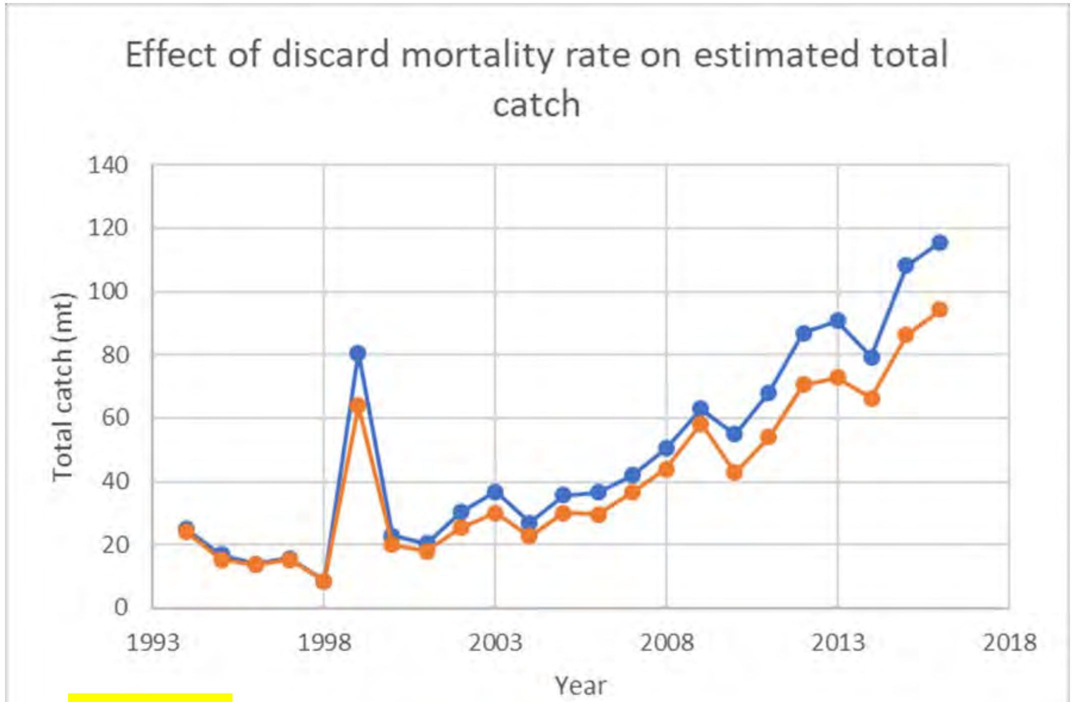

FIG 30

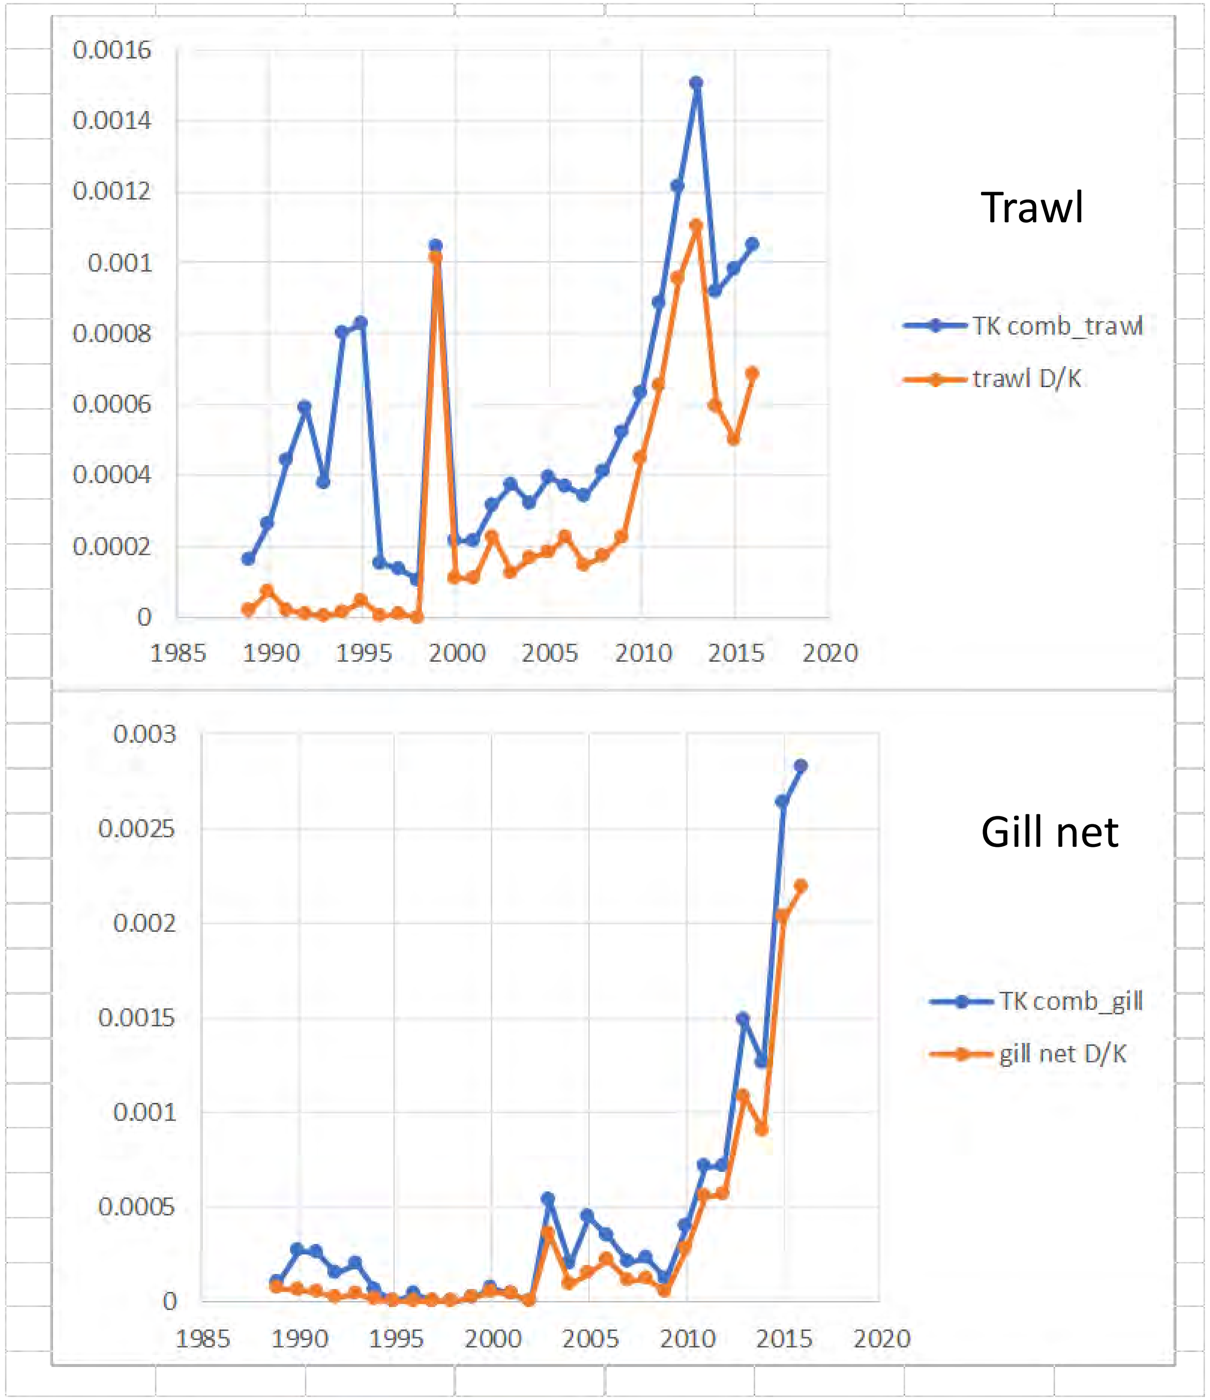
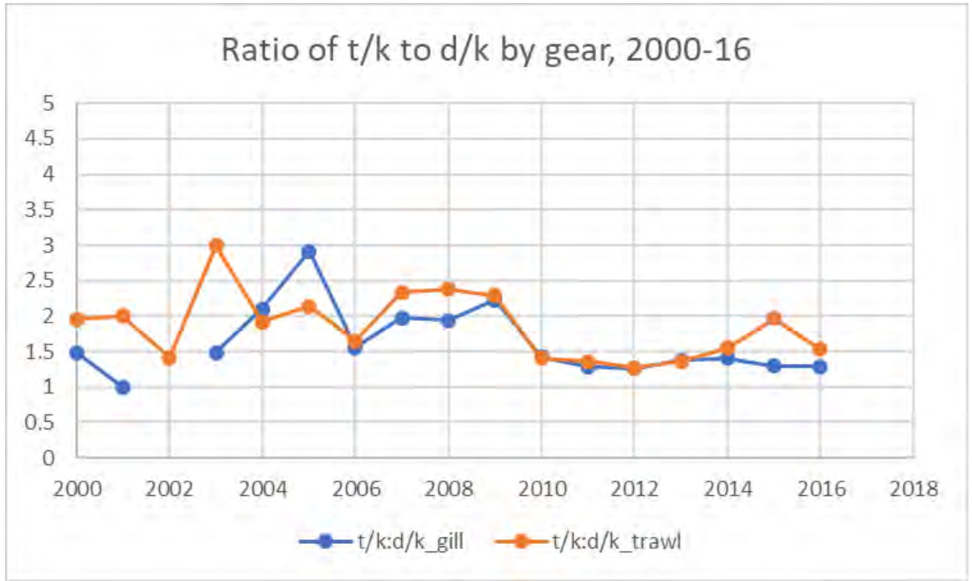


Hypothesis: total observed catch to kept all (t/k) is more representative of relative abundance than d/k ratio



Appendix 3. Figures 3.1 and 3.2

Application of discard mortality and use of t/k ratio have nominal effect on projected catch for 2018 UNLESS fraction of total discard by gear (ie trawl vs gill net vs hook) changes dramatically.

All models use Kp=0.75, Kd=0.5	Model based on d/k indices	Model Based on t/k indices
Assume 100% Mortality of discards	122.67 mt	122.82 mt
Assume discard Mortality varies by gear: 76% Trawl, 30% gill net, 10% hook	99.31 mt	99.44 mt

Summary

- Rcrit method may be useful for other stocks
- DCAC--a poor, assumption-driven, second choice
- Other methods require more assumptions, many of which would require “benchmark-level” discussions
- Proposed Model uses Management Procedure Approach for updating catches
- Does not introduce new data but uses d/k as measure of relative abundance.
- Method builds on the GB cod approach and examines the likely consequences for a population managed under such a policy.

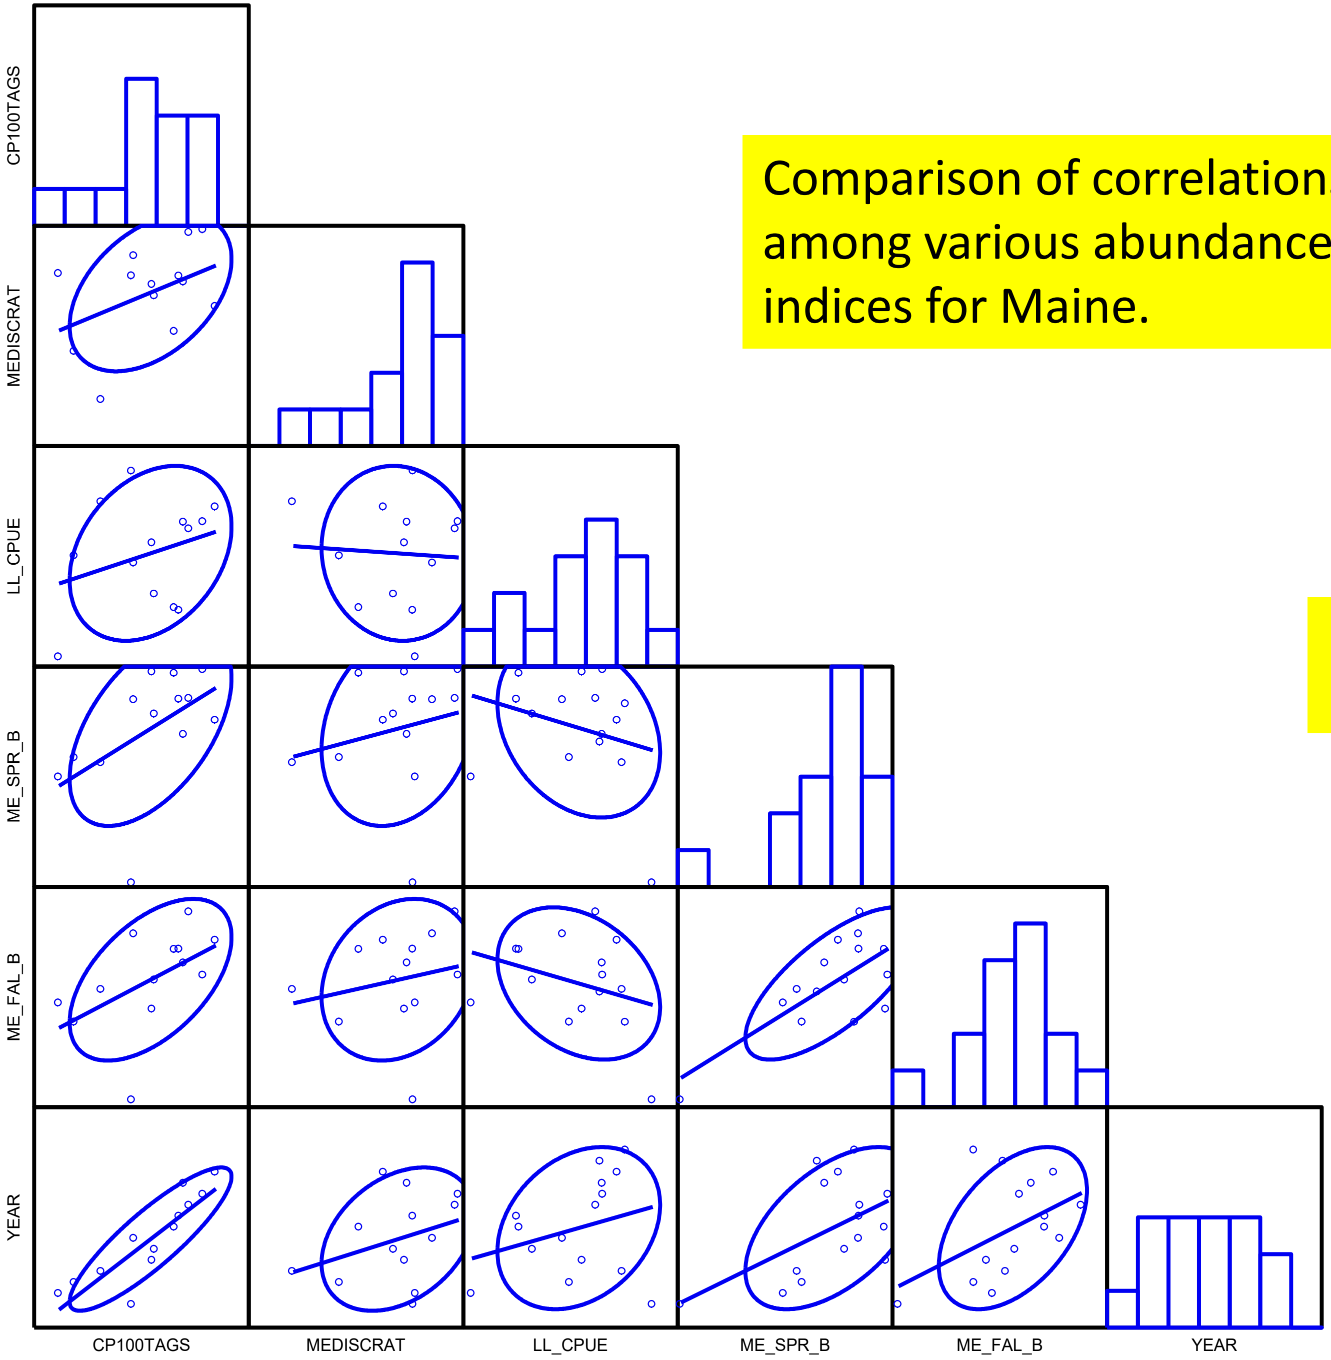
Proposed Model—Critique (1)

- Possible Advantages
  - Incorporates rate of change (slope) and CHANGES in rate of change (delta slope)
  - Does not assume equilibrium or constancy of model parameters
  - Does not assume density dependent regulation
  - Does not impose a causality model to observed patterns
  - Responds to what is rather than what we think it should be.
  - Recursively updates catch projections
  - Simulation experiments suggests that it is unlikely to cause overfishing during a rebuilding period
  - Can be used to examine trade-offs
  - Allows for evaluation of management options, e.g., max % TAC change/year
  - Can incorporate trends in multiple indices
  - Applications to other halibut stocks show some promise.

Proposed Model—Critique (2)

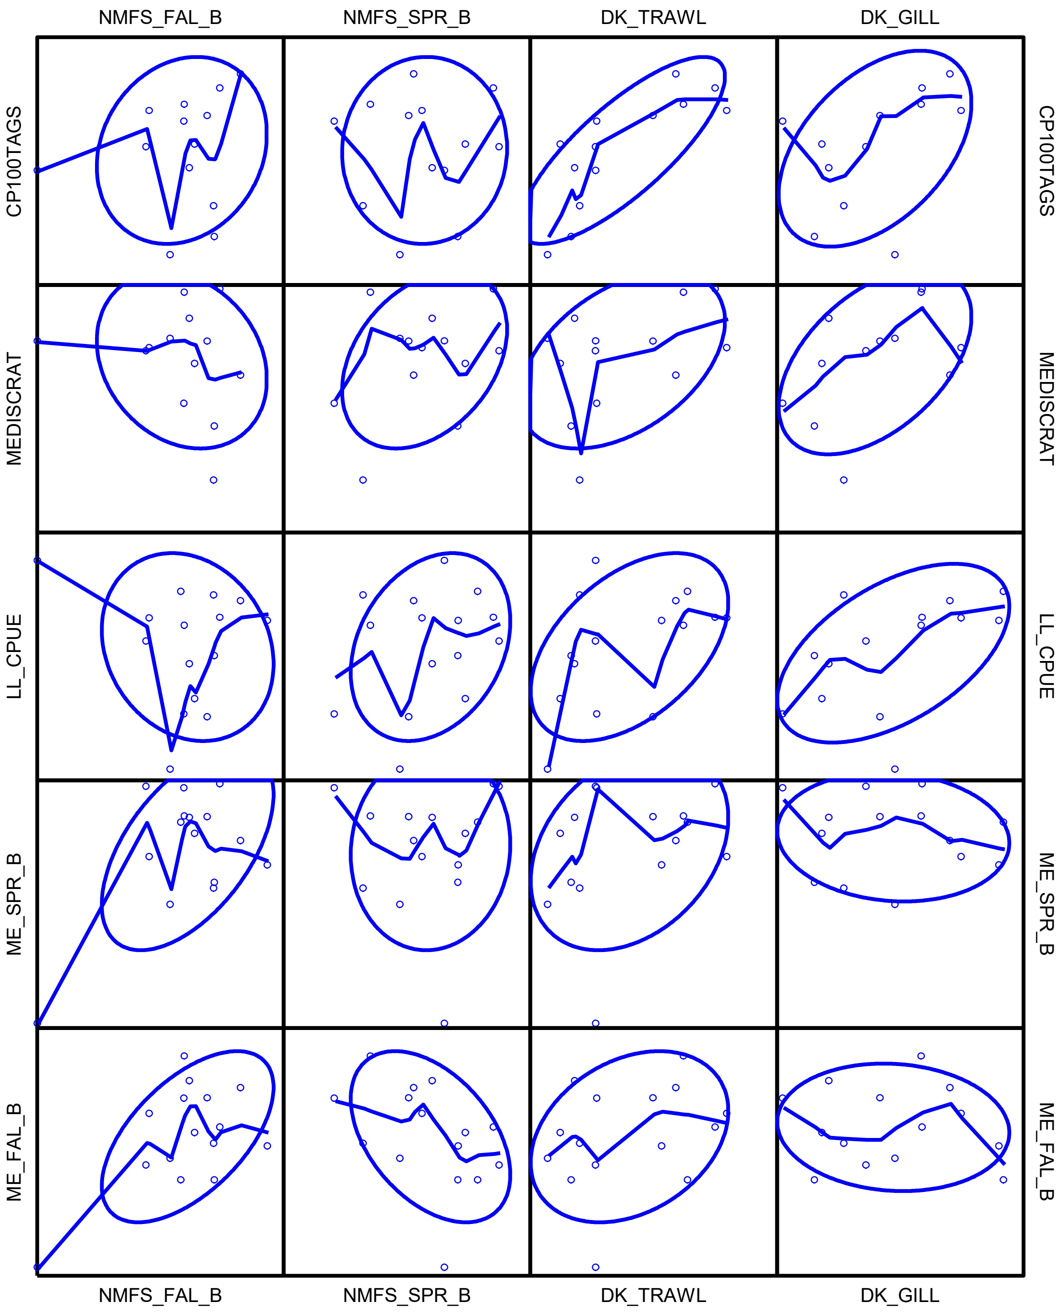
- Possible Disadvantages
  - A model too far—stretches the Plan B paradigm
  - Could follow false signals—e. g., makes unnecessary changes
  - Basis for selecting Kp and Kd is qualitative.
  - Potential for lags in signal identification—5 yr regression
  - Difficult to reduce catches quickly enough. Overshoots in catch can create long payback periods. (This is common to all models).
  - Observation error in indices may overwhelm ability to detect change
  - Effects of including indices without trend, (ie noise only) have not been evaluated. This is sometimes called the breakdown ratio—how much contaminated data can a model take?
  - Model is not designed to recalibrate for the effects of forgoing several years of potential increases. For example the model works only on the most recent year of catch, not the historical sequence.

MISC SLIDES



Comparison of correlations among various abundance indices for Maine.

FIG 10 in Report



Comparison of NEFSC and Maine abundance indices. Fig. 11, with log-log axes.

FIG 11 in Report

Q&D Executive Summary

- Alternative measures of abundance from Maine sources were considered.
- A review of data poor methods suggests that most have limited utility for Atlantic halibut, however the DCAC model was considered further.
- A ratio method (Rcrit) was developed and tested to determine robust measures of population change and the significance of these changes.
- ~~The Envelope Method was applied to estimate relative scale~~
- ~~Results of the Rcrit and Envelope method were combined to improve the DCAC model but its overall performance is unreliable and still governed by strong assumptions.~~
- An updating algorithm, called the FSD model was developed and tested via simulation. The approach allows use of short term information and multiple indices.
- FSD model results suggest that the 2018 Atlantic halibut catch would be in the range of 116-120 mt.
- Application of the FSD model to Atlantic halibut and Pacific halibut stocks assessed with advanced statistical catch-at-age models suggest reasonable agreement between Observed and predicted TACs.

Misc—DCAC Results

Envelope—finding a plausible range based on set of broad assumptions for q and F.

- *Biomass range based on q range*
- $B_t = \frac{I_t}{q'} \frac{A}{a}$ [13]
- Biomass range based on F range
- $B_{0,t} = \frac{C_t}{\frac{F}{F+M}(1-e^{-F-M})}$ [14]
- Upper bound = min of Max values
- Lower bound =max of minimum values
- Envelope satisfies both constraints

The pesky problems of singularities in DCAC when Delta is negative AND extreme sensitivity of Bt/Bo as Rcrit approaches one.

Putting Rcrit and Envelope Results back into DCAC

- Consider various values of potential increase based on Rcrit
- Consider various values of Bt/Bo based on Envelope
- Question
  - If Rcrit is 3.0 has the stock increased from 2% Bt/Bo to 6% Bt/Bo?
  - OR
  - Has the stock increased from 20% Bt/Bo to 60% Bt/Bo?
- Consequences for DELTA parameter in DCAC are different
  - Going from 2% to 6% means DELTA is -0.04
  - Going from 20% to 60% means DELTA is -0.40
  - There are an infinite range of possibilities in between!

Table hh. A. Summary of maximum fractional change in population abundance given alternative ranges of proportial stock increase for varying base period year ranges.

B. Derived Depletion corrected average catches of sustainable harvest alternative levels of rebuilding in 2016 and proportional increase in relative abundance.

Levels of rebuilding are based on envelope method. Natural mortality is assumed = 0.15

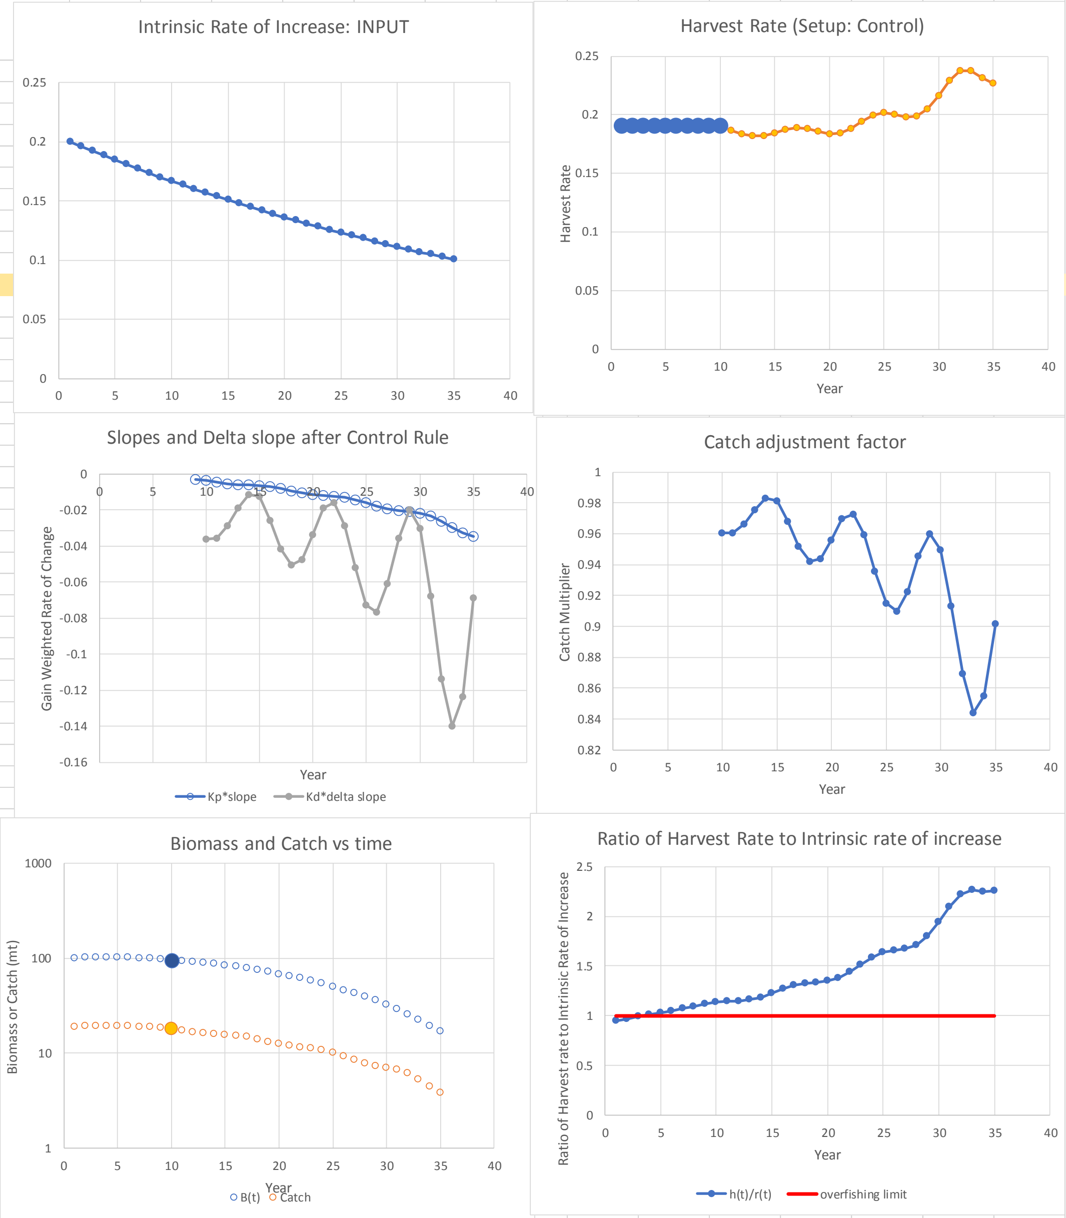
See Table 13 in report.

Assumed level of change in B(2016)/K is obtained from Table 12.

Ignoring the negative values, the sustained average catch ranges from 64 to 2,067 mt.

Ignoring negative values, the current recommended yield ranges from 1.3 to 905.7 mt.

Initial Harvest h(t) Scenario	Intrinsic rate of increase r(t) scenario	Number of years used for slope estimation	Kp Gain on Slope	KD Gain on slope derivative	Total Catch	CV of Catch	Max Cmult	Min Cmult	Fraction of Overfishing Events
3	4	5	0.25	10	272.9	0.379	0.983	0.844	0.91



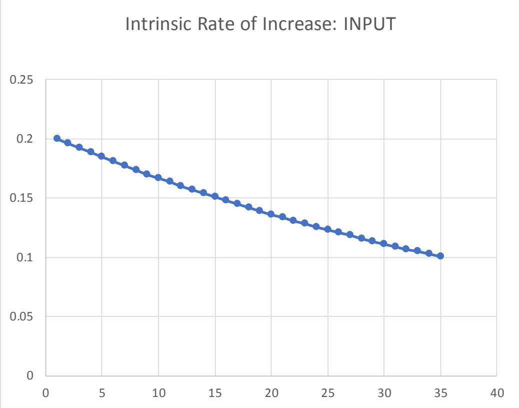
Example 4:

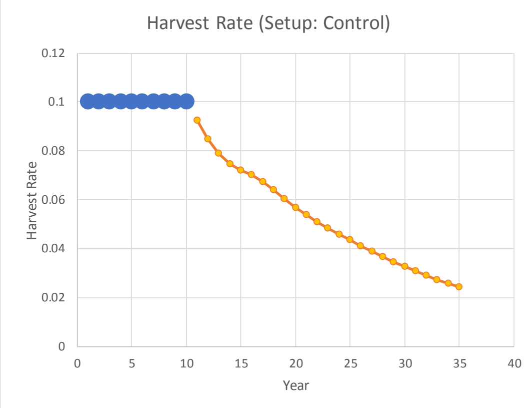
- Intrinsic rate of increase is DECLINING
- Initial Harvest rate is ABOVE intrinsic rate during much of the initial period
- Differential weights on proportional and derivative controls are SAME as Example 3:
  - Kp=0.25 (less weight on proportional change)
  - Kd=10

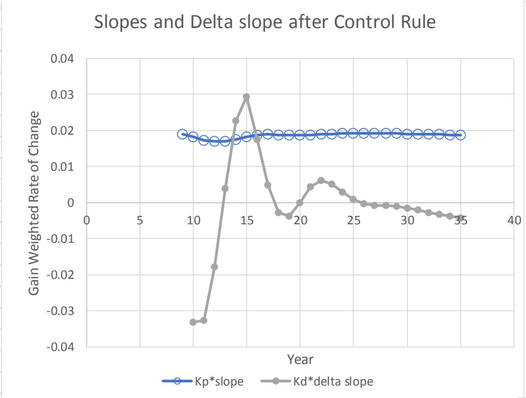
Key Results

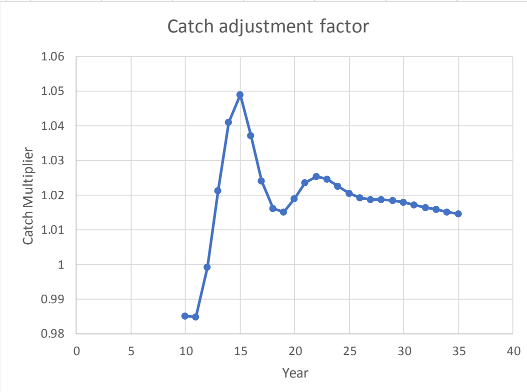
- Much lower cumulative catch 272 mt
- Overfishing over 91% of the entire period
- Maximum catch multiplier is 0.98 or 2% decrease
- Catch multiplier is always less than 1.0 and oscillates over a wide range, to as low as 84%
- Stock size and catches declines after initial control period.

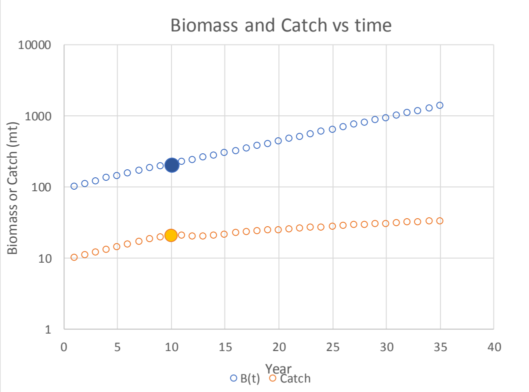
Initial Harvest h(t) Scenario	Intrinsic rate of increase r(t) scenario	Number of years used for slope estimation	Kp Gain on Slope	KD Gain on slope derivative	Total Catch	CV of Catch	Max Cmult	Min Cmult	Fraction of Overfishing Events
2	4	5	0.25	10	658.1	0.157	1.049	0.985	0.00

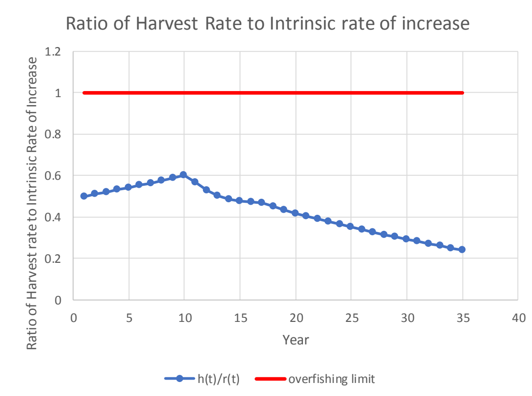












Example 5:

- Intrinsic rate of increase is DECLINING
- Initial Harvest rate is well BELOW intrinsic rate during the initial period
- Differential weights on proportional and derivative controls are SAME as Example 3 and 4:
  - Kp=0.25 (less weight on proportional change)
  - Kd=10

Key Results

- Much higher cumulative catch 658 mt
- NO Overfishing over the entire period
- Maximum catch multiplier is 1.05 or 5% decrease
- Catch multiplier is <u>mostly</u> above 1.0 and oscillates over a narrow range.
- Stock size and catches both increase at a steady pace but catch declines more slowly, thereby preserving the stock rebuilding program.
- Major difference is the lack of overfishing during the period prior to implementation of the control rule. This allows stock size to grow despite declines in productivity

Halibut Assessment Report for 2017

Draft

Paul J. Rago

for

New England Fishery Management Council

Last updated: December 1, 2017

Executive Summary

- Survey, landings and discard estimates were updated for the US stock area.
- Alternative measures of abundance from Maine sources were considered as potential measures of stock trend.
- A review of data poor methods suggests that most have limited utility for Atlantic halibut, however the DCAC model was considered further.
- A ratio method (Rcrit) was developed using randomization methods. Simulation tests suggested that the method had utility as a robust measure of population change and the significance of these changes.
- Application of the Rcrit method to the US and DFO stocks suggest comparable increases of about 9 to 12% per year since the early 2000's
- An "Envelope Method" was applied to estimate relative scale of the population. The Envelope consists of upper and lower bounds of relative abundance that jointly satisfy constraints on abundance based on a range of hypothesized historical fishing mortality and survey catchability estimates.
- Results of the Rcrit and Envelope method were combined to improve the DCAC model but its overall performance is considered unreliable and still governed by strong assumptions.
- A catch forecasting algorithm was developed based on the observed rates of change in one or more indices of relative abundance. The method resembles algorithms commonly used for control of linear systems in engineering applications. The magnitude of catch adjustment depends on the aggregate rate of change in one or more abundance indices in prior years. The method estimates the first and second derivative of population change using loglinear regression. The second derivative is approximated as the difference between successive n-point regressions.
- The method, termed the First and Second Derivative (FSD) model was tested via simulation of a wide variety of initial conditions and trends in stock productivity.
- No simple solution exists but instead the performance should be evaluated with respect to the risk of overfishing, magnitude and variability of projected catch, and the probability of continued increases in stock size.
- FSD model results suggest that the 2018 Atlantic halibut catch should be about 116-118 mt.
- A bootstrap approach was used to compute the uncertainty about the FSD prediction.

- Application of the FSD model to Atlantic halibut and Pacific halibut stocks assessed with advanced statistical catch at age models suggest reasonable agreement between Observed and predicted TACs.

<u>Background and Overview</u>

This is a “Plan B” assessment. It is a consequence of the unsuitability of the existing benchmark approach as a basis for deriving suitable catch limits for resource management. The Plan B assessment was conceived as an interim approach that could bridge the gap between the rejection of an existing methodology and a revised approach. The revised approach will be the product of a benchmark assessment that reviews all the existing information and potential modeling approaches and undergoes extensive levels of peer review. The distinctions between Plan B interim approaches and benchmark assessments are defined by various reports of the Northeast Regional Coordinating Committee (NRCC) (see NRCC 2011) and by precedents accrued over deliberations within the NRCC since 2012.

In general terms, the Plan B process constrains the introduction of new analytical assessment models whose applicability to the stock under consideration has not be subjected to extensive peer review. Practical application of stock assessment models typically requires numerous decisions about the definition of the “stock”, inclusion of available data, reliance of parameterization on literature values (e.g., natural mortality rates), plausibility of critical assumptions, and appropriate numerical methods. Such decisions usually benefit from the inclusion of a broad range of expert opinions. In view of the long-term biological and economic consequences of such decision, the benchmark process can lead to greater acceptance of model-based management decisions.

The Plan B process also implies restrictions on the introduction of new time series of indices or changes in estimation methodology. For example, use of time-series that have not been rigorously reviewed for applicability to stock assessments could be problematic, especially if such data are highly influential. Similarly, model parameters that are highly influential, but weakly supported by empirical data (e.g., natural mortality) are typically considered outside the range of Plan B assessments. Changes to the methods for estimating relative abundance or total removals have been allowed but are subject to a case-by-case examination. For example, revision of previous discard estimation methods to a the SBRM method has been allowed. Changes to discard mortality rates (i.e., the post capture survival of release fish) have been incorporated in several assessments (e.g., skates) when strong empirical evidence has been available.

An important management concern arises when the stock is in a rebuilding program. The rejection of the model on which the rebuilding program was based puts rebuilding in a limbo wherein the existing target biomass, rebuilding time-frame, and target fishing mortalities are obsolete. The management and legal processes are ill-suited to such reversals given the difficulties of putting existing targets in abeyance while new ones are derived. A rebuilding program without a target is ambiguous at best. For some species, the contrast between underlying biology (especially growth, longevity, geographic range) and existing population structure is sufficient to proceed with a rebuilding program, even when target biomasses and fishing mortality rates are unknown.

The preceding general issues aptly describe the particular issues for Atlantic halibut in US waters. The previous stock assessment model has been rejected and data to support a true benchmark analytical assessment are insufficient. The rebuilding target is officially defined for 2056 based on the perceived depleted stock abundance and expectations of slow growth and low recruitment. Harvests are restricted to a one fish per trip limit over the federal fishery but a more liberal harvest regulation is allowed in Maine state waters. Estimated discards constitute a large fraction of the fishery removals. While the stock in US waters is considered to be depleted, the immediately adjacent stock in Canada (NAFO areas 3NOPs4VWX5Zc) has been certified by MSC as sustainably harvested. Given the abundant tagging evidence of migrations of fish between the US and Canada, debates about stock definition will likely be a major component of a future benchmark assessment (Shackell et al. 2016, Tryzinski and Bowen 2016, Seitz et al. 2016).

One of the key objectives of this assessment is to employ intuitive and understandable approaches backed by theory and simulation testing. The methodology does not purport to develop biological reference points for a stock that has, by all accounts, declined considerably from a virgin stock size inferred to have existed about 200 years ago (Lear 1998). Given the massive change in fisheries, ecological and environmental conditions since then, it is unlikely that the present environment would support such biomasses in the short term. Or if it could, that a singular focus on catch reductions in halibut would be sufficient to achieve rebuilding to historic levels. The large historic stocks of halibut were also a function of lightly exploited stocks of many other species and unknown predator-prey and competitive relationships with these species.

The objectives of the approach herein are much more modest. Much of the available data suggests that the stock of halibut residing in US waters is increasing. Encounter rates in nontargeted fisheries and various fishermen reports support such perceptions. Various fishery independent surveys weakly support this hypothesis, however none of the current trawl surveys are efficient at capturing halibut. Perhaps the most compelling evidence for stock increase is the rapid changes observed in the Canadian stock. Large changes have occurred not only in targeted longline surveys but also in their trawl surveys which have low capture efficiency similar to US bottom trawl surveys

Stock structure and joint management of Atlantic halibut is well beyond the purview of this assessment report. One cannot deny the temptation to note that the current stock boundaries bisect habitats that are thought to be equivalent on either side of national boundaries. Moreover, tagging studies reveal widespread movements (>3000 km, Scott and Crossman 1988) of halibut. More recent data for electronically tagged fish at liberty for up to 210 days reveal maximum travel distances of about 200 km (Seitz et al. 2016). Conventional tagging studies can generate equivocal evidence unless differences in relative fishing effort and report rates of encountered tags are considered in the analyses of perceived migration patterns. Even Data Storage Tags can be problematic if they are not reported by fishermen.

Officially, halibut are in a rebuilding program with a target completion year of 2056. Increases in halibut abundance in US waters are desirable for both legal and economic reasons. Canada's stock has increased rapidly over the past 20 years but their recovery was also preceded by a long period of low abundance and catches. Comparisons shown later in this report reveal comparable patterns in the US stock area, although the baseline begins from a much lower relative abundance.

Under a rebuilding requirement, a desirable harvest control rule is one that does not reduce the rate of increase or decrease the chances for continued abundance increases. A desirable harvest rule should also avoid being overly restrictive. Increases in abundance that arise under contemporary rates of harvest will, under certain restrictive assumptions, continue to occur if the same harvest rate is applied in future years. These restrictive assumptions include constancy of recruitment, natural mortality and growth in future years. Of course, none of these factors are constant, so it is equally important that the aggregate effect of these processes is taken into account when catch limits are set. More critically, catch limits should be responsive to changes over time. Failure to increase catch limits, particularly when catches are driven largely by discards, may lead to accountability measures induced entirely by unavoidable encounters. At the limit, even elimination of all landings may be insufficient to achieve target catch. Failure to decrease catches when indicated can lead rapid increases in fishing mortality, and the loss of biomass accrued during the rebuilding period.

So the overall objective of the methodology described herein is to use readily available empirical data to adjust catches consistent with changes in relative abundance. The methodology is designed to be responsive and in particular, to be sensitive to metrics of changes in underlying productivity. Lessons learned in control of engineering problems suggest that slow responses to signals are one of the most difficult problems to overcome. As examples, low response times often lead to wide temperature swings in HVAC-controlled buildings and production losses in chemical plants. Simulation studies presented in this report support the need for regular updates of stock status information.

Biology Review

Among the world's flatfishes Atlantic halibut (*Hippoglossus hippoglossus*) attains the largest size (~2.5 m, but values up to 4.3 m are reported in fishbase.org) and oldest age (>40 y)(Seitz et al. 2016, Armsworthy and Campana 2010)). Maturation for females occurs at about age 9 (Armsworthy and Campana 2010). Despite their well-known history of serial depletion in US waters (Grasso 2008), Trzcinski and Bowen (2016) argue that rapid growth and high fecundity make the population resilient and capable of recovering quickly from a depleted state. Their modeling work suggested that reductions in landings quotas, increases in minimum sizes and reductions in otter trawl fleets were primary factors leading to the rebuilding of Atlantic halibut in Canada. Col and Legault (2009) provide an excellent summary of the history of halibut fishing in the US.

Shackell et al (2016) recently evaluated the distribution of imputed halibut habitat in US and Canadian waters and found occupancy rates four times higher in Canadian waters. Their analyses suggest finer scale stock structure than commonly assumed. Seitz et al. (2016) reporting on recent electronic tagging results also suggest that the failure of a concomitant increase in US compared to Canada may be due to different stock structures. Decisions about stock structure are among the most important in stock assessments and this topic will not be considered further in the Plan B assessment.

Past US YPR models (Brodziak 2002) used a natural mortality rate M =0.1 whereas the Canadian assessment model sets M=0.15.

Available Data

This report includes updated estimates of catch and discards consistent with estimates provided in past assessments, most recently in Hennen (2015). Estimates for spring and fall NEFSC and ME-NH bottom trawl surveys are also included. Several indices of commercial fishing catch per unit effort are also considered. The focus of this assessment is the interpretation of trends in recent years.

A succinct summary of the primary data considered in this assessment is found in Table1 for the years 2002-2016. Relevant data include recent landings, discards and total catch (FIG 1). Discards by gear type (Table 1.5) revealed that most discards were incidental takes in trawl fisheries until about 2009. Since then the proportion of gill net discards has increased to about 50% of the total. Estimates of average numbers and weight per tow in the NEFSC spring and fall bottom trawl surveys are summarized in FIG. 2. Catches are near detection limits over much of the survey period and inter-annual fluctuations were very large in the prior to about 2000. Abundance indices that rely on monitoring of commercial fisheries are depicted in FIG.3 for d/k ratios in observed trawl and gill net trips. These raw estimates are expanded to estimate total discards of halibut using the SBRM approach (Wigley et al. 2008). FIG.3 also includes trends in

ME-NH inshore bottom trawl survey. A standardized CPUE for long line fisheries in Maine was developed by Hansell,et al. (2017) and is shown with error bounds in FIG.4.

Data from an inshore sentinel longline and jig survey originally developed for monitoring cod were received from U. Maine (courtesy of Maddie Rodrigues and Yong Chen). The time series is relatively short (4 years). It was not possible to resolve key questions about survey methodology for inclusion in this report. The data may be useful as a measure of trend in a future assessment, particularly if state space modeling approaches described by Webster (2017) for Pacific halibut could be developed for Atlantic halibut

Trends in discard rates can be examined for several different measures of effort. In FIG. 5 discard rates in the gill net fishery are depicted as discards per trip, discards per days absent and discard per kept all. All metrics show a striking rise in discard rates (measured on a 6 month interval) beginning about 2002. For observed trawl trips the trends are remarkably similar (FIG. 6). Data depicted in FIG.5 and 6 were not used in the assessment directly but are shown at a finer temporal resolution to illustrate the consistency of encounters in fishing gears not directing on Atlantic halibut.

Relative abundance data for the Canadian 3NOPs4VWX5Zc stock are not part of this assessment but their results (courtesy of Nell den Heyer DFO, Halifax) are examined for coherence with trends observed in the US. All of the primary abundance indices in Canada show consistent increases since 2002 (FIG. 7). Trends in US surveys (FIG. 8) have generally increased but not as consistently as those in Canada. Correlations among the US and Canadian abundance indices (FIG. 9) show surprisingly good coherence given the large differences in scale and basis for these observations. Coherence among the Maine-based estimators of relative abundance is a little lower (FIG.10) with some slightly negative correlations for some indices. Similarly,correlations among the NEFSC and Maine-based indices (FIG. 11) is spotty, but this may overly pessimistic owing to the inclusion of all years.

Management Changes

Nies and Cournane (NEFMC, pers. Comm) summarized the major changes in regulations from 2001 to 2017. While many of the effort control measures could have reduced fishing mortality on Atlantic halibut, there have been only two measures directly related to halibut. In 2009 the one fish per trip regulation was put in place. Amendment 16 later implemented an increase in minimum size from 36 to 41 inches for the 2010 fishing year, beginning on May 1. Such changes would be expected to increase the discard rate, all thing being equal.

Previous Assessment Models

Prior to 2008 Atlantic halibut were assessed using index methods utilizing the NEFSC fall bottom trawl survey. Col and Legault (2009) succinctly summarized the early assessment history of halibut as follows:

> "In previous index-based assessments (NEFSC 2001; Brodziak 2002, Brodziak and Col 2005), Northeast Fisheries Science Center (NEFSC) autumn weight per tow survey indices were expanded to swept-area biomass estimates, and the 5-year average biomass index was compared to B_{MSY} proxy reference points for status determination (FIGure 3). Reference points for Atlantic halibut were originally determined by the New England Fisheries Management Council (Applegate et al. 1998) using Canadian Atlantic halibut length-weight equations (McCracken 1958) and von Bertalanffy growth curves (Nielson and Bowering 1989) to perform yield per recruit (YPR) and biomass per recruit analyses. Natural mortality was assumed to be 0.1, and a Maximum Sustainable Yield (MSY) proxy was chosen to be 300 mt, yielding a B_{MSY} proxy =5400 mt, a ½ B_{MSY} proxy = 2700 mt, and an F_{MSY} proxy (threshold) = $F_{0.1}$ = 0.06. Based on the Groundfish Assessment Review Meeting (GARM) 2005 assessment of Gulf of Maine-Georges Bank Atlantic halibut, the stock was overfished (B_{2004} was 5% of B_{MSY} proxy) and it was unknown whether overfishing was occurring (Brodziak and Col 2005)."

The Replacement Yield Model (RYM) was first applied to US Atlantic halibut in 2008 at the GARM III assessments (NEFSC 2009). The RYM was suggested by Butterworth (refs) at the 2008 GARM III meeting. Col and Legault (2009) implemented the model. The biomass at time t is expressed as

$$B_t = B_{t-1} + R_{t-1} - C_{t-1} \quad [1]$$

Where Bt is the biomass at time t, C_t is the catch at time t and R_t is the replacement yield. Replacement yield is based on the logistic growth model and is defined as

$$R_t = rB_t\left(1 - \frac{B_t}{K}\right) \quad [2]$$

Where K is defined as the estimated population size in 1800. Application of the model required several important assumptions

1. Catches between 1800 and 1893 are unknown but are assumed to increase linearly from zero in 1800 to 798 mt in 1893.
2. The intrinsic rate of increase in population size is assumed to be constant over the entire time series and equal to a life history approximation derived from a YPR analysis of contemporary estimates of growth rates and a natural mortality rate of ***M***=0.15. In the Col and Legault (2008) assessment, r was set to twice the value of $\boldsymbol{F_{0.1}}$.
3. A penalty function on survey catchabilty with ***q***=0.5 was imposed by Col and Legault for the NEFSC fall survey. Col and Legault (2009) also used a penalty function on population size.

4. The combination of an assumed trajectory of catch and a fixed value of $\boldsymbol{r}$ are sufficient to allow estimation of $\boldsymbol{K = B_{1800}}$ in the model. The carrying capacity $\boldsymbol{K}$ is also assumed to be constant over the assessment period.

When Hennen (2015) updated the assessment in 2015 the model estimates suggested that the stock had completely rebuilt to K, i.e., the population size in 1800 and twice the $\boldsymbol{SSB_{MSY}}$ proxy value (See Fig. 81 in Hennen 2015). Moreover, the population estimates had been well above SSB_{MSY} since the start of the fall survey time series in 1963. Analyses of the log likelihood profile over the $\boldsymbol{K}$ parameter revealed extreme sensitivity to $\boldsymbol{K}$ (Fig. 16 in Hennen 2015. (Supplemental material).

The combination of implausible estimates of stock status, extreme statistical uncertainty, and dependency on model assumptions, led to the rejection of this assessment approach for Atlantic halibut. While the model incorporates important biological information about growth and natural mortality, model cannot be estimated without imposing constraints on $\boldsymbol{q}$ and fixing the intrinsic rate of increase. In Col and Legault, penalty functions were included to help fix $\boldsymbol{q}$~0.5 and to impose bounds on biomass. Sensitivity analyses by Col and Legault revealed that the assumed trajectory for catch between 1800 and 1893 had almost no effect on estimation.

The Review Panel in 2015 concluded that "the updated assessment was not acceptable as a scientific basis for management advice. The updated assessment produced an unstable and unrealistic solution. Estimates of current stock size were highly sensitive to initial conditions and slight changes in assumed parameter values."

Plan B Assessment Process

In the Northeast US rejection of the accepted stock assessment model creates uncertainty about stock status and poses the problem of finding an alternative basis for setting catch limits. These are affectionately known as Plan B assessments (NRCC 2011). The written and implied constraints on Plan B assessments were discussed in the introduction. In the following sections, alternative approaches for providing scientific catch advice are considered. Numerous methods have been proposed for the assessment of data-poor stocks. A number of excellent reviews of both methodology and applications may be found in Berkson et al. (2011), Newman et al. (2015), Carruthers et al. (2014), and especially Edwards (2015). The potential utility of such methods for Atlantic halibut is considered in the following sections.

Life History Methods

Life-history based methods rely on various properties of growth and longevity, and draw upon so-called life history invariants for obtaining suitable target fishing mortality rates. If a population is at equilibrium then length frequency information should be sufficient to obtain a measure of total mortality. Assuming a rate of natural mortality then allows for derivation of a contemporary fishing mortality rate or target fishing mortality rate.

Length-based Methods

Length-based methods do not provide information on abundance or its trends (Edwards 2015). They are also typically slow to respond to changes fishing mortality because they rely on some degree of constancy in recruitment, fishery selectivity and natural mortality, and adequacy of biological sampling of landings and discards to define a meaningful rate of fishing mortality. Otherwise the derived rates can be biased. Gedamke and Hoenig (2006) developed approaches to address nonequilibrium populations.

Without a measure of scale, one can only interpret current fishing mortality rates with respect of target rates. If $F_t > F_{target}$, then the catch could be reduced by the degree of overage. However, such measures are not useful for setting catch limits unless they are viewed as part of feedback control system. Klaer et al (2012). noted that the feedback control rule had acceptable results for a high productivity demersal stock but that estimates of variability of length at age were essential for proper estimation. The overall sampling frequency for landed and discarded Atlantic halibut has increased in recent years but a full evaluation of the information content of such data is beyond the scope of this project. Introduction of new data requires consideration of potential sources of bias via a working group process.

Productivity-Susceptibility Analysis

The productivity susceptibility analysis method (Patrick et al. 2011) examines multiple attributes of life history, fisheries and habitats to derive a score for productivity P and susceptibility S. The overall vulnerability V of the species to overfishing is a function of P and S. Results suggest that halibut are only moderately vulnerable to overfishing owing to relatively high productivity scores. Regardless of the underlying PSA score, the widespread absence of halibut in the Gulf of Maine and in deeper waters of Georges Bank suggests that recovery has been slow since the peak periods of fishing in the early 1900's. The PSA method was not considered further for this assessment.

Catch-Based Methods

Catch-based methods are rely primarily on adjustments to recent average catches (Berkson et al. 2011). The basis for the adjustment varies but typically includes a scalar adjustment to recent average catches based on an assumed stock status. For example, Restrepo et al. (1998) employed 3 different scalars, all less than one, depending on whether the stock was below or above the inferred estimate of $\boldsymbol{B_{MSY}}$. While these methods are widely used in the US in data-poor stocks in the US, Carruthers et al. (2014) concluded that the utility of such methods as control strategies could not be evaluated reliably in a simulation context. Such measures are undoubtedly good starting points for managers until data collection procedures to support more robust measures can be implemented. However, the degree of data poverty in such stocks is far greater than for Atlantic halibut which has multiple indices of relative abundance and recent biological information. Catch-only based methods were not considered further for this assessment.

Depletion-Corrected Average Catch (DCAC)

Depletion corrected average catch methods were first proposed by MacCall (2009) as a way of interpreting catch histories in terms of an underlying surplus production model. The DCAC model represents an important conceptual advance for fisheries as it applies logical constructs to obtain rough estimates of sustainable yield and more importantly, contemporary catch for data poor stocks. The methodology combines standard principles of surplus production models with various “rules of thumb” from various meta-analyses in fisheries stock assessments. The Depletion-based Stock Reduction Analysis (DB-SRA) is conceptually similar but relies on more detailed biological information. Both DCAC and DB-SRA rely on assumptions about current stock status relative to biological reference points. As this is the usual *output* of an assessment, the need to supply it as an *input* does cause some conceptual problems.

Edwards(2015) provided a succinct summary of the utility of DCAC and DB-SRA as follows:

> “Both DCAC and DB-SRA have been shown to be highly sensitive to the assumed current status of the stock δ, and can easily produce overestimates of the OFL if an optimistic distribution for δ is assumed. This is a major shortcoming, since if depletion of the stock is known already, then it is unlikely to be considered data-poor. Consequently it is difficult to conclude that these methods are an improvement on the scalar methods already in use. Indeed it appears from recent simulation studies that DACS methods produce comparable results (Carruthers et al., 2014).”

Edwards conclusions were tempered somewhat by noting that most data poor assessment models embed such considerations into their definition (e.g., see Restrepo et al 1998 discussion above.)

> “Furthermore, when considering their utility it is worthwhile noting the philosophical stance represented by these catch-only methods. They are centrally based on prior assumptions regarding the state of the fishery (specifically the depletion), which is a departure from previous conceptions of prior information that typically refer directly to parameter values within a particular model specification. Including this type of “soft” information could allow more “sporadic, qualitative or subjective” data to partake in the estimation process (Bentley, 2015), and the methods described by MacCall (2009), Dick & MacCall (2011) and Martell & Froese (2013), represent an important step in that direction.”

Rewriting MacCall’s (2009) DCAC notation by replacing Y with C leads to

$$C_{sustainable} = \frac{\sum_{t=1}^{n} C_t}{n + \frac{Delta}{0.2\ M}} \quad [3]$$

Where ***Delta*** is defined as

$$Delta = \frac{B_t - B_{t+n}}{B_{MSY}} \quad [4]$$

MacCall noted that yields are sustainable only if the current biomass is greater than $\boldsymbol{B_{MSY}}$; otherwise the estimate of catch for the current time step may be approximated as

$$C_t = C_{sustainable} \frac{B_t}{B_{MSY}} \quad [5]$$

While conceptually simple and based on surplus production theory, the DCAC model requires an estimate of the biomass at MSY or equivalently the carrying capacity of the resource. Otherwise the proportion in the denominator of Eq. 3cannot be obtained.

The DCAC approach was first applied to US Atlantic halibut by Col and Legault (2009) as an exploratory exercise for two different cases. First they considered the entire time series of 208 years of catch (i.e., imputed+recorded) used in the replacement yield model (RYM). Using the model biomass estimates as a guide, the derived ***Delta***=0.987 estimate of $\boldsymbol{C_t}$ was 35 mt. Using the entire time series of recorded catch (1893-2007), ***Delta***=0.098, and the DCAC estimate of $\boldsymbol{C_t}$ is 10 mt. In their application of DCAC, the results of the RYM were used to estimate the key parameter ***Delta***.

Theory of DCAC implies that sustainable and current catch can be estimated when the population is increasing as well as decreasing. When the population is declining over time, ***Delta***>0 (and vice versa) but the magnitude of ***Delta*** depends not only the rate of change in abundance indices but also on the relative size of the current population. Col and Legault (2009) were able to use the results of the accepted assessment model to create their estimates. In the absence of such a model the estimation problem can be decomposed into two steps:

1. Estimate the relative rate of change in one or more abundance indices over some period of time. This is described in the section “Ratio Estimation”.
2. Obtain an estimate of approximate scale consistent with the catch and relative biomass indices. This is described in the section “Envelope” method.

The methodology for achieving steps 1 and 2 are described in the following sections.

The model requirement that the relative status of the resource must be known in order to estimate relative catch implies that the status must first be inferred from knowledge apart from the model. Several authors have noted the logical difficulty of this approach (Edwards 2015, Carruthers et al 2014) but have also noted that it is it valuable in many fisheries where reasonable guesses of stock status might be made. The approach has been used widely in the US for stocks in which biomass is thought to be well above $\boldsymbol{B_{MSY}}$**.** When biomass is well below $\boldsymbol{B_{MSY}}$ the scope for error in the ***Delta*** parameter is much less. Moreover, the method does not address the management requirement for rebuilding at very low stock levels. Both of these conditions are true for halibut, so it is important to define where the current stock is relative to some measure of $\boldsymbol{B_{MSY}}$ and to estimate the relative change that has occurred over the period of extraction.

Eq. 3 applies to instances where the stock has been increasing of the period in which catches have been taken. In this case Delta is less than zero. When ***Delta***/(0.2 ***M***) equals ***n*** the sustainable catch is undefined. When ***n*** <***Delta***/(0.2 ***M***) the predicted sustainable catch is negative. Subject to the assumptions underlying the model, the presence of infeasible solutions provides a rough boundary on the current relative state of the stock. The implications of this discontinuity for bounding of abundance estimates will be discussed later.

Ratio Estimation and Randomization Method

A randomization test is developed herein to estimate the magnitude of change in a time series of length t=1,…T. We are interested in the general problem of determining whether the observations at the end of the time series are statistically larger than the observations at the beginning of the time series. For the DCAC issue we are not particularly interested in the trajectory of the change, so a model-based approach is not necessary. Moreover, observation errors tend to be high so that a simple regression model may be misleading.

The first task is to create a test statistic that can be used to compare the population state at the ends of the series. For this exercise I assumed the population state could be estimated as the ratio of the average of the last three observations to the first three observations. Consider a time series with observations $\boldsymbol{x_1, x_2, \ldots x_T}$. If the times series is simply a random set of observations with no underlying trend, the test statistic should be near the center of the test statistics obtained by randomly shuffling the observations, and computing a new statistic. The collection of all statistics so generated is called the sampling distribution for the test statistic. The approximate significance level of the test statistic from the original time series can be compared to the sampling distribution. If it lies near the tails of the distribution on can assume that the observed value for the original series is improbable due to chance alone. These concepts are formalized in the following equations.

Let $\boldsymbol{I_{j,t}}$ represent the j-th index at time ***t*** where ***j=1,…J*** and ***t=1,…T.*** We compute the endpoint estimates of abundance using an average of multiple years (***n*** and ***m***) to help reduce the effects of random variation in catchability between years Let ***m***= number of years for most recent years and ***n*** for earlier period. Define test statistic or critical ratio for index $\boldsymbol{I_{jt}}$ as $\boldsymbol{R_{crit,j}}$ as

$$R_{crit,j} = \frac{\sum_{t=T-m+1}^{T} \frac{I_{j.t}}{m}}{\sum_{t=1}^{n} I_{j,t} \frac{I_{j.t}}{n}} \quad [6]$$

If the observations for the various $I_{j.}$ are not commensurate, then, without loss of generality, the indices can be standardized with respect to their individual means. The composite test statistic for multiple time series can be define as

$$R_{crit,.} = \frac{\sum_{j=1}^{J}\sum_{t=T-m+1}^{T}\frac{s(I_{j.t})}{m}}{\sum_{j=1}^{J}\sum_{t=1}^{n}\frac{s(I_{j,t})}{n}} \qquad [7]$$

Where ***s(.)*** refers to a standardization function in which the index is expressed as a ratio to its mean.

$$s(I_{j,t}) = \frac{I_{j,t}}{\sum_{t=1}^{T}\frac{I_{j,t}}{T}} \qquad [8]$$

The sampling distribution of the randomization statistic for ***Rcrit*** is obtained by shuffling the observed sequence of indices and computing a random realization of the indices. Let ***R(.)*** represent the randomization function which shuffles the original indices $I_{j,t}$ with respect to time. Let ***k*** represent the index for the ***k***th realization of the random ***Rcrit***.

$$R_{crit,k} = \frac{\sum_{j=1}^{J}\sum_{t=T-m+1}^{T} R_k\left(\frac{s(I_{j.t})}{m}\right)}{\sum_{j=1}^{J}\sum_{t=1}^{n} R_k\left(\frac{s(I_{j,t})}{n}\right)} \qquad [9]$$

The sampling distribution of ***Rcrit*** is obtained by repeatedly applying Eq. 9 over an arbitrarily large number of iterations, ***k=1…Nrand***. The approximate significance value of the observed ***Rcrit*** can be obtained by comparing it to the sampling distribution of realized observations $\{\mathbf{R_{crit,k}}\}$

The probability of obtaining a value greater than $R_{crit,obs}$ is simply

$$P(R_{crit,k} > Rcrit, obs) = \frac{\sum_{k}^{Nrand} g(R_{crit,k} \geq R_{crit,obs})}{N_{rand}} \qquad [10]$$

where g(.) is an indicator function equal to 1 when the logical argument is true and 0 otherwise. The probability of observing a critical value less the observed value may be obtained by simply reversing the order of the operator in the indicator function ***g(.)***

The sampling distribution of the ***Rcrit*** in Eq. 9 can be enumerated as the product of combinatorials. Total realizations = J* comb(T,n)* comb(T-n,T-m-n) * comb(m,m). For J=6, T=10, n=m=3, the number of potential combinations is 25,200. I approximated the sampling distribution with 2000 iterations.

SIMULATION TESTS for Randomization method

For the purposes of this assessment, the performance of the ***Rcrit*** statistic is defined as the ability to detect a true rate of change. This is affected by the magnitude a function of the true underlying rate of increase, the underlying observation error for each index and the number of indices. Intuitively one would expect the performance of ***Rcrit*** to improve with larger true rates of increase, as the observation error declines and as the number of indices increases. These hypotheses were tested in a series of simulations described below.

Let the true rate of annual increase be defined as $\boldsymbol{\lambda}$.

$$I_{true,t+1} = \exp(\lambda)\ I_{true,t} \quad [11]$$

The realized observations are assumed to be lognormally distributed random variables with mean defined by the true index value and the SD specifiec by the coefficient of variation CV.
Let

$$I_{realized,t} = LnNormal\left(I_{true,t}, SD\right) \quad [12]$$

Where $SD = \sqrt{\ln(CV^2 + 1)}$

Simulations were conducted for 3 levels of $\boldsymbol{\lambda}$,{0.1, 0.05,0.025} 12 levels of ***CV*** { 0.1, 0.15, 0.2,…0.65, 0.70} and four different levels of ***J***={1,2,3,5}. Random times series of 10 observations were computed for 1,000 realizations. For each realization, a $\boldsymbol{R_{crit,realized}}$ was computed. A randomization test with 2,000 iterations was then used to compute the significance level for each random realization Two million iterations were computed for each of the 3*12*4 combinations of $\boldsymbol{\lambda}$, ***CV*** and ***J***.

Randomization Simulation Results
Simulation tests suggest relatively little bias in the ratio estimator over a broad range of simulated values except when the true magnitude of increase is small (eg 2.5% per year) and the underlying variability of the observations is low (Table 2). Even then, the bias will decline as the number of indices increases. The probability of successfully detecting a change in population size is given in Table 3. As expected increases in the true magnitude of change, reductions in the variability of the observations and increases in the number of available indices all act to increase the probability of detecting the true change.

Overall results of the simulation studies are summarized in Tables 4, 5,6 and 7. Each table corresponds to different number of variables used for trend. Within each table lambda ranges from 0.1 to 0.25 and CV ranges from 0.1 to 0.7. The tabulated results are the fraction of test statistics that are significant at the P=0.005, 0.01, 0.05, …, 0.25 probability levels. For example, a value of 0.89 would mean that 89% of the test statistics were less than or equal to the probability level of the columns. In other words, the entries provide a metric of the ability of the estimator to correctly identify the true ratio. Color shading is scaled consistently across tables with green shading indicating good performance and red shading indicating poorer performance. As one would expect model performance generally increases with the magnitude of increase (eg. It’s easier to find the correct value when the true Rcrit is bigger), as CV gets smaller, and as the number of variables used for detection increases.

.

Application of Rcrit Method to US and Canadian Indices

The Rcrit randomization method was applied to six candidate indices for the US stock and three candidate variables for the DFO 3NOPs4VWX5Zc stock (TABLE 1). Candidate indices for the US stock included the NEFSC fall trawl survey biomass, the d/k ratios for halibut taken in observed trips on gill net and trawl vessels, a modeled index of commercial catch per unit effort, and the fall and spring weight per tow estimates from the ME-NH inshore trawl survey. The inclusion of the d/k ratios for gill nets and trawls should not be interpreted as introduction of a new time series in the model since these are components of the SBRM discard estimate. For the purpose of establishing trend, the selection of the NEFSC trawl survey and d/k ratios should be considered consistent with the time series used in previous assessments. Other indices from Maine are useful for illustrating overall coherence of available information.

No attempt was made to define the "best" set of variables. Instead, the Rcrit method was applied to all possible combinations of indices. For 6 variables, this implies 63 different models based on the sum of combinatorials denoted as (6,6) {ie. 6 items, taken 6 at a time) +(6,5)+ (6,4)+ (6,3)+ (6,2)+ (6,1)=63 possible models. Tables 8, 9, and 10 summarize the results of the complete set of models for 2002-2016, 2005-2016, and 2002-2013, respectively. Nearly all of models configurations were statistically significant. For 2002-2016 95% of the models has significance values less than 5%, for the 2005-2016 period 78% were significant, and for 2002-2013, 95% were significant. The average Rcrit over all models and year ranges went from a low of 2.44 for the 2005-2016 to 3.52 for the 2002-2016 period.

For the Canadian stock three abundance indices are used in their analytical model. The average increase in Rcrit over 6 possible models was 2.92 (P<0.001) (Table 11). The Rcrit for the modeled biomass was 2.763. Overall the comparisons suggest that the US stock has increased at a rate comparable to that observed in Canada. Of course, the scale of these changes is considerably different. Landings in Canada in the last 3 years have averaged ~3400 mt, whereas in the US stock landings have been about 100 mt.

The implied annual rates of increase in relative abundance, given the Rcrit estimates below are on the order of 9 to 15% per year. The similarity in rates of increase between US and Canada stock areas potentially suggests favorable conditions in both areas during the past decade.

		Changes in catches			Change in indices		
	Ratio Definition	Statistics	Value		Statistic	Value	Model
US	'02-04:'14-16	Rcrit(Catch)	3.227		Rcrit(Indices)	3.23	(all six indices)
						4.98	(DK_g, DK_t, Survey)
						3.52	average over 63 models
	'05-07:'14-16	Rcrit(Catch)	2.657		Rcrit(Indices)	2.44	average over 63 models
						2.2	(all six indices)
						4.11	DK_g,DK_t, Survey
	'02-04:'11-13	Rcrit(Catch)	2.617		Rcrit(indices)	2.893	(all six indices)
						5.033	(DK_g, DK_t, Survey)
						3.144	average over 63 models
Canada	2002-04: 2014-2016	Rcrit(Catch)		2.259	Rcrit(Indices)	2.703	(two survey , one CPUE
						2.923	average over 6 models
						2.763	Analytical model results

While Rcrit provides a way of quantifying the rate of change in population size, it cannot distinguish the change in scale. For example a population that increase 3 fold during some period could increase from 2% to 6% of the virgin stock size for from 20 to 60%. Application of DCAC requires one to estimate the ***Delta*** parameter in terms of change relative to virgin stock size. To establish scale, the Envelope method was applied, as shown in the next section.

Envelope Method

The envelope method (Miller and Rago 2010) is an approach to establish a range of feasible biomass estimates conditional on an assumed range of feasible catchability estimates q and historic ranges of fishing mortality rates ***F***. The method combines concepts of swept area biomass and the standard Baranov catch equation. Biomass estimates based on swept area estimation are dependent on an assumed range of catchability estimates ***q'***. Biomass estimates based on observed catches rely on an estimate of fishing mortality rate. For any given time series of catch, one can assume it is the realization of a small population being fished consistently at a high rate, or a large population being fished at a low rate. Using the standard definition for swept area biomass

$$B_t = \frac{I_t}{q'}\frac{A}{a} \qquad [13]$$

The ratio ***A/a*** is the total area ***A*** covered by the survey and ***a*** is the average area swept per tow. The biomass estimate consistent with observed catch can be obtained from the Baranov catch equation

$$B_{0,t} = \frac{C_t}{\frac{F}{F+M}(1-e^{-F-M})} \qquad [14]$$

$$B_{f,t} = B_{0,t}e^{-(F+M)f}$$

The second equation in Eq 14. adjusts the biomass estimate to be on the same time scale as the survey estimates in Eq. ss. If we use the general notation that ***B(I,q)*** is the biomass estimate based on the observed ***I*** and assumed ***q***, and ***B'(C,F,M)*** is the biomass estimate based on the observed ***C*** and assumed ***F*** and ***M***, then one can generate the following set of biomass estimates:

$$\widehat{B_{1,t}} = B(I_t, q_{Low}) \qquad [15]$$

$$\widehat{B_{2,t}} = B\left(I_t, q_{High}\right)$$

$$\widehat{B_{3,t}} = B'(C_t, F_{Low}, M)$$

$$\widehat{B_{4,t}} = B'\left(C_t, F_{High}, M\right)$$

For many species, prior information on a suitable range of ***q*** may obtainable from gear comparison studies. Calibration studies for NEFSC failed to catch sufficient numbers of halibut in either net type to allow estimation of a conversion coefficient (Miller et al. 2008). A plausible range of fishing mortality estimates may be obtained by analogy with other halibut or flatfish fisheries.

The key concept in the envelope method is that the bounds represent extremes in the feasible range of parameter values. The upper and lower bounds of biomass estimates can then be defined as the set of estimates that jointly satisfy both constraints. These values are defined as

$$\hat{B}_{upper,t} = min\left(\hat{B}_{1,t}, \hat{B}_{3,t}\right) \qquad [16]$$

$$\hat{B}_{lower,t} = max\left(\hat{B}_{2,t}, \hat{B}_{4,t}\right)$$

Values of biomass that exceed $\boldsymbol{B_{upper,t}}$ imply catchabilities smaller than $\boldsymbol{q_{low}}$ or fishing mortalities less than F_{low}. Conversely, values of biomass less than $\boldsymbol{B_{lower,t}}$ imply catchabilities greater than $\boldsymbol{q_{high}}$ or fishing mortalities greater than $\boldsymbol{F_{high}}$. The bounds defined by Eq. 16 describe a set of feasible estimates that are consistent with the assumed ranges of *both* ***q*** and ***F***. In theory, a more mechanistic model of stock dynamics should also be within this feasible range. Additional layers of constraints might be applied to the model to further reduce the range of uncertainty. For example, one could reasonably hypothesize that the biomass in US waters in recent years should be less than or equal to the Canadian stock biomass in 3NOPs4VWX5Zc. If a particular constraint is binding, then it can be used to further refine the feasible ranges of q and F for those years. A mid-range estimate of central tendency (sensu Tukey 1977) for $\boldsymbol{B}$ can be obtained as the average of $\boldsymbol{B_{upper,t}}$ and $\boldsymbol{B_{lower,t}}$.

Envelope Results

The model was applied to the catch estimates from 1963 to 2016 and NEFSC fall trawl survey estimates of swept area biomass. The assumed range of $\boldsymbol{F}$ is{0.02,0.40} and $\boldsymbol{q}$ is {0.02,1.0}. The envelope model can only be applied to catches before 1963. FIG. 12. The Envelope model was also applied to the Kalman smoothed biomass estimates of fall survey biomass (FIG. 13). As might be expected the biomass estimates from the RYM do lie within the boundaries of the Envelope and correspond well with the mid-range estimator of average abundance (FIG.13). Quantitative results of the maximum biomass estimate and 2016 biomasses are summarized in Table12. Depending on the range of years used for estimation of biomass the mid range of the 2016 estimate ranges from 2.4% to 98.2% of the maximum observed value. The derived range is not terribly useful but it does highlight that the perception of the resource varies considerably with the inclusion of more long term data. The wide range of uncertainty in the biomass results is consistent with our limited understanding of the dynamics of halibut in US waters.

Factoring the Rcrit and Envelope Results into DCAC

The results of Rcrit and the Envelope methods can now be factored into the computation of DCAC to obtain estimates of sustainable yield and predictions for 2018 catches. Table 13 combines the observed ratio increases from Rcrit and the Envelope estimates of fraction rebuilt in 2016 to derive a set of possible Delta parameters. In part B of Table 13 the derived Delta are used to estimate sustainable catches for each combination. As noted in the methods above, the DCAC model can become unstable as the denominator in Eq. 3 approaches zero. The model produces infeasible results when the denominator becomes negative. Table13 shows the specific behavior of the model for this application. FIG. 14 general behavior of the estimator for varying values of ***Delta*** and ***Rcrit***.
