The overall results of the DCAC approach are not reassuring even when the estimates of Delta are refined by explicit consideration of the recent trends in population indices. The fundamental problem appears to be uncertainty in the absolute biomass estimate. Even if a credible statistical catch at age model can be developed, the uncertainty of any biomass estimates is likely to be very large for the foreseeable future.

Proposed Assessment Approach

The proposed assessment approach is less ambitious in terms of estimating long-term parameters (***r, K***) and instead focuses on short-term changes in stock size and their implications for modifying catch. As a simplification, it is assumed that the current stock size is well below the historic carrying capacity K such that the expression $\boldsymbol{(1-B_t/K)}$ in Eq. 2 is negligible. This seems reasonable in the context of inferring an initial stock size that existed over 200 years ago and is

estimable only by assuming that the productivity of the stock has been fixed and constant at 2*$\boldsymbol{F_{0.1}}$ for a similar period. The $\boldsymbol{F_{0.1}}$ estimate is based on life history attributes from recent decades and the natural mortality is fixed at $\boldsymbol{M}$=0.15.
Relaxation of these assumptions leads to a simple linear equation for biomass as a function of a time-varying rate of increase $\boldsymbol{r_t}$ and a time-varying harvest rate $\boldsymbol{h_t}$.

$$B_{t+1} = B_t + r_t B_t - h_t B_t \qquad [17]$$

Catch is defined as the product of harvest rate and stock size

$$C_t = h_t B_t \qquad [18]$$

Which leads to

$$B_{t+1} = B_t + r_t B_t - C_t \qquad [19]$$

A key assumption in nearly all stock assessment models is that stock size is proportional to one or more indices of abundance $\boldsymbol{I_t}$ as

$$I_t = qB_t \qquad [20]$$

Stock assessment models can be fit to observed data by substituting Eq. 18 into Eq. 17 and by creating a likelihood function for one or more relative abundance indices. Derivation of $\boldsymbol{q}$ for each index and specifying an appropriate function for $\boldsymbol{r_t}$ can be problematic if $\boldsymbol{r_t}$ is changing and if observation error of $\boldsymbol{I_t}$ is high.
To avoid these problems the equation for biomass dynamics is transformed into a recursive expression for catch over time. The model can be derived as follows. The catch at time t+1 is written as

$$C_{t+1} = h_{t+1} B_{t+1} \qquad [21]$$

Dividing Eq. 21 by Eq. 18 gives

$$\frac{C_{t+1}}{C_t} = \frac{h_{t+1} B_{t+1}}{h_t B_t} \qquad [22]$$

Rearranging terms a bit provides a prediction of future catch as a function of current catch:

$$C_{t+1} = \frac{h_{t+1}}{h_t} \frac{B_{t+1}}{B_t} C_t \qquad [23]$$

Without loss of generality, one can substitute Eq. 20 $\boldsymbol{I_t=qB_t}$ in the Eq. 23 to obtain

$$C_{t+1} = \frac{h_{t+1}}{h_t} \frac{I_{t+1}}{I_t} C_t \qquad [24]$$

The problem with Eq. 24 is that it relies on having an estimate of I_{t+1} in order to estimate C_{t+1}. Furthermore, it also requires h_{t+1} and h_t which are also unknown. By definition the index I_{t+1} is a consequence of the removals at time C_t so it would not generally be available until most or all of the fishery that harvest catch in period t+1 would be complete.

However, from Eq[17] the ratio B_{t+1}/B_t is $1+r_t-h_t$ which is equivalent to I_{t+1}/I_t .

$$\frac{B_{t+1}}{B_t} = 1 + r_t - h_t \qquad [25]$$

Or by substituting Eq. 20 into Eq. 25.

$$\frac{B_{t+1}}{B_t} = \frac{qI_{t+1}}{qI_t} = \frac{I_{t+1}}{I_t} = 1 + r_t - h_t \qquad [26]$$

An approximate estimate of the expression ($1+r_t-h_t$) can be obtained by regression the $log(I_t)$ vs time. This is easily shown by recursively applying Eq. 6 over p time steps to obtain

$$B_{t+1} = (1 + r - h)B_t$$
$$\dots$$
$$B_{t+p} = (1 + r - h)^p B_t \qquad [27]$$

Taking log of both sides results in

$$\ln(B_{t+p}) = p\big(ln(1 + r - h) \quad + \ln(B_t\big) \quad [28]$$

Therefore, the slope of rate of change in biomass over time is $ln(1+r-h)$. The intercept is simply the log of the initial condition B_t. For an index I_t that is proportional to Biomass B_t as defined in Eq. 28, the slope is independent of the scaling factor q.

$$\ln(I_{t+p}) = p\big(ln(1 + r - h) \quad + \ln(I_t\big) \qquad [29]$$

Using a log-linear regression model for the abundance indices one can approximate as the slope of $ln(I_t)$vs t or the average slope of the composite indices. Recall that we hypothesized that the r and h were functions of time. The regression in Eq. 15 assumes that r and h are constant over the interval $t=t_1$ *to* t_2. To approximate the change in slope over time one can update the regression equation 15 by computing the slope at each time t for τ time steps (ie. A τ-point regression). For simplicity of notation, let

$$slope_t = \ln(1 + r_t + h_t) \qquad [30]$$

Substituting Eq. 26 and 30 into Eq. 24 gives

$$C_{t+1} \cong \frac{h_{t+1}}{h_t}(1+\widehat{r_t -} h_t)C_t$$

$$C_{t+1} \cong \frac{h_{t+1}}{h_t} e^{slope_t} C_t \qquad [31]$$

Technically Eq. 31 poses some additional problems since neither $\boldsymbol{h_t}$ nor $\boldsymbol{h_{t+1}}$ are known. The harvest rate $\boldsymbol{h_{t+1}}$ can be written as a function of the biomass and catch at t+1. So one is left with the assumption that the slope at time ***t+1*** is approximately equal to the slope at time ***t***.
In most real-world scenarios an index of the biomass at time ***t+1*** would not be available at the time when $\boldsymbol{C_{t+1}}$ is being set. In practical terms it means that the slope estimated over the set of points $\boldsymbol{\{t_i, t_{i+1}, \ldots t_{i+n}\}}$ approximates the slope estimated from the set $\boldsymbol{\{t_{i+1}, t_{i+2}, \ldots t_{i+n+1}\}}$. In other words, the slope estimate at time t_{i+n} is used to approximate the estimated slope at t_{i+n+1}.
Under these constraints, the updating function for catch can be written as

$$C_{t+1} \cong e^{slope_t} C_t \qquad [32]$$

Eq. 32 implies that the rate of change in catch should be equal to the rate of change in relative abundance. Note that scale of indices does not affect estimate of slope vs time.
The model can readily be extended to multiple indices by taking the simple average of the rates of change in index values when the $\boldsymbol{slope_j}$ is defined by the log-linear regression $\boldsymbol{ln(I_{j,t})}$ vs ***t***. Hence slopes from multiple indices can be combined without consideration of their underlying scale. One can estimate a common slope via a general linear model in which the various indices are considered factors. Alternatively, the common slope can be estimated as the average of the j=1,…J slope estimates. Without loss of generality Eq. 32 can be written as

$$C_{t+1} \cong e^{average\ \widehat{slope}(I_{j,t})}\ C_t \qquad [33]$$

The slope parameters of the composite regression incorporate a number of underlying proceses including growth, recruitment, natural mortality and harvesting. Since any or all of these processes can vary over time, it is important that the forecasting equation be responsive to processes as they begin to occur.
This type of control rule has been suggested by Geromont and Butterworth (2015a, 2015b) and several others (Pomaerde et al 2010, Apostaloki and Hillary 2009). Note that the control rule implies that next year's catch can be adjusted based on information about the stock trend in the current year. This basic concept can be extended by applying concepts from control theory as shown in the following section.

APPLICATION OF CONTROL THEORY CONCEPTS TO HARVEST Control Rules

Control theory, in the context of this assessment, refers to a general set of principles used to adjust a physical system toward a desired state. A simple example is the use of a thermostat to control temperature in a room. More complicated examples include control of complex chemical production processes or control of surfaces on airplane wings. In general control theory uses feedback from a monitoring device to adjust some input factor to achieve a desired output (e.g., the thermostat send a signal to the furnace or air conditioner depending on what the temperature is relative to the desired value).

One of the major concepts in control theory is that controls can destabilizing if signals about system state are corrupted by noise or delayed and if the change in input level is too large. Conceptually this could occur if the thermostat sensor drifts or is delayed by some software glitch. Consider the consequences if the daytime output of the furnace is governed by temperatures monitored the previous evening. Destabilization can also occur if the input control is too large relative to the observed deviation of system state. A simple example would be a large furnace in a well-insulated small house. Since most furnaces are simply on/off devices, the likelihood of putting out too much heat is possible, raising the temperature to too high a point which then persists.

So what does this have to do with fisheries management? Consider catch to be the input control and relative abundance to be the output signal. If a target output value is known, then catch can be adjusted to achieve a desired value by monitoring the system state. The system state is simply the slope of the relative abundance index or indices. If we want to continue to allow the population togrow then catch can be set at some level less than that indicated by the rate of change. In control theory terms this scalar is referred to as the proportional gain or ***Kp.*** A stock in a rebuilding program would be one in which the gain might be less than one, thereby allowing a population to continue to grow.

A stylized schematic of the proposed model is given in FIG 15. The population dynamics are treated as a black box that outputs one or more abundance indices as a function of changes in the input Catch. If some function of the output variable is less than the previous value, then it is assumed that the previous input signal was too high and the input value of catch for the next time step would be reduced. Conversely, if the index output function increased, there might be some scope for increased catch in the next time step. Of course, devil is always in the details and it is important to consider the responsiveness to the output signal and the magnitude of the inter-annual adjustments. In the following analyses some of these details are explored further for application to Atlantic halibut.

The history of fisheries science is replete with examples of where an underlying process that is assumed constant in a model changes over time. The consequences for management are often overfishing and economic loss. Decreases in growth rate, increases in unobserved mortality, or reduced recruitment will tend to increase the variability in model fit but more importantly, lead to bias in predictions. Analytical models accommodate such changes in varying ways, but many causes can give rise to the same symptoms, such as retrospective patterns. Unfortunately, models need the most adaptability at the end of the time series, where any emerging trends are difficult to distinguish from noise. As an example, decreases in average size of fish may be due to increased recruitment or changes in fishing areas where smaller fish are more abundant. Model parameters for selectivity are unlikely to reliably estimate this change as it could imply either an increase in the historical recruitment to match the observed catch at age, or it could adjust the fishery selectivity at age.

In the simple model proposed here it is not possible to dissect such changes from the measure of slope. The slope is an aggregate measure of multiple factors. However, it is possible to estimate the rate of change in slope as a measure of acceleration or deceleration of trends. In this context it might be called the second derivative of population change. If we let β(t,n)=average slope estimated at with terminal year t and based the last n points, then we can compute the second derivative of population change as

$$\beta(t,n) = slope(x_{t-n+1,}x_{t-n}, \ldots .\, x_{t-1}, x_t)$$
$$\Delta\beta(t,n) = \beta(t,n) - \beta(t-1,n) \qquad [34]$$

The relationship between the slope estimate and its rate of change is important for forecasting future catch. If ***β(t,n)*** and ***Δβ(t,n)*** are positive, then the population would be increasing at an increasing rate. If ***β(t,n)*** is positive and ***Δβ(t,n)*** is negative, then the population is increasing at a decreasing rate. In the former case, one would be more optimistic about continued increase in stock size. The latter case would suggest that population growth may be slowing. There are no hard and fast rules about how to weight the relative importance of these two situations but in the control theory literature, this is called a derivative control, and the weight assigned to this factor is called the derivative gain factor or ***Kd***.

With these concepts in mind, the updating function for catch can be improved by considering the proportional change in stock size and the derivative of the rate of change as follows:

$$C_{t+1} = e^{\left(K_p\beta(t,n)+K_d\Delta\beta(t,n)\right)}C_t \qquad [35]$$

The exponential term in Eq. 35 expresses the rate of change in catch as the weighted sum of the proportional change in abundance (i.e., the first derivative of population size with respect to time) and the derivative of the rate of population change (i.e., the second derivative). This leads to the somewhat hokey name of First and Second Derivative harvest control or FSD control for short. The utility of the model is evaluated over a broad range of simulation scenarios and by application of the model to two managed halibut stocks, the 3NOPs4VWX5Zc Atlantic halibut managed by DFO and Pacific halibut managed by the International Pacific Halibut Commission (IPHC). In both applications, the predicted catch from Eq. 35 is compared to the TAC derived from modern analytical models.

Simulation Experiments for FSD Control Rule

While the control rule (Eq. 35) has some intuitive appeal, its utility is ultimately governed by its ability to control a theoretical population subject to a variety of conditions that are largely unknown or unpredictable in a real world. Relevant factors for a simulation study include

- Observation error for the relative abundance indices ***CV={0.005,0.2}***
- Number of abundance indices available ***Nvar={2,6}***
- Number of years to consider for estimating average slope. ***Ntrend={3,5}***
- Effects of alternative measures of Kp and Kd
- The underlying rate of population increase (r(t)) during the period before and after the control rule is applied.
- The pattern of harvesting (h(t)) prior to the application of the control rule.

In this simulation experiment, the population was harvested without application of the control rule for the first 10 years. During the next 10 years the control was applied. Observation error of the indices was examined by letting the CV range between 0.005 and 0.2. A CV of 0.005 is highly improbable but allows for evaluation of performance in the near absence of observation error. The number of years to use for estimating the slope was varied between 3 and 5 data points. Increasing the number of years decreases the responsiveness of the slope estimator to rates of change. Decreased responsiveness trades off with the increased likelihood of noise-driven estimate of the slope when only 3 points are used. Of course, one expects the shorter interval slope estimators to less reliable as the observation error increases.

Process error in the simulation context was addressed by hypothesizing temporal trends in stock productivity r_t, during the control period. Prior to implementation of the control, all scenarios assumed r=0.2 for the first 10 years. After the control was implemented, ***r(t)*** in year 11 was assumed to be

- Constant for the next 10 years at 0.2
- Steadily increasing over the next 10 years to 0.3
- Steading decreasing over the next 10 years to 0.1
- Increased as a step function in year 11 to 0.3
- Decreased as a step function in year 11 to 0.2
- Increased steadily for 5 years followed by a steady decrease
- Decreased steadily for 5 years followed by a steady increase.

These scenarios are depicted in FIG. 16.

The history of harvesting prior to implementation of the control rule is important because it defines the set of indices that will be used to develop the average slope estimate. Deterministic simulations suggest that the proximity of the true fishing mortality rate to the true productivity of the stock is critical for the application of the control. Neither of these quantities are estimable, so the control rule should be robust to this uncertainty.

The harvest rate scenarios all assume that the true population is growing during the first 10 years. This mimics the observed pattern for US halibut (See ***Application of Rcrit Method to US and Canadian Indices***). Three scenarios assumed constant harvest rates with h_t=0.15, 0.19 and 0.10, for all t. Other scenarios assume continuously increasing h_t, continuously decreasing h_t, a harvest rate that increases then decreases, and one that decreases then increases (FIG. 17). 49 possible combinations of r_t and h_t were evaluated by pairing each r_t and h_t scenario.

The effect of the ***Kp*** and ***Kd*** gain parameters were developed by evaluating performance for each combination of ***Kp***={0, 0.25,0.5, 1.0} and ***Kd***={0,1,5,10}. Higher values of K_d were used to evaluate the consequences of testing quick responsiveness when the $\Delta\beta$ parameter was changing. There were a total of 16 combinations of ***Kp*** and ***Kd*** evaluated for each combination of ht, rt, Ntrend, and Nvar.

Each 20 year simulation was repeated 50 times resulting in 2*2*2*7*7*4*4*50=313,600 applications of the control rule. Summary statistics from each simulation during the control period included the average:

- Number of overfishing events induced by the control rule (i.e., when the predicted catch resulted in overfishing ($h_t > r_t$)
- Number of "extinctions" when the population is driven to arbitrarily low values
- Catch
- CV of catch
- Net rate of population increase

Simulation results are summarized in Table 14 for two levels of CV ={0.005,0.2} and 16 combinations of K_p and K_d. Averages are made over the 49 combinations of h_t and r_t and for tow values of Ntrend={3,5}. Results suggest that low rates of K_p reduce the frequency of overfishing events. As the weighting on the change in slope increases, the frequency of overfishing events tends to increase because of induced oscillations. The relative precision of the observations appears to have little effect on the probability of overfishing. As expected, increases in K_p result in increases in average catch, but the increases in average catch come at the expense of greater variability in catch.

The frequency of "extinctions" is more complicated to explain as it appears to be driven more by the underlying initial conditions based on r_t and h_t, rather than the control parameters K_p and K_d. When observation error is relatively low, there controls with K_d~5 appear to work well in terms of reducing the frequency of "extinctions". Further simulation work may be necessary to examine the dynamics related to overshooting catches.

The potential interactive effects of the r_t and h_t, can be examined by considering the extinction frequency summed over all values of K_p, K_d, ***Ntrend,*** and ***CV.*** The scenarios in the following text table are depicted in Fig. 16 and 17.

		R scenario							
		r=0.2	r_up	r_down	r_step_up	r_step_dn	r_up_dn	r_dn_up	
Descrip-tion	Harvest Scenario	1	2	3	4	5	6	7	average
h=0.15	1	0.0159	0.0241	0.0178	0.0256	0.0191	0.0225	0.0181	0.020
h=0.19	2	0.0394	0.0375	0.0363	0.0525	0.3281	0.0456	0.0419	0.083
h=0.10	3	0.0053	0.0078	0.0091	0.0078	0.0078	0.0094	0.0053	0.008
h_up	4	0.3722	0.0816	0.5066	0.0691	0.5500	0.1044	0.5113	0.314
h_down	5	0.0016	0.0016	0.0013	0.0028	0.0013	0.0025	0.0019	0.002
h_dn_up	6	0.0469	0.0363	0.3153	0.0316	0.5028	0.0534	0.4019	0.198
h_up_dn	7	0.0119	0.0188	0.0156	0.0231	0.0184	0.0203	0.0141	0.017
	average	0.070	0.030	0.129	0.030	0.204	0.037	0.142	0.092

Overshoots are more frequent when the harvest rates are increasing during the pre control period (Harvest #4) and when harvest rises just prior to the control period (Harvest #6). Declining productivity at the start of the control period is problematic as see in R scenarios #3,5 and 7. Most of the unstable trajectories occur at the intersections of H scenarios 4 and 6 with R scenarios 3, 5 and 7.

One of the primary factors influencing the responsiveness of the system is the number of data points in the regression equation. Slope estimates will always constitute lagged information. The high amount of observation error in available indices leads to concerns that short term changes, deduced from say the ratio of abundance indices in adjacent years is likely to be unreliable. Unfortunately, the most important information in the stock assessment is the changes in the current time period. Hence it is necessary to consider a larger number of time periods when estimating trend. There may be some improved methods for estimating trend that retain sufficient flexibility for signal detection. A Kalman filter that incorporates information about overall observation error may be useful in this regard for future research.

Application of the FSD Model to US Stock Area

Input data for the US stock area are given in Table1. The model was based on a Kp=0.9 and Kd=0.9 for three indices dk_trawl, dk_gillnet, and NEFSC fall bottom trawl biomass. (See Appendix 1 for the input data and relative errors in each index). A five-point slope regression was used compute the slope for all indices FIG 18. The composite average slope has been positive since 2009 but the slope estimates have been decreasing since 2012. The catch multiplier for each year (based on the K_p and K_d factors of 0.75 and 0.50, respectively) suggests that the rate of increase is declining. FIG 19.

Comparison of observed and predicted catches show reasonable coherence (FIG 20) and surprisingly, the forecasted estimates of catch for 2011 to 2014 given in Blaylock and Legault (2012) line up well with observed values.

Model forecasts for 2018 were examined over a range of $\boldsymbol{K_p}$ {0, 0.3,,1.0}and $\boldsymbol{K_d}$ gain factors from {0, 0.25,…, 4.0} in Table 15. The model performance was estimated by computing a total sum of squares differences between the observed and projected values. Over the range of gain factors tested, the 2018 catches range 110.3 to 141.7 mt. Using the region where the SSQ is within 10% of the minimum value, the highest possible catch is 118.1 mt.

Uncertainty Estimation for Catch Forecasts

The uncertainty in the projected catch forecast includes process error related to the potential change in relative productivity of the stock (i.e., r(t)), the inherent lag in information owing to the number of data points in the estimator of the slope, and the gain factors applied to the first and second derivatives. Observation error in the abundance indices themselves also contributes to the uncertainty of the estimate. While simulation experiments address some of the uncertainty for idealized abundance indices (in particular, indices with homogeneous CVs for all indices), simulations do not capture a real-world example with heterogeneous variability over time and among indices. To address the realized uncertainty of the FSD model applied to the US stock area, a parametric bootstrap method was applied to each index time series. Indices were assumed to be lognormally distributed with means equal to the observed value and standard deviations equal to the log of square root of the coefficient of variation squared plus one.

$$Irand_{k,j,t} \sim LogNormal(Iobs_{j,t}, \sqrt{\ln(CV_{j,t}^2 + 1\,)}, \qquad [36]$$

Note that the ***k***-th realization of the ***j***-th index at time t is a function of time varying means and variances. The sampling distribution of the projected catches were based on 5000 bootstrap realizations.

Projected catches by year are given in Fig. 21 and the sampling distribution of projected catch in 2018 is shown in Fig. 22. The sampling percentile statistics for this distribution are

1%	5%	10%	25%	50%	75%	90%	95%	99%
98.24	104.98	108.61	114.88	122.65	130.69	138.34	143.16	152.26

The bootstrap mean of projected catch is 123.10 mt with a CV equal to 0.095.

Application of the FSD control rule to DFO Canada and IPHC Pacific halibut

The FSD model was applied to both the DFO Atlantic halibut and the IPHC Pacific halibut stocks. For the DFO application, the $\boldsymbol{K_p}$ and $\boldsymbol{K_d}$ parameters were set to the same values used or the US application. The forecasted catches tend to be higher than the model based TACs (FIG. 23). While the apparent coherence of the methods is somewhat reassuring, the differences between the two methods are likely to be not inconsequential in any real world application. However further analyses of the differences in model fit may be useful for improving the decision rules for the US stock area.

The application of FSD to the Pacific halibut stock is summarized in FIG. 24. Data used in this application were obtained from Stewart (2017). Given the tight controls on the TACs for Pacific halibut, it is assumed that the realized catch is close to the TAC. Although the FSD model has some large outliers over the entire time series, the model forecasts are relatively close to the realized catches from 2003 onward. Maximum deviations between the observed and predicted catches are less than 8 mt and generally under 4 mt.

Parametric bootstrap results are summarized in Figure 25 and 26. In general the distribution of predicted catches based on the model covered the range of observed total removals. lTabular summaries of the relative error in the survey and commercial WPUE indices from the IPHC were not available. I assumed the CVs for surveys were 0.2 for WPUE were 0.25 based on overall patterns summarized in Stewart (2017).

These results are likely attributable to consistent downward trend in catches and reliable signals from the IPHC surveys. A comparison of these relative trends with modeled biomass is given in Fig. 27

Effects of discard mortality on catch projections

The survival of released halibut is a function of many factors including the type of gear employed and handling of catch on deck. Estimated and assumed discard mortality rates vary widely among fisheries. In Pacific halibut fisheries managed by the International Pacific Halibut Commission (IPHC), discard mortality rates are estimated directly by observers when available. For unobserved trips the IPHC uses a range of discard mortality rates that vary by region (Bering Sea vs Gulf of Alaska), by target species , by tow depth, and by gear type (trawl, pot, and longline). Forty two possible combinations are considered in Table 2 in Dykstra (2017). Averages across gears are as follows: trawls 75.6%, pot 14.3%, longline 9.9%.) The DFO assessments for Atlantic halibut. Davis and Ryer (2003) reported a mortality rate of 100% after 30 days of holding in laboratory setting but the effects of captivity could not be isolated.
den Heyer et al. (2015) reported roughly similar results for Atlantic halibut,

> "In general, halibut are thought to be robust to handling relative to other groundfish. Neilson et al. (1989) found that 35% of otter trawl-caught halibut and 77% of longline-caught halibut survived 48 hours in holding tanks. Recent deployments of PSAT tags

> suggest that the survival of larger halibut caught by longline gear could be 100% (Armsworthy et al. 2014). Kaimmer and Trumble (1998) found that careful handling of Pacific halibut can increase discard survival and that even those fish with mild or moderate injuries have a higher than expected probability of survival. For example, 69% of Pacific halibut with moderate injuries survived and 43% of halibut with severe injuries survived."

Handling mortality for fish with expensive tags is likely to be low given likely bias in the capture, selection and handling of such fish. Nonetheless, the discard mortality in fixed gear is likely to be lower than in mobile gear. Given the current mixture of gears (primarily longlines) used to prosecute the Canadian fishery, den Heyer et al. (2015) used a discard mortality rate of 23%. DFO (2015) noted that their parameterization of discard mortality in their assessment and management models was based on rather old data and needed to be updated. Similar concerns were expressed by Leaman and Stewart (2017) in their scholarly review of the bases for discard mortality rates for Pacific halibut.

Given that US trawl fisheries are unlikely to target halibut, it seems reasonable to use the average of the discard mortality rates applied to Pacific halibut of 76%. To the best of my knowledge, there are no documented studies of discard mortality rates of halibut in gill nets. It seems reasonable to hypothesize it should be lower than trawl caught mortality but greater than longline estimates. Field studies for spiny dogfish yielded estimates of 30% mortality (Rulifson, East Carolina State Univ., personal communication).

The expected effects of discard mortality rates on total yield can be described simply as

$$C_t = L_t + \sum_{g=1}^{G} \alpha_g D_{g,t} \qquad [37]$$

Where $\boldsymbol{\alpha_g}$ is the discard mortality rate for gear $\boldsymbol{g}$ and Dg,t is the total discard estimate for gear $\boldsymbol{g}$ at time $\boldsymbol{t}$. The relative effect of $\boldsymbol{\alpha_g}$ on the catch estimate will depend on the magnitude of the discard estimates. The FSD model projects the catch in year t+1 by adjusting the observed catch in year t by the estimated rates of change in the indices in year t. In terms of the observed index data, the effects of changes in the estimated catch do not change the adjustment factor applied. The two quantities are decoupled in this context. Discard mortality will not have any effect on the quota IF the relative magnitudes of the $\boldsymbol{D_{g,t}}$ remains constant. However, if the balance of discards shift to say a less lethal gear, then there may be some room for increased landings, or less penalty for discards.

The relative importance of discarding in gill nets has been increasing relative to trawls (Fig. 28) in recent years. Estimated discards with and without adjustment for discard mortality (Fig. 29) show some divergence in recent years due the increase in discarding by gill net trip. However, the overall effect on total catch (Fig. 30) shows less divergence.

Use of total rates (discard+kept) in observer data

The proposed methodology was presented to the NEFMC Plan Development Team on November 27, 2017. It was noted that the d/k ratio as a measure of relative abundance may underestimate relative abundance. The team suggested that the total catch of halibut (i.e., landings plus discards) would be a better estimate of relative abundance. Comparisons of the ratio of total halibut caught to the total landings of all species (t/k) with the halibut discard to total landings of all species (d/k) are summarized in Appendix 3 and Figure 3.1. As expected the t/k ratio is consistently greater than d/k but there are no marked changes in recent years (Appendix Fig. 3.2)

1%	5%	10%	25%	50%	75%	90%	95%	99%
98.51	105.14	109.21	115.539	122.80	130.90	138.64	143.37	151.91

The overall mean catch for 2018 using these parameters is 123.43 mt with a CV equal to 0.094. The time series projected catches based on t/k and the sampling distribution of catch in 2018 are shown in Fig. 31 and 32, respectively. FSD model results suggest no significant differences between catch estimates derived using the t/k indices vs the d/k indices. (See also FIG 3.3 to 3.5 in APPENDIX 3).

DISCUSSION

Quantification of the virgin stock size for a halibut fishery that began a quarter century after the Revolutionary War is difficult. Lear (1998) reported that Boston's Atlantic halibut market "began to outstrip the inshore supplies" in the 1820's and by 1836 a fishery was established on Georges Bank. Catches peaked in 1849 and declined rapidly since then. Landings reported in Hennen (2015) show a curious 2 year spike of 4,200 and 4,908 mt in 1895 and 1896 but no other landings have exceeded 943 mt since then. In the first 40 years of recorded landings (1893-1932) landings averaged about 5.5 times greater than during next 60 years (1933-2002).

Two factors, 1) large catches that occurred prior to the collection of synoptic catch recording programs and 2) an apparent dispersal of fishing activity to more fishing grounds even in the earliest years of the fishery, will make it difficult to interpret historic scale in analytic stock assessments. Such estimates will be driven necessarily by strong, but weakly supported assumptions. Whether the derived quantities are useful as an accurate reconstruction of the past is debatable. But the utility of such estimates for contemporary management will be undeniably low. Current stock sizes are likely to be a small fraction of the virgin abundance and rebuilding strategies will likely devolve into debates about the scientific credibility of the targets or dire externalities of restricting other fisheries to achieve halibut rebuilding targets.

These same basic concerns constrain the applicability of data poor methods. The basic methods essentially fall into four categories:

1. Methods that rely some arbitrary scalar adjustment to recent average catches with no rigorous analyses of population consequences.
2. Methods that rely on strong assumptions about current stock status
3. Methods that apply a biologically based harvest rate to a swept area estimate of abundance
4. Methods that adjust current catches based on measures of current trends or trends.

Methods based on category 1 are difficult to justify scientifically even if risk averse reductions are selected. Economic and social considerations, e.g., acceptable inter-annual percentage changes, will necessarily be major considerations. Many poor methods (Category 2) rely on assumptions that are usually the outcomes of complicated assessment models rather than the inputs to data-poor models. Swept area models (Category 3) were not considered for this analysis because catch rates for halibut appear to be very low. Given the low rates of encounter and likely overall low abundance it did not seem prudent to construct a proxy value for halibut capture efficiency. Notably, it was not possible to estimate calibration coefficients for halibut from experimental comparisons (Miller et al. 2010). Instead the calibration coefficient of 2.057 for halibut was taken as an average of estimates for 5 other flatfish species (Blaylock and Legault 2015).

The proposed approach is similar to Management Procedure (MP) approaches or Management Strategy Evaluation (MSE) methods as described by Geromont and Butterworth (2015), Kelly and Codling(2006), and many others. MPA methods have been applied to several ICES stocks, Greenland halibut (NAFO) and advocated by Parma (2002) for Pacific halibut and later by Webster (2017), Hicks and Stewart (2017)for Pacific halibut. Many recent surveys of data-poor methods conclude by supporting MP approaches in one form or another, and often concurrently highlighting poor performance of typical data poor methods (Carrruthers et al. 2014, Wilberg et al. 2011).

A set of papers in Aquatic Living Resources by Apostolaki and Hillary (2009) and Pomarede et al. (2010) provide a nice series of applications on the utility of control theory methods in fisheries assessments. Hillary (2009) illustrates these methods further and provides software appropriate for evaluating a suite of harvest control rules. Pomarede et al appears to be one of the first papers to introduce the PID control theory application. PID stands for Proportional Integral Derivative Controllers (Betts 2011, also http://controlguru.com). Geromont and Butterworth (2015, also 2001) describe a general “slope parameter” that is equivalent to what is typically referred to as a P controller. The FSD model would be referred to as a P-D controller (Betts 2010).

The proposed approach (FSD) to model halibut departs from the RYM in several important ways:

1. Does not assume r and K are constants
2. Focuses on recent changes and implications for catches
3. Does not attempt to estimate long-term reference points
4. Does not utilize M, or YPR concepts to define optimal r or F rates
5. Assumes that stock can be described by linear dynamics, i.e., stock is well below K
6. Applies no estimation of parameters except for aggregate rates of change in indices.

Two parameters are required to apply the FSD model. These are defined as the gain parameters for the proportional and derivative slope components. Their final selection is not currently based on any optimization. Instead, they are based on the likely tradeoffs such parameters imply in terms of average catch, variation in average catch, the likelihood of continued population growth and the risk of overfishing.

Because the FSD model does not compute any of the standard stock status parameters, it is not possible to rigorously define stock status. However, results of the Rcrit analyses do offer some insights into stock status. The review panel for the Operational Assessment in 2015 wrote:

> "The GARMIII benchmark assessment and the 2012 update assessment concluded that the stock was overfished but overfishing was not occurring. All information available in the update assessment indicates that stock size has not substantially increased. Therefore, based on the long-term exploitation history and survey trends, the Panel concludes that the stock is still overfished. However, the overfishing status is unknown. Considering the instability of the assessment model, the overfishing threshold was not updated."

Using the results of the Rcrit analyses, it would appear that the stock size has significantly increased since 2005. The overall Rcrit value for the 2005-2016 period suggests an increase of 3 to 5 times (Table 9). In turn these rates suggest annual abundance increases or 9 to 12% per year over the past decade. Randomization tests suggest that all of the increases are statistically significant ($P<0.01$, Table 9). Catches have increased about 3 fold over this period as well.

Computation of population increases (both relative and absolute) and total catch in the Canadian 3NOPs4VWX5Zc stock reveal increases of 2.25X in catch and 2.92X in relative abundance and 2.73X in modeled absolute abundance (Table 11). Hence the changes in US stock relative abundance have mirrored those observed for the much larger Canadian stock. Such increases in US stock would be unlikely if overfishing were still occurring. Model-based estimates of fishing mortality appear to be decreasing. Taken together, the evidence suggest that recent catches have been sufficiently low to allow the stock in US waters to increase at a rate comparable to that observed in Canada.

Results of the DCAC model based on the combination of Rcrit and Envelope methods were largely inconclusive with respect to the determination of overfished status. In contrast, the proposed FSD harvest control rule appears to have some desirable properties with respect to detection of underlying trends and with respect to continuation of rebuilding program for halibut. Simulation methods suggest the model can control populations when productivity is changing temporally. Bootstrap analyses of the model forecasts suggest and 80% confidence interval of 109 to 138 mt and median of 123 mt for 2018. Note that this assumes a K_p=0.75 and K_d=0.5

Applications of the model to two other managed halibut stocks suggests potential utility for the US stock of Atlantic halibut and perhaps other stocks in the Northeast. Comparisons between the FSD model and analytical models would be a first step. Another important consideration is the estimation of the slope and change in slope. The 5-point regression might be improved by using a Kalman filter or other state-space model. In theory a MLE based smooth of the index data would be preferable to slopes estimated by an n-point regression.

Acknowledgements

This work was sponsored by the New England Fishery Management Council. I am grateful for the support of Tom Nies, Chris Kellogg, Jamie Cournane and Robin Frede. Jamie was particularly helpful in providing data and relevant background and feedback from the Groundfish Plan Development Team. I also thank members of the PDT for helpful feedback on an earlier draft of this report and for suggestions regarding alternative abundance indices.

I thank Nell den Heyer (DFO-BIO,) for survey and landings data, model output and helpful discussions along the way. Similarly, discussion with NEFSC (Russ Brown and Jim Weinberg) regarding the Plan B process were helpful.

Colleagues from the NEFSC Population Dynamic Branch provided invaluable help during this project. Mike Palmer guided me through the "Adios" data system for obtaining landings, discard and survey data. Susan Wigley provided considerable assistance in the formulation of the t/k ratio as an abundance index. Chris Legault, Liz Brooks, Paul Nitschke, Mike Palmer, Jon Deroab, and Dan Hennen provided valuable feedback on the model and suggested the bootrapping approach for FSD used herein. Finally I am indebted to Dan Hennen for many valuable discussions, guidance to the data, background on previous assessments, and refinement of the ideas in this report. Dan is the lead scientist for halibut who may utilize some of these proposed methods in the next operational assessment.

Table 2.

Table xx. Summary of ratio test simulations for estimation of bias in mean and median of Rcrit as a function of the magnitude of true rate of change (Rcrit_true), the variation of the observation error (CV) and the number of relative abundance indices (Nvar). All simulations were based on a time series of length 10, and the ratio of the average of the last 3 to the first 3 observations for 2000 randomizations of each of 1000 stochastic realizations.

		Relative Bias in Estimated Rcrit vs True Rcrit							
		Nvar=1		Nvar=2		Nvar=3		Nvar=5	
Rcrit_true	CV	Rel Bias (mean)	Rel Bias (median)	Rel Bias (mean)2	Rel Bias (median)3	Rel Bias (mean)4	Rel Bias (median)5	Rel Bias (mean)6	Rel Bias (median)7

Table 5. Summary of fraction of simulations with significance probabilities less than or equal to the column headers (P0.005, P0.01…) for varying levels of lambda, Rcrit and the CV of the simulated observations. Estimates in this table assume **two** indices of abundance are available. The color formatting in this table is consistent for all tables 4,5, 6, and 7.

[1] 3.144086
[1] fraction of models with significance probability <0.05
[1] 0.952381

Table 11. Summary of Rcrit and Probability values for all possible models based on three indices of relative abundance and the assessment based estimate of absolute abundance in the Canadian 3NOPs4VWX5Zc assessment. Simulations are based Canadian data from 2002-2013. 50,000 replicates were used for each model. The shaded boxes indicate models that include the modeled biomass estimates from the DFO assessment. Results can be compared with Table 10 for US indices.

Table 14.

Table xx Summary of relevant population outputs for varying combinations of Kp and Kd gain parameters by assumed CV level for observation error. The low CV (0.005) assumes almost no observation error in the abundance indices. Effects are averaged over all combinations of r(t) scenarios and harvest scenarios (h(t)) prior to implementation of the control rule.
Simulation failures occur when the population size goes to zero because harvest rates are too high.

Average % of overfishing events

Table 15. Summary of derived estimates of catch in 2018 based on the FSD model for alternative values of the gain parameters Kp and Kd. The top table shows the effect of the parameters on estimated catch in mt. The lower table illustrates the effect of the gain parameters on the degree of concordance with historical estimates of observed and predicted catch for the time period 2007 to 2016. Table entries are ratios of the sum of squares difference between observed and predicted to the minimum value.

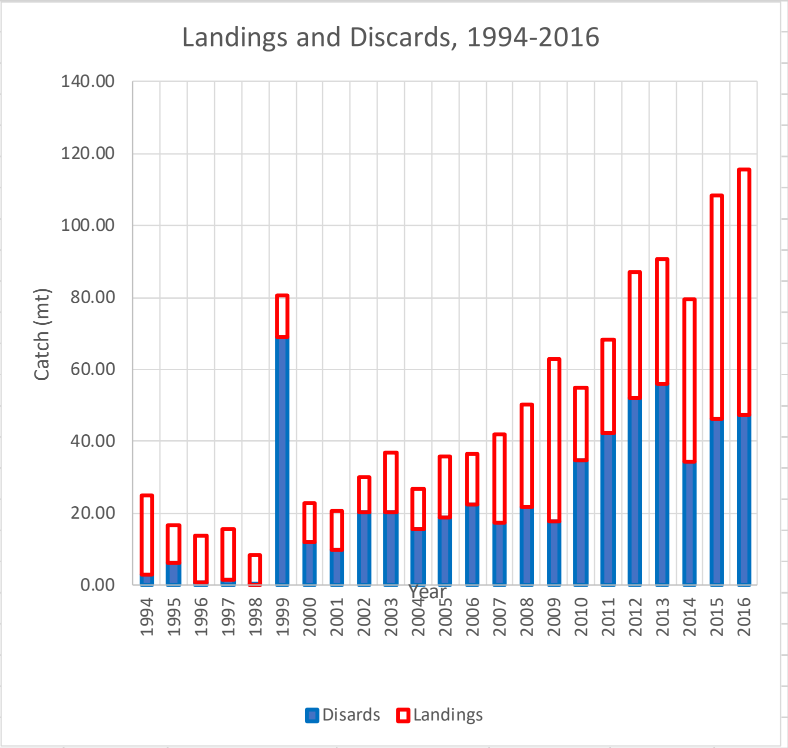

Figure 1. Landings and discards (mt) for Atlantic halibut in US stock area, 1994-2016, used in this assessment.

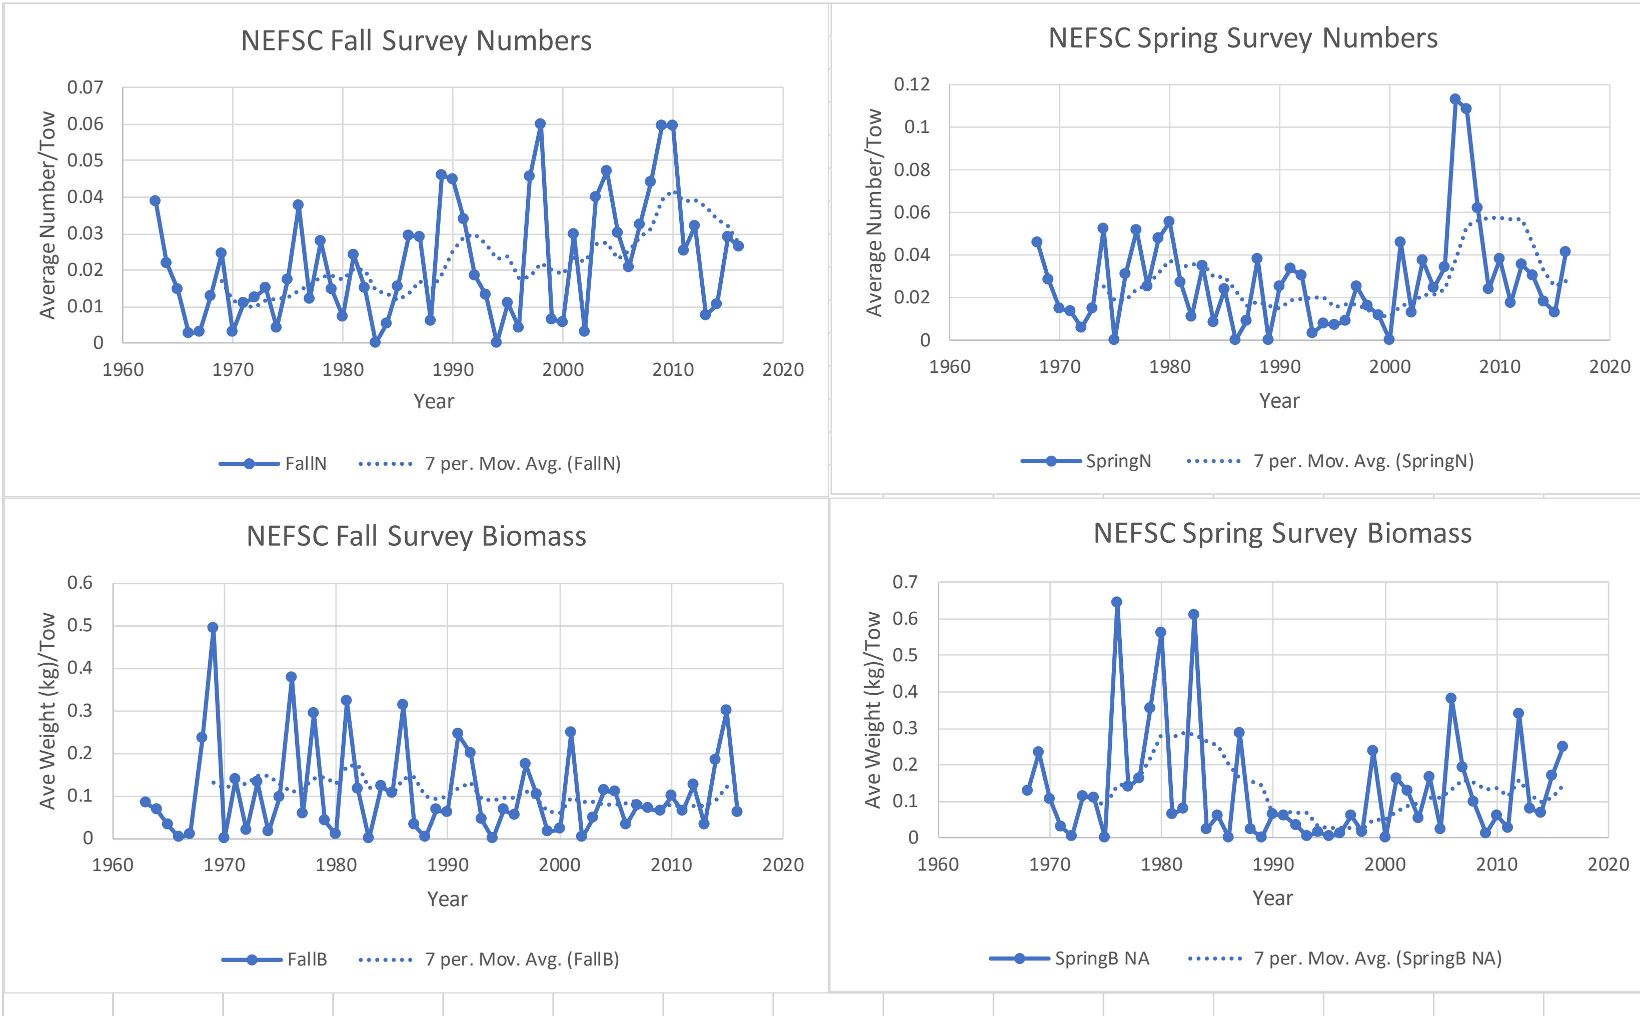

Figure 2. Summary of NEFSC bottom trawl survey indices 1963-2016 for fall and spring surveys expressed in terms of both average numbers per tow and average weight (kg) per tow. A 7 point moving average is used to dampen interannual variability.

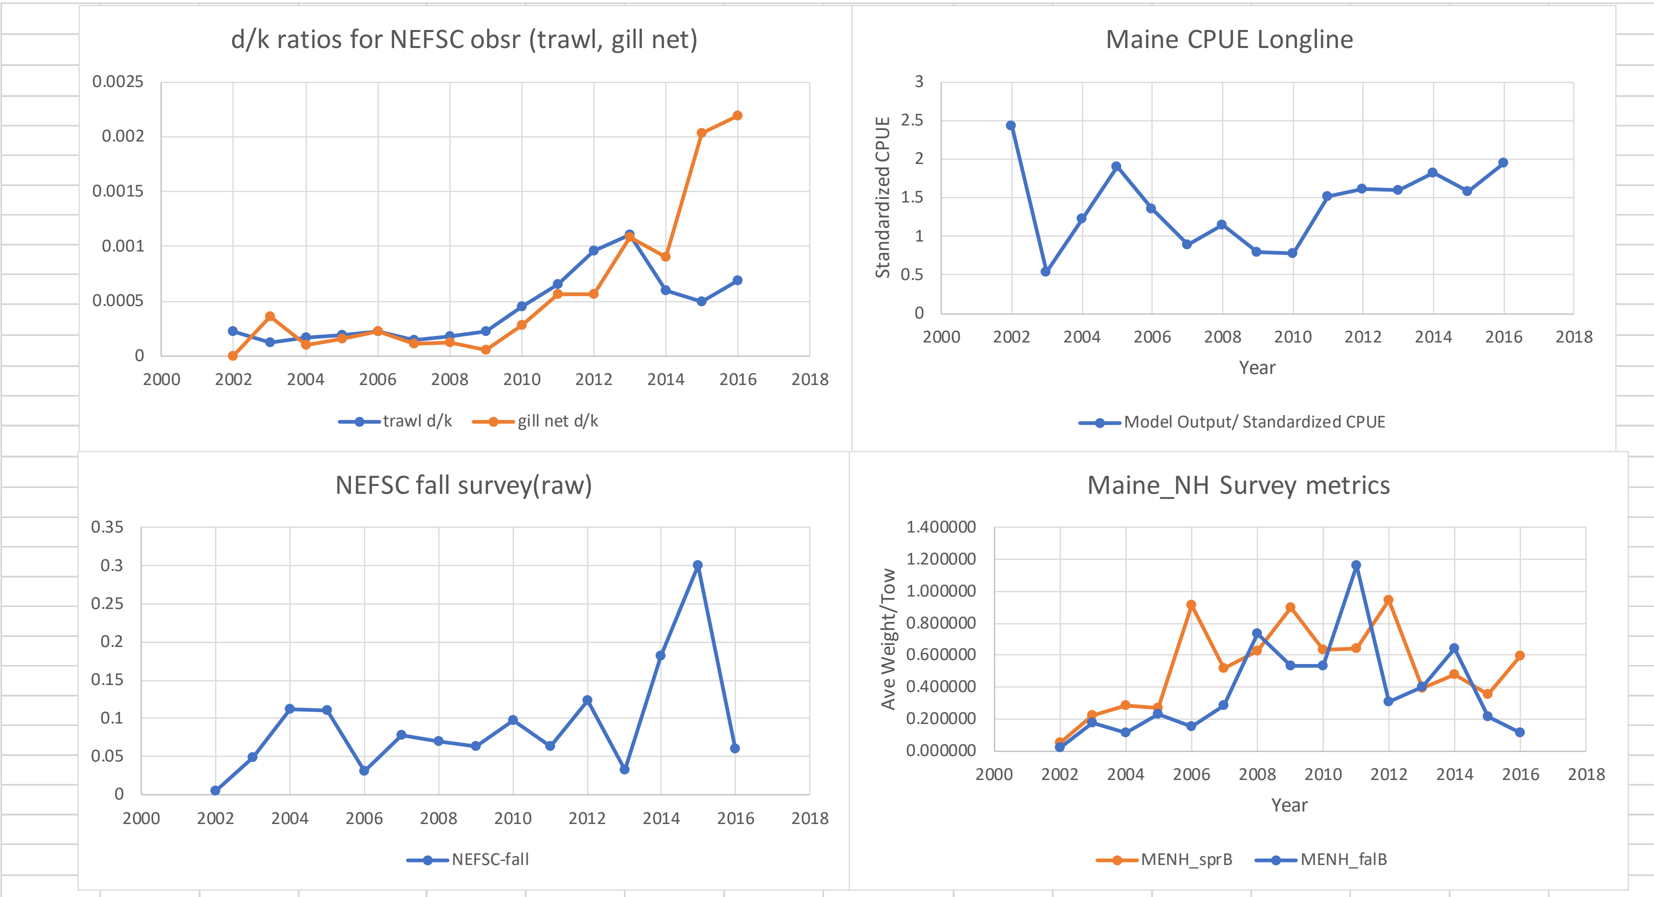

Figure 3. Candidate relative abundance indices considered in Rcrit and FSD models. The Standardized longline CPUE data were obtained from Hansell et al (2017 ms). Results for the Maine-New Hampshire inshore bottom trawl survey were obtained from Sally Sherman, MEDMR. The d/k ratios were obtained from Susan Wigley, NEFSC. NEFSC bottom trawl estimates were obtained from Daniel Hennen, NEFSC. See Appendix 4 for variable definitions.

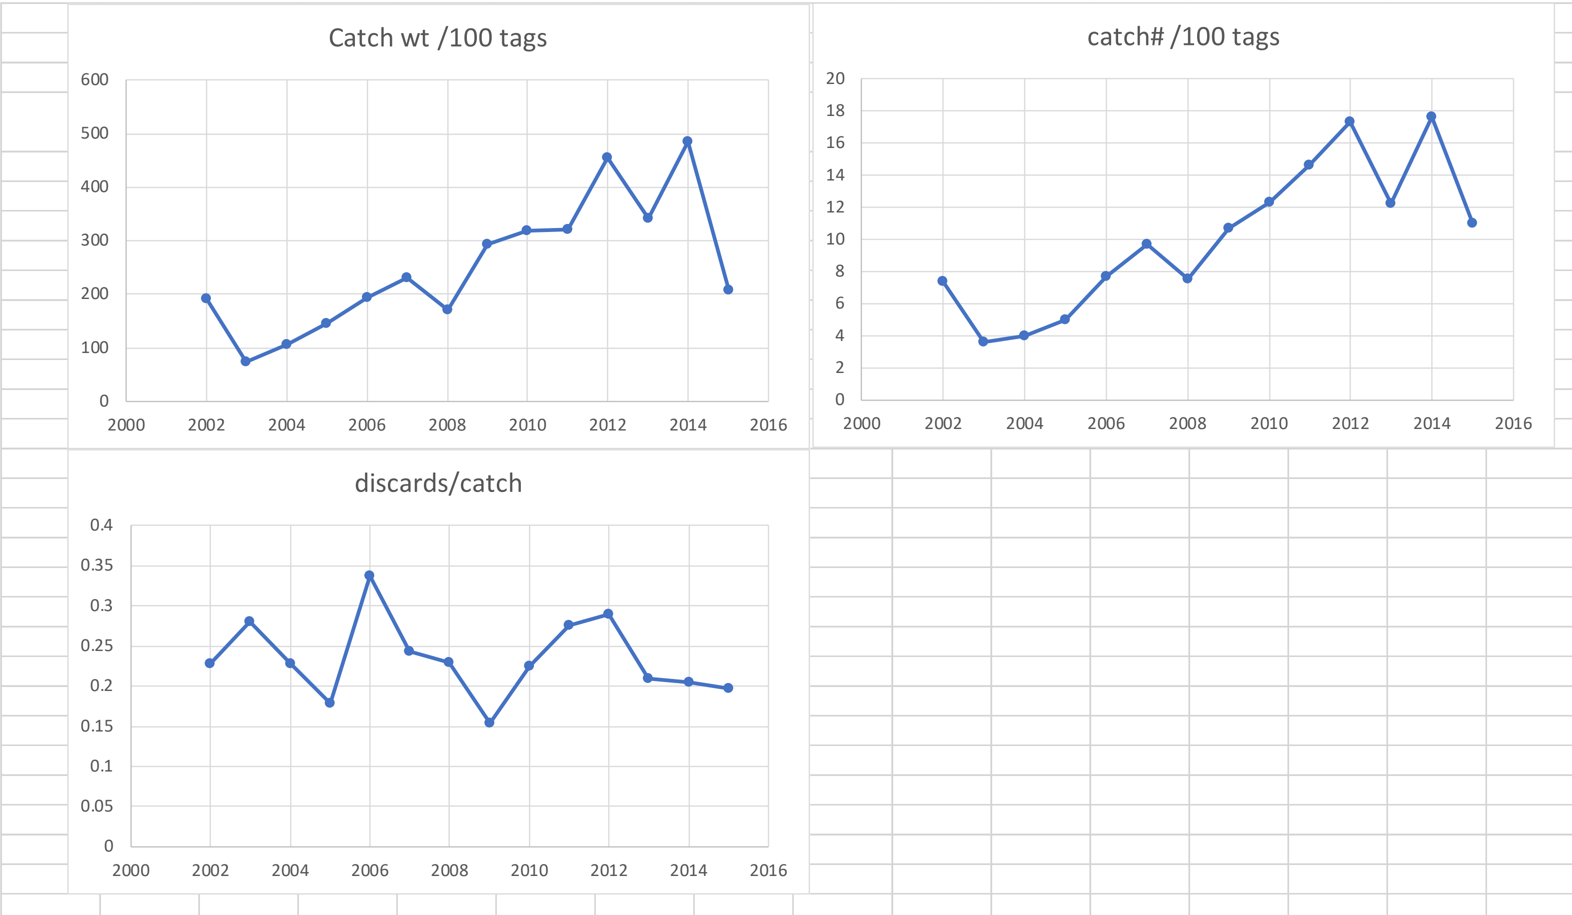

Fig 3.5 Estimates of catch per unit effort based on state data from Maine DMR. Effort is expressed in terms of number of tags issued, and discard to catch ratios were based on fishermen logbooks. Given uncertainties about the data and the availability of a more refined measure of CPUE from Hansell et al. these data were not considered further in this assessment. See Appendix 4 for variable definitions.

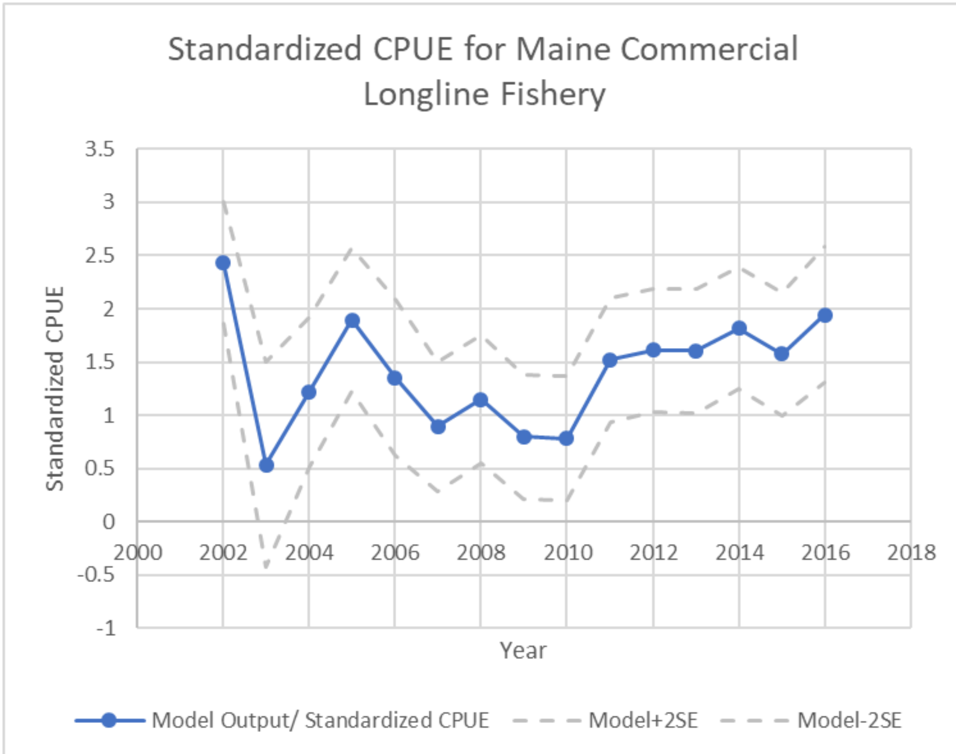

Figure 4. Standardized CPUE from Maine Commercial longline fishery, 2002-2016 provided courtesy of Hansell et al. Estimates and Error bounds are derived from a general linear model analysis.

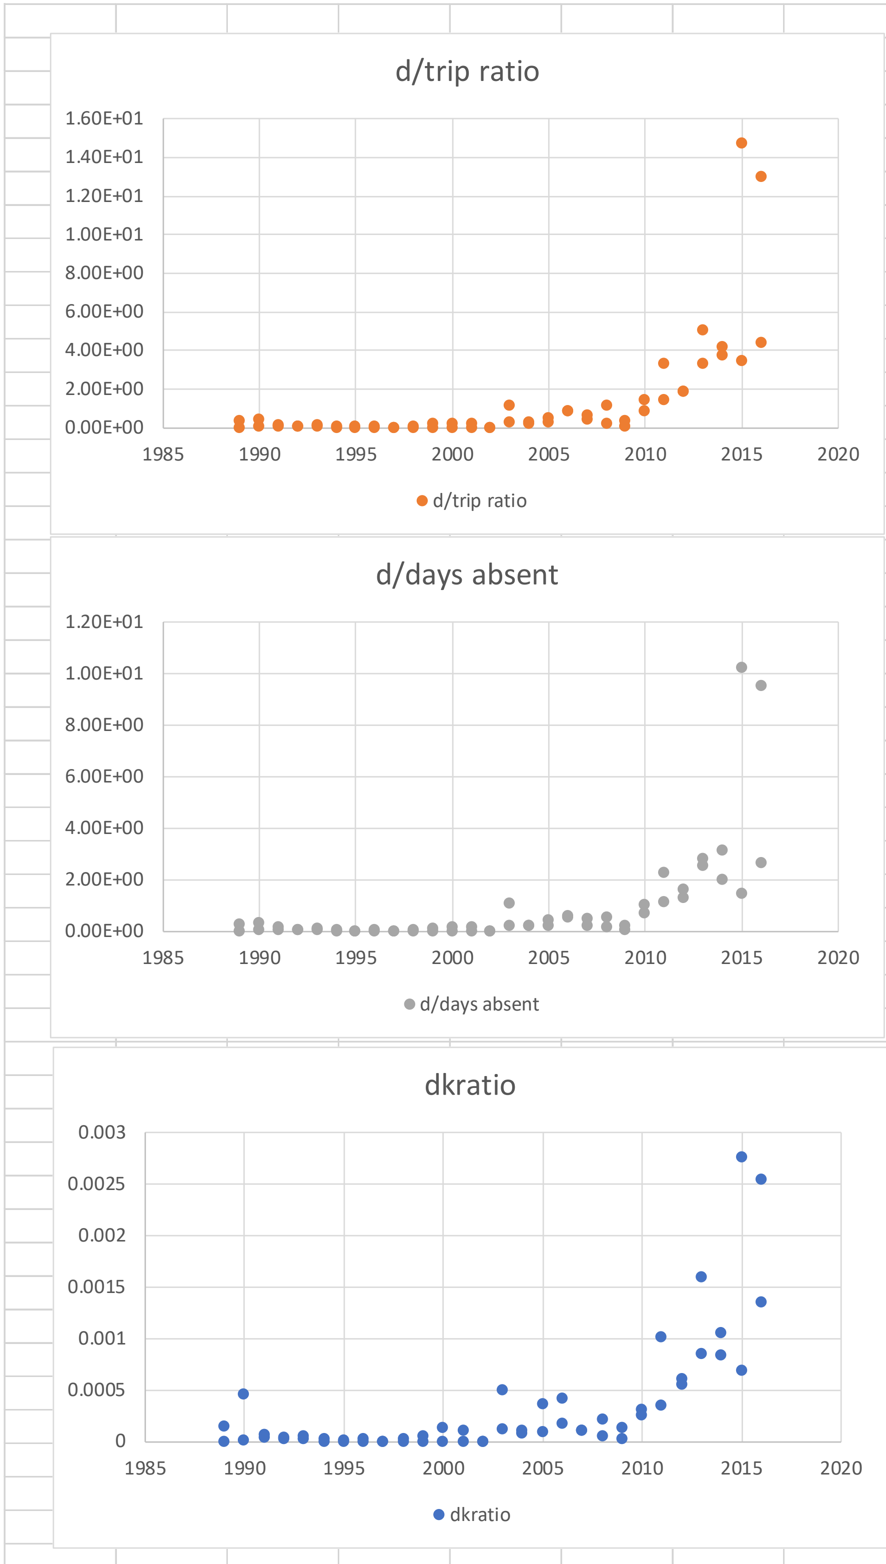

Figure 5. Discard ratios for observed gill net trips from 1989 to 2016 expressed in half year increments. Measures of effort include number of trips, number of days absent and total landed catch. Data courtesy of Susan Wigley, NEFSC

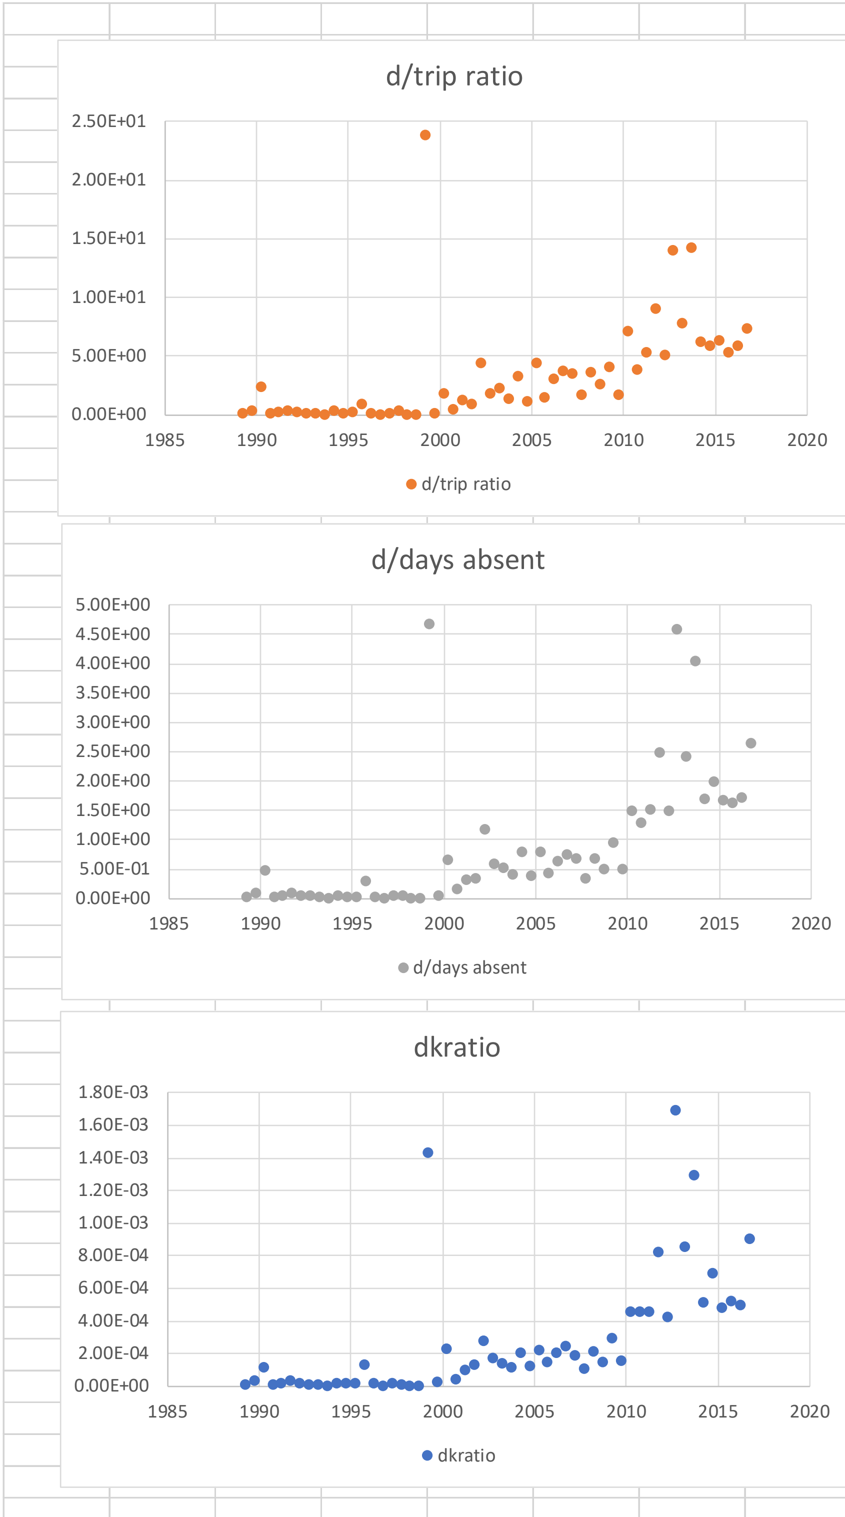

Figure 6. Discard ratios for observed otter trawl trips from 1989 to 2016 expressed in half year increments. Measures of effort include number of trips, number of days absent and total landed catch. Data courtesy of Susan Wigley, NEFSC

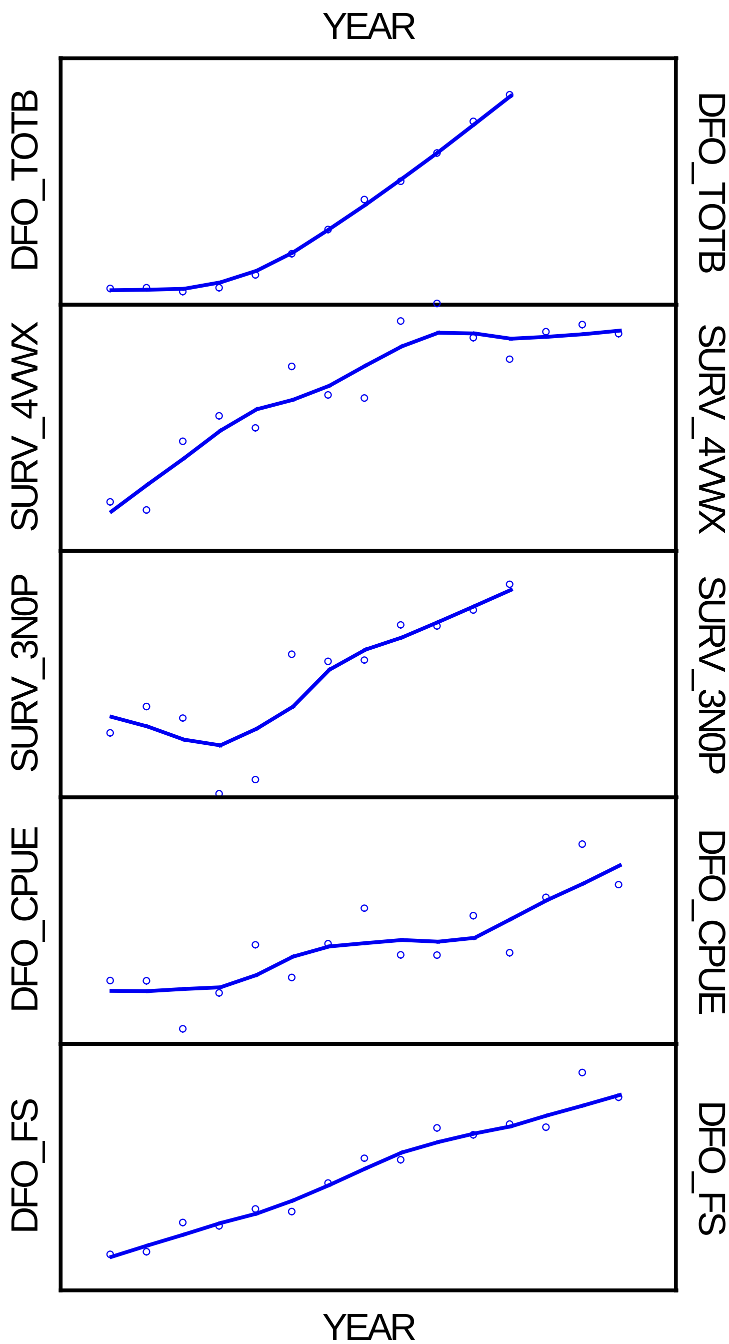

Figure 7. DFO abundance indices 2002-2016. DFO_TOTB is model based estimate of total biomass. Lines represent lowess smooths with tension =0.5. Variable names are DFO_FS, DFO_CPUE, SURV_3NOP, SURV_4VWX. See Appendix 4 for variable definitions.

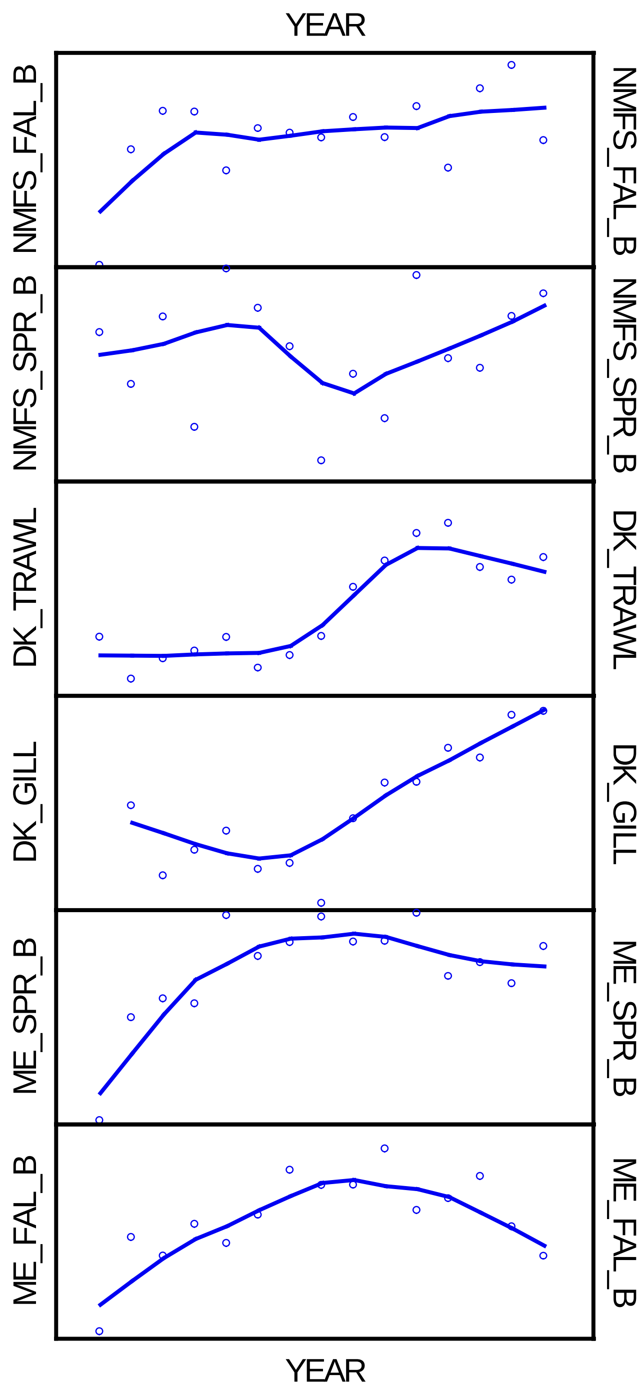

Figure 8. US abundance indices 2002-2016. Lines represent lowess smooths with tension =0.5. Variable names are ME_FAL_B, ME_SPR_B, DK_GILL, DK_TRAWL, NMFS_SPR_B, NMFS_FAL_B. See Appendix 4 for variable definitions.

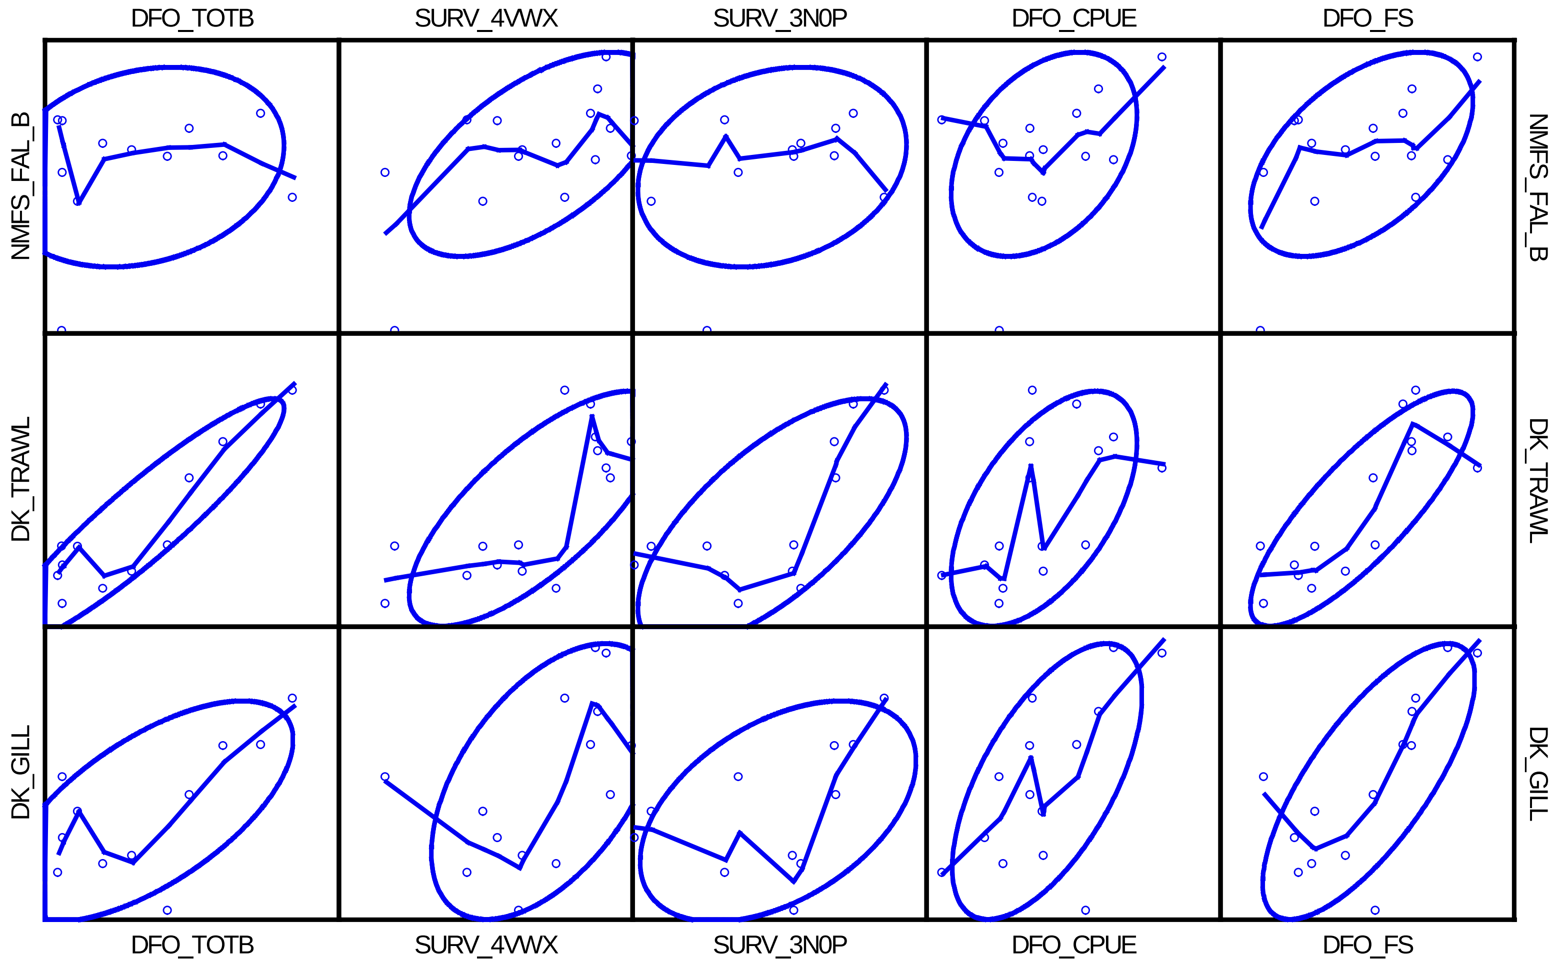

Fig 9. Comparison of DFO and US abundance indices for 2002-2016. Data are smoothed with a lowess mdethod with tension = 0.5. ME_FAL_B, ME_SPR_B, DK_GILL, DK_TRAWL, NMFS_SPR_B, NMFS_FAL_B. DFO_TOTB is model based estimate of total biomass. Variable names are DFO_FS, DFO_CPUE, SURV_3NOP, SURV_4VWX**.** See Appendix 4 for variable definitions.

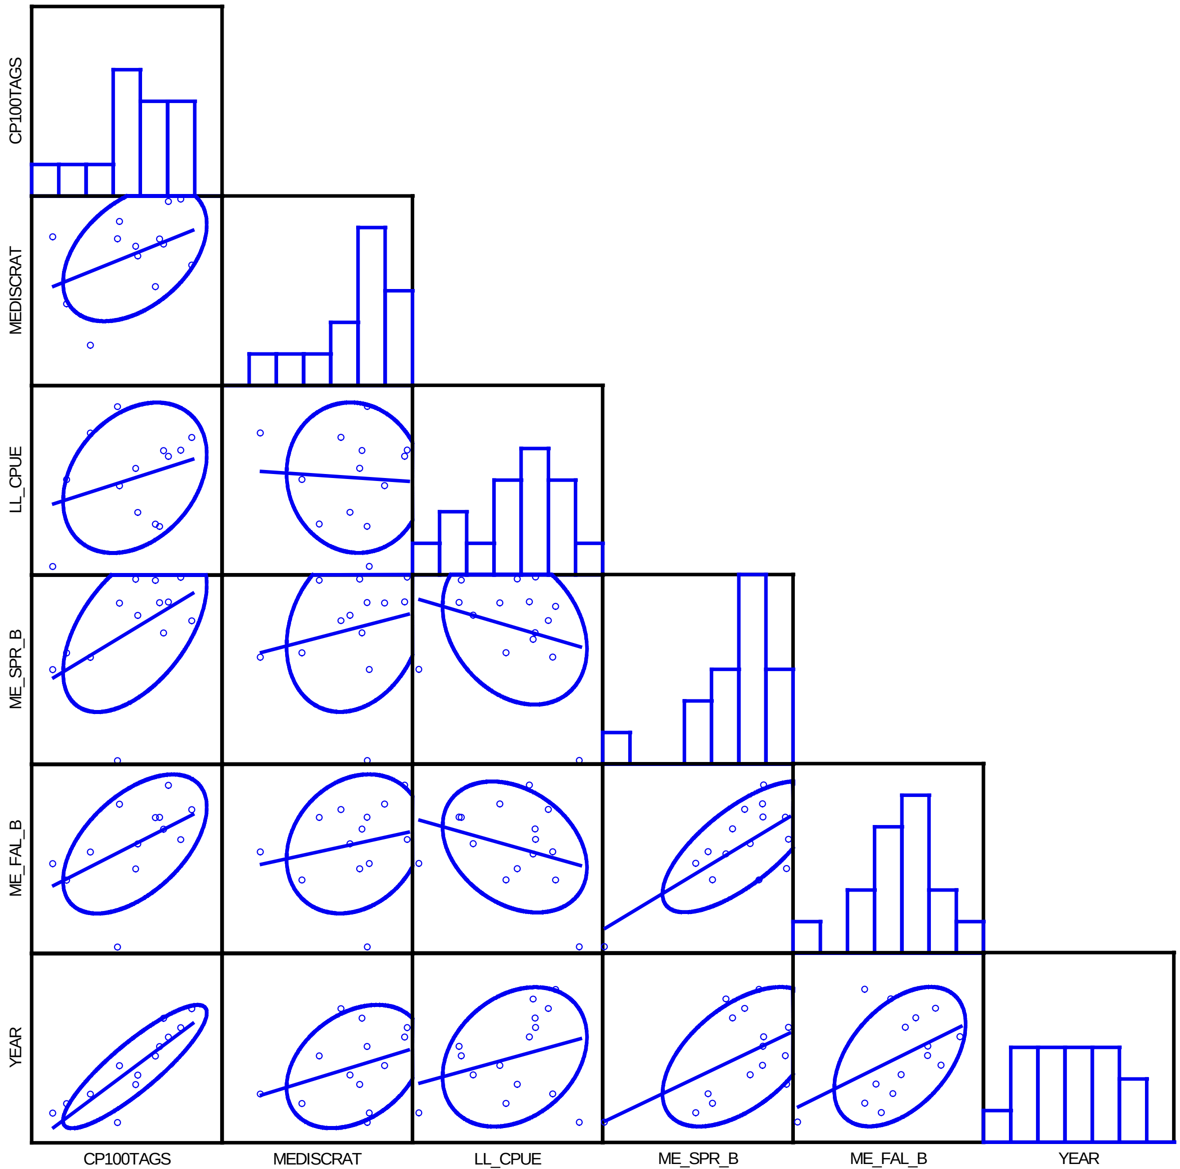

Figure 10. Scatterplot matrix for indices of abundance from Maine surveys and commercial CPUE. Lines represent simple linear regressions. ME_FAL_B, ME_SPR_B, DK_GILL, DK_TRAWL, NMFS_SPR_B, NMFS_FAL_B, LL_CPUE, MEDISCRAT, CP100TAGS. See Appendix 4 for variable definitions.

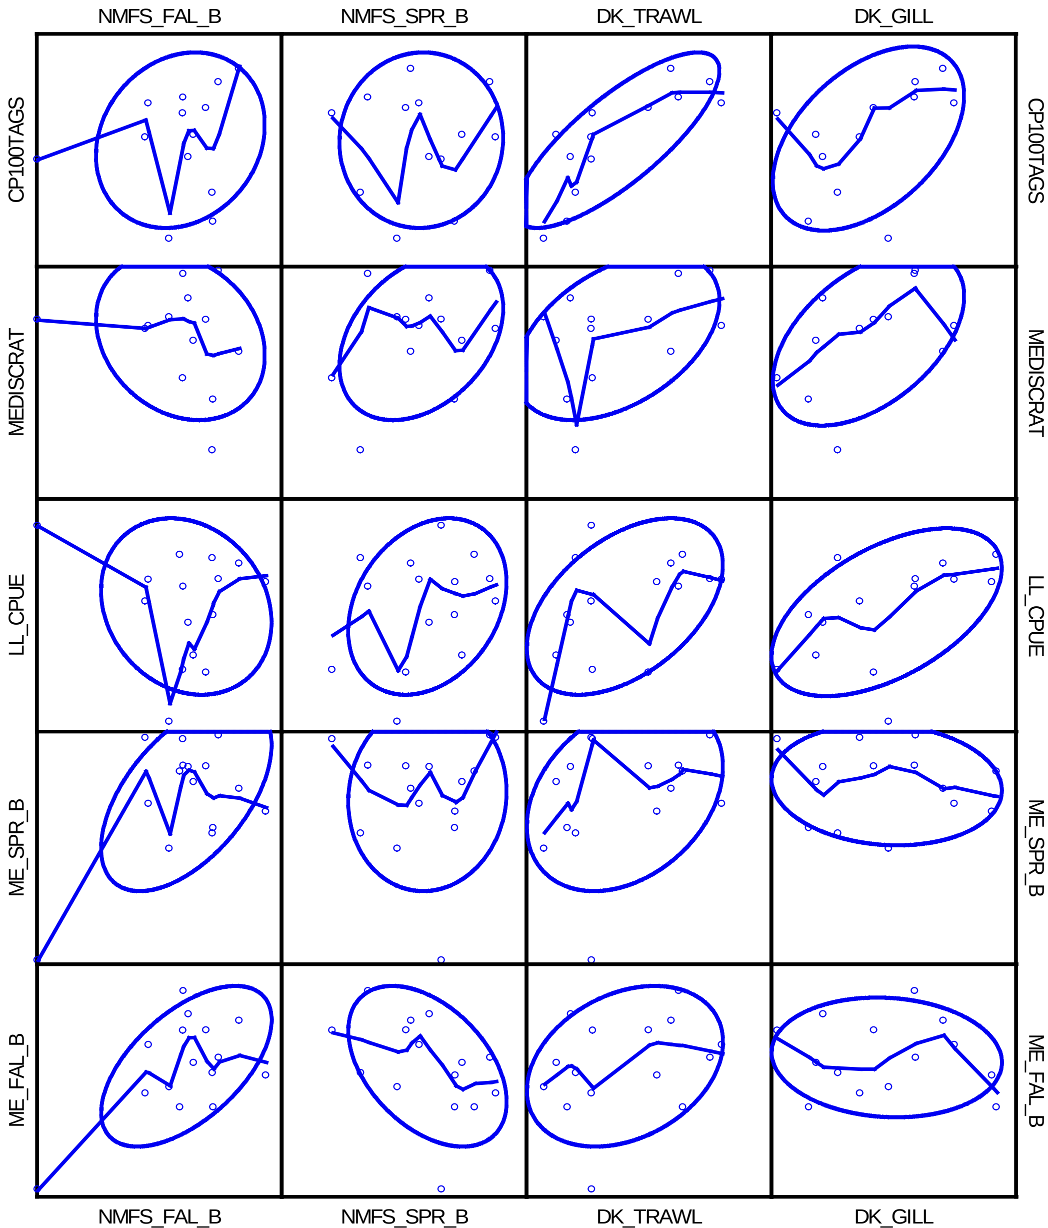

Figure 11. Scatterplot matrix comparison of Maine indices (rows) to NMFS indices. Lines represent lowess smooths with tension =0.5. ME_FAL_B, ME_SPR_B, DK_GILL, DK_TRAWL, NMFS_SPR_B, NMFS_FAL_B, LL_CPUE, MEDISCRAT, CP100TAGS. See Appendix 4 for variable definitions.

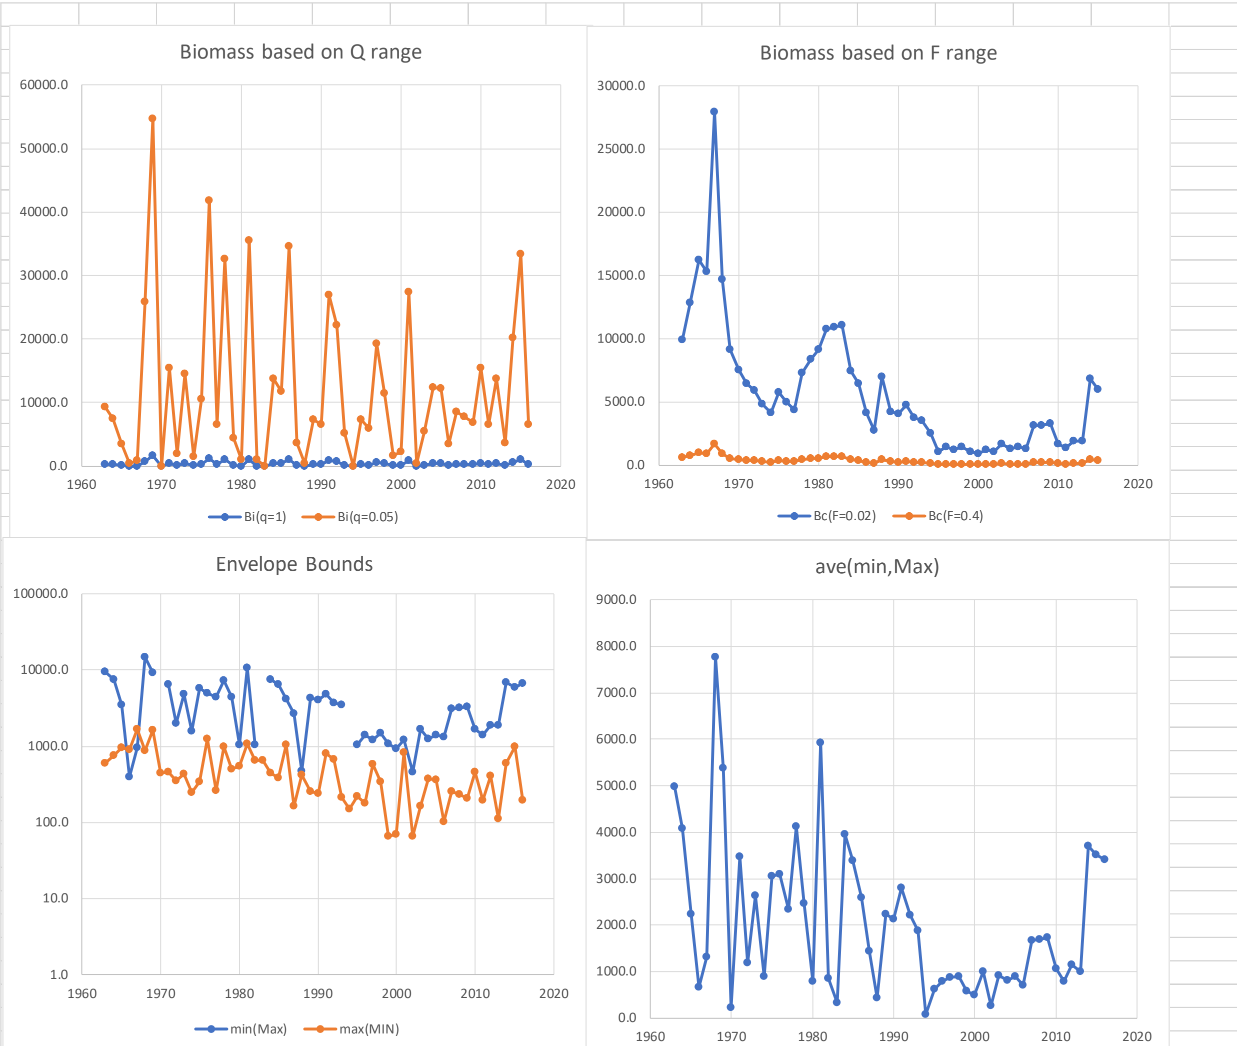

Figure 12. Result of Envelope model analyses of landings and NMFS fall bottom trawl survey estimates. Envelope bounds(lower left plot) represent constrained limits on a log scale. The lower right graph shows the average of the min and max envelope values. Estimates are based on raw survey data.

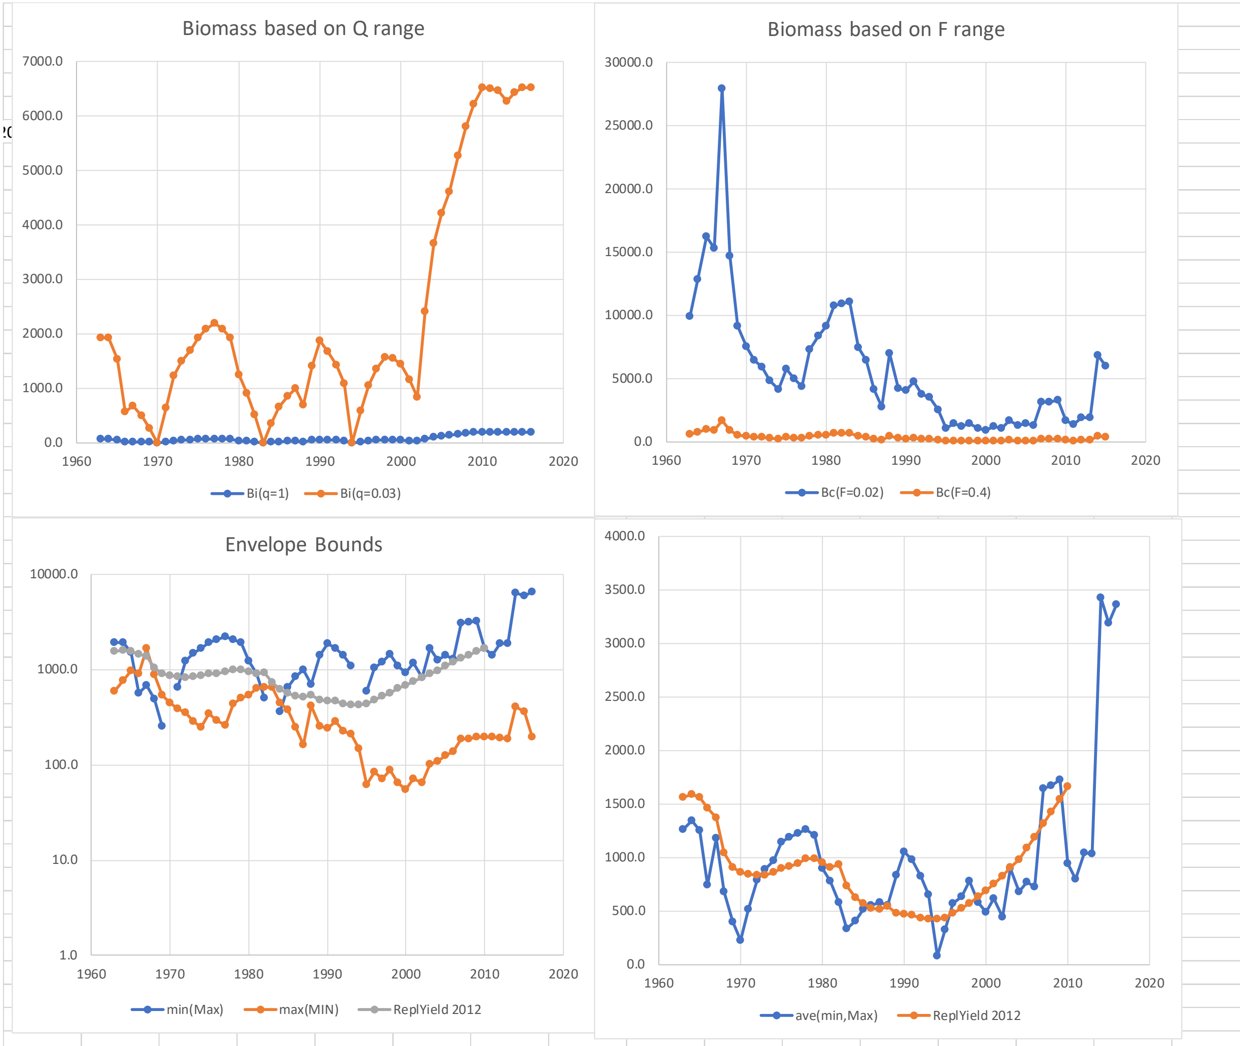

Figure 13. Result of Envelope model analyses of landings and NMFS fall bottom trawl survey estimates. Envelope bounds(lower left plot) represent constrained limits on a log scale.   The lower right graph shows the average of the min and max envelope values. Estimates are based on Kalman smoothed survey data. Biomass estimates from Replacement Yield model (Col and Legault 2012) are provide for reference.

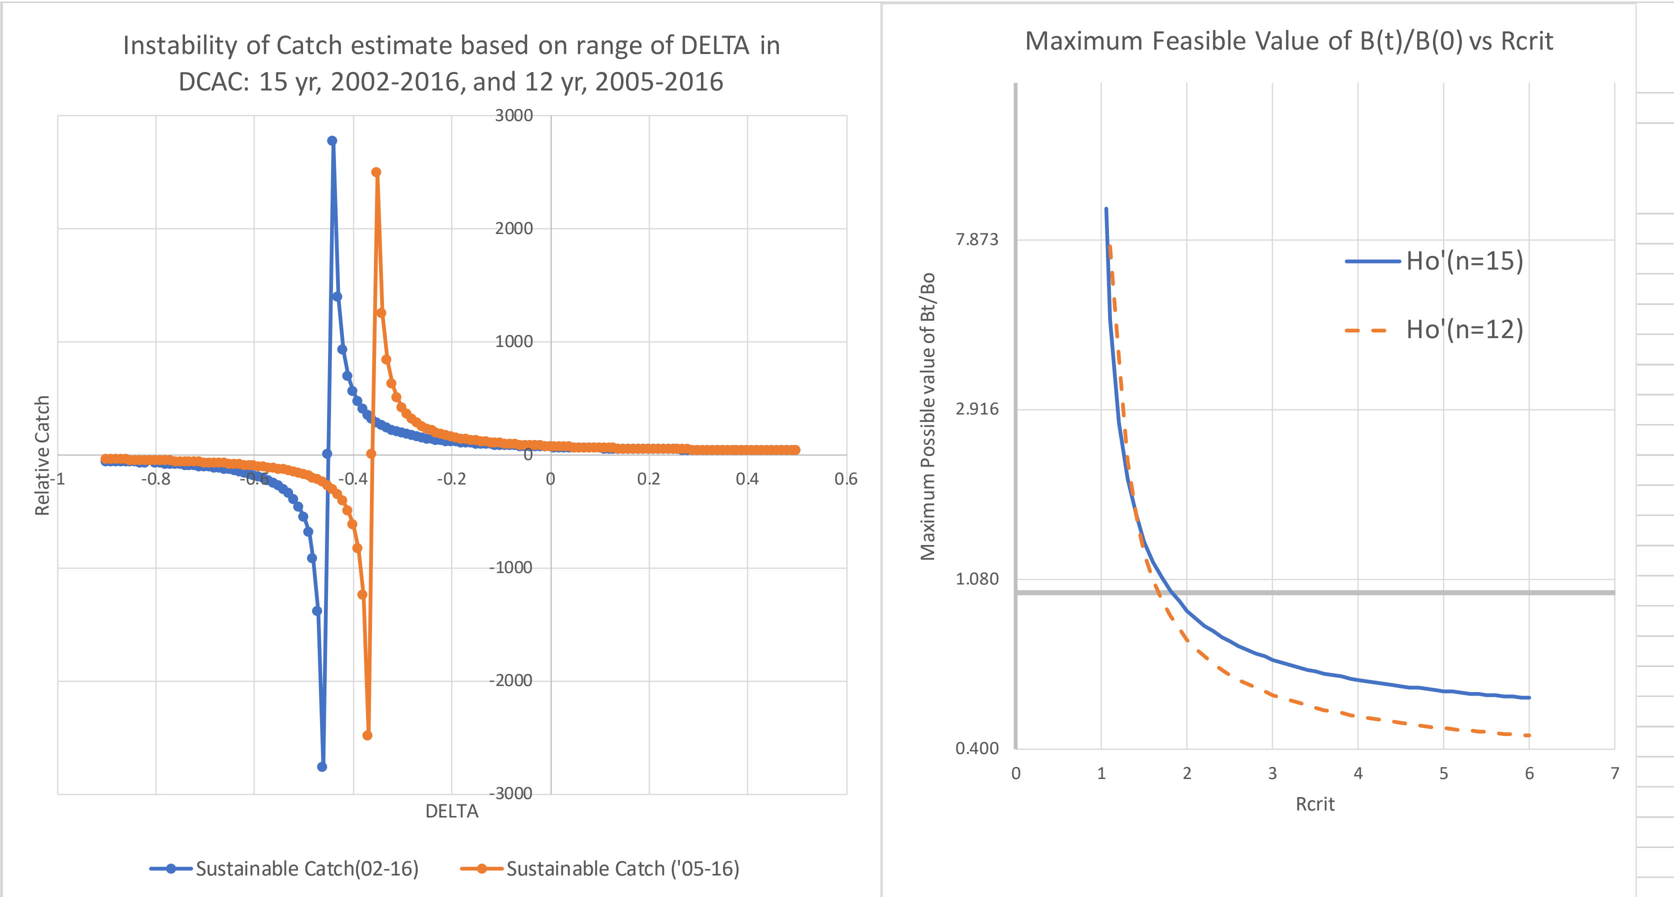

Figure 14. Singularity issues in DCAC for instances where the denominator becomes negative (left plot). The right plot shows the maximum possible value of Bt/B0 for alternative values of Rcrit given 12 or 15 years of catch data.

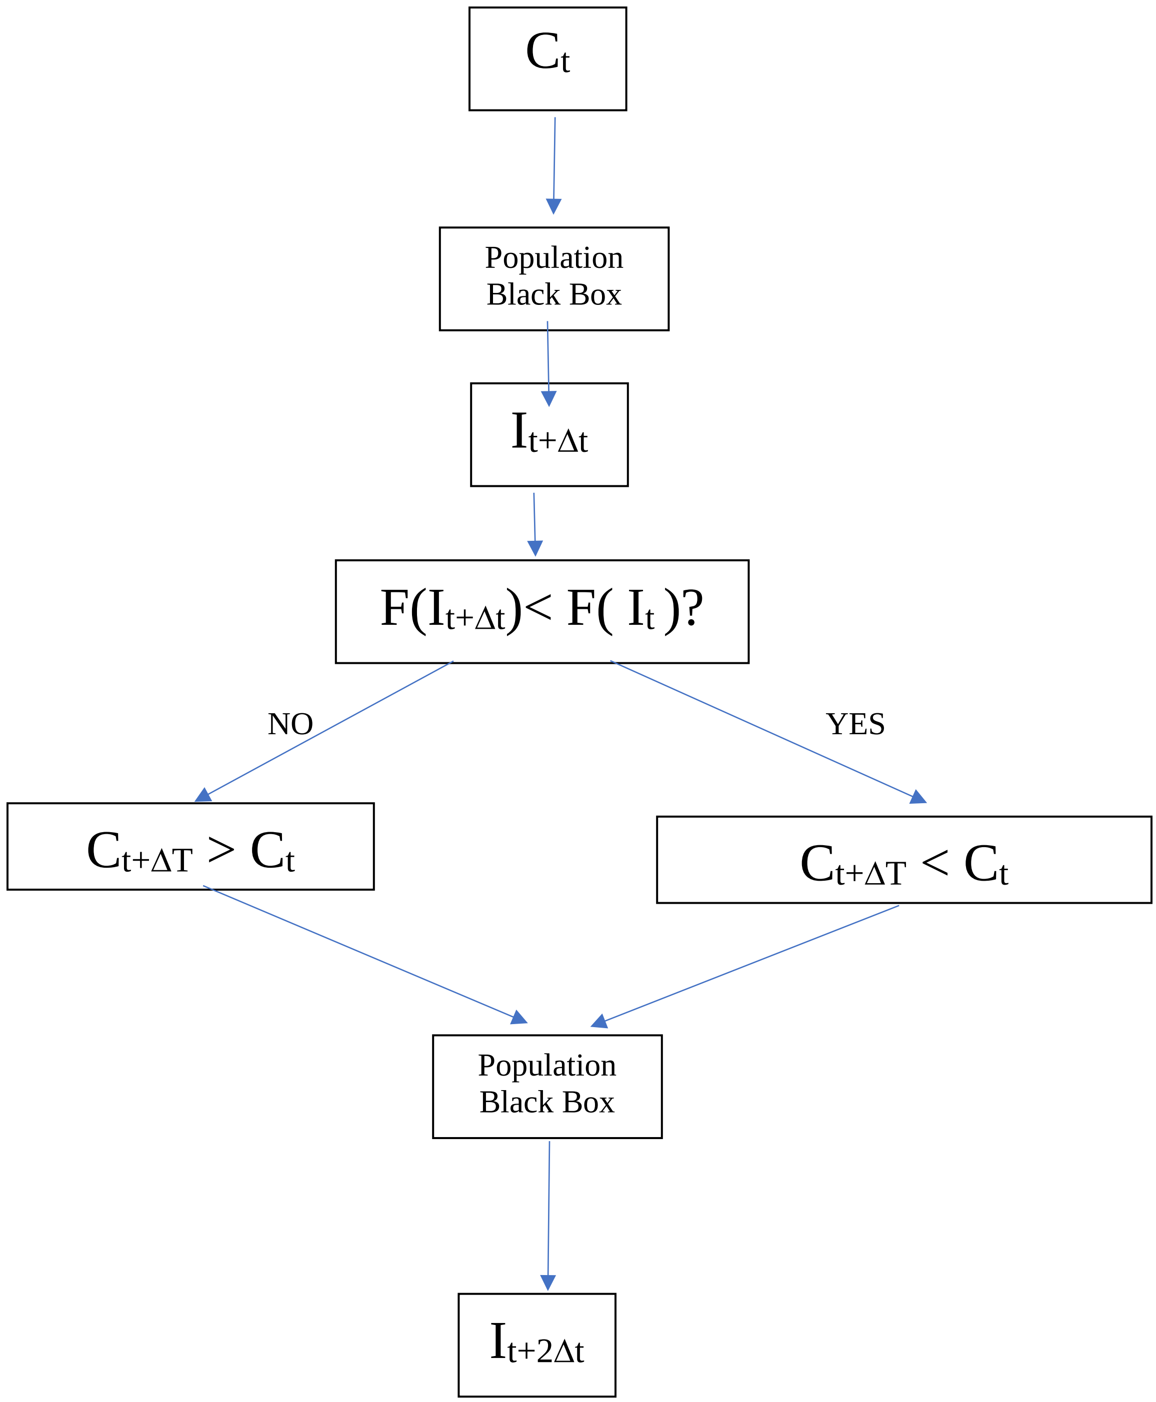

Figure 15. Schematic depiction of the feedback loop used in the FSD model.

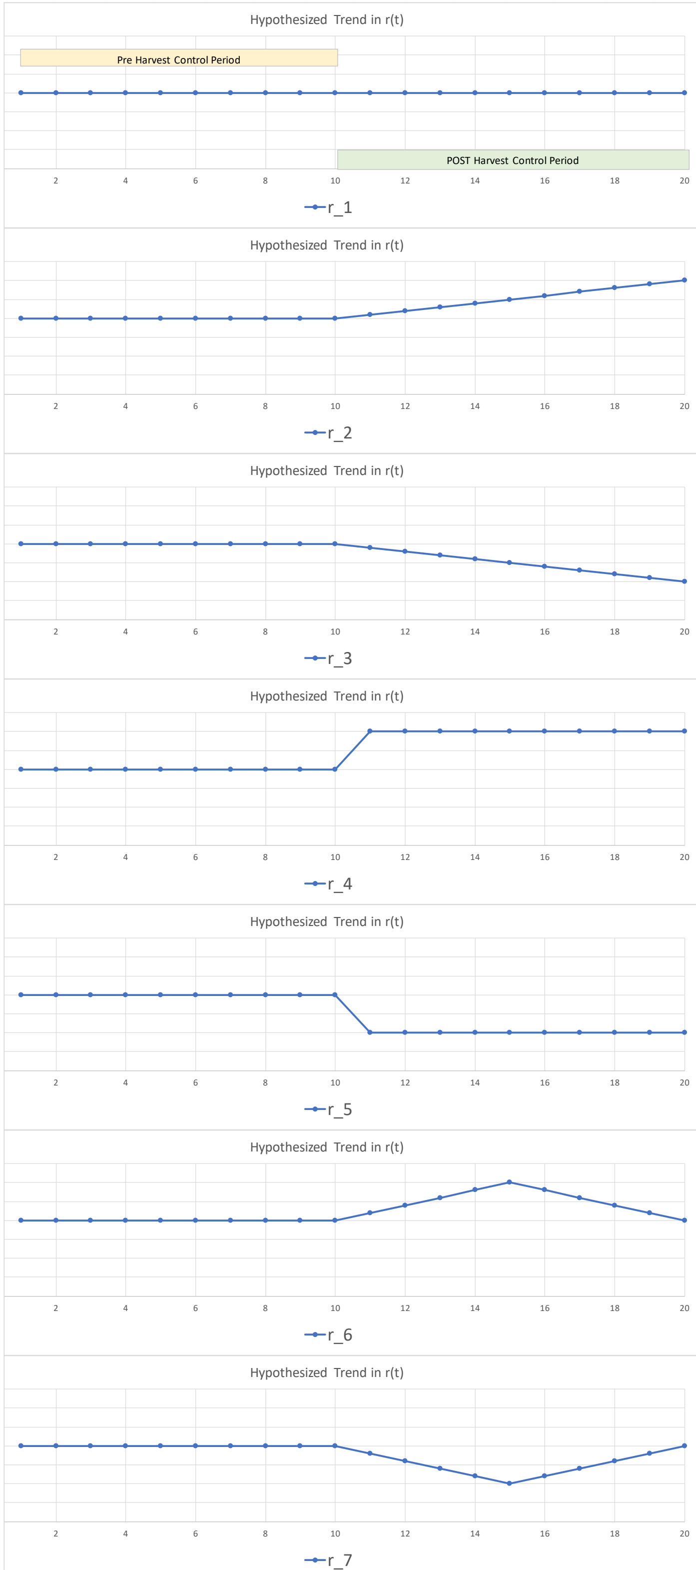

Figure 16. Scenarios for the intrinsic rate of increase r(t) used in the simulation analysis of the FSD model. Note that r(t) is constant during the first ten years, prior to implementation of the FSD control rule.

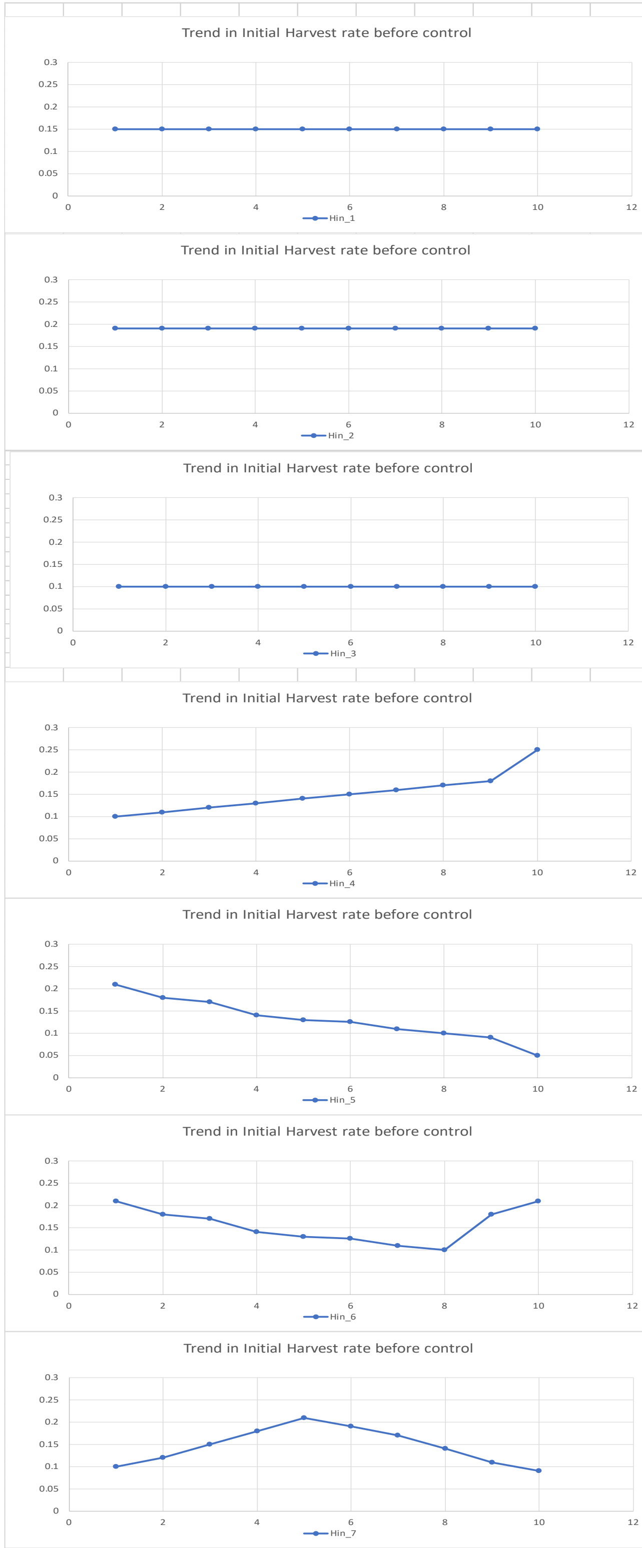

Figure 17. Scenarios for the initial harvest rate h(t) used in the simulation analysis of the FSD model. Note that the harvest rate is used only for the first 10 years. After that, harvest is controlled by the FSD harvest control rule.

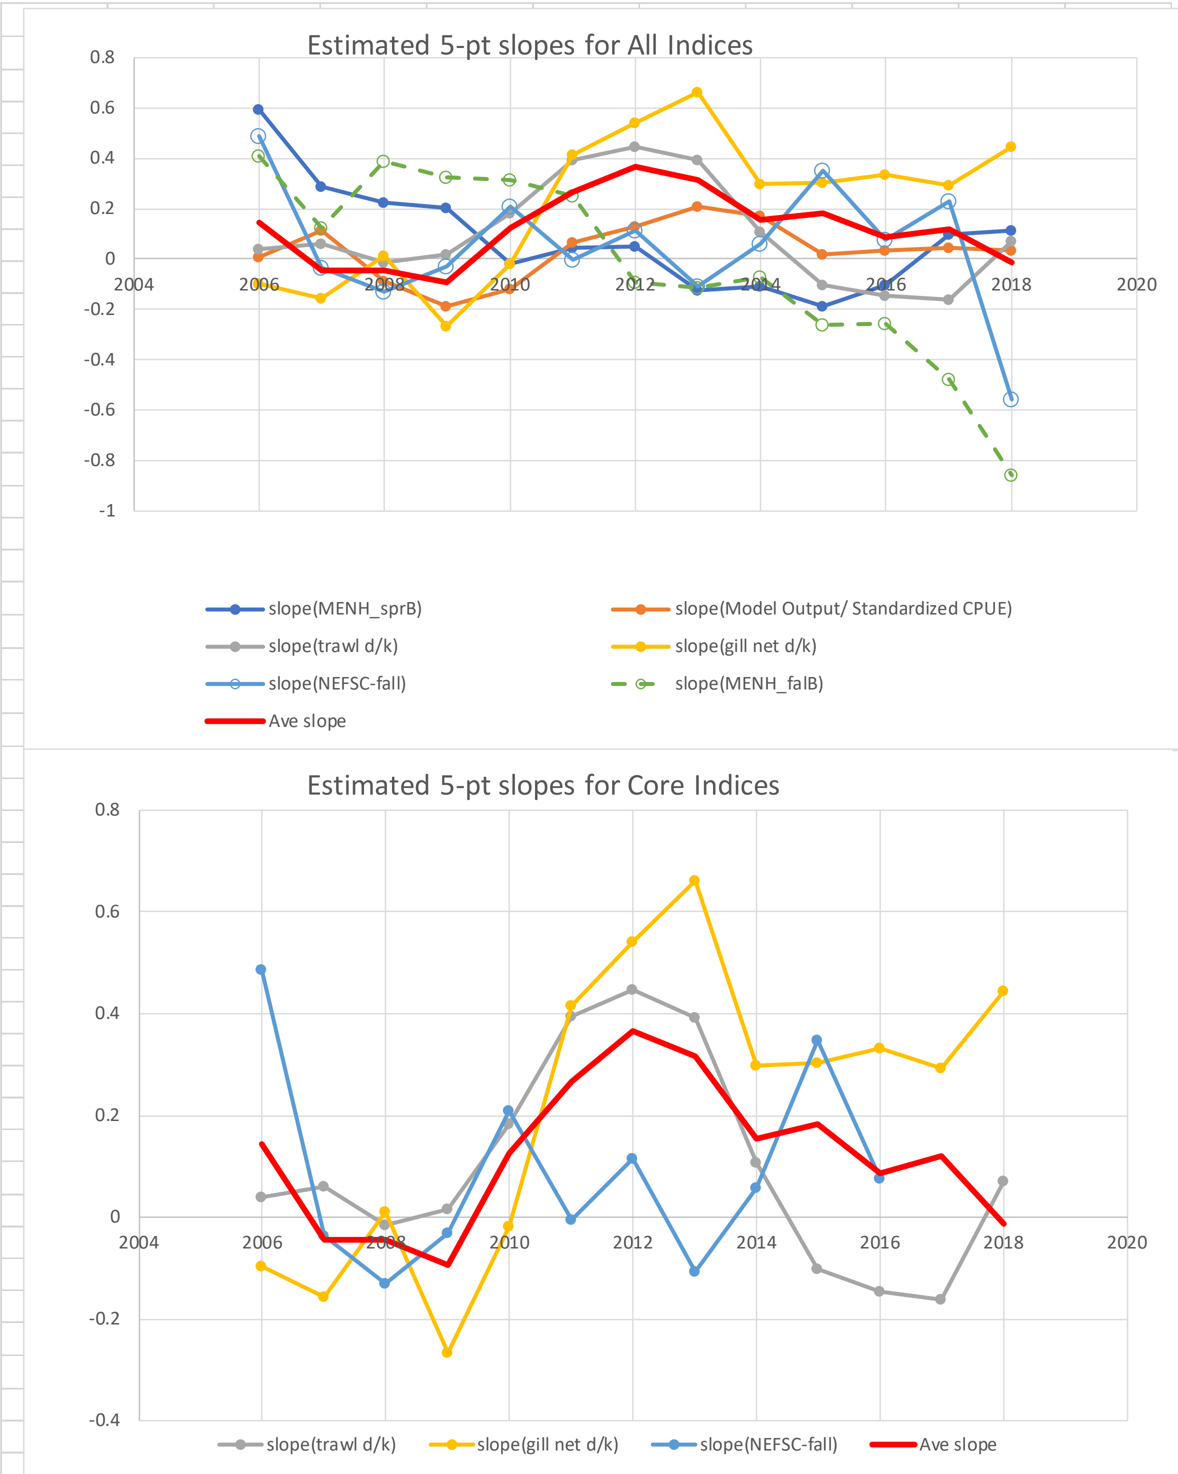

`

Figure 18. Trends in abundance indices based on 5 point regressions. Top plot shows full model with 5 indices. Bottom plot shows reduced model using only existing indices.

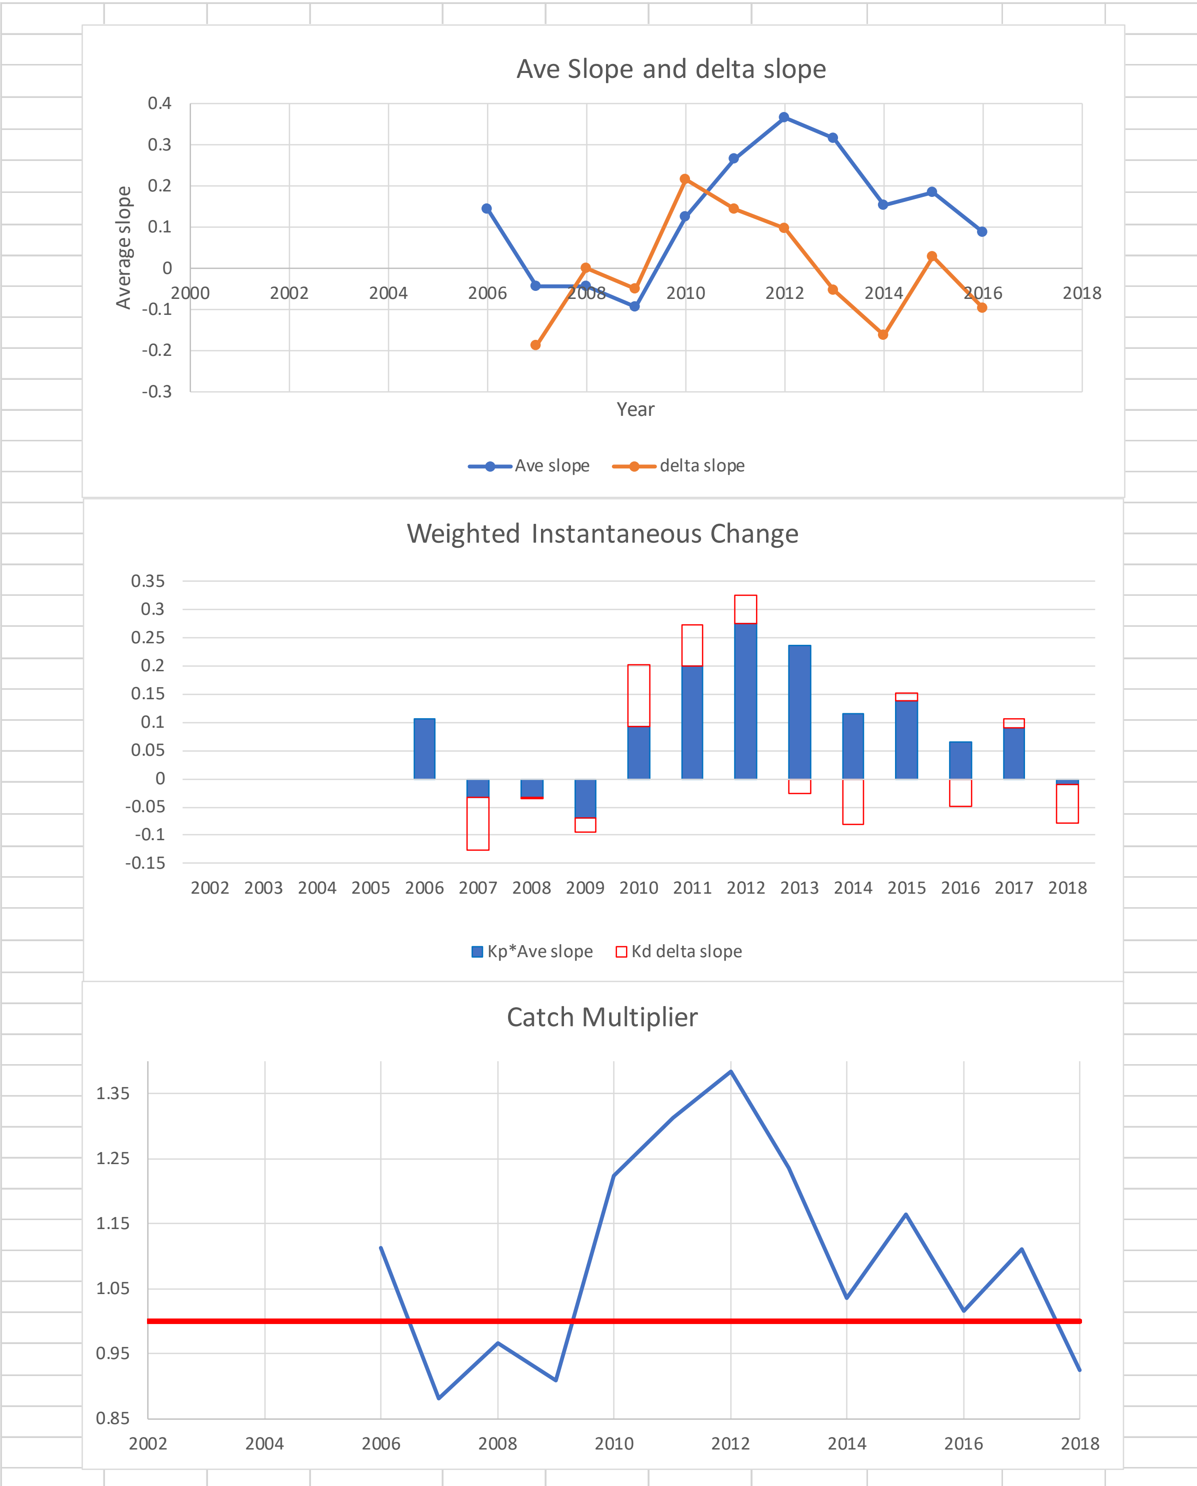

Figure 19. Summary of FSD model results for US Atlantic halibut based on d/k trawl, d/k gill net and NEFSC fall survey abundance indices (See Fig. 18 bottom). Instantaneous rates of change represent Kp and Kd weighted values of the first and second derivative (top figure). The bottom figure show the Catch multiplier used to forecast catch. . The gain parameters for proportional and derivative were set at Kp=0.75 and Kd=0.50, respectively.

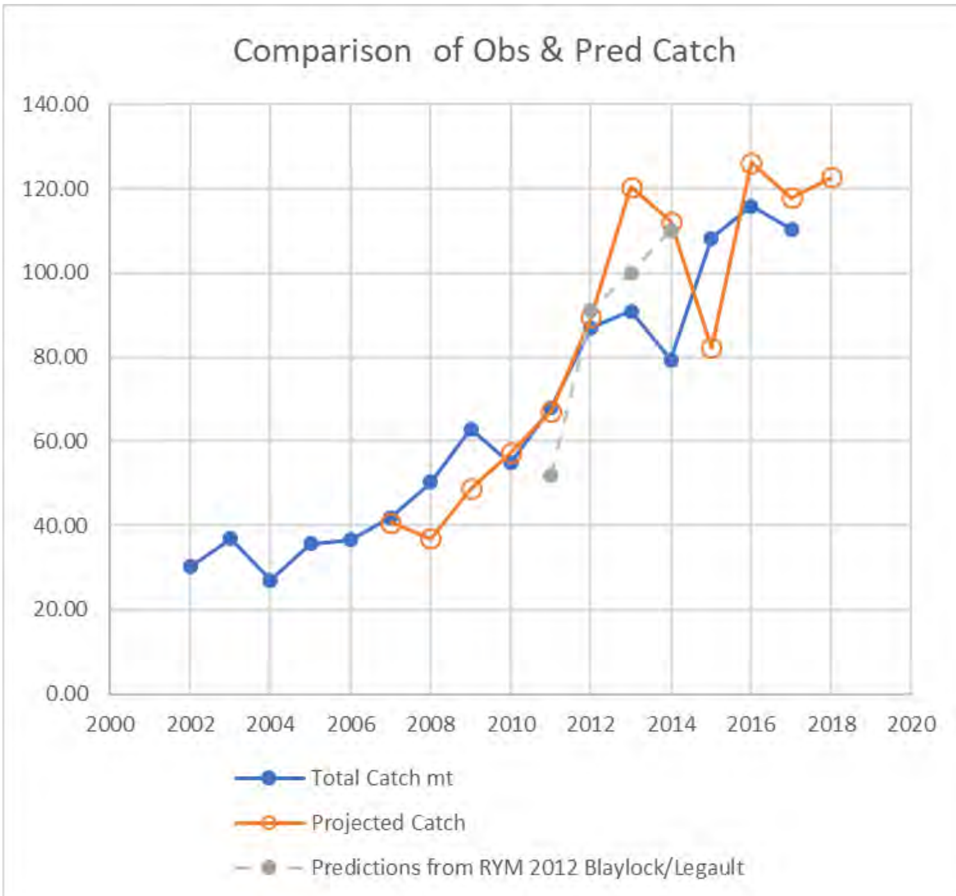

Figure 20. Comparison of observed vs predicted catches based on the FSD model applied to US stock area. Forecasts from RYM application (Blaylock and Legault, 2012) are included for comparison. The gain parameters for proportional and derivative were set at Kp=0.75 and Kd=0.50, respectively.

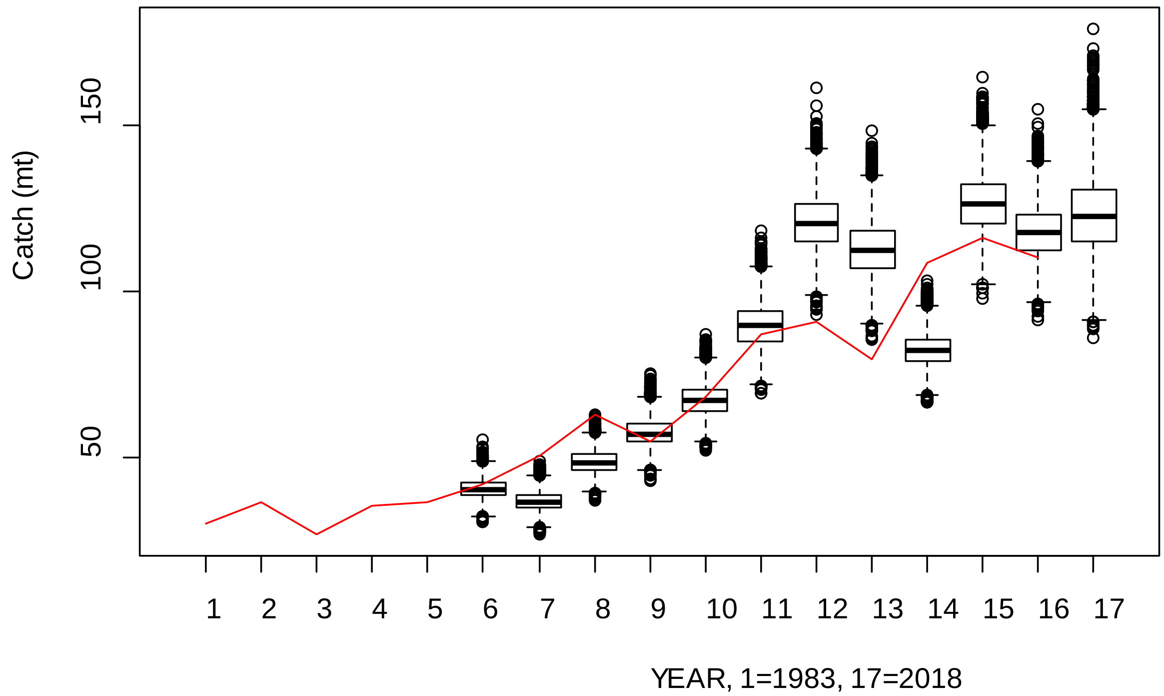

Figure 21. Comparison of observed and predicted distribution of catches for FSD model applied to the US stock area. Uncertainty estimates are based on a parametric bootstrap method described in the text. The gain parameters for proportional and derivative were set at Kp=0.75 and Kd=0.50, respectively.

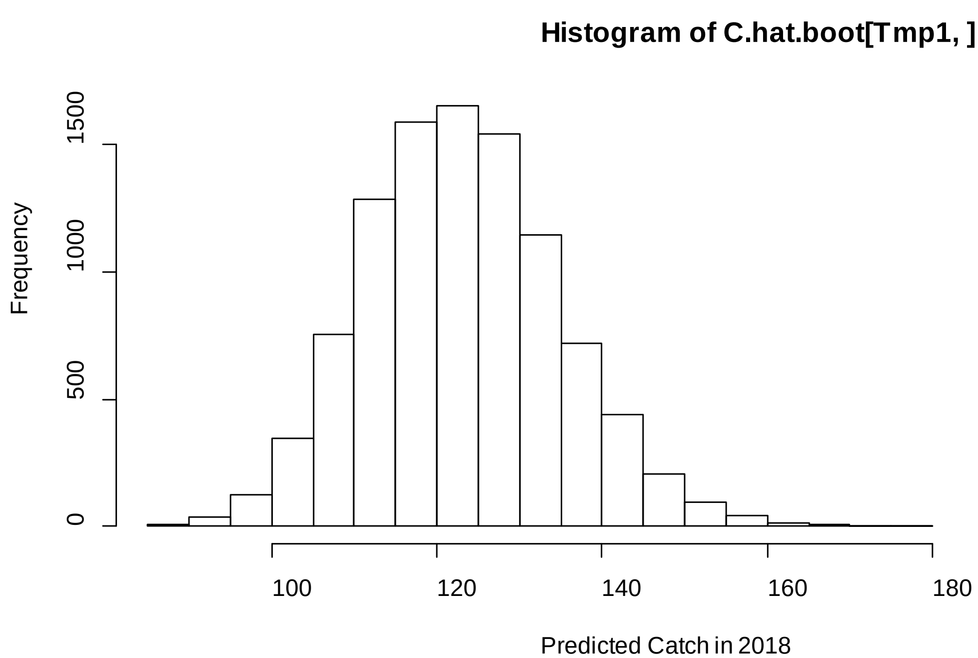

Figure 22. Sampling distribution of predicted catch for 2018 based on parametric bootstrap method with 5000 replications.

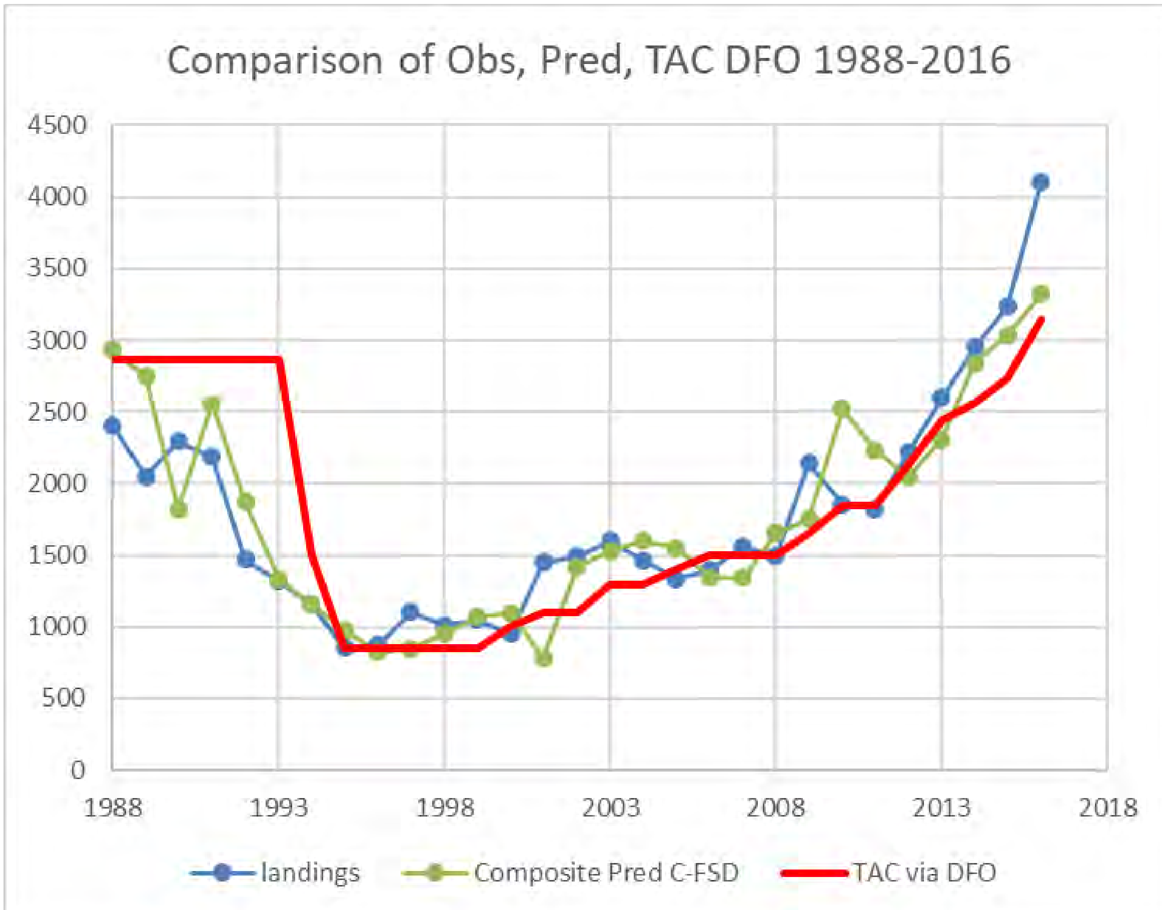

Figure 23. Comparison of FSD prediction with observed landings and TAC for DFO 3NOPs4VWX5Zc stock of Atlantic halibut.

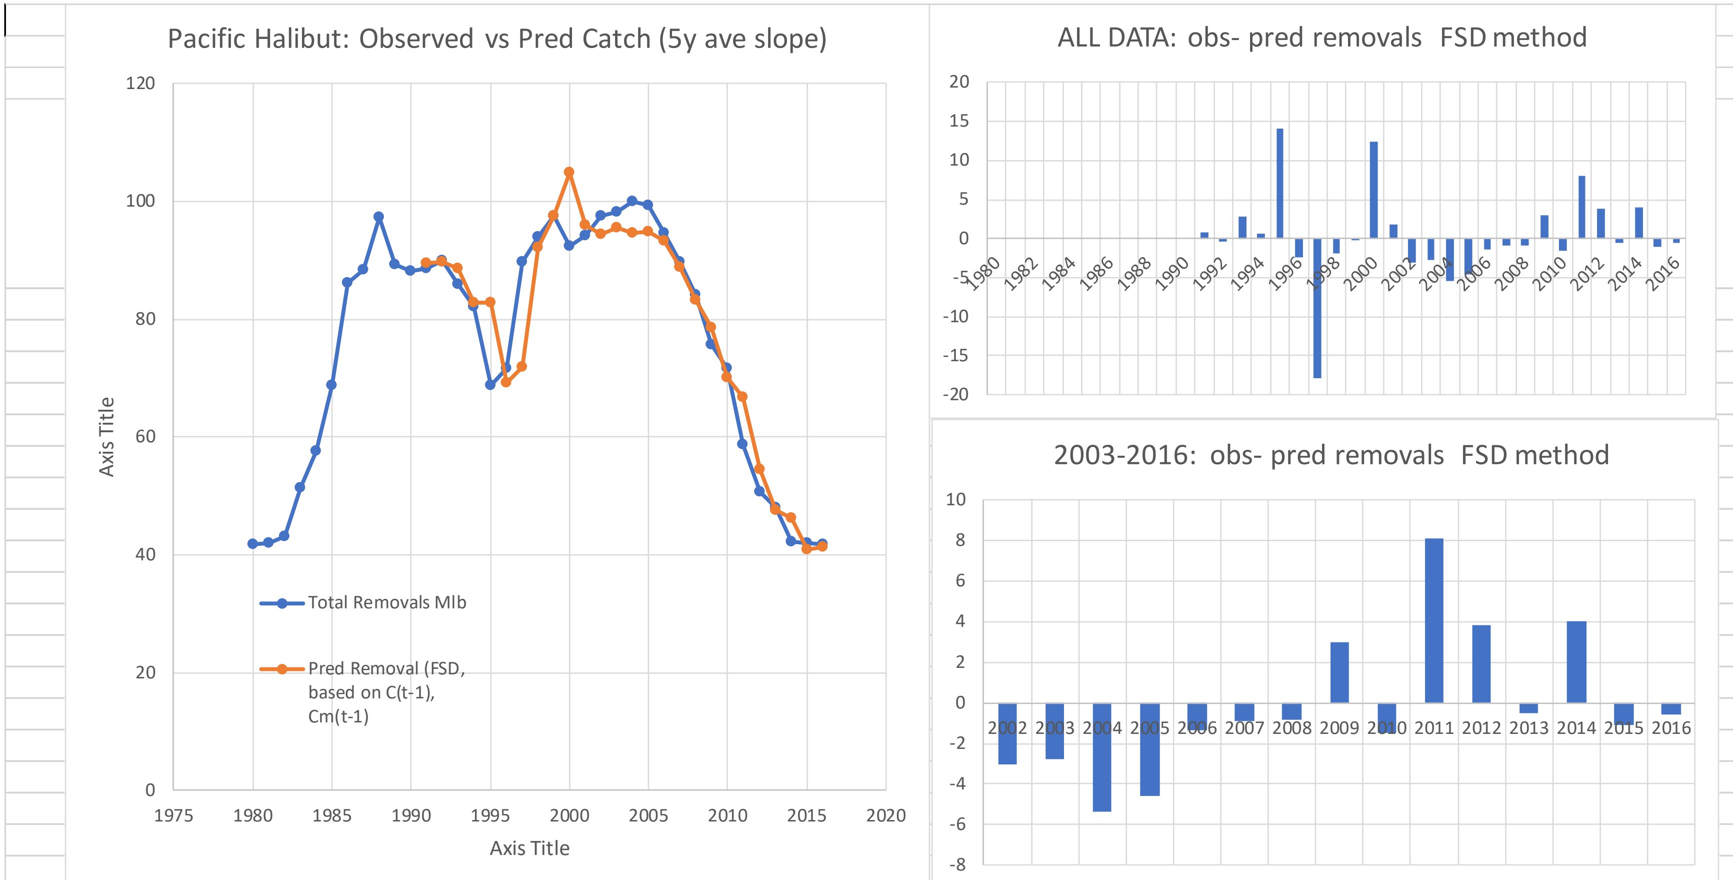

Figure 24. Example application of FSD model to observed catches of IPHC Pacific halibut. Residuals are shown on right hand plots for the full and reduced time series.

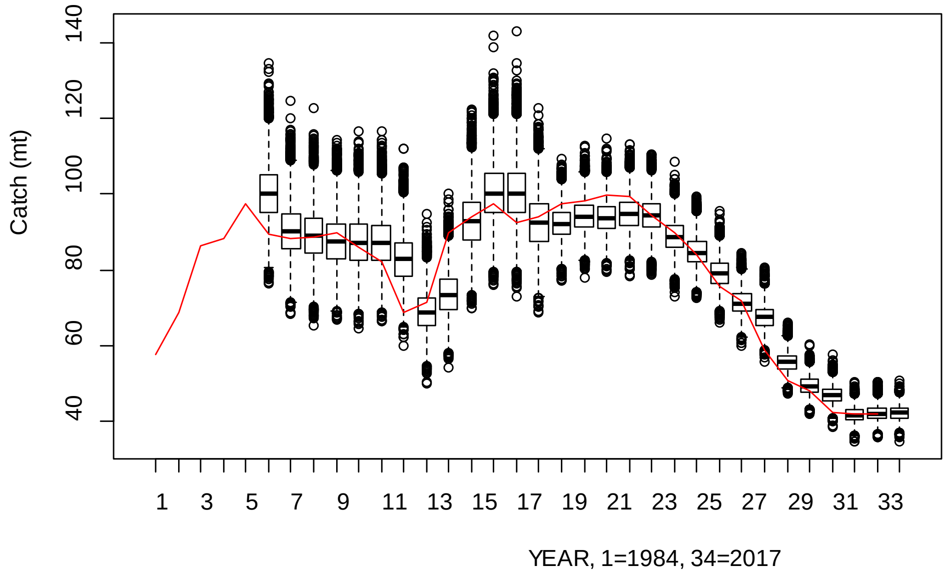

Figure 25. Comparison of observed and predicted catches based on the FSD model with Kp=0.778 and Kd=0.1. Research survey indices were assumed to have a CV=0.2 and Commercial CPUE indices were assumed to have a CV=0.25.

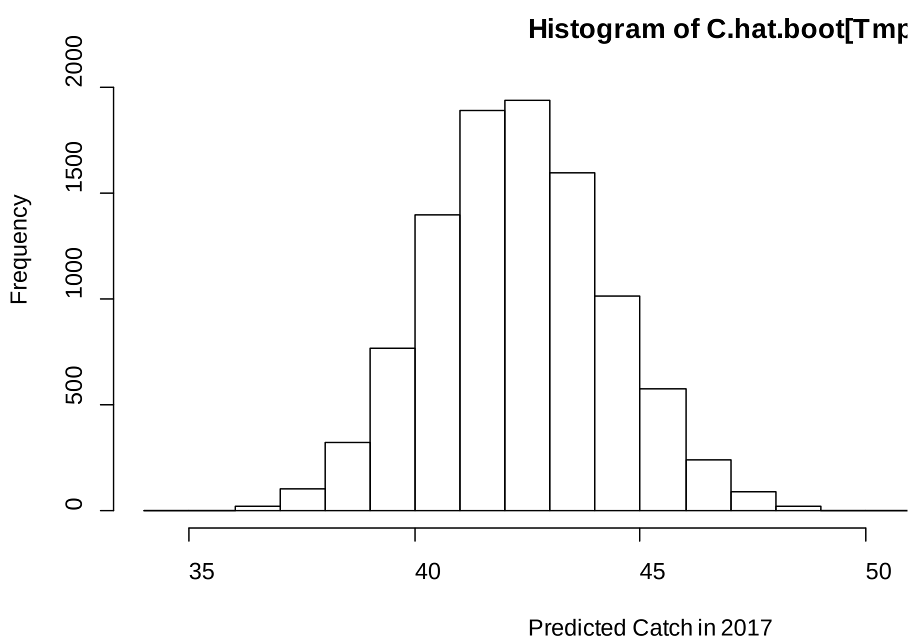

Figure 26. Predicted sampling distribution of estimated total removals in 2017 for Pacific halibut. The FSD model used Kp=0.778 and Kd=0.1. Research survey indices were assumed to have a CV=0.2 and Commercial CPUE indices were assumed to have a CV=0.25

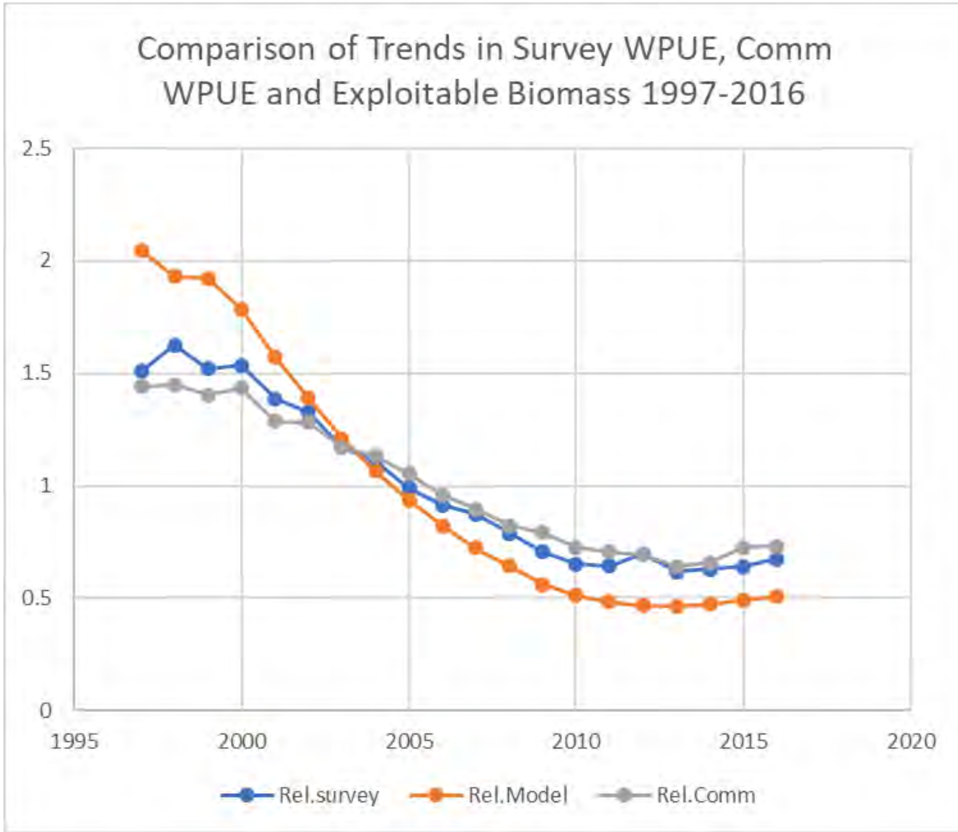

Figure 27. Comparison of relative trends in biomass for IPHC Pacific halibut surveys and modeled biomass. Quantities are expressed as ratio of observed value to its mean for the period 1997-2017. Data were obtained from Stewart(2017) and Stewart and Hicks (2017).

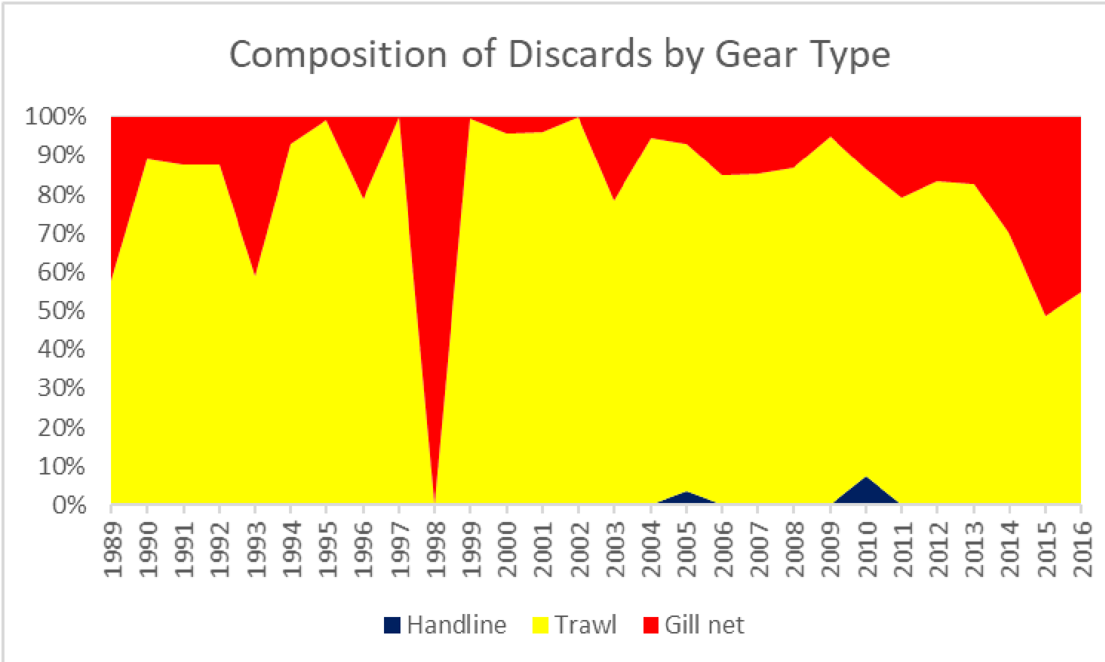

Figure 28. Estimated proportions of discards by gear type, 1989-2016. Estimates are based on an assumed 100% mortality.

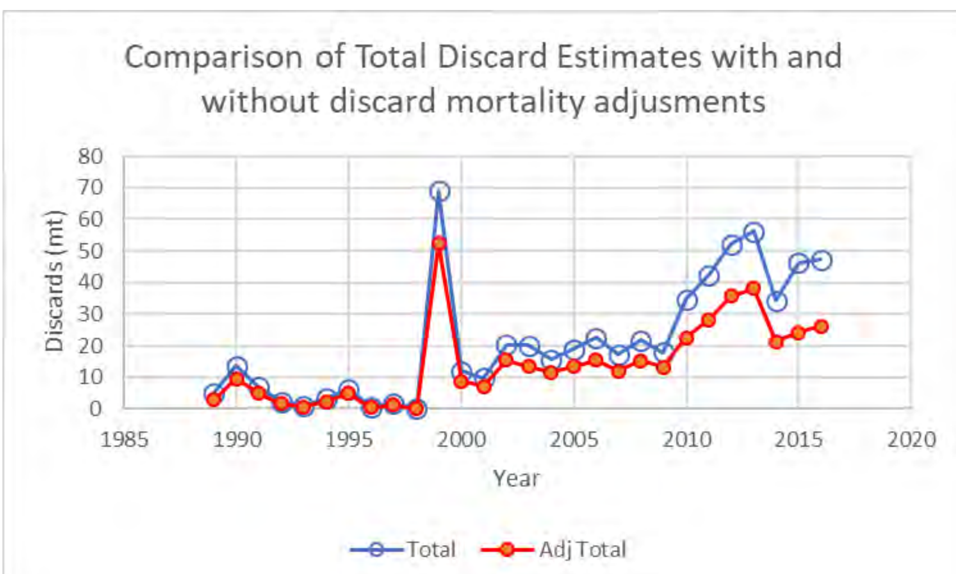

Figure 29. Comparison of total discard estimates based on assumed rates of discard mortality: Trawls 76%, Gill nets 30% and hook gear 10%.

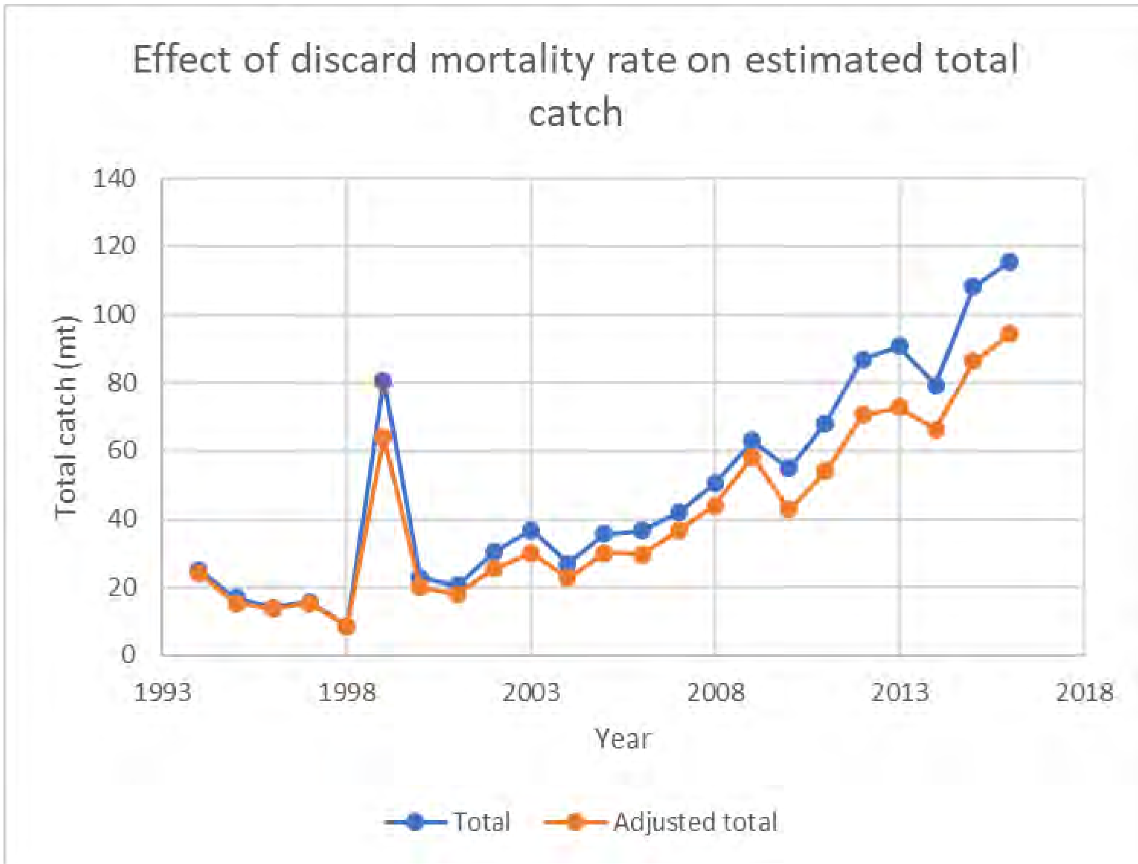

Figure 30. Comparison of total catch estimate based on alternative assumptions about discard mortality. Total assumes 100% mortality, Adjusted total assumes gear specific discard mortality rates of 76% for trawls, 30% for gill nets and 10% for hook gear.

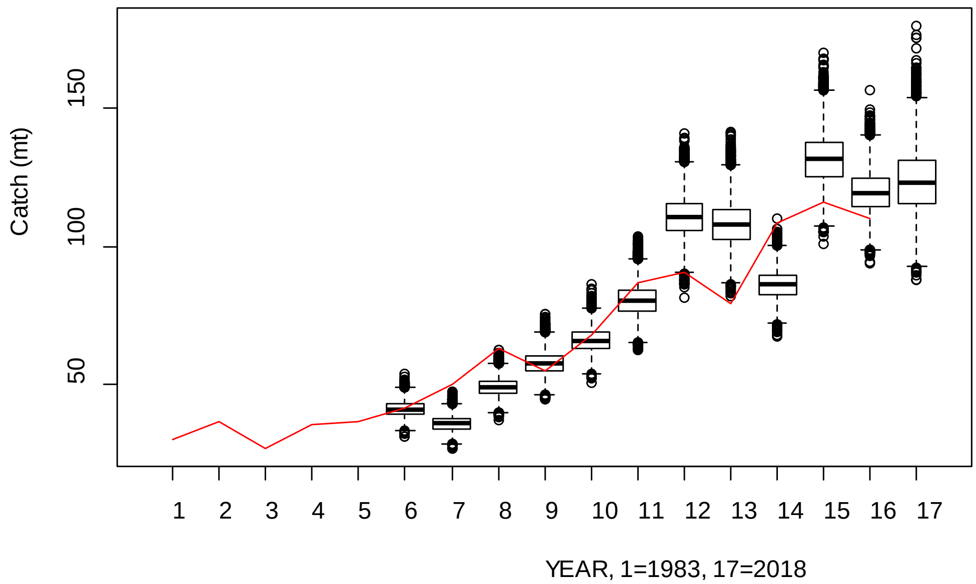

Figure 31. Comparison of observed and predicted distribution of catches for FSD model applied to the US stock **area using total catch to total kept all indices as measures of relative abundance**. Uncertainty estimates are based on a parametric bootstrap method described in the text. The gain parameters for proportional and derivative were set at Kp=0.75 and Kd=0.50, respectively.

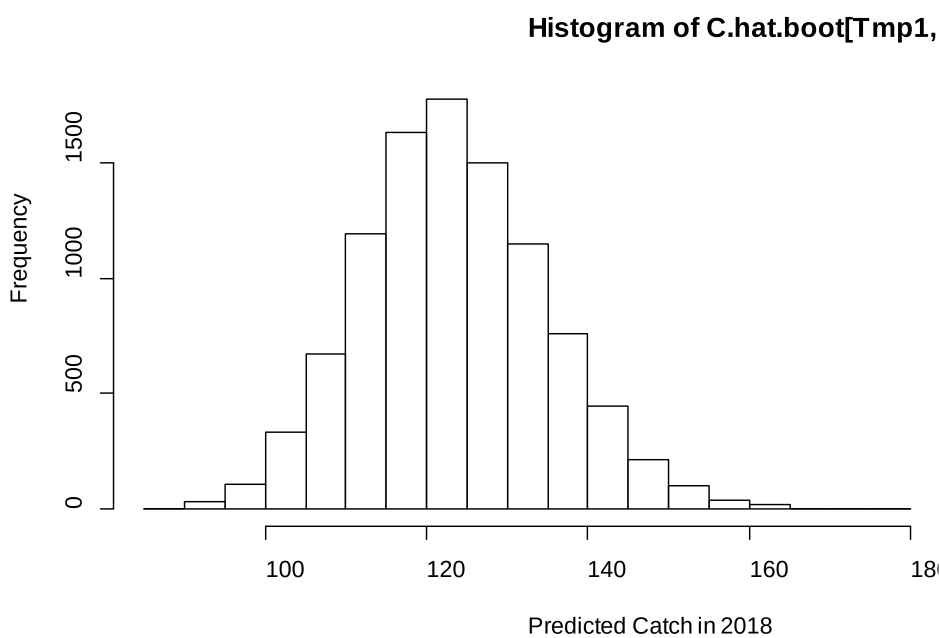

Figure 32. Distribution of forecasted catch for 2018 based on t/k ratio for the US stock area Atlantic halibut. Kp=0.75, Kd=0.5. The model uses t/k ratio for gill nets and trawl trips as measure of relative abundance.

APPENDIX 1. Summary of Input Data considered for use in FSD model for US stock area.

Table 1.1 Summary of average weight per to in the NEFSC bottom trawl survey for fall and spring seasons, 1968-2016.

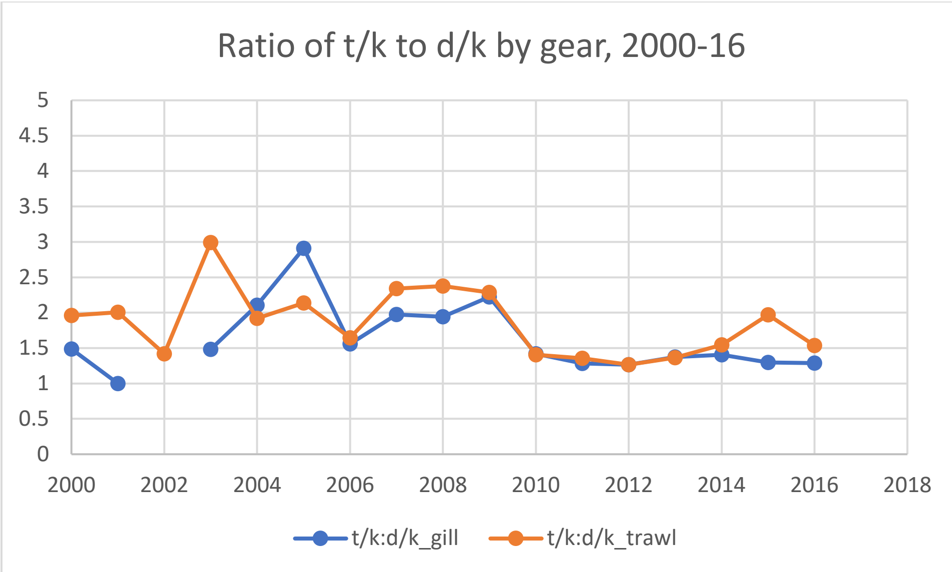

Fig. 3.2 Ratio of t/k to d/k for observed trips on gill net and trawl vessels.

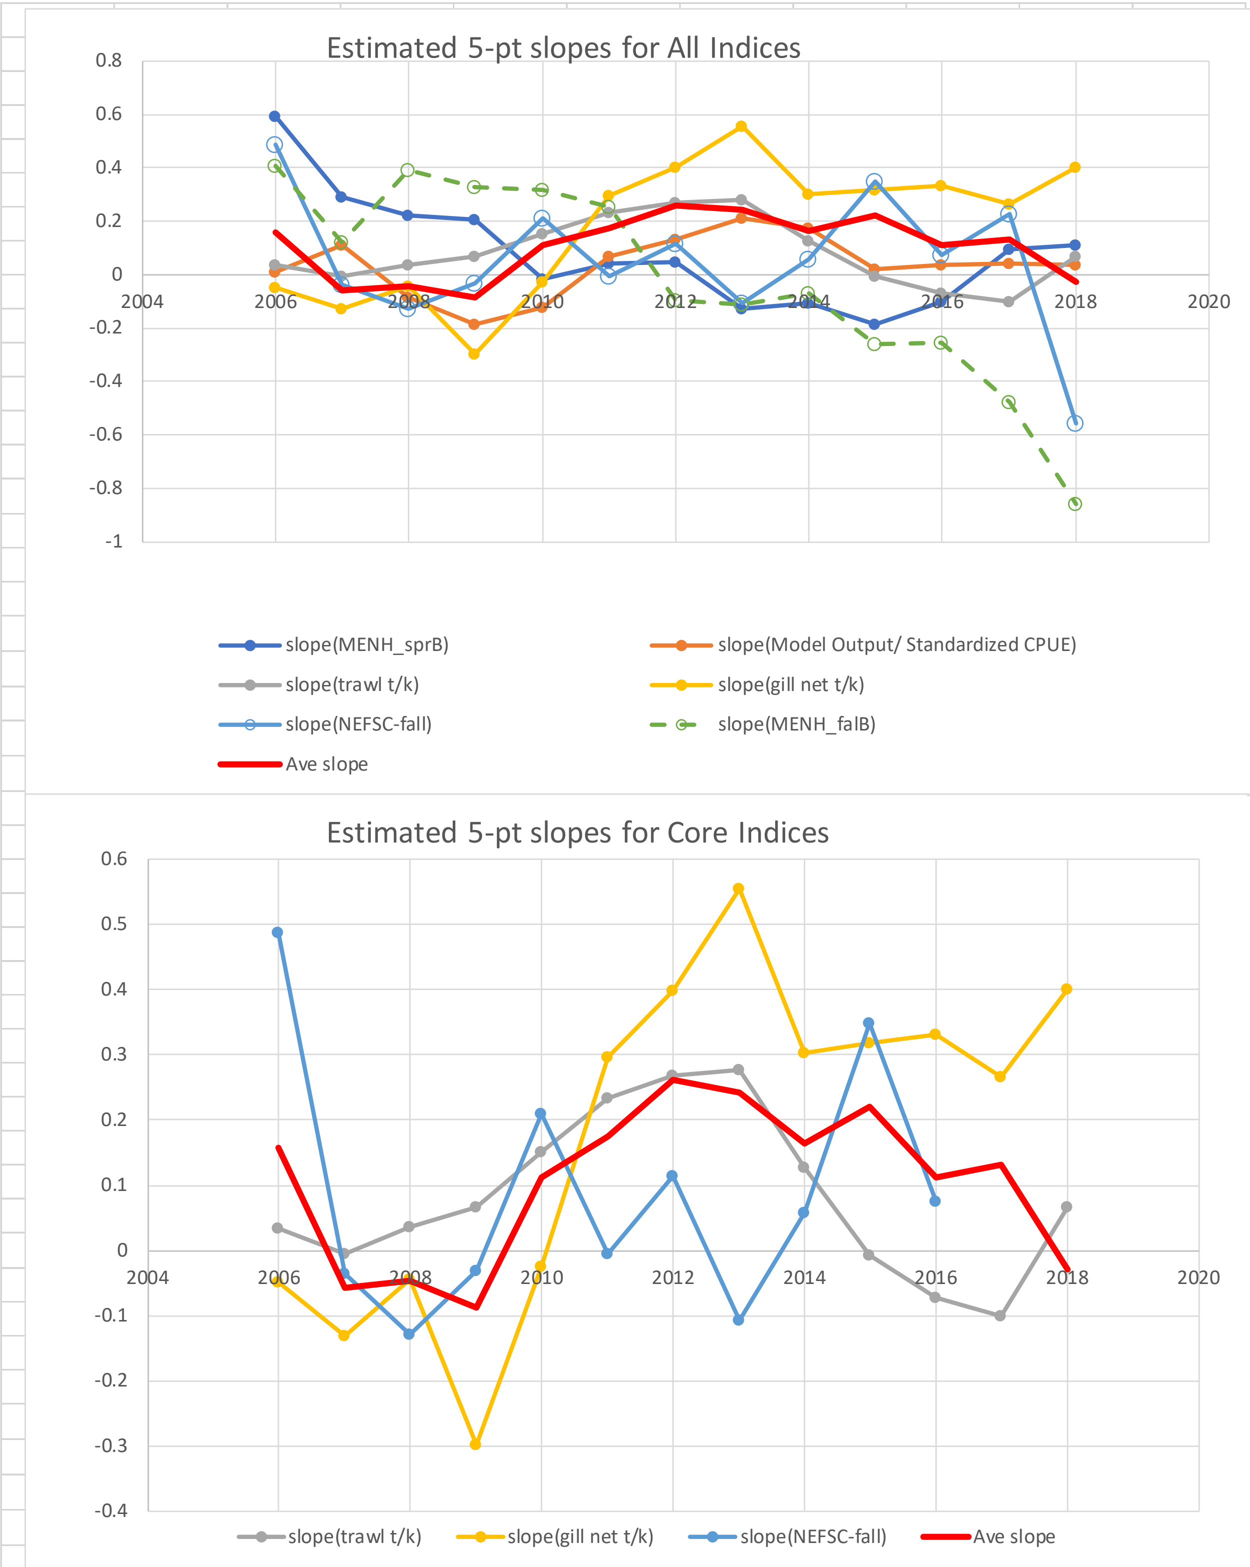

Figure 3.3 Trends in abundance indices based on 5 point regressions. Top plot shows full model with 5 indices. Bottom plot shows reduced model using only existing indices. **Model uses the t/k ratio for gill nets and trawls rather than the d/k ratio as measures of relative abundance**

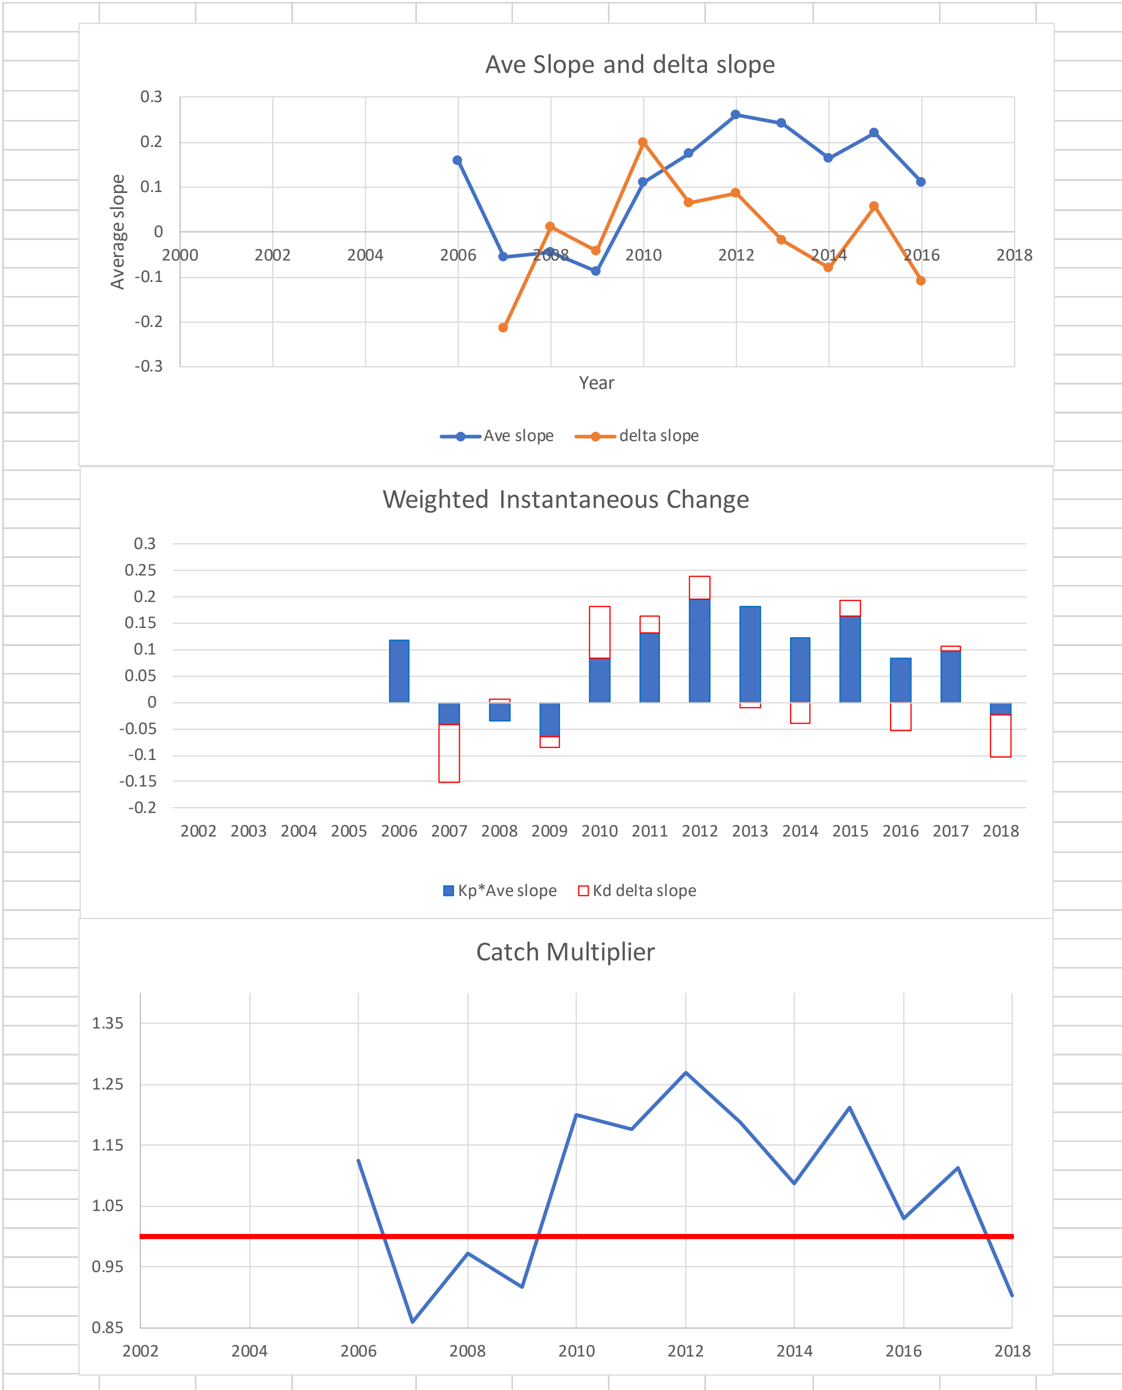

Figure 3.4. Summary of FSD model results for US Atlantic halibut based on d/k trawl, d/k gill net and NEFSC fall survey abundance indices (See Fig. 18 bottom). **Model uses the t/k ratio for gill nets and trawls rather than the d/k ratio as measures of relative abundance** Instantaneous rates of change represent Kp and Kd weighted values of the first and second derivative (top figure). The bottom figure show the Catch multiplier used to forecast catch. . The gain parameters for proportional and derivative were set at Kp=0.75 and Kd=0.50, respectively.

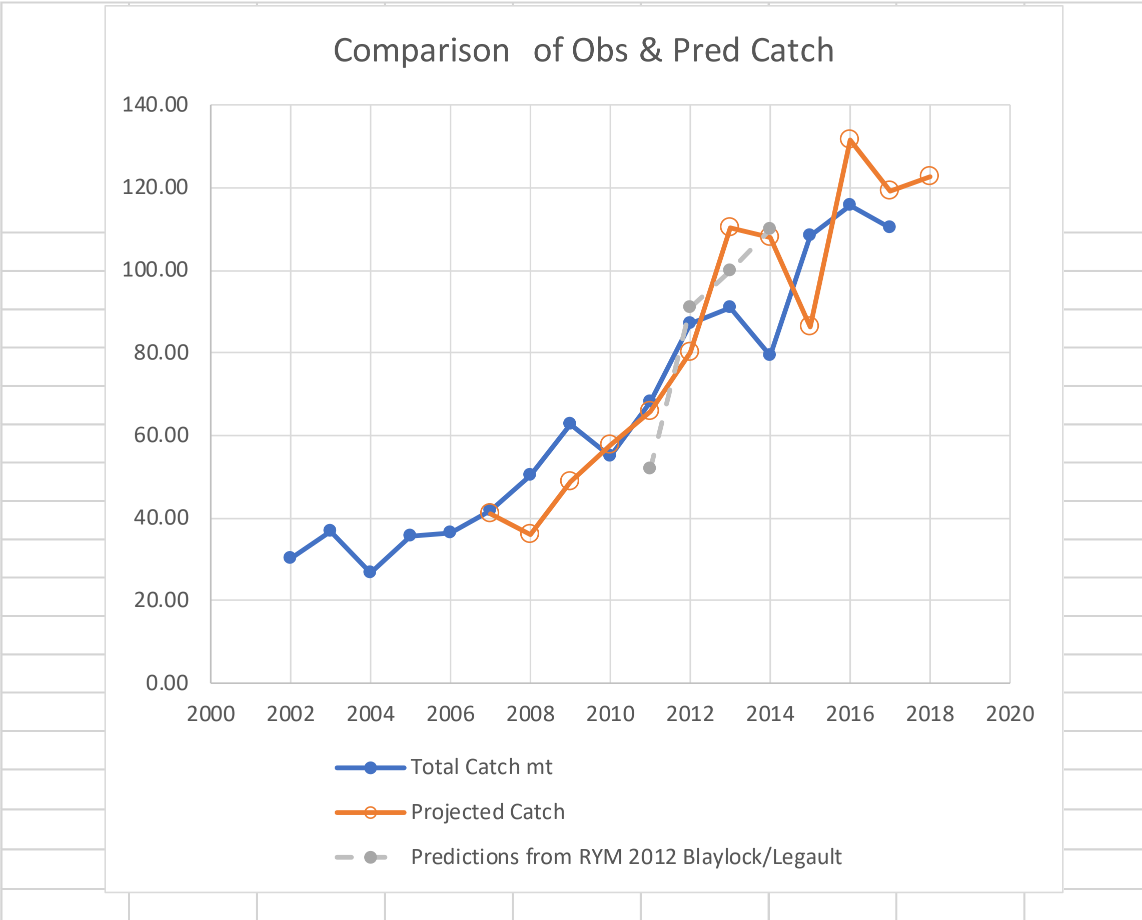

Figure 3.5. Comparison of observed vs predicted catches based on the FSD model applied to US stock area. **Model uses the t/k ratio for gill nets and trawls rather than the d/k ratio as measures of relative abundance**. . Forecasts from RYM application (Blaylock and Legault, 2012) are included for comparison. The gain parameters for proportional and derivative were set at Kp=0.75 and Kd=0.50, respectively.

APPENDIX 4. Summary of variable acronyms used in report.

Variable Name	***Definition***
ME_FAL_B	Average weight per tow in the Maine-New Hampshire bottom trawl survey conducted in Fall, 2001-2016.
ME_SPR_B	Average weight per tow in the Maine-New Hampshire bottom trawl survey conducted in Spring 2001-2016.
DK_GILL	Average ratio of weight of halibut discarded to total weight of all species kept (ie landed) for observed trips on gill net vessels departing from ports in New England Region (Rhode Island and north), 1989-2016.
DK_TRAWL	Average ratio of weight of halibut discarded to total weight of all species kept (ie landed) for observed trips on trawl vessels departing from ports in New England Region (Rhode Island and north), 1989-2016.
TK_GILL	Average ratio of total weight of halibut kept plus discarded to total weight of all species kept (ie landed) for observed trips on gill net vessels departing from ports in New England Region (Rhode Island and north), 1989-2016.
TK_TRAWL	Average ratio of total weight of halibut kept plus discarded to total weight of all species kept (ie landed) for observed trips on trawl vessels departing from ports in New England Region (Rhode Island and north), 1989-2016.
NMFS_SPR_B	Average weight per tow in the Northeast Fisheries Science Center bottom trawl survey conducted in Spring, 1968-2016.
NMFS_FAL_B	Average weight per tow in the Northeast Fisheries Science Center bottom trawl survey conducted in Fall, 1963-2016.
LL_CPUE	Model adjusted estimates of longline fishing catch per unit effort for commercial fishing vessels in Maine, 2002-2016. Based on work of Hansell et al. 2017
MEDISCRAT	Halibut discard rate reported by Maine longline harvesters
CP100TAGS	Total catch of halibut per 100 tags issued by Maine DMR
DFO_FS	Average weight per set for halibut captured in a scientific long line survey conducted jointly by DFO and commercial fishermen, 1998-2016. Fixed stations only. Based on results of GLM.
DFO_CPUE	Average weight per set for halibut reported by commercial fishermen. CI index is just mean and se of all ci sets (600*catchkg/(#hooks)/(DURATION), last reported in data update for 2014 asssessment, 1998-2016
SURV_3NOP	Average number per tow for halibut captured in DFO bottom trawl survey in NAFO area 3NOPs in spring, 1971-2013.
SURV_4VWX	Average number per tow for halibut captured in DFO bottom trawl survey in NAFO area 4VWX in summer,1970-2016
DFO_TOTB	Total biomass estimate derived from analytical model 1970-2013.

2014 TRAC Georges Bank Yellowtail Flounder Diagnostic Review and Empirical Approach Benchmark

SUMMARY –OVERVIEW

A Diagnostic Review and Empirical Approach Benchmark have never been conducted in the TRAC process before. The goal is to explore all sources of data, including those typically not included in stock assessments directly, looking for possible causes of the poor diagnostics in the current VPA for Yellowtail Flounder.

The diagnostic issues from the current assessment can be summarized as: Given the large reductions in catch in recent years, why has the population not responded by increasing abundance and expanding its age structure? The relative fishing mortality rate, computed as the catch divided by any of the three bottom trawl surveys, declined substantially in 1995 and has remained low since. In contrast, the total mortality estimated from the age structure of these same surveys (and confirmed with an independent tagging study) indicated a high and relatively constant level throughout the time series, with perhaps an increase in recent years. These conflicting signals result in a strong retrospective pattern in the current VPA for this stock. Splitting the surveys to alias the source of this conflict initially resolved the retrospective pattern, but the retrospective pattern has returned recently. Additionally, splitting the surveys has resulted in abundance estimates from the VPA which are less than some estimates of the population abundance from independent sources. All three bottom trawl surveys have shown a strong declining trend in recent years despite low catches. Thus, issues to consider as diagnostic problems include: trends in abundance over time, the magnitude of the population, the disparity between trends in F and Z, the lack of expansion in the age structure of the population, the spatial concentration of yellowtail, and the retrospective pattern. These issues are the same ones that led to the 2005 benchmark assessment for this stock.

The Term of Reference for this meeting are:

1) Summarize all available data for Georges Bank yellowtail flounder which can be used to explore possible causes of the poor diagnostics in the current VPA for this stock.

2) Determine which pieces of information are consistent with alternative hypotheses regarding current stock status (e.g., current population is near carrying capacity, current population is near a desired amount, and current population is well below a desired amount).

3) If possible, describe how catch advice could be provided based only on the data (e.g. without relying on a stock assessment model). If feasible, identify and estimate appropriate fishing mortality reference points.

The following summarizes decisions made by the TRAC during the Benchmark.

- **Movement and Distribution** Movement of Georges Bank Yellowtail Flounder outside of stock boundaries is not a likely source for the poor diagnostics in the current VPA formulation.

- **Missing Catch** Examination of the magnitude of change required in the estimated discards or reported landings to explain the amount of missing catch needed to fix the retrospective pattern demonstrated these are unlikely the primary sources of the retrospective pattern.

- There has been a consisten**t aging** of yellowtail that has been verified historically and also recently based on the number of growth marks from tagged and recaptured yellowtail. Issues with age determination do not appear to be a major source of uncertainty in the stock assessment.

- **Natural Mortality** Based on the expected equilibrium age compositions and the range of M values estimated from life history attributes, the TRAC agreed that M =0.2 is likely an underestimate and that an M=0.4 is more consistent with these attributes. *TRAC recommends that the M=0.4 be applied as a sensitivity VPA for the June 1014*

- **Productivity** Several indicators suggest major change in productivity in recent years**.** The most recent survey biomass estimates are among the lowest in the time series and recent recruitment has generally been below average. The Georges Bank Yellowtail Flounder larval index dropped sharply since 2006. Condition factor has been variable but declining since 1998 and fecundity declines with poor condition factor. *TRAC concluded that the stock biomass is low and productivity is poor.*

- **Catchability** Absolute biomass estimates for NEFSC and DFO survey trawl time series will be based on the door spread footprint rather than by the wing spread as done previously. Estimation of biomass based on wing spread is confounded by the herding effect. Empirical estimates of survey efficiency, e.g. whole net efficiency for trawl surveys, should be considered to inform the scale of area swept biomass estimates. Such estimates impose realistic constraints on estimated catchability from the model outputs. *TRAC recommends that door spread swept area biomass estimates be applied in a sensitivity VPA for the June 2014. TRAC also recommends further research to refine estimates of survey gear efficiency.*

- **Absolute Biomass** estimates from surveys or other approaches can be used to inform the plausibility of model estimates, even in cases when the information applies to only part of the stock area. Model results well below the absolute estimates can be used to reject model results, but only when uncertainty in both estimates indicates a real difference. *TRAC agreed that the empirical estimates of biomass should be used to inform and evaluate consistency of VPA biomass estimates*

- There is **gear avoidance** in all surveys. Catchability should always be assumed to be less than one for whole gear. Preliminary analyses indicate there is gear avoidance by yellowtail flounder even during HABCAM surveys, in which catchability has previously been assumed to be 1.0.

- **Biomass Estimation and Exploitation** TRAC agreed to use time series from 1995 forward for interpretation of biomass estimated in the empirical approach. Current biomass will be estimated as the average of the estimated absolute biomass from the NMFS spring and DFO bottom trawl surveys from year *i* and the NMFS autumn bottom trawl survey from year *i-1*. Although these are multi-species surveys, these are the only surveys that sample the entire stock area. A Mass Balance Approach was developed that reconciles time series of survey biomass, catch, survey based total mortality, and individual growth. This approach estimates that M has ranged between 0.8 and 2.0 since 2009. This M represents all losses other than those due to estimated catch. The exploitation rate is calculated as catch/the average of the survey biomasses.

  This method was used to guide the selection of an appropriate harvest rate based on yield per recruit analyses. The target *exploitation rate*, based on the ratio of yield per recruit / total biomass per recruit over a range of M = 0.4 to 1.1, ranged between 0.24-0.27 at $F_{0.1}$ and between 0.22-0.24 at $F_{40\%}$ and is estimated to be = 0.25 (averaged over all 16 values).

- **Catch advice** will be based on the current average biomass described above, the target exploitation rate and qualitative criteria (e.g. is there convincing evidence that the stock is increasing or decreasing; is recent recruitment above or below average, etc.). In the current year *y*, the catch is being set for the next fishing year, *y* +1, without making projections for population dynamics (e.g. catch, survey catch, recruitment, weight at age, selectivity) in year *y*.

Proposal for a Transboundary Resource Assessment Committee Benchmark of the Georges Bank Yellowtail Flounder Empirical Approach

National Marine Fisheries Service
Northeast Fisheries Science Center
Population Dynamics Branch
Woods Hole, MA 02543

January 14, 2014

In December 2013 the Population Dynamics Branch of the Northeast Fisheries Science Center (NEFSC) finalized a proposal to develop an empirical approach for estimating abundance and setting catch limits for Georges Bank yellowtail flounder. The empirical approach will evaluate all relevant data sources with respect to their support for alternative hypotheses on stock status and, if possible, their directional impact on catch advice (Attachment #1). Drafts of the proposal have been considered by scientists within the NEFSC, staff at the Northeast Regional Office (NERO), members and staff of the New England Fishery Management Council (NEFMC), and colleagues at the Department of Fisheries and Oceans (DFO), Canada. Various concerns have been raised about the proposal including questions about the methodology, the process for review, and how it will be used to formulate catch advice. Management advice for this stock is determined by negotiation within the Transboundary Management Guidance Committee (TMGC), a bilateral understanding between the US and Canada and translated into fishery regulations by each country's authorized organizations. As such, it is important to have a mutually acceptable process for convening and vetting the scientific basis for the catch advice. Discussions between scientific staff and NEFSC and DFO have led to a proposal in which the Empirical Approach would be reviewed as a "diagnostic benchmark" within the Transboundary Resource Assessment Committee (TRAC).

Attachment #1 is a general outline of how a TRAC benchmark would be conducted and a discussion of the merits of such an approach. A TRAC Benchmark review would occur April 14th-18th, 2014 in Woods Hole with participation from US and Canadian scientists, academics, interested parties from both countries, and a number of external reviewers selected and supported by both countries. The Terms of Reference (TOR) for the meeting will be restricted to evaluation of information relevant to the estimation of biomass and age composition from various data sources. The TRAC benchmark will not be a forum for introduction of alternative stock assessment models. That review has already taken place at the 2013 International Council for the Exploration of the Seas (ICES) Strategic Initiative for Stock Assessment Methods (SISAM) meeting in Boston. Analyses by leading scientists from around the world demonstrated that further consideration of alternative stock assessment models was unlikely to reveal the underlying causes for the lack of model fit. Lack of fit, presumably due to one or more changes in the data, or assumed or estimated parameters, was a common feature in all models. The SISAM review suggested that stock assessment models were not sufficient to uniquely identify such changes. Instead, a focus on external information would be an appropriate approach to explore problems in model diagnostics and retrospective patterns. The TRAC "diagnostic" benchmark would address these concerns directly but we acknowledge that this departs from the conventional understanding of benchmark assessments.

A diagnostic benchmark assessment through the TRAC will follow well-established and understood conventions for evaluating the scientific basis for catch advice within the US-Canada understanding (Attachment #2) and ensure participation by Canadian colleagues. A diagnostic benchmark also allows for a more thorough external review of the proposed approach and increase the likelihood that it can be used for management. In Attachment #3 we provide draft terms of reference for consideration.

Attachment #1

An Empirical Approach to Setting Catch Limits for Georges Bank Yellowtail Flounder

Problem Statement: The stock assessment for Georges Bank yellowtail flounder suffers from a severe retrospective pattern. Likely causes of the retrospective pattern include misreporting of landings, underestimation of discards, or increases in natural mortality. Unfortunately neither the model nor ancillary evidence is sufficient to distinguish among these competing hypotheses. In the absence of unequivocal evidence, there is no expectation that an update of the current assessment approach will alleviate any of the concerns raised about this assessment. Independent reviews and tests of alternative models by stock assessment scientists at the recent ICES World Conference on Stock Assessment Methods failed to find acceptable alternatives. All of the models suggested that a change in the underlying data or assumed magnitude of natural mortality had occurred, although none of the models could identify a proximate cause. Given the continuing need for stock assessment advice and the likely futility of identifying the perfect model, we propose a new approach that relies heavily on contemporary information. In pursuing this new path, it must be recognized that some of the desirable features of stock assessment models, such as biomass reference points, rebuilding strategies, and forecasting, will be given up. Instead, the approach will focus on a more narrowly defined question of "What is the appropriate level of harvest in the upcoming fishing year?"

Technical Details: There are conflicting signals in the data. Survey trends indicate a rapid increase in the population from the mid 1990s through early 2000s followed by a slower decline. Age distributions from the surveys indicate high total mortality rates throughout the entire time period. Recent tagging studies confirm this high total mortality rate during 2003-2006. Catches have markedly declined in recent years. Dividing the catch time series by the survey time series produces a simple relative fishing mortality rate that shows high values in the 1970s, 1980s, and early 1990s then a sharp decline in 1995 to low levels since then. There is no evidence of a change in natural mortality rate, although fish condition (weight at length) has declined from the early 1990s through recent years. The conflict in the data arises because surveys suggest a high and steady total mortality (Z) despite a large sudden decline in relative fishing mortality (F) in recent years. When natural mortality (M) is assumed to be low and constant the current total mortality (Z) is much greater than F plus M, when in fact Z should exactly equal F plus M.

Proposed Solution: Given the aforementioned concerns, an entirely empirical approach could be used instead. This approach would be based strictly on the data observations: surveys, catch, and any empirical information available. No model would be used beyond Z = F + M.

Instead, the implications of different assumptions regarding recent natural and fishing mortality rate would be explored systematically to demonstrate the potential impact of different catch advice along with notes about the implications of these changes. The proposed method would use as much contemporary information as possible but require that proposed catch levels were logically consistent with the underlying hypotheses used to generate the abundance estimate.

Proposed Process for Georges Bank Yellowtail Flounder Empirical Approach

At its June 2013 meeting, TRAC agreed that a full conventional benchmark for yellowtail flounder was not feasible given the absence of any new data series and that the decision would be reconsidered pending the results of the July 2013 ICES World Conference on Stock Assessment Methods. The ICES Conference subsequently confirmed that none of the models tested provided unequivocal measures of stock abundance. The empirical approach presented here is considered a more complete analysis of the "trends in relative abundance and relative mortality rates derived from survey and fishery data" recommended as part of the benchmark formulation for this stock (Gavaris et al. 2005). However, since this approach is an expansion of the 2005 benchmark, further peer review is warranted. To meet this need we propose to conduct a diagnostic benchmark following the TRAC benchmark review process.

Development of the empirical approach will require close coordination with industry, academic and government partners. Prior to a TRAC integrated peer review, a series of informal meetings will be held with these partners to describe the proposed process and to more fully understand field experiments that may contribute to the formulation of biomass estimates. These meetings will be designed to explore the evidence with the same rigor applied when developing stock assessment models (See Term of Reference 1 in Attachment #3). The scope and timing of these meetings has not been determined but will be dictated by the current schedule of assessments for the Population Dynamics Branch and availability of Canadian colleagues. Following these informal meetings an integrated peer review will be held April 14th-18th, 2014 to examine the data analyses conducted for the empirical approach. Meeting participants will include TRAC members, NEFSC, DFO, and state scientists, academics, Council staff, industry stakeholders and invited external reviewers. The purpose of the peer review diagnostic benchmark is to determine if the empirical approach has correctly evaluated and summarized the available data for Georges Bank yellowtail flounder (See Term of Reference 1 in Attachment #3). One of the most challenging Terms of Reference is TOR 2 in which the consistency of alternative hypotheses will be evaluated. The meeting will address how the empirical approach could be used for catch advice but will not actually derive catch advice (See Term of Reference 3 in Attachment #3).

At the June 2014 TRAC meeting, the recommendations from the diagnostic benchmark meeting will be used to derive catch recommendations. Depending upon the outcome of the benchmark, results will either be considered alone as a basis for catch advice or considered along with the current virtual population analysis (VPA) modeling results and relevant VPA sensitivity runs as have been conducted in the past[1]. The TRAC will synthesize all the available information to provide its recommendation on catch advice to the TMGC.

Gavaris, S., R. O'Boyle, and W. Overholtz. 2005. Proceedings of the Transboundary Resources Assessment Committee (TRAC) Benchmark Review of Stock Assessment Models for the Georges Bank Yellowtail Flounder Stock. TRAC Proceedings 2005/01. 36 p.

[1] An earlier draft document generated some concern regarding how the empirical approach might be used. This is due to the following statements in that draft: *"This would require TRAC rejecting the benchmark assessment model formulations and relying on the benchmark recommendation of using survey and catch information to generate catch advice. Thus, a benchmark would not be required…".* This wording reflects only one possible way in which the TRAC could synthesize all the information according to the benchmark formulation, but is not the only way (as noted by use of the words could and would in this section of the document). Other outcomes include placing more emphasis on the VPA results for catch advice, or using a blended approach of relying on some aspects of the VPA results but not the exact numbers, as has been done by TRAC in the last two years. The expectation is that the empirical approach will more clearly demonstrate the conflicts among the data sources for the Georges Bank yellowtail flounder stock and lead to a better understanding by scientists and managers about why modeling this stock has been so challenging.

Appendix: Technical Details for Proposed Solution

Given the uncertainties described above, current catch data and assumed levels of natural mortality can no longer be used to compute stock size estimates consistent with abundance measures derived from synoptic surveys. A new approach is proposed that relies on analyses of contemporary data and evaluation of alternative hypotheses. These hypotheses will be evaluated with respect to their internal consistency and with respect to their implications for other factors. A mass balance approach will be used to illustrate the implications of alternative estimates of stock size on the likely magnitudes of unreported landings, discard mortality, non-catch mortality, and natural mortality. For parameters that can be bounded but not estimated (e.g. trawl efficiency, post release survival of tagged fish, fraction of stock in Canada, etc.) sensitivity analyses will be used to construct profiles of stock sizes consistent with plausible hypotheses.

Some approaches that may prove useful include

1. Synoptic swept area estimates of abundance from multiple NEFSC and DFO surveys
2. Swept area estimates of abundance over a limited spatial domain, (e.g., 2013 cooperative survey)
3. Gear comparison studies of roller vs. cookie sweep gear conducted under Cooperative Research program
4. Cohort and static catch curves to estimate total Z
5. Long term tagging studies (Wood and Cadrin) to estimate survival rates
6. Short term tagging studies (Peterson estimate by Melgey) to estimate abundance
7. Analyses of condition factor and weights at age as predictors of natural mortality.
8. Sensitivity analyses of potential impacts of mortality from disease (*Ichthyophonus*) or predators (seals?).
9. Seasonal variation in abundance from Cooperative Research/RSA projects.
10. HabCam-based estimates of relative density.

The basic model of abundance would be based on empirical measures of abundance and assumed parameters as follows

$$N = \frac{A_d}{ap_d}\frac{I_t}{e}$$

Where **N** is the estimated total population , $\mathbf{I_t}$ is the index of abundance expressed as numbers or weight per tow, $\mathbf{A_d}$ is the total area within the sampling domain, a is the average area swept per tow, $\mathbf{p_d}$ is the fraction of the total area within the population domain, (*i.e.,* $\mathbf{p_d=A_d/A}$ where **A** is the total area where the stock resides), and **e** is the efficiency of the gear, expressed as probability of capture given encounter.

Some of these parameters are unknown or poorly known. An objective of the evaluation would be to develop realistic empirical bounds on efficiency derived from comparative experiments and to use survey indices to derive estimates of the fraction of total stock within US waters. The uncertainty in the unknown parameters and the sampling variability in the observations would be fully incorporated into overall abundance estimates.

Mortality estimates derived from catch curves and tagging studies would be compared to estimated catches and assumed values of M to create a similar range of population estimates. It is hoped that this piecewise construction of population estimates can be used to identify a range of plausible values for unknown parameters. A mass balance approach will be used to identify the magnitude of missing removals consistent with the swept area biomass estimates and the known removals via landings and discards.

The sampling distribution of population size would be carried through to create a distribution of catches consistent with the population estimates. Several approaches could be used. One approach would be a status quo method that multiplies the estimated abundance by the ratio of catch to relative biomass in recent years. Uncertainty in the estimate of the relative F could be propagated to develop a broad measure of uncertainty in the suitable catch level. Another approach that may be useful is to use an F derived from a yield per recruit analysis. An important aspect of this analysis would be the uncertainty in the discard rate and natural mortality rate. One would focus on predicted magnitude of landings, discards, and natural deaths to gauge their plausibility. Thus, catch advice would not be provided based on a standard assessment approach formula, but rather have to be agreed to by the TRAC (and SSC) given a range of possible quotas and plausible outcomes associated with each possible quota. Feedback from one year to the next in terms of responses in the fishery catch, survey time series, survey age structure, and other pieces of information would be an important component of this approach.

One potential advantage of this approach is that it might give participants a better understanding of the piecewise components of the assessment model. It might also create buy-in and acceptance from constituents who otherwise feel disenfranchised. It is also possible that none of these goals will be achieved, but we do not expect much acceptance from solely pursuing another update or, convening a conventional benchmark.

Attachment #2

Criteria for Evaluation and Modification of TRAC Benchmark Assessments [2]

At the April 2013 TRAC Benchmark meeting the following term of reference was addressed:

"Discuss criteria to determine:
1) When a benchmark assessment should be conducted and
2) What degree of modification is acceptable to make to benchmark model formulation during an update assessment."

The TRAC concluded the following:

"Without new information or modeling approach, requesting a benchmark would not be productive. During a TRAC update, changes to a benchmark model formulation would be presented as a sensitivity run and evaluated to see if a future benchmark would be required based on points outlined below. In all future TRAC assessments, a cumulative summary of changes to the current benchmark model will be included in the assessment research document.

1. Accumulation of data changes result in substantial change in catch advice relative to the benchmark formulation.
2. Change in either data or model results in substantial change in perception of stock size or stock structure.
3. On a regular basis, e.g. every five years, evaluate whether a benchmark review would be justified.
4. New data becomes available, e.g., new survey, that would affect model results.
5. Model results are inconsistent with observations; poor diagnostics.

In a TRAC update, if a sensitivity run suggests that a benchmark is required, the TRAC will present catch advice for both models with rationale as to why the sensitivity run would be preferred in the interim."

Attachment #3

Draft Terms of Reference for TRAC Georges Bank Yellowtail Flounder Diagnostic Benchmark 2014

In the 2013 TRAC Status Report (TSR) the following Special Comments were provided:

> *The TRAC acknowledges that the assumptions made about population dynamics in the model do not fully capture the trends in the data. However, the model's conclusion that stock conditions are poor is valid.*
>
> *There is a continued need to conduct research to limit the possible causes for the retrospective bias exhibited in this assessment.*

In response to these comments, the 2014 benchmark meeting is designed to explore all the data available for Georges Bank yellowtail flounder, including data that cannot easily or feasibly be incorporated in a stock assessment model. The purpose of this exploration is to evaluate possible sources of the poor diagnostics exhibited by the current Virtual Population Analysis (VPA). The work to be reviewed during this 2014 benchmark extends the 2005 benchmark assessment which recommended consideration of "trends in relative abundance and relative mortality rates derived from survey and fishery data" (Gavaris et al. 2005). The 2014 diagnostic benchmark will not examine alternative stock assessment models. Such an examination was conducted during the ICES World Conference on Stock Assessment Methods (July 2013, Boston, MA) where no model was found that performed well relative to all the data. As such, the following terms of reference are strictly limited to exploration of the data.

<u>Terms of Reference</u>

1) Summarize all available data for Georges Bank yellowtail flounder which can be used to explore possible causes of the poor diagnostics in the current VPA for this stock.
2) Determine which pieces of information are consistent with alternative hypotheses regarding current stock status (e.g., current population is near carrying capacity, current population is near a desired amount, and current population is well below a desired amount).
3) If possible, describe how catch advice could be provided based only on the data (e.g. without relying on a stock assessment model).

Date of the benchmark meeting: Week of April 14, 2014.

All individuals interested in presenting a working paper for this meeting must contact the US and Canada Co-Chairs no later than February 10, 2014 to indicate their intention to present and to identify their intended topic. Working papers will be due 2 weeks prior to the meeting, so the deadline to submit working papers will be March 28, 2014. Authors must be present at the meeting or via webex to present their working papers. Failure to adhere to these TRAC protocols will result in the working paper being excluded from the meeting agenda. These protocols are designed to allow sufficient time for meeting participants to review the material and to ask questions of the authors during the meeting.

Gavaris, S., R. O'Boyle, and W. Overholtz. 2005. Proceedings of the Transboundary Resources Assessment Committee (TRAC) Benchmark Review of Stock Assessment Models for the Georges Bank Yellowtail Flounder Stock. TRAC Proceedings 2005/01. 36 p.

16 Gulf of Maine - Georges Bank windowpane flounder

Toni Chute

This assessment of the Gulf of Maine - Georges Bank windowpane flounder (Scophthalmus aquosus) stock is an operational update of the 2015 assessment which was based on survey and fishery data through 2014 (NEFSC 2015). Based on the 2015 assessment the stock was overfished, but overfishing was not ocurring. This assessment updates commercial fishery catch data, survey biomass indices, AIM model results, and reference points through 2016.

State of Stock: Based on this updated assessment, the Gulf of Maine - Georges Bank windowpane flounder (*Scophthalmus aquosus*) stock is overfished but overfishing is not occurring (Figures 78-79). Retrospective adjustments were not made to the model results. The mean NEFSC fall bottom trawl survey index from years 2014, 2015 and 2016 (a 3-year moving average is used as a biomass index) was 0.359 kg/tow which is lower than the $B_{Threshold}$ of 1.030 kg/tow. The 2016 relative fishing mortality was estimated to be 0.222 kt per kg/tow which is lower than the F_{MSY} *proxy* of 0.340 kt per kg/tow.

Table 48: Catch and model results table for Gulf of Maine - Georges Bank windowpane flounder. All landings and discard weights are rounded to the nearest metric ton. Biomass index is in units of kg/tow, and relative F is in units of kt per kg/tow (catch in kt per kg/tow of the survey index).

	2007	2008	2009	2010	2011	2012	2013	2014	2015	2016
Data										
Commercial discards	974	329	412	235	180	198	355	215	187	85
Commercial landings	117	46	28	0	0	1	0	0	0	0
Total catch	1,091	376	440	236	180	199	355	215	188	85
Model Results										
Biomass index	0.524	0.448	0.442	0.467	0.433	0.343	0.518	0.535	0.536	0.36
Relative F	2.079	0.849	0.996	0.514	0.416	0.584	0.676	0.393	0.354	0.222

Table 49: Reference points estimated in the 2015 assessment and in the current assessment update. F_{MSY} *proxy* is in units of kt per kg/tow.

	2015	2017
F_{MSY} *proxy*	0.450	0.340 (0.009 - 0.659)
B_{MSY} *proxy* (kg/tow)	1.554	2.060
MSY proxy (mt)	700	700
Overfishing	No	No
Overfished	Yes	Yes

Special Comments:

- What are the most important sources of uncertainty in this stock assessment? Explain, and describe qualitatively how they affect the assessment results (such as estimates of biomass, F, recruitment, and population projections).

  Even though estimated catch has decreased in recent years, the survey index has not shown any resulting increase despite evidence of regular recruitment from survey length frequencies. Since there has been a 'no possession' rule in place since 2010, almost 100% of catch has consisted of estimated discards. These estimates have a higher CV than those for the southern stock but are still fairly low at a mean of 0.124 since 2010 so it is unlikely discards are being poorly estimated. Removals by Canadian fisheries occur from the northern stock area and are not used as a catch component in the model. Using them, especially if they have changed over time, might improve the model fit, which is not as good as the southern stock.

- Does this assessment model have a retrospective pattern? If so, is the pattern minor, or major? (A major retrospective pattern occurs when the adjusted SSB or F_{Full} lies outside of the approximate joint confidence region for SSB and F_{Full}).

  The AIM (An Index Model) model used to estimate status of this stock does not allow estimation of a retrospective pattern.

- Based on this stock assessment, are population projections well determined or uncertain? If this stock is in a rebuilding plan, how do the projections compare to the rebuilding schedule?

  The GARM benchmark indicated that projections should not be made based on discards, so no projections are run for windowpane flounder. Northern windowpane flounder was supposed to be rebuilt by 2017, however the 2008 GARM report states 'Given that current catch is mostly incidental and also given the high uncertainty of index based assessments, it was concluded that it was not appropriate to calculate F rebuild for this stock'.

- Describe any changes that were made to the current stock assessment, beyond incorporating additional years of data and the effect these changes had on the assessment and stock status.

  No changes were made to the Gulf of Maine - Georges Bank windowpane flounder assessment for this update other than the incorporation of 2015 and 2016 NEFSC fall bottom trawl survey data and 2015 and 2016 U.S. commercial landings and discard data.

- If the stock status has changed a lot since the previous assessment, explain why this occurred.

  The stock status of Gulf of Maine - Georges Bank windowpane flounder has not changed since the previous assessment. In 2015, the F status changed from overfishing to no overfishing.

- Provide qualitative statements describing the condition of the stock that relate to stock status.

  Since the year 2000, Gulf of Maine - Georges Bank windowpane flounder has shown decreasing survey indices despite reductions in catch and relative F levels, and the model output replacement ratio for 2016 was only 0.68. The stock was declared overfished in 2007 (the final year of data for GARM 2008) and was scheduled to be rebuilt by 2017, but the stock still remains below the biomass threshold. According to 21.6, windowpane flounder has low *overall climate vulnerability and both males and females are currently showing high condition indices. There are also new recruits regularly present in the fall bottom trawl survey catches.*

- Indicate what data or studies are currently lacking and which would be needed most to improve this stock assessment in the future.

  While the Gulf of Maine - Georges Bank windowpane flounder AIM model fit is reasonable (the relationship between ln(relative F) and ln(replacement ratio), a measure of the relationship between catch and survey index values, has a p-value of 0.11) there may be catches (such as from the Canadian groundfishery on Georges Bank), discards, or incidental mortality unaccounted for in the model. The fit might be improved in the future by estimating additional sources of mortality or removal from the population that may be increasing over recent years. There may also be value in looking carefully at the windowpane stock definitions to see if there might be reason to change them. For the last several years the NEFSC has been collecting otoliths from northern windowpane during the fall survey and we now have several year's worth of ages, enough to explore an age-based model such as ASAP which could provide insight into the population dynamics of northern windowpane.

- Are there other important issues?

  None.

16.1 Reviewer Comments: Gulf of Maine - Georges Bank windowpane flounder

Assessment Recommendation:

The panel concluded that the operational assessment was acceptable as a scientific basis for management advice.

Alternative Assessment Approach:

Not applicable

Status Recommendation:

Based on this updated assessment, the panel agrees with the conclusion that the Gulf of Maine-Georges Bank windowpane flounder stock is overfished but overfishing is not occurring. Since the year 2000, Gulf of Maine-Georges Bank windowpane flounder has shown decreasing survey indices despite reductions in catch and relative F levels. The stock was declared overfished in 2007 (the final year of data for Groundfish Assessment Review Meeting 2008) and was scheduled to be rebuilt by 2017, but the stock still remains below the biomass threshold. Windowpane flounder has low overall climate vulnerability, the larval index has been stable over many years, and both males and females are currently showing high condition indices. There are also new recruits regularly present in the fall bottom trawl survey catches.

Key Sources of Uncertainty:

Even though estimated catch has decreased in recent years, the survey index has not shown any resulting increase despite evidence of regular recruitment from survey length frequencies. There are uncertainties around discard estimates. Removals by Canadian fisheries occur from the Gulf of Maine-Georges Bank stock area and are not used as a catch component in the model. The model fit is notably poor and is worse than in the 2015 operational assessment.

Research Needs:

The panel recommends research focused on estimating additional sources of mortality or removal from the population that may be increasing over recent years. There may also be value in looking carefully at the windowpane stock definitions to see if there might be reason to change them. For the last several years the National Marine Fisheries Service has been collecting otoliths from Gulf of Maine-Georges Bank windowpane during the fall survey and now has several years' worth of ages, enough to explore a statistical catch-at-age model, which could provide insight into the population dynamics of Gulf of Maine-Georges Bank windowpane.

17 Southern New England - mid-Atlantic windowpane flounder

Toni Chute

This assessment of the southern New England - mid-Atlantic windowpane flounder (Scophthalmus aquosus) stock is an operational update of the 2015 assessment which was based on fishery and survey data through 2014 (NEFSC 2015). Based on the 2015 assessment the stock was not overfished, and overfishing was not ocurring. This assessment updates commercial fishery catch data, survey indices of abundance, AIM model results, and reference points through 2016.

State of Stock: Based on this updated assessment, the southern New England - mid-Atlantic windowpane flounder (*Scophthalmus aquosus*) stock is not overfished and overfishing is not occurring (Figures 82-83). Retrospective adjustments were not made to the model results. The mean NEFSC fall bottom trawl survey index from years 2014, 2015, and 2016 (a 3-year moving average is used as a biomass index) was 0.329 (kg/tow) which is higher than the $B_{Threshold}$ of 0.126 (kg/tow). The 2016 relative fishing mortality was estimated to be 1.733 (kt per kg/tow) which is lower than the F_{MSY} *proxy* of 1.918 (kt per kg/tow).

Table 50: Catch and model results table for southern New England - mid-Atlantic windowpane flounder. All landings and discard weights are rounded to the nearest metric ton. Biomass index is in units of kg/tow, and relative F is in units of kt per kg/tow (catch in kt per kg/tow of the survey index).

	2007	2008	2009	2010	2011	2012	2013	2014	2015	2016
Data										
Commercial discards	266	246	405	435	445	701	681	525	516	557
Commercial landings	83	74	53	53	32	29	22	14	22	13
Catch for Assessment	349	321	458	489	477	730	703	539	539	571
Model Results										
Biomass index	0.191	0.204	0.245	0.345	0.435	0.517	0.464	0.413	0.318	0.329
Relative F	1.83	1.572	1.88	1.419	1.103	1.413	1.507	1.308	1.694	1.733

Table 51: Reference points estimated in the 2012 assessment and in the current assessment update. F_{MSY} *proxy* is in units of kt per kg/tow.

	2015	2017
F_{MSY} *proxy*	2.027	1.918 (0.972 - 2.420)
B_{MSY} *proxy* (kg/tow)	0.247	0.253
MSY proxy (mt)	500	500
Overfishing	No	No
Overfished	No	No

Special Comments:

- What are the most important sources of uncertainty in this stock assessment? Explain, and describe qualitatively how they affect the assessment results (such as estimates of biomass, F, recruitment, and population projections).

  Since there has been a 'no posession' rule in place since 2010, commercial windowpane landings have been essentially zero. As a result, in recent years almost 100% of the catch input to the model has been estimated discards. The CVs for these estimates have been small, however, with a mean of 0.93 since 2010, so it is unlikely discards are being severely overestimated or underestimated or the trend over time has been obscured. Discard estimates from the general category scallop fleet (operating largely in the southern stock area) are not included in the model. Using these estimated discards would add about 3% to the catch, but does not change the results of the model.

- Does this assessment model have a retrospective pattern? If so, is the pattern minor, or major? (A major retrospective pattern occurs when the adjusted SSB or F_{Full} lies outside of the approximate joint confidence region for SSB and F_{Full}).

  The AIM (An Index Model) model used to estimate status of this stock does not allow estimation of a retrospective pattern.

- Based on this stock assessment, are population projections well determined or uncertain? If this stock is in a rebuilding plan, how do the projections compare to the rebuilding schedule?

  The GARM benchmark indicated that projections should not be made based on discards, so no projections are run for windowpane flounder.

- Describe any changes that were made to the current stock assessment, beyond incorporating additional years of data and the affect these changes had on the assessment and stock status.

  No changes were made to the southern New England - mid-Atlantic windowpane flounder assessment for this update other than the incorporation of two years of new NEFSC fall bottom trawl survey data and two years of new U.S. commercial landings and discard data (2015 and 2016).

- If the stock status has changed a lot since the previous assessment, explain why this occurred.

  The stock status of southern New England - mid-Atlantic windowpane flounder has not changed since the previous assessment.

- Provide qualitative statements describing the condition of the stock that relate to stock status.

  Since the year 2000, southern New England - mid-Atlantic windowpane flounder has shown increased survey indices and fairly stable catch and relative F levels. There is some noise in the replacement ratio model output, but the 2016 estimate of 0.92, although lower than desired, exceeds the estimates from the previous three years. The stock was declared overfished in 2005 (although the AIM model was not used) and recovered in 2008, so there is a recent history of the stock falling below reference points for biomass, but also having the ability to recover within a fairly short time period. Overfishing was occurring in 2007 (the final year of data used for the 2008 assessment) but has not occurred in the two most recent assessment updates. According to 21.6, windowpane has low overall climate vulnerability and females are currently showing high condition indices.

- Indicate what data or studies are currently lacking and which would be needed most to improve this stock assessment in the future.

  The AIM model fit is presently good with a randomization test indicating the correlation between ln(relative F) and ln(replacement ratio), a measure of the relationship between catch and survey index values, is significant (p = 0.002) so it is not clear what new information would help acheive better results with the AIM model. There has been some ageing work for southern windowpane done at VIMS which we are currently exploring for use in an age-based model such as ASAP which might provide insight into the population dynamics of southern windowpane.

- Are there other important issues?

  None.

17.1 Reviewer Comments: Southern New England - mid-Atlantic windowpane flounder

Assessment Recommendation:

The panel concluded that the operational assessment was acceptable as a scientific basis for management advice.

Alternative Assessment Approach:

Not applicable

Status Recommendation:

Based on this operational assessment, the panel supports the conclusion that the Southern New England-Mid-Atlantic windowpane flounder stock is not overfished and overfishing is not occurring. Since the year 2000, Southern New England-Mid-Atlantic windowpane flounder has shown increased survey indices, fairly stable catch and relative F levels. The stock was declared overfished in 2005 and recovered in 2008, so there is a recent history of the stock falling below reference points for biomass, but also having the ability to recover within a fairly short time period. Overfishing was occurring in 2007 (the final year of data used for the 2008 assessment) but has not occurred in the two most recent assessment updates. Southern New England-Mid-Atlantic windowpane has low overall climate vulnerability and are currently showing high condition indices (only females were analyzed).

Key Sources of Uncertainty:

There is some noise in the replacement ratio model output, but the 2016 estimate exceeds the estimates from the previous three years and is close to 1. Discard estimates from the general category scallop fleet (operating largely in the Southern New England-Mid-Atlantic stock area) are not included in the model. Using these estimated discards would add about 3% to the catch, but does not change the overall results of the model.

Research Needs:

The panel recommends considering incorporation of the ageing work for Southern New England-Mid-Atlantic windowpane done by the Virginia Institute of Marine Science (Northeast Area Monitoring and Assessment Program - NEAMAP) for use in an age-based model. This might provide further insight into the population dynamics of Southern New England-Mid-Atlantic windowpane.

National Oceanic and Atmospheric Administration
National Marine Fisheries Service
Southwest Fisheries Science Center

The National Oceanic and Atmospheric Administration (NOAA), organized in 1970, has evolved into an agency that establishes national policies and manages and conserves our oceanic, coastal, and atmospheric resources. An organizational element within NOAA, the Office of Fisheries, is responsible for fisheries policy and the direction of the National Marine Fisheries Service (NMFS).

In addition to its formal publications, NMFS uses the NOAA Technical Memorandum series to issue informal scientific and technical publications when complete formal review and editorial processing are not appropriate or feasible. Documents within this series, however, reflect sound professional work and may be referenced in the formal scientific and technical literature.

SWFSC Technical Memorandums are accessible online at the SWFSC web site (http//swfsc.noaa.gov). Print copies are available from the National Technical Information Service, 5285 Port Royal Road, Springfield, VA 22151 (http://www.ntis.gov).

PREFACE

The Pacific sardine resource is assessed each year in support of the Pacific Fishery Management Council (PFMC) process of stipulating annual harvest specifications for the U.S. fishery. This report serves as a full stock assessment for purposes of advising management for the 2017-18 fishing year. Presently, the assessment/management schedule for Pacific sardine is based on a full assessment conducted every three years, with an update assessment conducted in the interim years. A full stock assessment was conducted in 2014 (Hill et al. 2014; STAR 2014) and update assessments were completed in 2015 and 2016 (Hill et al. 2015, 2016).

Two assessment approaches are presented here, including a survey-based assessment (preferred by the stock assessment team, STAT) and a model-based assessment (alternative, model ALT). The report includes three primary sections: first, a timeline with background information concerning fishery operations and management associated with the Pacific sardine resource (Introduction); second, summaries for various sources of sample data used in the assessments (Data); and third, methods/models used to conduct the assessments (Assessment). The Assessment section includes two parts based on the assessment approach (survey and model). In this context, readers should first consult the section 'Assessment – Acoustic-trawl Survey, Overview,' which serves as the basis of the report, i.e., preferences and justifications regarding the STAT's choice of assessment approach. The two assessment approaches were evaluated at the formal stock assessment review (STAR) in February 2017. Readers should refer to STAR (2017) for details regarding merits and drawbacks of the assessments highlighted during the review, and final decisions from the Panel concerning both short- and long-term recommendations for adopting an assessment approach for advising management in the future. That is, while the survey-based assessment was viewed as the better long-term approach by both the STAT and STAR Panel, the Panel identified a notable shortcoming of the survey-based assessment in the short-term, given the need to forecast stock biomass one full year after the last survey observation. Both the STAT and STAR Panel agreed that the preferred survey-based assessment could be effectively implemented by shifting the fishery start date a few to several months to minimize the time lag between the most recent survey and the official start date of the fishery, e.g., moving the start of the fishery from July 1st to January 1st would accomplish this goal. To summarize, model ALT presently represents the recommended assessment approach to adopt for the upcoming fishing year (2017-18), with a survey-based assessment that accommodates a more workable projection period recommended for subsequent fishing years.

Finally, field, laboratory, and analytical work conducted in support of the ongoing Pacific sardine assessment is the responsibility of the SWFSC and its staff, including: principal investigators (K. T. Hill, P. R. Crone, J. P. Zwolinski); and collaborators (D.A. Demer, E. Dorval, B. J. Macewicz, D. Griffith, and Y. Gu). Principal investigators are responsible for developing assessments, presenting relevant background information, and addressing the merits/drawbacks of the two assessment approaches in the context of meeting the management goal (current estimate of stock biomass each year), which is needed for implementing an established harvest control rule policy for Pacific sardine. An inclusive list of individuals and institutions that have provided information for carrying out the Pacific sardine assessment is presented in Acknowledgements below.

EXECUTIVE SUMMARY

The following Pacific sardine assessment was conducted to inform U.S. fishery management for the cycle that begins July 1, 2017 and ends June 30, 2018. Two assessment approaches were reviewed at the STAR Panel in February 2017: an AT survey-based approach (preferred by the STAT); and a model-based assessment (model ALT). Given forecasting issues highlighted in the review (see STAR 2017 and 'Unresolved Problems and Major Uncertainties' below), the Panel ultimately recommended that management advice be based on model ALT for the 2017-18 fishing year. Model ALT represents the final base model from the February 2017 STAR (Hill et al. 2017, STAR 2017).

Stock

This assessment focuses on the northern subpopulation of Pacific sardine (NSP) that ranges from northern Baja California, México to British Columbia, Canada and extends up to 300 nm offshore. In all past assessments, the default approach has been to assume that all catches landed in ports from Ensenada (ENS) to British Columbia (BC) were from the northern subpopulation. There is now general scientific consensus that catches landed in the Southern California Bight (SCB, i.e., Ensenada and southern California) likely represent a mixture of the southern subpopulation (warm months) and northern subpopulation (cool months) (Felix-Uraga et al. 2004, 2005; Garcia-Morales 2012; Zwolinski et al. 2011; Demer and Zwolinski 2014). Although the ranges of the northern and southern subpopulations can overlap within the SCB, the adult spawning stocks likely move north and south in synchrony each year and do not occupy the same space simultaneously to any significant extent (Garcia-Morales 2012). Satellite oceanography data (Demer and Zwolinski 2014) were used to partition catch data from Ensenada (ENS) and southern California (SCA) ports to exclude both landings and biological compositions attributed to the southern subpopulation.

Catches

The assessment includes sardine landings (mt) from six major fishing regions: Ensenada (ENS), southern California (SCA), central California (CCA), Oregon (OR), Washington (WA), and British Columbia (BC). Landings for each port and for the NSP over the modeled years/seasons follow:

Calendar Yr-Sem	Model Yr-Seas	ENS Total	ENS NSP	SCA Total	SCA NSP	CCA	OR	WA	BC

Data and Assessment

The integrated assessment model was developed using Stock Synthesis (SS version 3.24aa), and includes fishery and survey data collected from mid-2005 through 2016. The model is based on a July-June biological year (aka 'model year'), with two semester-based seasons per year (S1=Jul-Dec and S2=Jan-Jun). Catches and biological samples for the fisheries off ENS, SCA, and CCA were pooled into a single MEXCAL fleet (fishery), for which selectivity was modeled separately in each season (S1 and S2). Catches and biological samples from OR, WA, and BC were modeled by season as a single PNW fleet (fishery). A single AT survey index of abundance from ongoing SWFSC surveys (2006-2016) was included in the model.

Model ALT incorporates the following specifications:

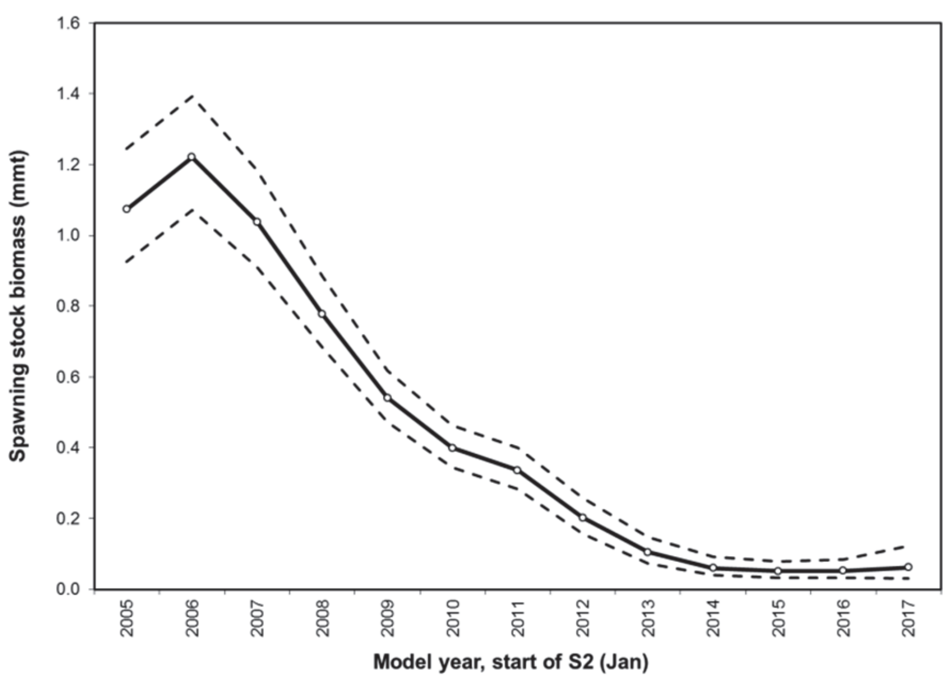
- NSP catches for the MEXCAL fleet computed using an environmental-based optimal habitat index;
- two seasons (semesters, Jul-Dec=S1 and Jan-Jun=S2) for each model year (2005-16);
- sexes were combined;
- maximum age=10, with nine age bins (ages 0-8+);
- two fleets (MEXCAL and PNW), with an annual selectivity pattern for the PNW fleet and seasonal selectivity patterns (S1 and S2) for the MEXCAL fleet;
    - MEXCAL fleet: dome-shaped, age-based selectivity (one parameter per age)
    - PNW fleet: asymptotic, age-based selectivity;
    - age compositions with effective sample sizes calculated by dividing the number of fish sampled by 25 (externally);

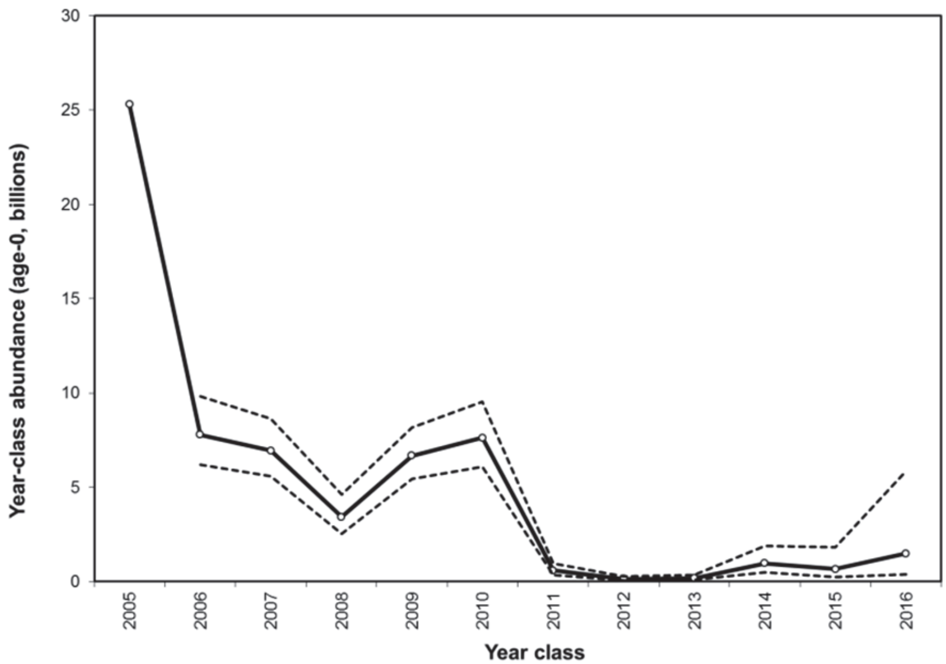
- Beverton-Holt stock-recruitment relationship, with virgin recruitment (R_0), steepness (*h*), and initial equilibrium recruitment offset (R_1) estimated, and average recruitment variability fixed (σ_R=0.75);
- *M* was fixed (0.6 yr^{-1});
- recruitment deviations estimated from 2005-15;
- initial fishing mortality (*F*) was estimated for the MEXCAL_S1 fishery and fixed=0 for MEXCAL_S2 and PNW fisheries;
- single AT survey index of abundance (2006-2013) that includes seasonal (spring and summer) observations in some years, and catchability (*Q*) estimated;
    - o age compositions with effective sample sizes set (externally) to 1 per trawl cluster;
    - o selectivity was assumed to be uniform (fully selected) for age 1+ and zero for age 0; and
- no additional data weighting via variance adjustment factors or lambdas was implemented.

Spawning Stock Biomass and Recruitment

Time series of estimated spawning stock biomass (SSB, mmt) and associated 95% confidence intervals are displayed in the figure and table below. The virgin level of SSB was estimated to be 107,915 mt (0.11 mmt). The SSB has continually declined since 2005-06, reaching historically low levels in recent years (2014-present). The SSB was projected to be 61,684 mt (CV=36%) in January 2018.

Time series of estimated recruitment (age-0, billions) abundance is presented in the figure and table below. The virgin level of recruitment (R_0) was estimated to be 1.52 billion age-0 fish. As indicated for SSB above, recruitment has largely declined since 2005-06, with the exception of a brief period of modest recruitment success from 2009-10. In particular, the 2011-15 year classes have been among the weakest in recent history. A small increase in recruitment was observed in 2016, albeit a highly variable estimate (CV=79%) based on limited data.





Calendar Yr-Sem	Model Yr-Seas	SSB (mt)	SSB Std Dev	Year class abundance (1000s)	Recruits Std Dev

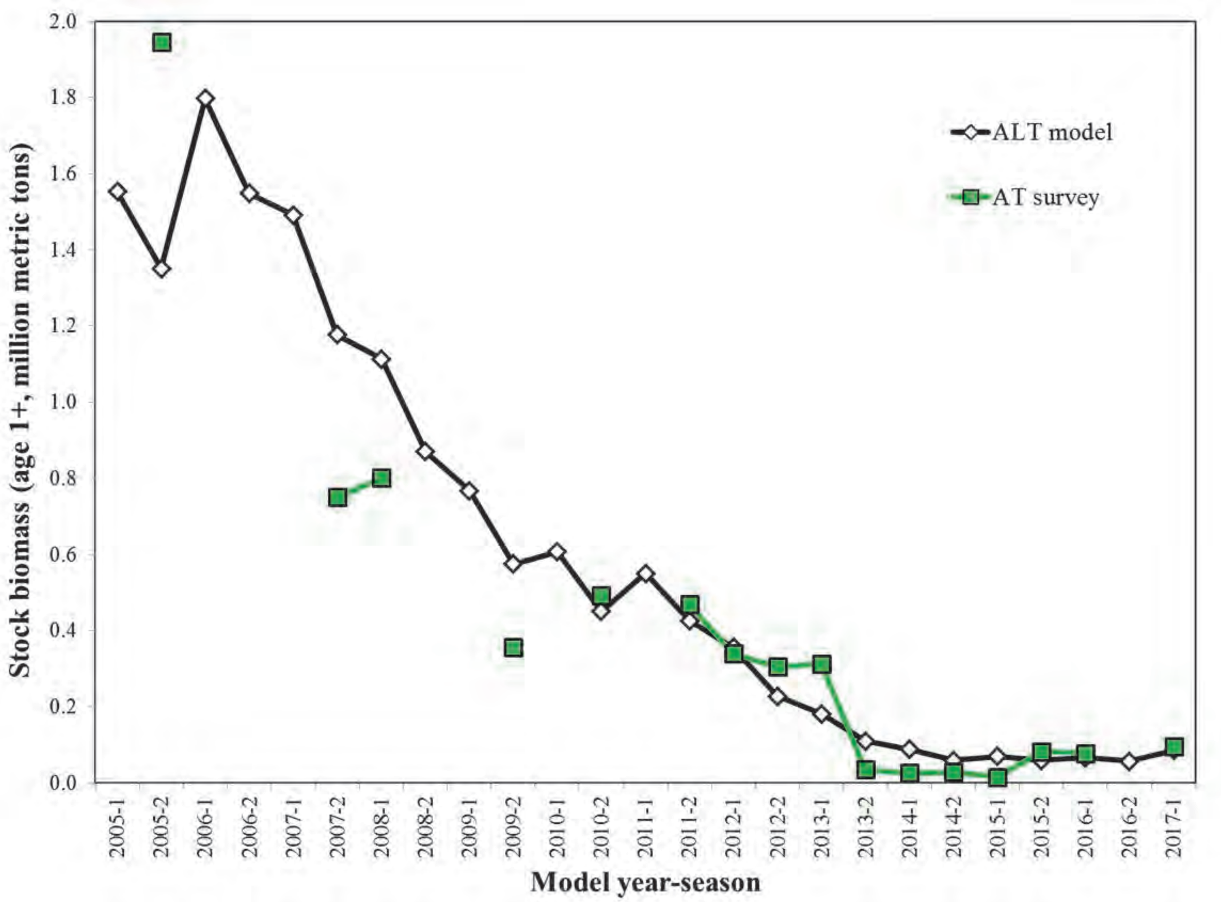
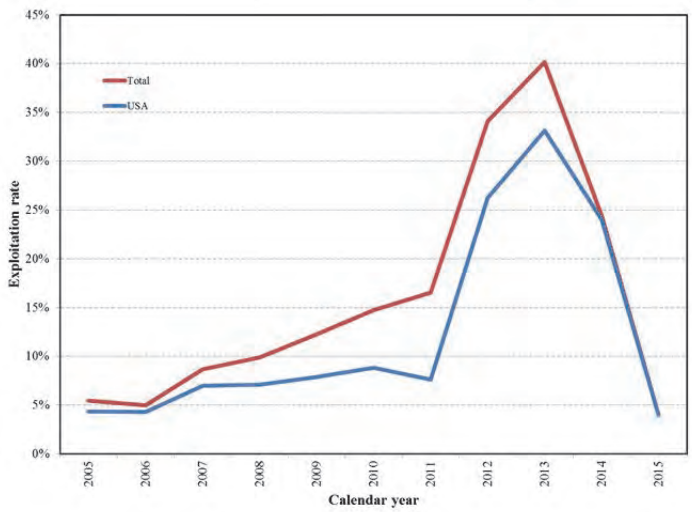
Stock Biomass for PFMC Management in 2017-18

Stock biomass, used for calculating annual harvest specifications, is defined as the sum of the biomass for sardine ages one and older (age 1+) at the start of the management year. Time series of estimated stock biomass (mmt) from model ALT and the AT survey are presented in the figure below. As discussed above for both SSB and recruitment, a similar trend of declining stock biomass has been observed since 2005-06, peaking at 1.8 mmt in 2006, and plateauing at recent historical low levels since 2014. Model ALT stock biomass is projected to be **86,586 mt in July 2017**.



Exploitation Status

Exploitation rate is defined as the calendar year NSP catch divided by the total mid-year biomass (July-1, ages 0+). Based on model ALT estimates, the U.S. exploitation rate has averaged about 11% since 2005, peaking at 33% in 2013. The U.S. and total exploitation rates were <1% in 2016. The U.S. and total exploitation rates for the NSP, calculated from model ALT, are presented in the figure and table below.



Calendar Year	USA	Total
2005	4.4%	5.4%
2006	4.3%	5.0%
2007	7.0%	8.7%
2008	7.1%	9.9%
2009	7.9%	12.2%
2010	8.8%	14.7%
2011	7.6%	16.5%
2012	26.2%	34.1%
2013	33.1%	40.1%
2014	24.0%	24.4%
2015	4.0%	4.0%
2016	0.4%	0.4%

Ecosystem Considerations

Pacific sardine represent an important forage base in the California Current Ecosystem (CCE). At times of high abundance, Pacific sardine can compose a substantial portion of biomass in the CCE. However, periods of low recruitment success driven by prevailing oceanographic conditions can lead to low population abundance over extended periods of time. Readers should consult PFMC (1998), PFMC (2014), and NMFS (2016a,b) for comprehensive information regarding environmental processes generally hypothesized to influence small pelagic species that inhabit the CCE.

Harvest Control Rules

Harvest guideline

The annual harvest guideline (HG) is calculated as follows:

HG = (BIOMASS – CUTOFF) • FRACTION • DISTRIBUTION;

where HG is the total U.S. directed harvest for the period July 2017 to June 2018, BIOMASS is the stock biomass (ages 1+, mt) projected as of July 1, 2017, CUTOFF (150,000 mt) is the lowest level of biomass for which directed harvest is allowed, FRACTION (E_{MSY} bounded 0.05-0.20) is the percentage of biomass above the CUTOFF that can be harvested, and DISTRIBUTION (87%) is the average portion of BIOMASS assumed in U.S. waters. Based on results from model ALT, estimated stock biomass is projected to be below the 150,000 mt threshold and thus, the HG for 2017-18 would be 0 mt.

OFL and ABC

On March 11, 2014, the PFMC adopted the use of CalCOFI sea-surface temperature (SST) data for specifying environmentally-dependent E_{MSY} each year. The E_{MSY} is calculated as,

$$E_{\mathrm{MSY}} = -18.46452+3.25209(T)-0.19723(T^2)+0.0041863(T^3),$$

where T is the three-year running average of CalCOFI SST, and E_{MSY} for OFL and ABC is bounded between 0 to 0.25. Based on the recent warmer conditions in the CCE, the average temperature for 2014-16 increased to 15.9999 °C, resulting in E_{MSY}=0.2251.

Harvest estimates for model ALT are presented in the following table. Estimated stock biomass in July 2017 was **86,586 mt**. The overfishing limit (OFL, 2017-18) associated with that biomass was **16,957 mt**.

Acceptable biological catches (ABC, 2017-18) for a range of *P-star* values (Tier 1 σ=0.36; Tier 2 σ=0.72) associated with model ALT are presented in the following table.

Harvest control rules for the model-based assessment (model ALT):

Harvest Control Rule Formulas									
OFL = BIOMASS * E_{MSY} * DISTRIBUTION; where E_{MSY} is bounded 0.00 to 0.25									
$ABC_{P\text{-}star}$ = BIOMASS * $BUFFER_{P\text{-}star}$ * E_{MSY} * DISTRIBUTION; where E_{MSY} is bounded 0.00 to 0.25									
HG = (BIOMASS - CUTOFF) * FRACTION * DISTRIBUTION; where FRACTION is E_{MSY} bounded 0.05 to 0.20									
Harvest Formula Parameters									
BIOMASS (ages 1+, mt)	86,586

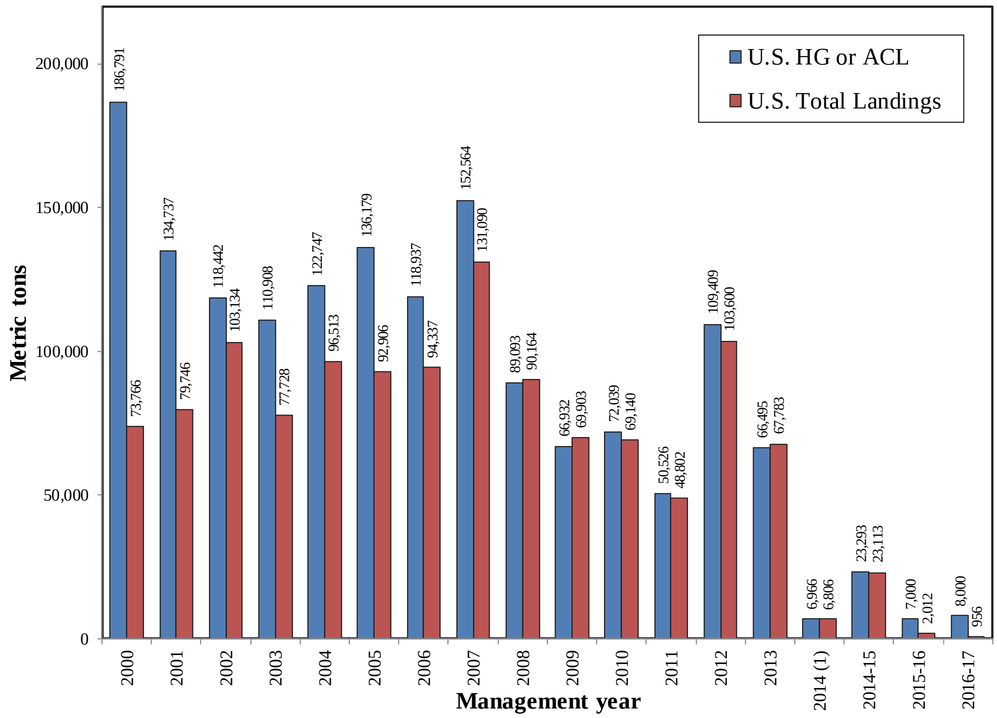
Management Performance

The U.S. HG/ACL values and catches since the onset of federal management are presented in the figure below.



Unresolved Problems and Major Uncertainties

As indicated in the Preface above, the survey-based assessment remains the STAT's preferred approach for advising management regarding Pacific sardine abundance in the future. However, the STAR Panel identified a notable shortcoming of the survey-based assessment that would need to be addressed before adopting this approach for purposes of advising management in the future. Specifically, the issue is related to a need to forecast stock biomass one full year after the last survey observation, i.e., a time lag exists between obtaining the final estimate of stock biomass from the summer AT survey and the start date of the fishery the following year. In particular, it is inherently difficult to reliably estimate the strength of the most recent cohort (age-0 fish) from the previous summer that would be expected to contribute substantially to the age-1+ biomass the following year (e.g., projecting the 2016 year-class size/biomass into July 2017). It is important to note, recent recruitment strength will continue to represent a considerable area of uncertainty, regardless of species or assessment approach (i.e., survey- or model-based), particularly, for coastal pelagic species (e.g., sardine and anchovy) that exhibit highly variable recruitment success in any given year given their high rates of natural mortality. Both the STAT and STAR Panel agreed that uncertainty associated with the forecast needed in the survey-based assessment would be effectively minimized by simply shifting the fishery start date to reduce the time lag between the most recent survey and start date for the fishery (e.g., from July 1st to January 1st).

The STAR Panel ultimately recommended using results from model ALT for sardine management in 2017-18. The Panel identified a number of areas of uncertainty in model ALT, including: 1) best treatment of empirical weight-at-age data from the fisheries and AT survey; 2) treatment of population weight-at-age (time varying vs. time-invariant); 3) use of time-invariant age-length keys to convert AT length compositions to age compositions; 4) selectivity parameterization for the AT survey; 5) lack of empirical justification for increasing natural mortality from 0.4 to 0.6 yr^{-1}; and 6) ongoing concerns about acoustic species identification, target strength estimation, and boundary zone (sea floor, surface, and shore) observations associated with the AT survey (readers should consult sections 3 and 5 in STAR (2017) for further details).

Research and Data Needs

Research and data for improving stock assessments of the Pacific sardine resource in the future address three major areas of need, including AT survey operations, biological data sampling from fisheries, and laboratory-based biology studies (see Research and Data Needs below for further discussion regarding areas of improvement).

INTRODUCTION

Distribution, Migration, Stock Structure, Management Units

Information regarding Pacific sardine (*Sardinops sagax caerulea*) biology and population dynamics is available in Clark and Marr (1955), Ahlstrom (1960), Murphy (1966), MacCall (1979), Leet et al. (2001), as well as references cited below.

The Pacific sardine has at times been the most abundant fish species in the California Current Ecosystem (CCE). When the population is large, it is abundant from the tip of Baja California (23^{o}N latitude) to southeastern Alaska (57^{o}N latitude) and throughout the Gulf of California. Occurrence tends to be seasonal in the northern extent of its range. When abundance was low during the 1960-70s, sardines did not generally occur in significant quantities north of Baja California.

There is a longstanding consensus in the scientific community that sardines off the west coast of North America represent three subpopulations (see review by Smith 2005). A northern subpopulation ('NSP'; northern Baja California to Alaska; Figure 1), a southern subpopulation ('SSP'; outer coastal Baja California to southern California), and a Gulf of California subpopulation were distinguished on the basis of serological techniques (Vrooman 1964) and in studies of oceanography as pertaining to temperature-at-capture (Felix-Uraga et al., 2004, 2005; Garcia-Morales et al. 2012; Demer and Zwolinski 2014). An electrophoretic study (Hedgecock et al. 1989) showed, however, no genetic variation among sardines from central and southern California, the Pacific coast of Baja California, or the Gulf of California. Although the ranges of the northern and southern subpopulations can overlap within the Southern California Bight, the adult spawning stocks likely move north and south in synchrony and do not occupy the same space simultaneously to a significant extent (Garcia-Morales 2012). The northern subpopulation (NSP) is exploited by fisheries off Canada, the U.S., and northern Baja California (Figure 1), and represents the stock included in the CPS Fishery Management Plan (CPS-FMP; PFMC 1998). The 2014 assessment (Hill et al. 2014) addressed the above stock structure hypotheses in a more explicit manner, by partitioning southern (ENS and SCA ports) fishery catches and composition data using an environment-based approach described by Demer and Zwolinski (2014) and in the following sections. The same subpopulation hypothesis is carried forward in the following assessment.

Pacific sardine migrate extensively when abundance is high, moving as far north as British Columbia in the summer and returning to southern California and northern Baja California in the fall. Early tagging studies indicated that the older and larger fish moved farther north (Janssen 1938; Clark & Janssen 1945). Movement patterns were probably complex, and the timing and extent of movement were affected by oceanographic conditions (Hart 1973) and stock biomass levels. During the 1950s to 1970s, a period of reduced stock size and unfavorably cold sea-surface temperatures together likely caused the stock to abandon the northern portion of its range. In recent decades, the combination of increased stock size and warmer sea-surface temperatures resulted in the stock re-occupying areas off Central California, Oregon, Washington, and British Columbia, as well as distant offshore waters off California. During a cooperative U.S.-U.S.S.R. research cruise for jack mackerel in 1991, several tons of sardine were collected 300 nm west of the Southern California Bight (SCB) (Macewicz and Abramenkoff 1993). Resumption of seasonal movement between the southern spawning habitat and the northern feeding habitat has been inferred by presence/absence of size classes in focused regional surveys (Lo et al. 2011) and measured directly using the acoustic-trawl method (Demer et al. 2012).

Life History Features Affecting Management

Pacific sardines may reach 41 cm in length (Eschmeyer et al. 1983), but are seldom longer than 30 cm in fishery catches and survey samples. The heaviest sardine on record weighed 0.323 kg. Oldest recorded age of sardine is 15 years, but fish in California commercial catches are usually younger than five years and fish in the PNW are less than 10 years old. Sardine are typically larger and two to three years older in regions off the Pacific Northwest than observed further south in waters off California. There is evidence for regional variation in size-at-age, with size increasing from south to north and from inshore to offshore (Phillips 1948, Hill 1999). McDaniel et al. (2016) analyzed recent fishery and survey data and found evidence for age-based (as opposed to size-based) movement from inshore to offshore and from south to north.

Historically, sardines fully recruited to the fishery when they were ages three and older (MacCall 1979). Recent fishery data indicate that sardines begin to recruit to the SCA fishery at age zero during the late winter-early spring. Age-dependent availability to the fishery depends upon the location of the fishery, with young fish unlikely to be fully available to fisheries located in the north and older fish less likely to be fully available to fisheries south of Point Conception.

Sardines spawn in loosely aggregated schools in the upper 50 meters of the water column. Sardines are oviparous, multiple-batch spawners, with annual fecundity that is indeterminate, and age- or size-dependent (Macewicz et al. 1996). Spawning of the northern subpopulation typically begins in January off northern Baja California and ends by August off the Pacific Northwest (Oregon, Washington, and Vancouver Island), typically peaking off California in April. Sardine eggs are most abundant at sea-surface temperatures of 13 to 15 ^{o}C, and larvae are most abundant at 13 to 16 ^{o}C. The spatial and seasonal distribution of spawning is influenced by temperature. During warm ocean conditions, the center of sardine spawning shifts northward and spawning extends over a longer period of time (Butler 1987; Ahlstrom 1960; Dorval et al. 2016, 2017). Spawning is typically concentrated in the region offshore and north of Point Conception (Lo et al. 1996, 2005) to areas off San Francisco. However, during April 2015 and 2016 spawning was observed in areas north of Cape Mendocino to central Oregon (Dorval et al. 2016; Dorval et al. 2017 in Appendix A).

Ecosystem Considerations

Pacific sardine represent an important forage base in the California Current Ecosystem (CCE). At times of high abundance, Pacific sardine can compose a substantial portion of biomass in the CCE. However, periods of low recruitment success driven by prevailing oceanographic conditions can lead to low population abundance over extended periods of time. Readers should consult PFMC (1998), PFMC (2014), and NMFS (2016a,b) for comprehensive information regarding environmental processes generally hypothesized to influence small pelagic species that inhabit the CCE.

Abundance, Recruitment, and Population Dynamics

Extreme natural variability is characteristic of clupeid stocks, such as Pacific sardine (Cushing 1971). Estimates of sardine abundance from as early as 300 AD through 1970 have been reconstructed from the deposition of fish scales in sediment cores from the Santa Barbara basin off SCA (Soutar and Issacs 1969, 1974; Baumgartner et al. 1992; McClatchie et al. 2017). Sardine populations existed throughout the period, with abundance varying widely on decadal time scales. Both sardine and anchovy populations tend to vary over periods of roughly 60 years, although sardines have varied more than anchovies. Declines in sardine populations have generally lasted an average of 36 years and recoveries an average of 30 years.

Pacific sardine spawning biomass (age 2+), estimated from virtual population analysis methods, averaged 3.5 mmt from 1932 through 1934, fluctuated from 1.2 to 2.8 mmt over the next ten years, then declined steeply from 1945 to 1965, with some short-term reversals following periods of strong recruitment success (Murphy 1966; MacCall 1979). During the 1960s and 1970s, spawning biomass levels were as low as 10,000 mt (Barnes et al. 1992). The sardine stock began to increase by an average annual rate of 27% in the early 1980s (Barnes et al. 1992).

As exhibited by many members of the small pelagic fish assemblage of the CCE, Pacific sardine recruitment is highly variable, with large fluctuations observed over short timeframes. Analyses of the sardine stock-recruitment relationship have resulted in inconsistent findings, with some studies showing a strong density-dependent relationship (production of young sardine declines at high levels of spawning biomass) and others, concluding no relationship (Clark and Marr 1955; Murphy 1966; MacCall 1979). Jacobson and MacCall (1995) found both density-dependent and environmental factors to be important, as was also agreed during a sardine harvest control rule workshop held in 2013 (PFMC 2013). The current U.S. harvest control rules for sardine couple prevailing SST to exploitation rate (see *Harvest Control Rules* section).

Relevant History of the Fishery and Important Features of the Current Fishery

The sardine fishery was first developed in response to demand for food during World War I. Landings increased rapidly from 1916 to 1936, peaking at over 700,000 mt. Pacific sardine supported the largest fishery in the western hemisphere during the 1930s and 1940s, with landings in Mexico to Canada. The population and fishery soon declined, beginning in the late 1940s and with some short-term reversals, to extremely low levels in the 1970s. There was a southward shift in catch as the fishery collapsed, with landings ceasing in the Pacific Northwest in 1947 through 1948 and in San Francisco, from 1951 through 1952. The San Pedro fishery closed in the mid-1960s. Sardines were primarily reduced to fish meal, oil, and canned food, with small quantities used for bait.

In the early 1980s, sardines were taken incidentally with Pacific and jack mackerel in the SCA mackerel fishery. As sardine continued to increase in abundance, a directed purse-seine fishery was re-established. The incidental fishery for sardines ceased in 1991 when the directed fishery was offered higher quotas. The renewed fishery initiated in ENS and SCA, expanded to CCA, and by the early 2000s, substantial quantities of Pacific sardine were landed at OR, WA, and BC. Volumes have reduced dramatically in the past several years. Harvest by the Mexican (ENS) fishery is not currently regulated by quotas, but there is a minimum legal size limit of 150 mm SL. The Canadian fishery failed to capture sardine in summer 2013, and has been under a moratorium since summer 2015. The U.S. directed fishery has been subject to a moratorium since July 1, 2015.

Recent Management Performance

Management authority for the U.S. Pacific sardine fishery was transferred to the PFMC in January 2000. The Pacific sardine was one of five species included in the federal CPS-FMP (PFMC 1998). The CPS-FMP includes harvest control rules intended to prevent Pacific sardines from being overfished and to maintain relatively high and consistent, long-term catch levels. Harvest control rules for Pacific sardine are described at the end of this report. A thorough description of PFMC management actions for sardines, including HG values, may be found in the most recent CPS SAFE document (PFMC 2014). U.S. harvest specifications and landings since 2000 are displayed in Table 1 and Figure 2. Harvests in major fishing regions from ENS to BC are provided in Table 2 and Figure 3.

ASSESSMENT DATA

Biological Parameters

Stock structure
We presume to model the NSP that, at times, ranges from northern Baja California, México to British Columbia, Canada. As mentioned above, there is general consensus that catches landed in ENS and SCA likely represent a mixture of SSP (during warm months) and NSP (cool months) (Felix-Uraga et al. 2004, 2005; Garcia-Morales 2012; Zwolinski et al. 2011; Demer and Zwolinski 2014) (Figure 1). The approach involves analyzing satellite oceanographic data to objectively partition monthly catches and biological compositions from ENS and SCA ports to exclude data from the SSP (Demer and Zwolinski 2014). This approach was adopted in the 2014 full assessment (Hill et al. 2014; STAR 2014), in the 2015 and 2016 update assessments (Hill et al. 2015, 2016), and is carried forward in the following assessment.

Growth
Analysis of size-at-age from fishery samples (1993-2013) provided no indication of sexual dimorphism related to growth (Figure 4; Hill et al. 2014), so combined sexes were included in the present assessment model with a sex ratio of 50:50.

Past Pacific sardine stock assessments conducted with the CANSAR and ASAP statistical catch-at-age frameworks accounted for growth using empirical weight-at-age time series as fixed model inputs (e.g. Hill et al. 1999; Hill et al. 2006). Stock synthesis models used for management from 2007 through 2016 estimated growth internally using conditional age-at-length compositions and a fixed length-weight relationship (e.g., Hill et al. 2016). Disadvantages to estimating growth internally within the stock assessment include: 1) inability to account for regional differences in age-at-size due to age-based movements (McDaniel et al. 2016); 2) difficulty in modeling cohort-specific growth patterns; 3) potential model interactions between growth estimation and selectivity; and 4) models using conditional age-at-length data are data-heavy, requiring more estimable model parameters than the empirical weight-at-age approach. For these reasons, the model ALT was constructed to bypass growth estimation internally in SS, instead opting for a return to the use of empirical weights-at-age.

Empirical weight-at-age data were included as fixed inputs in model ALT. Fleet- and survey-specific empirical weight-at-age estimates were compiled for each model year and semester. Fishery mean weight-at-age estimates were calculated for seasons with greater than two samples available. Growth patterns were examined by cohort and were smoothed as needed. Specifically, fish of the same cohort were not allowed to shrink in subsequent time steps, and negative deviations were substituted by interpolation. Likewise, missing values were substituted through interpolation. Further details regarding empirical weight-at-age time series for the AT survey are provided in the section 'Fishery-Independent Data \ Acoustic-trawl survey'. All fishery and AT survey weight-at-age vectors are displayed in Figures 5-7. During the STAR Panel (Feb 2017), it was discovered that PNW weight-at-age had not been smoothed by cohort as described above, but instead were input as nominal estimates of weight-at-age. A sensitivity run based on cohort-smoothed PNW data resulted in a negligible impact (<1%) on population estimates, i.e., revised weight-at-age matrix was not included in the final model ALT.

Empirical weight-at-age models require population weight-at-age vectors to convert population number-at-age to biomass-at-age. Model ALT population weight-at-age vectors were derived from the last assessment model (T_2016) after it had been updated with newly available maturity, catch, and survey data (T_2017). Model T_2017 was run once to derive estimates of population weight-at-age at the beginning and middle of each semester. A fecundity*maturity-at-age vector, used to calculate SSB-at-age, was also derived from model T_2017 (see 'Maturity' below). Population- and SSB-at-age vectors are displayed in Figure 8.

Maturity

Maturity was modeled using a fixed vector of fecundity*maturity by age (Figure 8). The vector was derived from the 2016 assessment model after it was updated with newly available information (T_2017). In addition to other data sources, model T_2017 was updated with new parameters for the logistic maturity-at-length function using female sardine sampled from survey trawls conducted from 1994 to 2016 (n=4,561). Reproductive state was primarily established through histological examination, although some immature individuals were simply identified through gross visual inspection. Parameters for the logistic maturity function were estimated using,

$$\text{Maturity} = 1/(1+\exp(slope*L-L_{\text{inflexion}}));$$

where slope = -0.9051 and inflexion = 16.06 cm-SL. Maturity-at-length parameters were fixed in the updated assessment model (T_2017) and fecundity was fixed at 1 egg/gram body weight. Once model T_2017 was run, the fecundity*maturity-at-age vector was extracted for use in the current alternative assessment model (ALT) (Figure 8).

Natural mortality

Age-specific mortality estimates are available for the entire suite of life history stages (Butler et al. 1993). Mortality is high at the egg and yolk sac larvae stages (instantaneous rates in excess of 0.66 d^{-1}). The adult natural mortality rate has been estimated to be M=0.4-0.8 yr^{-1} (Murphy 1966; MacCall 1979) and 0.51 yr^{-1} (Clark and Marr 1955). Zwolinski and Demer (2013) studied natural mortality using trends in abundance from the acoustic-trawl method (ATM) surveys (2006-2011), accounting for fishery removals, and estimated M=0.52 yr^{-1}.

Murphy's (1966) virtual population analysis of the Pacific sardine used M=0.4 yr^{-1} to fit data from the 1930s and 1940s, but M was doubled to 0.8 yr^{-1} from 1950 to 1960 to better fit the trend in CalCOFI egg and larval data (Murphy 1966). Early natural mortality estimates may not be as applicable to the present population, given the significant increase in predator populations since the historic era (Vetter and McClatchie, *in review*). To date, Pacific sardine stock assessments for PFMC management have used M=0.4 yr^{-1}. For reasons explained subsequently, the present alternative assessment (model ALT) was conducted using M=0.6 yr^{-1}. An instantaneous M rate of 0.6 yr^{-1} translates to an annual M rate of 45% of the adult sardine stock dying each year from natural causes. Sensitivities to assumptions regarding M are further explored in this assessment.

Fishery-dependent Data

Overview

Available fishery data include commercial landings and biological samples from six regional fisheries: Ensenada (ENS); Southern California (SCA); Central California (CCA); Oregon (OR); Washington (WA); and British Columbia (BC). Standard biological samples include individual weight (kg), standard length (cm), sex, maturity, and otoliths for age determination (not in all cases). A complete list of available port sample data by fishing region, model year, and season is provided in Table 3.

All fishery catches and compositions were compiled based on the sardine's biological year ('model year') to match the July 1st birth-date assumption used in age assignments. Each model year is labeled with the first of two calendar years spanned (e.g., model year '2005' includes data from July 1, 2005 through June 30, 2006). Further, each model year has two six-month seasons, including 'S1'=Jul-Dec and 'S2'=Jan-Jun. Major fishery regions were pooled to represent a southern 'MEXCAL' fleet (ENS+SCA+CCA) and a northern 'PNW' fleet (OR+WA+BC). The MEXCAL fleet was treated with semester-based selectivities ('MEXCAL_S1' and 'MEXCAL_S2'). Rationale for this fleet design is provided in Hill et al. (2011).

Landings

Ensenada monthly landings from 1993-02 were compiled using the 'Boletín Anual' series previously produced by INAPESCA's Ensenada office (e.g., Garcia and Sánchez 2003). Monthly landings from 2003-14 were taken from CONAPESCA's web archive of Mexican fishery yearbook statistics (CONAPESCA 2015). The ENS monthly landings for 2015-16 were provided by INAPESCA-Ensenada (Concepción Enciso-Enciso, pers. comm.).

California (SCA and CCA) directed commercial landings were obtained from the PacFIN database (2005-2015) and CDFW's 'Wetfish Tables' (2016). Given the California live bait industry is currently the only active sector in the U.S. sardine fishery, live bait landings were also included in this assessment for the first time. California live bait landings are recorded on 'Live Bait Logbooks' provided to the CDFW on a voluntary basis. The CDFW compiles estimates of catch weight based on a conversion of scoop number to kg (Kirk Lynn, CDFW, pers. comm.). Monthly live bait landings were pooled with other commercial catches in the MEXCAL fleet.

Oregon (OR) and Washington (WA) landings (2005-16) were obtained from PacFIN. British Columbia (BC) monthly landing statistics (2005-12) were provided by CDFO (Linnea Flostrand and Jordan Mah, pers. comm.). Sardine were not landed in Canada during 2013-16. The BC landings were pooled with OR and WA as part of the PNW fleet.

Available information concerning bycatch and discard mortality of Pacific sardine, as well as other members of the small pelagic fish assemblage of the California Current Ecosystem, is presented in PFMC (2014). Limited information from observer programs implemented in the past indicated minimal discard of Pacific sardine in the commercial purse seine fishery that targets the small pelagic fish assemblage off the USA Pacific coast.

As stated above, satellite oceanography data were used to characterize ocean climate (SST) within typical fishing zones off Ensenada and Southern California and attribute monthly catch for each fishery to either the southern (SSP) or northern subpopulation (NSP). The NSP landings by model year-season for each fishing region are presented in Table 2 and Figure 3. The current Stock Synthesis model aggregates regional fisheries into a southern 'MEXCAL' fleet and a northern 'PNW' fleet (Figure 1). Landings aggregated by model year-season and fleet are presented in Table 4 and Figure 9.

Age compositions

Age compositions for each fleet and season were the sums of catch-weighted age observations, with monthly landings within each port and season serving as the weighting unit. As indicated above, environmental criteria used to assign landings to subpopulations were also applied to monthly port samples to categorize NSP-based biological compositions.

Age-composition data were partitioned into 9 age bins, representing ages 0 through 8+. Total numbers for ages observed in each fleet-semester stratum were divided by the typical number of fish collected per sampled load (25 fish per sample) to set the sample sizes for compositions included in the assessment model. Seasons with fewer than three samples were excluded from the model. Age compositions were input as proportions. Age-composition time series are presented in Figures 10-12.

Oregon and Washington fishery ages from season 2 (S2, Jan-Jun), were omitted from all models due to inter-laboratory inconsistencies in the application of birth-date criteria during this semester (noting that OR and WA landings and associated samples during S2 are typically trivial). Age data were not available for the BC or ENS fisheries, so PNW and MEXCAL fleet compositions only represent catch-at-age by the OR-WA and CA fisheries, respectively.

Ageing error
Sardine ageing using otolith methods was first described by Walford and Mosher (1943) and extended by Yaremko (1996). Pacific sardines are routinely aged by fishery biologists in CDFW, WDFW, and SWFSC using annuli enumerated in whole sagittae. A birth date of July 1st is assumed when assigning ages.

Ageing-error vectors for fishery data were unchanged from Hill et al. (2011, 2014). Ageing error vectors (SD at true age) were linked to fishery-specific age-composition data (Figure 13). For complete details regarding age-reading data sets, model development and assumptions, see Hill et al. (2011, Appendix 2), as well as Dorval et al. (2013).

Fishery-independent Data

Overview
This assessment uses a single time series of biomass based on the SWFSC's acoustic-trawl (AT) survey. This survey and estimation methods were vetted through a formal methodology review process in February 2011 (PFMC 2011, Simmonds 2011). The AT survey will be reviewed by the PFMC in January 2018.

Acoustic-trawl survey
The AT time series is based on SWFSC surveys conducted along the Pacific coast since 2006 (Cutter and Demer 2008; Zwolinski et al. 2011, 2012, 2014, 2016, Demer et al. 2012, and Zwolinski et al. in preparation). The AT survey and estimation methods were reviewed by a panel of independent experts in February 2011 (PFMC 2011) and the results from these surveys have been included in the assessment since 2011 (Hill et al. 2011, 2012, 2014, 2015, 2016).

Two new AT-based biomass estimates were included in this assessment; one from the spring 2016 survey off central California to Oregon, and the other from the summer 2016 survey spanning San Diego to northern Vancouver Island, Canada. Biomass estimates and associated size distributions from the 2016 surveys are described in the section 'Assessment – Acoustic Trawl Survey' and Zwolinski et al. (in preparation). Biomass estimates from the spring and summer 2016 surveys, 83,037 (CV=0.493) mt and 78,776 (CV=0.539) mt respectively, represent roughly a four-fold increase from those of 2015 (Table 5, Figure 20). The higher AT biomass estimates are consistent with evidence of moderately successful recruitments in 2014 and 2015 (Table 8, Figure 12).

The time series of AT biomass estimates is presented in Table 5 and Figure 20. In order to comply with the model ALT formulation, estimates of abundance at length (Figure 12) were converted into abundance-at-age using seasonal (spring and summer) age-length keys constructed from survey data from 2006 to the present. Age-length keys were constructed for each survey season using the function 'multinom' from the R package 'nnet'. The 'nnet' function fits a multinomial log-linear model using neural networks. The response is a discrete probability distribution of age-at-length. The AT survey biomass estimates (2006-2016) were used as a single time-series, with q being estimated. Age compositions were fit using asymptotic age-selectivity (ages 1+ fully selected; SS age selectivity option 10) which was fixed for the entire time series. Empirical weight-at-age time series (Figure 7) were calculated for every survey using the following process: 1) The AT-derived abundance-at-length was converted to biomass-at-length using a time-invariant length-to-weight relationship. 2) The biomass- and numbers-at-length were converted to biomass-at-age and numbers-at-age, respectively, using the above-mentioned age-length key. 3) mean weights-at-age were calculated by dividing biomass-at-age by the respective numbers-at-age.

Data Sources Considered but not Used

Daily egg production method spawning biomass
Past sardine stock assessments have included a time series of daily egg production method (DEPM) spawning stock biomass (SSB). The time series was included in the assessments as an index of relative female SSB (*Q* estimated) and has always been considered an underestimate of true SSB (Deriso et al. 1996). The DEPM time series has been described in numerous publications and stock assessment reports. The DEPM time series since 2005 is provided in Table 5. The spring 2016 DEPM survey estimate is summarized in Appendix A of this report. It is worth noting that the 2016 estimate of female SSB was only 5,929 mt, the lowest level since mid-1980s. As stated elsewhere, the DEPM series was excluded from model ALT. As indicated in past assessments, exclusion of the DEPM time series continues to have negligible impact on the stock assessment outcome. Nonetheless, DEPM estimates are still considered useful to corroborate/refute results from either the AT survey and/or model ALT (see 'Assessment – Acoustic-trawl survey \ Additional assessment considerations' below).

ASSESSMENT – ACOUSTIC-TRAWL SURVEY

Overview

Current management of the Pacific sardine population inhabiting the California Current of the northeast Pacific Ocean relies on an estimate of stock biomass (age-1+ fish in mt), which is needed for implementing an established harvest control rule policy for this species on an annual basis (see Harvest Control Rules for the 2017-18 Management Cycle below). It is important to note that the stock assessment team (STAT) recommended that the preferred assessment approach for meeting the management goal was to use results from the acoustic-trawl (AT) survey alone, i.e., not results from an integrated population dynamics model (see Preface above). For purposes of conducting the formal stock assessment review (STAR) in February 2017, methods and results from both the survey-based (AT) and model-based (ALT) approaches were presented in the assessment report distributed for review purposes at the meeting. The final assessment report presented here is similar to the review draft, including the STAT's criteria for choosing an assessment approach for advising management of Pacific sardine in the future, as well as data, parameterizations, and results associated with the two assessment approaches.

Merits of AT survey-based assessment
The AT survey employs objective sampling methods based on state of the art echosounder equipment and an expansive data collection design in the field (Zwolinski et al. 2014). Stock assessments since 2011 indicate that the survey produces the strongest signal of Pacific sardine biomass available for assessing absolute abundance of the stock on an annual basis (i.e.,

management goal, see Overview above). The survey design is based on an optimal habitat index (Zwolinski et al. 2011), established catchability ($Q\approx1.0$), and commitment to long-term support. Biomass estimates produced by the survey are primarily subjected to random sampling variability and not affected by uncertainty surrounding poorly understood population processes that must be addressed to varying degrees when fitting population dynamics models, simple or complex.

Drawbacks of model-based assessment

In the context of meeting the management goal, a model-based assessment includes considerable additional uncertainty in recent estimated stock biomass of Pacific sardine, given the need to explicitly model critical stock parameters in the assessment that is unnecessary using a survey-based assessment approach. For example, uncertainty surrounding natural mortality (*M*), recruitment variability (stock-recruitment relationship), biology (longevity, maturity, and growth), and particularly, selectivity, which can substantially influence bottom-line results useful to management. That is, the model-based assessment necessarily includes additional structural and process error, given varying degrees of bias associated with sample data and parameter misspecifications in the model. Further, addressing potential improvements to the AT survey methods and/or design over time (e.g., varying catchability, *Q*) is less straightforward and more problematic in a model-based assessment approach than basing the formal assessment on the estimate of stock biomass produced from the AT survey each year. Finally, including additional sources of data necessarily degrades the influence of the highest quality data available in the integrated model (AT survey abundance index) for determining recent stock biomass.

Additional assessment considerations

Most importantly, employing a survey-based assessment approach requires projecting estimated stock biomass from the AT survey one year (also required for the model-based approach), given the current assessment/review/management schedule. Currently, management stipulations are set roughly one year following the last year of sample data available for assessing the stock. The Pacific sardine stock assessment reviews (STAR) are conducted early in the year (e.g., February 2017) for applying new management stipulations for the upcoming ‘fishing year’ (2017-18). Thus, the AT survey biomass estimated in 2016 needs to be projected one year to summer 2017, see Preface above and Projected Estimates (2016-17) below. Second, the integrated model (e.g., model ALT) should be maintained along with the survey-based assessment to evaluate stock parameters of interest, including the stock-recruitment relationship and recent estimates of recruitment, age/length structure of the population, catches and fishing intensity, etc., as well as to use in the unlikely event that the AT survey is unable to be conducted in a particular year. Finally, if workable in the future, the DEPM time series should be maintained as a complementary index of abundance for corroborating/refuting information generated from the AT survey, as well as to help continually improve the AT survey design (e.g., better understanding of the spawning aggregation/migration/timing in the context of range variability exhibited by the population over time).

Methods

Methods and results for the most recent AT survey cruises conducted in spring and summer 2016 are presented in this report. Methods and sampling designs in the field have been generally similar since the survey was first employed in 2006 (model year 2005), noting that changes to areas surveyed occurred seasonally and annually, given the environmental-based optimal habitat index used to select actual transect lines each year. Readers should consult Zwolinski et al. (2014) and Zwolinski et al. (2016) for survey cruises conducted in past years.

The 2016 surveys were conducted onboard the NOAA Fisheries Survey Vessel (FSV) *Reuben Lasker*. Acoustic data were collected during the day to allow sampling of fish schools aggregated throughout the surface mixed layer. Trawling was conducted during the night to sample fish dispersed near the surface (Mais 1974). The spring survey occurred over 30 days (March 22 to April 22), with transects based on sampling the largest extent of the potential sardine habitat, from north to south. Due to persisting warm conditions in the northeast Pacific Ocean, the sardine potential habitat extended into northern California waters farther north than usual for spring and thus, the survey design was modified to accommodate the expanded habitat (Figure 14). The survey started approximately 10 nm north of Newport, Oregon and progressed south to Bodega Bay, California.

The summer survey occurred over 80 days (June 28 – September 22), and transects spanned the west coast of the U.S. and Canada, from the northern end of Vancouver Island to San Diego (Figure 15). Further details on echosounder calibrations, survey design, and sampling protocols are detailed in Stierhoff et al. (*in preparation*) and Zwolinski et al. (*in preparation*).

Acoustic data from each transect were processed using estimates of sound speed and absorption coefficients calculated with contemporary data from Conductivity-Temperature-Depth (CTD) probes. Echoes from schooling CPS were identified with a semi-automated data processing algorithm as described in Demer et al. (2012). The CPS backscatter was integrated within an observational range of 10 m below the sea surface to the bottom of the surface mixed layer or, if the seabed was shallower, to 3 m above the estimated acoustic dead zone (Demer et al. 2009). The vertically integrated backscatter was averaged along 100-m intervals, and the resulting nautical area backscattering coefficients (s_A; m^2 nm^{-2}) were apportioned based on the proportion of the various CPS found in the nearest trawl cluster. The s_A were converted to biomass and numerical densities using species- and length-specific estimates of weight and individual backscattering properties (see details in Demer et al. 2012 and Zwolinski et al. 2014).

Survey data were post-stratified to account for spatial heterogeneity in sampling effort and sardine density. Total biomass in the survey area was estimated as the sum of the biomasses in each individual stratum. Sampling variance in each stratum was estimated from the inter-transect variance calculated using bootstrap methods (Efron 1981), and total sampling variance was calculated as the sum of the variances across strata (see Demer et al. 2012; Zwolinski et al. 2012; and references therein for details). The 95% confidence intervals (CIs) were estimated as the 0.025 and 0.975 percentiles of the distribution of 1,000 bootstrap biomass estimates. Coefficient of variation (CV) for each of the mean values was obtained by dividing the bootstrapped standard errors by the point estimates (Efron 1981).

For each stratum, estimates of abundance were broken down to 1-cm standard length (SL) classes. These abundance-at-length estimates were obtained by raising the length-frequency distribution from each cluster to the abundance assigned to the respective distribution based on the acoustic backscatter. Age-length keys by season were constructed using age and length data from surveys conducted since 2006. In conjunction with a time-invariant weight-length relationship, the number-at-length estimates from the AT survey were transformed into estimates of number-at-age and biomass-at-age for each year. Mean weight-at-age vectors were constructed by dividing the biomass-at-age vectors by the respective vectors of number-at-age. During the STAR Panel (Feb 2017), the STAT was asked to recompile AT weight-at-age matrices using the cohort-smoothing approach applied to fishery samples (see ‘Biological Parameters \ Growth’). As noted above, and in STAR (2017), results based on this approach were negligibly different (<1% change in biomass, and one likelihood point improvement) and thus, not included in final model ALT.

The management process requires an estimate of stock biomass (age-1+ fish, mt) at the beginning of the fishing year (July 2017). Since the survey occurred in summer 2016 (considered here July 1, 2016 for simplicity), projection of the biomass to 2017, involved 3 steps: 1) estimating age-0 abundance for 2016; 2) accounting for abundance decrease into 2017 due to natural mortality (M); and 3) accounting for biomass increase due to somatic growth. Because age-0 abundance of sardine is not well characterized from the AT survey (see ‘Assessment – Model \ Model Description \ Selectivity’ below), the abundance of this age class in July 2016 was estimated using the stock-recruitment (S-R) relationship from the alternative assessment model, model ALT (see ‘Assessment – Model \ Results \ Stock-recruitment’ below). The SSB input needed for the S-R relationship was obtained by back-calculating the number-at-age estimates for summer 2016 to January 2016 (semester 2 of model year 2015) assuming M=0.3 per semester, followed by conversion into SSB using mean-weight-at-age estimates from the survey and the maturity ogive. The predicted recruitment was then combined accordingly with the vector of other number-at-age estimates from the survey and projected one year into the future assuming M=0.6 yr^{-1} (as assumed in model ALT). The final number-at-age estimates were converted to estimates of biomass-at-age using the estimated mean weight-at-age vector in 2017.

Results

The spring survey totaled 3,850 nm of daytime east-west tracklines and 43 night-time surface trawls resulting in the formation of 18 clusters that were used for species identification and length measurements. The longer summer survey totaled 4,627 nm of daytime east-west tracklines and 121 night-time surface trawls combined into 49 trawl clusters. Post-cruise strata were defined for each survey, considering transect spacing, echoes or catches of CPS, sardine eggs in the Continuous Underway Fish Egg Sampler (CUFES), and the presence of sardine potential habitat (Figures 14 and 16).

In the spring, sardine were primarily concentrated in an area 160 nm long along the coasts of southern Oregon and northern California (Figure 16) and out to 80 nm offshore. Sardine biomass was estimated using 2 strata (Table 6, Figure 16). Stratum 1 contained the largest concentration of CPS backscatter, trawl clusters with sardine, and CUFES samples with sardine eggs (Figures 14 and 16). To the south, stratum 2 contained few adult sardine, no eggs, and relatively low backscatter. Stratum 2 had considerably lower biomass than stratum 1, contributing significantly less to the total biomass in the survey area, which was estimated to be 83,037 mt ($CI_{95\%}$=18,906 to 172,109 mt, CV=49.3 %, Table 6). Globally, the distribution of abundance-at-length estimates had modes at SL=14, 20, and 25 cm (Table 8, Figure 17). The larger-sized cohort was composed of fish age 3 and older, whereas the smaller fish were likely sardine spawned in 2015. The clear separation between the central mode and the two other modes indicates that the central mode encompassed sardine predominantly spawned in 2014.

At the time of the beginning of the summer survey, the sardine potential habitat extended beyond the north of Vancouver Island (Figure 15). Nonetheless, despite the availability of suitable habitat, sardine were only found on the southern end of the Island, around 49 ° N. From there to the south, the stock was highly fragmented and observed in small abundances, except immediately to the north of Point Conception (Figure 15). The entire survey area included an estimated 78,776 mt of Pacific sardine ($CI_{95\%}$=9,538 to 148,287 mt, CV=53.9%, Table 7), with strata 1 and 6 contributing considerably larger biomasses than other strata. The distribution of abundance-at-length estimates had two major modes at 17 and 19 cm, with only minor contributions from other length classes (Table 8, Figure 19). This pattern observed in the length distribution was caused by the disproportionately large abundances observed in strata 1 and 6, which in turn were characterized by a reduced number of clusters. Given the high uncertainty associated with the estimation in these two strata (CV=68.9% and 92.9% for strata 1 and 6, respectively; Table 7), estimated length-at-age of the population was also subject to substantial uncertainty.

Projected Estimates (2016-17)

The projected total estimate of stock biomass (age 1+, mt) for July 2017 from the AT survey was 96,930 mt (Tables 9 and 11). As discussed in Methods above, the projection calculation was based on using number-at-age estimates from the summer 2016 survey (Table 9), along with the recruitment estimate associated with the stock-recruitment relationship in 2016 (from model ALT) discounted for natural mortality (M = 0.6), and finally, converting abundance in numbers to biomass using mean weight-at-age estimates derived from the survey. It is worth noting that this projection is dependent not only on the biomass observed in 2016, but also on the estimated recruitment for 2016. Given the stochastic nature of the past recruitments, it should be expected that a rectification of the 2017 biomass will occur after analysis of the 2017 summer survey. The entire stock biomass time series estimated from the AT survey for 2005-16, including the projected estimate for 2017, is presented in Figure 20. See Appendix 2 in STAR (2017) for additional details regarding biomass projection.

Areas of Improvement for AT Survey

Presently, the AT survey with Q=1.0 is considered to generally provide unbiased measurements of the sardine population (see 'Changes between Last and Current Assessment Model \ Catchability'). Despite this assertion of quality, continued refinement and verification of the survey assumptions will continue in the future. In particular, it is essential that the survey design in the field continues to encompass the entire range of the stock in any given year, as well as expanding areas surveyed by using ancillary sampling tools in situations where the research vessel may have difficulty operating. Combined efforts with state fishery agencies to complement acoustic sampling with optical observations are already underway. Additionally, starting this spring, the SWFSC will begin testing the use of Unmanned Aerial Systems (UAS) to expand its survey capabilities in real time. Besides providing information about the presence of CPS in unnavigable areas, UAS will supplement the use of acoustic sensor to monitor the presence of fish schools near the surface.

Further improvement will continue both in the study of species' target strength (TS), a central parameter to convert acoustic backscatter to numerical densities, and in the improvement of the survey design, particularly in the use of more aggressive adaptive rules that will allow increasing sampling effort in areas with unusually large concentrations of CPS. The use of adaptive sampling procedures will likely reduce the uncertainty of both biomass, species composition, and demography of target species. Also, see 'Assessment Model – Acoustic-trawl Survey / Overview / Additional assessment considerations' above and 'Research and Data Needs' below.

ASSESSMENT – MODEL

History of Modeling Approaches

The population's dynamics and status of Pacific sardine prior to the collapse in the mid-1900s was first modeled by Murphy (1966). MacCall (1979) refined Murphy's virtual population analysis (VPA) model using additional data and prorated portions of Mexican landings to exclude the southern subpopulation. Deriso et al. (1996) modeled the recovering population (1982 forward) using CANSAR, a modification of Deriso's (1985) CAGEAN model. The CANSAR was subsequently modified by Jacobson (Hill et al. 1999) into a *quasi*, two-area model CANSAR-TAM to account for net losses from the core model area. The CANSAR and CANSAR-TAM models were used for annual stock assessments and management advice from 1996 through 2004 (e.g., Hill et al. 1999; Conser et al. 2003). In 2004, a STAR Panel endorsed the use of an Age Structured Assessment Program (ASAP) model for routine assessments. The ASAP model was used for sardine assessment and management advice from 2005 to 2007 (Conser et al. 2003, 2004; Hill et al. 2006a, 2006b). In 2007, a STAR Panel reviewed and endorsed an assessment using Stock Synthesis (SS) 2 (Methot 2005, 2007), and the results were adopted for management in 2008 (Hill et al. 2007), as well as an update for 2009 management (Hill et al. 2008). The sardine model was transitioned to SS version 3.03a in 2009 (Methot 2009) and was again used for an update assessment in 2010 (Hill et al. 2009, 2010). Stock Synthesis version 3.21d was used for the 2011 full assessment (Hill et al. 2011), the 2012 update assessment (Hill et al. 2012), and the 2013 catch-only projection assessment (Hill 2013). The 2014 sardine full assessment (Hill et al. 2014), 2015 update assessment (Hill et al. 2015), and 2016 update assessment (Hill et al. 2016) were based on SS version 3.24s. The 2017 full assessment presented here was based on SS version 3.24aa. SS version 3.24aa corrected errors associated with empirical weight-at-age models having multiple seasons.

Responses to 2014 STAR Panel Recommendations

Many of the following recommendations are based on using an integrated model and not directly applicable to the current assessment, given the survey-based assessment represents the preferred approach for advising management of the Pacific sardine resource in the future. Regardless, brief responses are provided for relevant recommendations in the context of the model-based assessment approach using model ALT.

High priority

A. The assessment would benefit not only from data from Mexico and Canada, but also from joint assessment activities, which would include assessment team members from both countries during assessment development.

Response: Bilateral stock assessment has long been considered a worthwhile goal. However, a more immediate priority is international collaboration to obtain synoptic survey coverage of the northern subpopulation. Synoptic surveys would also simultaneously provide population estimates of the southern subpopulation, as well as other transboundary CPS stocks (i.e., Pacific mackerel, northern anchovy central subpopulation, and jack mackerel). Synoptic CPS surveys are discussed each year at the Trinational Sardine Forum and Mexico-U.S. bilateral meetings.

B. Modify Stock Synthesis so that the standard errors of the logarithms of age-1+ biomass can be reported. These biomasses are used when computing the Overfishing Level, the Acceptable Biological catch, and the Harvest Level, but the CV used when applying the ABC control rule is currently that associated with spawning biomass and not age-1+ biomass.

Response: Requests for this addition to SS have been made in the past, i.e., it is possible that SS ver. 3.0 will include the error estimate associated with estimated stock biomass. André Punt revised an earlier version of SS to produce this output, however, the results were not markedly different than error estimates produced for SSB.

C. Explore models that consider a much longer time-period (e.g. 1931 onwards) to determine whether it is possible to model the entire period and determine whether this leads to a more informative assessment as well as provide a broader context for evaluating changes in productivity.

Response: Fishery managers require advice regarding current and near-future abundance. The STAT considers the above recommendation worthwhile for developing research models, but counterproductive for providing annual management advice.

D. Investigate sensitivity of the assessment to the threshold used in the environmental-based method (currently 50% favorable habitat) to further delineate the southern and northern subpopulations of Pacific sardine. The exploration of sensitivity in the present assessment was limited given time available, but indicated potential sensitivity to this cut-off.

Response: No further work has been conducted to address this recommendation.

E. Compute age-composition data for the ATM survey by multiplying weighted length-frequencies by appropriately constructed age-length keys (i.e. taking account of where the samples were taken).

Response: This recommendation was implemented in model ALT and for the projection model for the AT survey. Methods are described under the Fishery-independent data section above.

F. Investigate alternative approaches for dealing with highly uncertain estimates of recruitment that have an impact on the most recent estimate of age-1+ biomass that is important for management. Possible approaches are outlined in Section 3 of this report.

Response: *No work has been conducted to address this recommendation*.

G. Validation of the environmentally-based stock splitting method should be carried out if management is to be based on separating the northern and southern subpopulations using the habitat model. It may be possible to develop simple discriminant factors to differentiate the two sub-populations by comparing metrics from areas where mixing does not occur. Once statistically significant discriminant metrics (e.g. morphometric, otolith morphology, otolith microstructure, and possibly using more recent developments in genetic methods) have been chosen, these should be applied to samples from areas where mixing may be occurring or where habitat is close to the environmentally-based boundary. This can be used to help set either a threshold or to allocate proportions if mixing is occurring.

Response: Somatic and otolith morphometric analyses were conducted that generally address this recommendation (Felix et al. 2005). The Felix et al. (2005) study complemented a SST-based method published by Felix et al. (2004). Subsequent validation studies have not been undertaken. Genetic methods have been inconclusive.

H. Continue to investigate the merits/drawbacks of model configurations that include age compositions rather than length-composition and conditional age-at-length data, given some evidence for time- and spatially-varying growth.

Response: Model ALT incorporates age compositions, age-based selectivity, and empirical weight-at-age time series.

Medium priority

I. Continue to explore possible additional fishery-independent data sources. However, inclusion of a substantial new data source would likely require review, which would not be easily accomplished during a standard STAR Panel meeting and would likely need to be reviewed during a Council-sponsored Methodology Review.

Response: While other potential fishery-independent data sources may exist for Pacific sardine (e.g., SWFSC juvenile rockfish survey or California's aerial survey), none have been vetted through a Council-sponsored methodology review. The STAT continues to support and promote use of the single, most objective survey tool available for estimating abundance of CPS, i.e., the SWFSC's AT survey.

J. The reasons for the discrepancy between the observed and expected proportions of old fish in the length and age compositions should be explored further. Possible factors to consider in this investigation include ageing error / ageing bias and the way dome-shaped selectivity has been modelled.

Response: Very few sardine older than 6 years of age have been observed in either the fishery or survey samples collected to date. Model ALT has been revised to reduce the maximum age from 15 to 10 and the 'accumulator' age for single binning older fish reduced to age 8+.

K. The Panel continues to support expansion of coast-wide sampling of adult fish for use when estimating parameters in the DEPM method (and when computing biomass from the ATM surveys). It also encourages sampling in waters off Mexico and Canada.

Response: The SWFSC has conducted two surveys per year (spring and summer) since 2012. Summer surveys have typically extended to the northern tip of Vancouver Island, Canada. U.S. survey vessels have not yet had access to Mexican waters and are unlikely to in the near future. INAPESCA recently obtained a new, advanced technology research vessel (BIPO) for surveying the Gulf of California and Baja peninsula. Unfortunately, the BIPO was recently relocated to the Gulf of Mexico and its status for future surveys remains uncertain.

L. Consider spatial models for Pacific sardine that can be used to explore the implications of regional recruitment patterns and region-specific biological parameters. These models could be used to identify critical biological data gaps as well as better represent the latitudinal variation in size-at-age.

Response: No progress has been made toward spatial modeling. Some of the concerns raised regarding regional size-at-age have been accounted for by the use of empirical weight-at-age data and age-based selectivity in model ALT.

M. Consider a model that explicitly models the sex-structure of the population and the catch. An analysis of length-at-age samples did not indicate sexual dimorphism for this stock (see Figure 4a in Hill et al. 2014), so all models presented were combined-sex configurations. Nevertheless, it was felt that a sex-specific model was needed minimally as a sensitivity test to investigate the possibility that accounting for sex will have an impact on stock-assessment results for this resource.

Response: No further work has been conducted to address this recommendation. That is, this exercise is considered a low priority and unwarranted at this time in the ongoing assessment, given no evidence of sex-specific growth has been observed from biological sample information collected to data (see Assessment Data, Biological Parameters, Growth above).

N. Consider a model that has separate fleets for Mexico, California, Oregon-Washington and Canada.

Response: In the past, the STAT has modeled each of these regional fisheries as fleet, which s resulted in an unstable, over-parameterized model. That is, the goal of current model development is to construct a parsimonious assessment model that meets the overriding management objective using/emphasizing the highest quality data available (AT survey abundance time series) in the most straightforward manner (not developed around fine-scale fishery catch and selectivity data).

O. Compare annual length-composition data for the Ensenada fishery that are included in the MEXCAL data sets for the NSP scenario with the corresponding southern California length compositions. Also, compare the annual length composition data for the Oregon-Washington catches with those from the British Columbia fishery. This is particularly important if a future age data/age-based selectivity model scenario is further developed and presented for review.

Response: Ensenada fishery length-composition time series are only available at the semester level, so it is not possible to disaggregate the data (either length or age) to account for contribution of NSP fish. For the last several length-based assessments, the semester *level data were simply down-weighted to account for the NSP catch. The BC fishery length data were not converted to age distributions for model ALT, although this would be theoretically possible to do using an age-length key from the SS model or using data from the OR-WA fisheries. Given the large size of sardines harvested in the BC fishery, this transformation would likely result in skewed age distributions.*

P. Further explore methods to reduce between-reader ageing bias. In particular, consider comparisons among laboratories and assess whether the age-reading protocol can be improved to reduce among-ager variation.

Response: The SWFSC regularly exchanges survey otolith samples with key personnel with the CDFW for double-reading evaluations. However, as noted in Research and Data Needs below, the STAT has suggested more coordination is needed regarding production ageing across multiple laboratories or possibly, more centralized ageing efforts for Pacific sardine, as well as other CPS stocks.

Q. Change the method for allocating area in the DEPM method so that the appropriate area allocation for each point is included in the relevant stratum. Also, apply a method that better accounts for transect-based sampling and correlated observations that reflects the presence of a spawning aggregation.

Response: The DEPM time series is excluded from model ALT.

R. Consider future research on natural mortality. Note that changes to the assumed value for natural mortality may lead to a need for further changes to harvest control rules.

Response: Assessment model ALT has implemented a change in M from 0.4 yr^{-1} *to 0.6* yr^{-1}*. Rationale for the change is provided under: Assessment Data, Biological Parameters, Natural mortality above; Changes between Current and Last Assessment Model, Longevity and natural mortality below; and Natural mortality profile below.*

Low priority

S. Develop a relationship between egg production and fish age that accounts for the duration of spawning, batch fecundity, etc. by age. Using this information in the assessment would require that the stock-recruitment relationship in SS be modified appropriately.

Response: Although the newest version of SS (beta ver. 3.0) has added more flexibility for modeling stock-recruitment dynamics, it is uncertain whether such age-specific details will be available in the future.

Finally, the Panel notes that value of the Small Pelagic Ageing Research Cooperative, which should improve consistency in age-reading methods generally, and in particular for Pacific sardine. Lack of consistency in age estimates was the reason for not using age data for British Columbia.

Response: The SPARC has not met for several years. Canada has no new samples to age, and the majority of existing samples that have been aged are from their summer swept-area trawl survey. The WDFW has aged all samples from the states of Oregon and Washington, but no new samples have been collected since the moratorium. The CDFW and the SWFSC regularly exchange subsamples from the SWFSC's surveys for double reading analysis. Also, see recommendation P above.

Responses to Recent STAR (2017) Panel Requests

During the review in February 2017, additional requests were made during the week-long meeting regarding the proposed survey- and alternative model-based assessments, including evaluating different methods for projecting survey biomass from 2016 to 2017, examining different combinations of data and parameterizations (e.g., growth via empirical weight-at-age matrices and selectivity estimation based on age-vs. length-composition time series) associated with model ALT, and revising outputs and contrasting results across respective models and survey abundance time series. Detailed requests, rationales, and responses associated with sensitivity analysis conducted during the review are presented under Requests made to the STAT during the meeting (STAR 2017).

Changes between Current and Last Assessment Model

Overview

General differences between the current assessment model (ALT) proposed here and the last assessment model (T_2016) used to advise management, as well as model T_2017 that represents an updated T_2016 model are presented in Table 10. Model T_2017 is parameterized similarly as T_2016, with newly available sample information (e.g., catch, composition, and abundance data). As indicated in recent assessments conducted in the past, selectivity estimation continued to result in problematic scaling in model T_2017, with updated length-composition data associated with the AT survey once again resulting in unrealistic estimates of total stock biomass (Figure 21). The AT length-composition time series has continually been poorly fit in the model, with estimated selectivity curves sensitive to even minor additions of new length data. Estimated selectivity of very small, young sardines (6-9 cm, age-0 fish) in the AT survey is low (i.e., in most years, the AT survey does not encounter such sizes/age), so that when small fish are observed occasionally in the survey in limited numbers, selection probabilities translate to implausibly high numbers of young fish present in the population (see STAR 2017). As addressed in past reviews, omitting new length data in the updated assessment alleviated suspect scaling issues (Figure 21) and resulted in a more robust model (e.g., minimized potential for generating retrospective errors generally associated with highly variable terminal estimates of abundance). Given drawbacks of the length-based model above, as well as other data and parameterization considerations noted below (e.g., see Selectivity below), the STAT's proposed model-based assessment in 2017 was model ALT.

In general, model ALT was developed around the most relevant and highest quality source of data available for assessing the status of Pacific sardine, i.e., the focus of model ALT is fitting to the AT survey abundance time series. Finally, it is important to note that model ALT represents the proposed model-based assessment for advising management, but the preferred assessment is a survey-based approach as discussed above (see 'Preface' and 'Assessment – Acoustic-trawl survey \ Overview'). Further details regarding differences/similarities between model ALT and T_2016/T_2017 follow (see accompanying Table 10).

Time period and time step

The modeled timeframe has been shortened by roughly one decade, with the first year in model ALT being 2005, rather than 1993. Time steps in model ALT are treated similarly as in past assessments, being based on two, six-month semester blocks for each fishing year (semester 1=July-December and semester 2=January-June). The need for an extended time period in the model is not supported by the management goal, given that years prior to the start of the AT survey time series provide limited additional information for evaluating terminal stock biomass in the integrated model. Further, although a longer time series of catch may be helpful in a model for accurately determining scale in estimated quantities of interest, estimated trend and scale were not sensitive to changes in start year for model ALT. Finally, Pacific sardine biology (relatively few fish >5 years old observed in fisheries or surveys) further negates the utility of an extended time period in a population dynamics model employed for estimating terminal stock biomass of a short-lived species.

Surveys

Model ALT now includes only an acoustic-trawl survey index of abundance, omitting abundance time series used in past assessments associated with eggs/larvae surveys (daily egg production method – DEPM, and total egg production – TEP). Justification for removing eggs/larvae data from the current model follow: AT survey covers the full range of the stock vs. strictly the spawning aggregation covered by the eggs-larvae surveys; AT survey provides a direct measure of stock biomass vs. an indirect estimate of spawning biomass produced by the eggs/larvae surveys; AT survey provides a snapshot of recent absolute abundance vs. a snapshot of recent relative spawning production generated by the eggs/larvae surveys; and AT survey is based on an efficient survey design that minimizes temporal/sampling biases and maximizes estimate precision vs. much less flexible eggs/larvae surveys that are more prone to sampling biases in the field. Further, shortening the modeled time period necessarily results in omission of the TEP time series, which ended in 2005 (also noting that the TEP method results in a lower quality index of egg production due to lack of adult reproductive parameters). Additionally, the DEPM time series is essentially uninformative in model ALT, which produces similar results with or without inclusion of the eggs/larvae survey. Finally, the AT survey abundance time series in the ALT model is no longer partitioned into independent indices based on spring and summer cruises, but rather, now reflects a single abundance index that, in some years, includes multiple (seasonal) estimates.

Fisheries

Fishery structure in model ALT is similar to past assessments. Three fisheries are included in the model, including two Mexico-California *fleets* separated into semesters (MEXCAL_S1 and MEXCAL_S2) and one *fleet* representing Pacific Northwest fisheries (Canada-WA-OR, PNW). Also, because the California live bait industry currently reflects the only active sector in the U.S. sardine fishery, minor amounts of live bait landings were included in the current assessment based on model ALT.

Longevity and natural mortality

Biology assumptions for Pacific sardine in model ALT have been revised, including decreasing longevity and increasing natural mortality (*M*). Justification for revised assumptions for longevity (15 to 10 years) and *M* (0.4 to 0.6 yr^{-1}) follow: recommended in past assessment reviews; biological parameters are now consistent with observed length and age data collected from the fisheries and surveys (limited numbers of fish >5 years old observed in composition time series since 2000); supportive evidence from mortality studies from AT survey research

(Zwolinski and Demer 2013), as well as from general research addressing underlying correlation between maximum lifespan and mortality (Hoenig 1983); and finally, higher *M* estimates (0.55-0.65 yr^{-1}) were consistent with other estimated parameters associated with the highest priority data in the model, e.g., assumption that AT survey catch rates are applicable to the entire population in any given year (Q≈1), see Natural mortality profile below. Also, see 'Assessment Data \ Biological Parameters \ Natural mortality' above and 'Natural mortality profile' below.

Growth

A matrix of empirical weight-at-age estimates by year/semester is now used in model ALT to translate derived numbers-at-age into biomass-at-age, rather than estimating growth internally in the model as conducted previously in past assessments. Treatment of growth using empirical weight-at-age matrices associated with the fisheries, survey, and population greatly simplifies the overall assessment, while also allowing growth to vary across time and minimizing potential conflicts with selectivity parameterization. Also, see 'Assessment Data \ Biological Parameters \ Growth' above.

Stock-recruitment relationship

Beverton-Holt stock-recruitment (*S*-*R*) parameters are estimated in model ALT, including both virgin recruitment ($\log R_0$) and steepness (*h*), which represents a change from recently conducted assessments that estimated $\log R_0$, but fixed h=0.8. That is, fixing *h* at an assumed higher value in concert with fixed *M* necessarily constrained the model, resulting in relatively optimistic results, given the assumption that productivity remains high at low parent stock size. Finally, general sensitivity analysis during development of model ALT resulted in robust estimates of $\log R_0$ (~14.2) and *h* (~0.36). Also, see 'Model Description \ Stock-recruitment relationship,' 'Results \ Stock-recruitment relationship,' and 'Uncertainty Analyses \ Sensitivity analysis' below.

Selectivity

Selectivity in model ALT is based on age compositions and age-based selectivity, rather than length compositions and length-based selectivity as used in recently conducted past assessments. Primary justification for changing how selectivity is treated in the integrated model is based on the overriding goal to develop a parsimonious model that includes the most efficient parameterizations in the age-structured modeling platform (SS). Further, results from recent assessments have been particularly sensitive to minor changes (updates) to length-composition time series, which has been highlighted as a problematic area over the last few years in the ongoing assessment (Hill et al. 2014, 2015, 2016; STAR 2014). Also, see 'Model Description \ Selectivity' below.

Catchability

Catchability (*Q*) is freely estimated for the AT survey in model ALT, which is a major change from past assessments that have assumed Q=1.0 for the primary index of abundance in the assessment. That is, model ALT illustrates that a critical assumption underlying the survey-based assessment approach (i.e., AT survey methods and design allow efficient sampling within the stock's range in any given year, or Q≈1) is supported using a relatively simple integrated assessment model that includes other ancillary sources of data (e.g., catch and composition data), is based on realistic assumptions/parameterizations (e.g., *M*, growth, and stock-recruitment), is internally consistent (data conflicts are minimized), and generates robust results.

Model Description

Important parameterizations in model ALT are described below. Information for particular parameterizations is also presented under 'Changes between Current and Last Assessment Model' above.

Assessment program with last revision date
In 2014, the stock assessment team (STAT) transitioned from Stock Synthesis (SS) version 3.21d to version 3.24s (Methot 2013, Methot and Wetzel 2013), which was used for all assessments through 2016. In 2017, the SS model received some additional minor revisions and recompiled (version 3.24aa) to accommodate empirical weight-at-age data in a semester-based model. The SS model is comprised of three sub-models: (1) a population dynamics sub-model, where abundance, mortality, and growth patterns are incorporated to create a synthetic representation of the true population; (2) an observation sub-model that defines various processes and filters to derive expected values for different types of data; and (3) a statistical sub-model that quantifies the difference between observed data and their expected values and implements algorithms to search for the set of parameters that maximizes goodness of fit. The modeling framework allows for the full integration of both population size and age structure, with explicit parameterization both spatially and temporally. The model incorporates all relevant sources of variability and estimates goodness of fit in terms of the original data, allowing for final estimates of precision that accurately reflect uncertainty associated with the sources of data used as input in the modeling effort.

Definitions of fleets and areas
Data from major fishing regions are aggregated to represent southern and northern fleets (fisheries). The southern 'MEXCAL' fleet includes data from three major fishing areas at the southern end of the stock's distribution: northern Baja California (Ensenada, Mexico), southern California (Los Angeles to Santa Barbara), and central California (Monterey Bay). Fishing can occur throughout the year in the southern region. However, availability-at-size/age changes due to migration. Selectivity for the southern MEXCAL fleet was therefore modeled separately for seasons 1 and 2 (semesters, S1 and S2).

The 'PNW' fleet (fishery) includes data from the northern range of the stock's distribution, where sardine are typically abundant between late spring and early fall. The PNW fleet includes aggregate data from Oregon, Washington, and Vancouver Island (British Columbia, Canada). The majority of fishing in the northern region typically occurs between July and October (S1).

Likelihood components and model parameters
A complete list of model parameters for model ALT is presented in Table 12. The total objective function was based on the following individual likelihood components: 1) fits to catch time series; 2) fits to the AT survey abundance index; 3) fits to age compositions from the three fleets and AT survey; 4) deviations about the stock-recruitment relationship; and 5) minor contributions from soft-bound penalties associated with particular estimated parameters.

Initial population and fishing conditions

Given the Pacific sardine stock has been exploited since the early 20th Century (i.e., well before the start year used in model ALT), further information is needed to address equilibrium assumptions related to starting population dynamics calculations in the assessment model. One approach is to extend the modeled time period backwards in time to the start of the small pelagic fisheries off the U.S. west coast and in effect, ensure no fishing occurred prior to the start year in the model. In an integrated model, this method can be implemented by: 1) extending the catch time series back in time and confirming that harvest continues to decline generally as the onset of the fishery is approached; or 2) estimating additional parameters regarding initial population and fishing conditions in the model. Given assumptions regarding initial equilibrium for Pacific sardine (a shorter-lived species with relatively high intrinsic rates of increase) are necessarily difficult to support regardless of when the modeled time period begins, as well as the extreme length of an extended catch time series (early 1900s) that would be needed in this case, the approach above was adopted in this assessment, as conducted in all previous assessments to date.

The initial population was defined by estimating 'early' recruitment deviations from 1999-04, i.e., six years prior to the start year in the model. Initial fishing mortality (*F*) was estimated for the MEXCAL_S1 fishery and fixed=0 for MEXCAL_S2 and PNW fisheries, noting that results were robust to different combinations of estimated vs. fixed initial *F* for the three fisheries. In effect, the initial equilibrium age composition in the model is adjusted via application of early recruitment deviations prior to the start year of the model, whereby the model applies the initial *F* level to an equilibrium age composition to get a preliminary number-at-age time series, then applies the recruitment deviations for the specified number of younger ages in this initial vector. If the number of estimated ages in the initial age composition is less than the total number of age groups assumed in the model (as is the case here), then the older ages will retain their equilibrium levels. Because the older ages in the initial age composition will have progressively less information from which to estimate their true deviation, the start of the bias adjustment was set accordingly (see Methot 2013; Methot and Wetzel 2013). Ultimately, this parsimonious approach reflects a non-equilibrium analysis or rather, allows for a relaxed equilibrium assumption of the virgin (unfished) age structure at the start of the model as implied by the assumed natural mortality rate (*M*). Finally, an equilibrium 'offset' from the stock-recruitment relationship was estimated and along with the early recruitment deviation estimates allowed the most flexibility for matching the population age structure to the initial age-composition data at the start of the modeled time period.

Growth

See 'Changes between Current and Last Assessment Model \ Growth' above.

Stock-recruitment relationship

Pacific sardines are believed to have a broad spawning season, beginning in January off northern Baja California and ending by July off the Pacific Northwest. In the semester-based model ALT, spawning stock biomass (SSB) is calculated at the beginning of S2 (January). Recruitment was specified to occur in S1 of the following model year (consistent with the July 1st birth-date assumption). In past assessments, a Ricker stock-recruitment (S-R) relationship had been assumed following Jacobson and MacCall (1995), however, following recommendations from past reviews, a Beverton-Holt S-R has been implemented in all assessments since 2014.

Virgin recruitment (R_0), initial equilibrium recruitment offset (R_1), and steepness (h) were estimated. Following recommendations from past assessments, the estimate of average recruitment variability (σ_R) assumed in the S-R relationship was set to 0.75 since 2014. Recruitment deviations were estimated as separate vectors for the early and main data periods in the overall model. Early recruitment deviations for the initial population were estimated from 1999-04 (six years before the start of the model). A recruitment bias adjustment ramp (Methot and Taylor 2011) was applied to the early period and bias-adjusted recruitment estimated in the main period of the model (Figure 31). Main period recruitment deviations were advanced one year from that used in the last assessment, i.e., estimated from 2005-15 (S2 of each model year), which translates to the 2016 year class being freely estimated (albeit poorly) from the 2016 data available in the model.

It is important to note that there exists little information in the assessment to directly evaluate recent recruitment strength (e.g., absolute numbers of age-0, 6-9 cm fish in the most recent year), with the exception of age data from the southern fisheries, which have caught these juveniles infrequently in past years in low volume during their first semester of life (S1), but in greater amounts during their second semester (MEXCAL_S2). Age-0 recruits are rarely observed in the PNW fishery. Age-0 fish are not typically encountered by the AT survey, except for limited occurrences in particular years and in relatively high numbers observed in one cruise (summer 2015).

Selectivity

Age-composition time series from the MEXCAL and PNW fisheries were modeled using age-based selectivity. The MEXCAL compositions were fit based on each age as a random walk from the previous age, which resulted in domed-shaped selectivity similar to fits from a double-normal selectivity form as used in past assessments, i.e., supporting the assumption that older/larger fish are not generally available to the southern fisheries, both historically and presently. Selectivity for the MEXCAL fleet was estimated by semester (S1 and S2) to better account for both seasonal- and decadal-scale shifts in sardine availability to the southern region. The PNW fishery age compositions were fit using asymptotic selectivity (two-parameter logistic form), given this stock's biology and strong evidence that larger, older sardines typically migrate to more northern feeding habitats each summer. A simple asymptotic selectivity form was used for the AT survey, whereby age-0 fish were assumed to be unavailable and age 1+ fish fully selected. Justifications for a simplified selectivity form for the AT survey follow: the survey is based on sound technical methods and an expansive sampling operation in the field using an optimal habitat index for efficiently encountering all adult fish in the stock (Demer and Zwolinski 2014); observations of age-1 fish in length- and age-composition time series, to some degree, in every year; recognition of some level of ageing bias in the laboratory that may confound explicit interpretation of estimated age compositions, e.g., low probability of selection of age-1 fish in a particular year may be attributed to incorrectly assigned ages for age-0 or age-2 fish; and minor constraints to selectivity estimation, which typically reflects a sensitive parameterization that can substantially impact model results, supports the overriding goal of the assessment, i.e., parsimonious model that is developed around the AT survey abundance index. Finally, in addition to potential biases associated with the trawling and ageing processes, the age-1+ selectivity assumption recognizes the vulnerability of adult sardine with fully-developed swim bladders to echosounder energy in the acoustic sampling process. That is, there are three selectivity components to consider with the acoustic-trawl method: 1) fish availability with regard to the actual area surveyed each year; 2) vulnerability of fish to the acoustic sampling gear; and 3) vulnerability of fish to the mid-water trawl (avoidance and/or extrusion). No evidence exists that sardine with fully-developed swim bladders (i.e., greater than age 0) are missed by the acoustic equipment, further supporting the assumption that age-1+ fish are fully-selected by the survey in any given year.

Catchability
See ‘Changes between Current and Last Assessment Model \ Catchability’ above.

Convergence criteria and status
The iterative process for determining numerical solutions in the model was continued until the difference between successive likelihood estimates was <0.00001. The total likelihood and final gradient estimates for model ALT were 333.256 and 8.97*e*-6, respectively.

Results

The following results pertain to model ALT. Estimates for important parameterizations and derived quantities useful to management are also presented in Tables 10-16.

Parameter estimates and errors
Parameter estimates and standard errors (SE) for model ALT are presented in Table 12.

Growth estimates
Growth parameters were not estimated in model ALT, rather, empirical weight-at-age estimates by year were used to convert estimated numbers into weight of fish for calculating important biomass quantities useful to management (Figures 5-8).

Selectivity estimates and fits to fishery and survey age-composition time series
Age-based selectivity estimates (ogives) for the three fisheries and AT survey are presented in Figure 22. Model fit displays to fishery and AT survey age compositions (including observed and effective sample sizes) and associated Pearson residual plots are presented in Figures 23-26. The fishery (MEXCAL_S1, MEXCAL_S2, and PNW) age-composition time series were fit relatively well in most years, but poor fits were observed in some years, particularly, for the most recent years in the time series (Figures 23-26). Poor fits to the AT survey age-composition time series were indicated in most years (Figure 26). See ‘Uncertainty Analyses / Selectivity analysis’ below.

Fit to survey index of abundance
Model fits to the AT survey abundance index in arithmetic and log scale are presented in Figure 27. The predicted fit to the survey index was generally good (near mean estimates and within error bounds), particularly, for the most recent years of the time series (Figure 27). As illustrated in past assessments, the notable exception in the fitted time series was for the initial survey year 2005 (spring 2006 cruise), which was under-estimated and outside the estimated confidence interval. Estimated catchability (*Q*) for the AT survey was 1.1 (Table 12). Also, see ‘Changes between Current and Last Assessment Model / Catchability’ above.

Stock-recruitment relationship
Recruitment was modeled using a Beverton-Holt stock-recruitment (S-R) relationship (Figure 28). The assumed level of underlying recruitment deviation error was fixed (σ_R=0.75), virgin (unfished) recruitment was estimated (logR_0=14.2), and steepness was estimated (*h*=0.36) (Table 12). Recruitment deviations for the early (1999-04), main (2005-15), and forecast (2016-17) periods in the model are presented in Figure 29). Asymptotic standard errors for recruitment deviations are displayed in Figure 30 and the recruitment bias adjustment plot for early, main, and forecast periods in model ALT is shown in Figure 31.

Population number- and biomass-at-age estimates
Population number-at-age estimates for model ALT are presented in Table 13. On average, age 0-3 fish have comprised roughly 85% of the total number of Pacific sardine in each year from 2005-17. Corresponding estimates of population biomass-at-age, total biomass (age-0+ fish, mt) and stock biomass (age-1+ fish, mt) are shown in Table 14. On average, age 0-3 fish have comprised roughly 65% of the total population biomass in each year from 2005-17.

Spawning stock biomass
Time series of estimated spawning stock biomass (SSB, mmt) and associated 95% confidence intervals are presented in Table 15 and Figure 32. The virgin level of SSB was estimated to be 107,915 mt (0.11 mmt). The SSB has continually declined since 2005-06, reaching historically low levels in recent years (2014-present).

Recruitment
Time series of estimated recruitment (age 0, billions) abundance is presented in Table 15 and Figure 34. The virgin level of recruitment (R_0) was estimated to be 1.52 billion age-0 fish. As indicated for SSB above, recruitment has largely declined since 2005-06, with the exception of a brief period of modest recruitment success from 2009-10. In particular, the 2011-15 year classes have been among the weakest in recent history. A small increase in recruitment was observed in 2016, albeit a highly variable estimate (CV=79%) based on limited data.

Stock biomass for PFMC management
Stock biomass, used for calculating annual harvest specifications, is defined as the sum of the biomass for sardine ages one and older (age 1+) at the start of the management year. Time series of estimated stock biomass (mmt) are presented Table 14 and Figure 33. As discussed above for both SSB and recruitment, a similar trend of declining stock biomass has been observed since 2005-06, plateauing at recent historical low levels since 2014 (roughly 78,000 mt, 0.08 mmt).

Fishing and exploitation rates
Estimated fishing mortality (*F*) time series by fishery are presented in Figure 35. Fishing mortality has been generally less than 0.4 yr^{-1} since 2005-06, with the exception of the PNW fishery in 2005 and from 2012-13, with *F* estimates above 1.0 yr^{-1}.

Exploitation rate is defined as the calendar year northern sub-population (NSP) catch divided by the total mid-year biomass (July 1^{st}, ages 0+). The U.S. and total exploitation rates for the NSP are shown in Figure 36. The U.S. exploitation rate was less than 10% from 2005-11, increased sharply from 2012-14 to over 25%, and dropped again to under 5% recent years. The total exploitation rate time series followed a similar trend, with exploitation rates less than 17% from 2005-11, increasing to 40% by 2013, and decreasing to similar levels as for the U.S. in recent years.

Uncertainty Analyses

Virgin recruitment profile
Virgin recruitment (R_0) profiles are useful for identifying the extent conflicts between data components included in the assessment potentially influence underlying scale in the model (Lee et al. 2014). Components in model ALT include composition (fishery and survey age-composition time series) and abundance (AT survey index of abundance) data. A R_0 profile for model ALT is presented in Figure 37. The profile was conducted over a range of assumed (fixed) R_0 values from 13.5 to 15, with multiple runs at each R_0 level, based on jittering starting values for estimated parameters to ensure model convergence. The profile indicated all sources of data in model ALT were generally consistent, with each component illustrating better fitting models were associated with lower vs. higher assumed levels of R_0. The individual total profile indicates the model ALT configuration (R_0=14.236) appears to have realized a global minimum total likelihood estimate.

Natural mortality profile
Treatment of natural mortality (*M*) in model ALT is discussed above, see 'Longevity and natural mortality.' Uncertainty associated with the assumed (fixed) level of natural mortality in model ALT (M=0.6 yr^{-1}) was also evaluated by profiling across a range of fixed levels of the stock parameter of interest, *M* (Table 16 and Figure 38). The profile was conducted using a range of *M* values from 0.35 to 0.75 yr^{-1}. In the context of the ALT model, models with higher assumed levels of *M* resulted in lower estimates of AT survey catchability (*Q*), and higher terminal estimates of spawning stock biomass and stock biomass. Model fits to most data components, as well as total likelihood estimates indicated slightly better fits to lower estimates of *M*, however, the AT survey index of abundance and MEXCAL_S1 age-composition data indicated better fitting models at higher *M* (Table 16 and Figure 38). The range of recent estimated stock biomass (2014-17) associated with the *M* profile is presented in Figure 38, with terminal year estimates (2017) that ranged from roughly 40,000 mt (M=0.35 yr^{-1}) to 160,000 mt (M=0.75 yr^{-1}).

Retrospective analysis
Retrospective analysis provides another means of examining model properties and characterizing uncertainty. A retrospective analysis was performed for model ALT, whereby data were incrementally removed from the terminal year backwards in time to 2000. Estimated stock biomass time series from this analysis are presented in Figure 39. For the most part, no notable retrospective pattern was indicated by the analysis, i.e., no systematic bias of overestimating biomass in the terminal year was illustrated through sequentially removing data from the model backwards in time. A slight retrospective bias was indicated as data were removed four or more years back in time. It is important to note that some degree of retrospective bias would be expected from a stock assessment of short-lived, productive species like Pacific sardine, given little information is available in the integrated model for estimating recruitment that typically is highly variable in any given year based on immediate oceanographic conditions.

Sensitivity analysis (survey abundance indices, AT survey selectivity, stock-recruitment steepness, data weighting methods, and fishery time-varying selectivity)

Sensitivity analyses were conducted prior and during the review in February that addressed assumptions for survey (AT and DEPM) time series included in the model, AT survey selectivity forms, stock-recruitment (S-R) steepness (*h*), and alternative data weighting approaches for model ALT. Estimates for likelihood components, specific parameters, and derived quantities of interest associated with the models evaluated in sensitivity analysis are presented in Table 17. Estimated stock biomass (age-1+ fish, mt) time series are compared between the different model scenarios in Figure 40. Also, further discussion regarding models evaluated in sensitivity analysis, as well as other configurations investigated during the review are presented in STAR (2017). As illustrated in past assessments, inclusion of the DEPM index of abundance in the model had little influence on results, with nearly identical stock biomass trajectories observed and slightly higher terminal estimate of stock biomass for the model that included both indices of abundance. Basing the AT survey selectivity on a simple (two-parameter logistic) asymptotic form as used for the PNW fishery resulted in generally similar estimated selectivity as the age-1+ fully-selected form used in model ALT, but indicating only partially selected younger ages (i.e., 5% vs. 0%, 25% vs. 100%, and 70% vs. 100% selection for ages 0, 1, and 2, respectively), which resulted in higher estimated stock biomass in the terminal year (approximately 153,000 mt vs. 87,000 mt in model ALT). Fixing S-R steepness at the level assumed in recent assessments (h=0.8) had little effect in the model, with estimated stock biomass in the terminal year equal to roughly 112,00 mt vs. 87,000 mt for model ALT (estimated steepness, h=0.36). Two alternative data weighting approaches ('Francis method' and 'harmonic-mean method' in Stock Synthesis) implemented in model ALT resulted in generally similar findings as the non-weighted baseline model, with slightly higher estimated stock biomass in the terminal year than model ALT; see Francis (2011), Methot and Wetzel 2013, and Punt (in press). Finally, modeling time-varying selectivity for the fisheries resulted in notably better fits to the fishery age-composition time series, with generally similar estimates of derived quantities useful to management as estimated in model ALT (i.e., time invariant selectivity configuration). However, models with time-varying fishery selectivity were inherently less stable, with lack of convergence for many runs or indications of local minima when convergence was realized.

Convergence tests

Convergence properties of model ALT were tested to ensure the model represented an optimal solution. Model ALT was run with a wide range of initial starting values for R_0 (13.1 to 15.1). For each run, phase order for estimating parameter components (e.g., R_0, R_1, steepness, initial F, selectivity, and AT survey Q) was randomized from 1 to 5, and all parameters were jittered by 20% (Table 18). All models converged to the same total negative log likelihood estimate (333.256) and had identical final estimates of R_0 (14.2359). Model ALT appeared to have converged to a global minimum (also, see 'Virgin recruitment profile' above).

Historical analysis

Estimates of stock biomass (age-1+ fish, mt) and recruitment (age-0 fish, billions) for model ALT were compared to recently conducted assessments in Figure 41. Full and updated stock assessments since 2009 (Hill et al. 2009-16) are included in the comparison. Stock biomass and recruitment trends were generally similar, with notable differences in scale between particular years. It is important to note that all previous assessments (since 2009) were structured very similarly (e.g., similar model dimensions, data, assumptions, and parameterizations). Whereas, the newly developed ALT model (2017) reflects a much simpler version of past assessments models (See ‘Changes between Current and Last Assessment Model’ above), necessarily confounding direct comparisons between results from this year’s model with past assessments.

HARVEST CONTROL RULES FOR THE 2017-18 MANAGEMENT CYCLE

Harvest Guideline

The annual harvest guideline (HG) is calculated as follows:

HG = (BIOMASS – CUTOFF) • FRACTION • DISTRIBUTION;

where HG is the total U.S. directed harvest for the period July 2017 to June 2018, BIOMASS is the stock biomass (ages 1+, mt) projected as of July 1, 2017, CUTOFF (150,000 mt) is the lowest level of biomass for which directed harvest is allowed, FRACTION (E_{MSY} bounded 0.05-0.20) is the percentage of biomass above the CUTOFF that can be harvested, and DISTRIBUTION (87%) is the average portion of BIOMASS assumed in U.S. waters. Based on results from model ALT, estimated stock biomass is projected to be below the 150,000 mt threshold and thus, the HG for 2017-18 would be 0 mt. Harvest estimates for model ALT are presented in Table 19.

OFL and ABC

On March 11, 2014, the PFMC adopted the use of CalCOFI sea-surface temperature (SST) data for specifying environmentally-dependent E_{MSY} each year. The E_{MSY} is calculated as,

$$E_{\mathrm{MSY}} = -18.46452+3.25209(T)-0.19723(T^2)+0.0041863(T^3),$$

where T is the three-year running average of CalCOFI SST (Table 20, Figure 42), and E_{MSY} for OFL and ABC is bounded between 0 to 0.25 (Figure 42). Based on the recent warmer conditions in the CCE, the average temperature for 2014-16 increased to 15.9999 °C, resulting in E_{MSY}=0.2251.

Estimated stock biomass in July 2017 for model ALT was **86,586 mt** (Table 19). The overfishing limit (OFL, 2017-18) associated with that biomass was **16,957 mt** (Table 19). Acceptable biological catches (ABC, 2017-18) for a range of *P-star* values (Tier 1 σ=0.36; Tier 2 σ=0.72) associated with model ALT are presented in Table 19.

REGIONAL MANAGEMENT CONSIDERATIONS

Pacific sardine, as well as other species considered in the CPS FMP, are not managed formally on a regional basis within the USA, due primarily to the extensive distribution and annual migration exhibited by these small pelagic stocks. A form of regional (spatial/temporal) management has been adopted for Pacific sardine, whereby seasonal allocations are stipulated in attempts to ensure regional fishing sectors have at least some access to the directed harvest each year (PFMC 2014).

RESEARCH AND DATA NEEDS

Research and data needed for improving stock assessments of the Pacific sardine resource in the future address three major areas that are presented in descending order of importance below.

First and foremost, the most important area of focus should be improvements associated with the highest priority data available for assessing recent stock biomass on an annual basis, namely, the acoustic-trawl (AT) survey index of abundance (see 'Assessment – Acoustic-trawl Survey \ Overview' above). This is the case whether future management will be based directly on the AT survey or via an integrated model. The AT survey methods and design are founded currently on objective scientific bases, however, the need for continual improvement for specific areas include: 1) Target-strength estimation for local species; 2) determine potential biases due to the non-sampling of near-surface waters and shallow regions on the east end of the transects; and 3) implications of the time-lag between acoustic observations and trawl sampling operations (see 'Assessment – Acoustic-trawl Survey \ Areas of Improvement for the AT Survey' above). Additionally, improved relations with neighboring countries that also commercially target the northern sub-population of Pacific sardine (particularly, Mexico) are needed to establish a broader survey boundary than possible presently (e.g., Baja California, Mexico to Vancouver Island, Canada), which would allow stock structure hypotheses for this species to be evaluated more objectively. Finally, long-term support and commitment to the AT survey will benefit more than Pacific sardine alone, given these data represent the highest quality information available for determining recent stock biomass for all members of the small pelagic fish assemblage of the California Current ecosystem, including northern anchovy (northern and central sub-stocks), as well as mackerel populations (e.g., Pacific and jack)—noting that further attention is needed surrounding catchability issues that remain unresolved for these transboundary stocks and the extent to which a species' range in any given year may be outside the survey design's boundaries.

Second, maintaining a high quality (accurate and precise) composition time series, both age and size (length and weight), is critical for either assessment approach, but particularly, for using an integrated model for assessing the status of the stock. Data collection of biological samples by the three state fishery agencies (CDFW, ODFW, and WDFW) is adequate presently, but obtaining such data from Canada and particularly Mexico, has been somewhat problematic in the past. Further, multiple ageing operations are relied on currently, which would benefit from further coordination that ensures samples are efficiently processed in a timely manner and related ageing bias is minimized across laboratories. In this context, a major change that warrants further consideration would be to revisit the merits and drawbacks of using multiple ageing laboratories vs. trying to better centralize ageing operations under a single laboratory.

Third, a schedule should be adopted for conducting biology-related studies for informing critical biological parameters in a model-based assessment. For example, revisiting assumed maturity schedules currently used for Pacific sardine (this is done every year when the DEPM data are processed), as well as periodically evaluating growth parameters applicable to the stock, even though growth is no longer an estimated parameter in the model-based assessment. That is, it is important that data for generally informing biology parameters applicable to the stock continue to be collected and processed according to an efficient schedule that allows both the survey- and particularly, model-based assessment to be updated systematically. For example, an ideal schedule for conducting (coastwide) biology projects related to Pacific sardine would be every 5-7 years.

ACKNOWLEDGMENTS

The annual sardine assessment depends, in large part, on the diligence of many colleagues and the timely receipt of their data products. Port samples for the Ensenada, México fishery were collected by INAPESCA (Ensenada). Recent landings data from the Ensenada fishery were kindly provided by Concepción Enciso-Enciso (INAPESCA-Ensenada). Port samples and ageing data for the California fishery were provided by CDFW Marine Region personnel in Monterey (Chelsea Protasio, Laura Ryley, Anna Holder, Nichole Rodriguez, Ciera Cross, and Abril Zarate), Los Alamitos (Dianna Porzio, Mandy Lewis, Trung Nguyen, and Roy Kim), and Santa Barbara (Erica Hadley and David Gottesman). Thanks also go to the staffs of ODFW (Jill Smith, Nick Wilsman, Dean Headlee, Cyreis Schmitt) and WDFW (Carol Henry, Kristen Hinton, Bob Le Goff, and Lorna Wargo) for collecting and processing biological samples from the fisheries off the Pacific Northwest. All ODFW and WDFW otolith samples were aged by Sandy Rosenfield and Jennifer Topping of WDFW-Olympia. We thank Alan Sarich of the Quinault Indian Nation for providing sample data from their fishery during June and July of 2015. Monthly landings and size data for the British Columbia fishery were collected by D&D Pacific Fisheries Ltd which is a 3rd party contracted service (dockside validation, at sea sampling, catch and sample data entry and management) funded by the Canadian Pacific Sardine Association and First Nations Sardine Association. DFO-Canada staff are custodians and users of the data, and Linnea Flostrand, Vanessa Hodes, Sean MacConnachie, and Jordan Mah kindly provided the data as used in this assessment. Numerous staff from the SWFSC assisted in the ongoing collection and processing of ichthyoplankton samples, mid-water trawl samples, and acoustic data used in this assessment. We thank Richard Methot (NWFSC) for developing and continuously improving the Stock Synthesis mode, and thank Ian Taylor (NWFSC) for maintaining the R4SS package that allows SS outputs to be efficiently summarized and displayed.

Table 5. Fishery-independent indices of Pacific sardine relative abundance. The DEPM time series was not included in model ALT. Complete details regarding calculation of DEPM estimates are provided in Appendix A. In the SS model, indices had a lognormal error structure with units of standard error of log*e*(index). Variances of the observations were available as a CVs, so the SEs were approximated as sqrt(log*e*(1+CV^2)).

Model Yr-Sem	DEPM	S.E. ln(index)	Acoustic	S.E. ln(index)

APPENDICES

APPENDIX A

SPAWNING BIOMASS OF PACIFIC SARDINE (*SARDINOPS SAGAX*) ESTIMATED FROM THE DAILY EGG PRODUCTION METHOD OFF THE U.S. WEST COAST IN 2016 (SUMMARY)

Emmanis Dorval[1,2], Beverly J. Macewicz[1], David A. Griffith[1], and Yuhong Gu[1,2]
[1]Southwest Fisheries Science Center, La Jolla Laboratory
[2]Ocean Associates contractor at Southwest Fisheries Science Center

From 1994 to 2013 DEPM and TEP estimates of SSB were based on SWFSC ship-based surveys conducted each April between San Diego and San Francisco, California (i.e. standard DEPM area), although in some years the surveys were extended as far north as Washington. In 2015 the survey was mostly north of the standard DEPM area and in 2016 it was completely north of this region. Therefore, in both years the SSB estimate was based on the whole DEPM survey area. The DEPM index of female SSB is used when data for eggs, larvae and adult daily-specific fecundity are available from the survey. The total egg production (TEP) index of SSB is used when survey-specific adult reproductive data are unavailable. The DEPM and TEP series have been used for sardine stock assessment since the 1990s, and the surveys and estimation method were reviewed by a STAR Panel in May 2009. Both time series are treated as indices of relative SSB, with catchability coefficients (q) being estimated (Figure 1).

In 2016 the SWFSC conducted the sardine DEPM biomass survey aboard the NOAA ship *Rueben Lasker* (March 22 – April 22) from about Lincoln Beach, Oregon (44.85°N) to north of Muir Beach, California (ending at 37.84°N on CalCOFI line 56.7) (Figure 1). The spring CalCOFI survey was conducted on the NOAA Ship *Bell M. Shimada* (April 1 – April 22) from San Diego to San Francisco Bay. However, data from the CalCOFI survey were not used because no trawling was conducted. Further, during CalCOFI no eggs were collected from CalVET tows, one egg was caught in Bongo tows, and no larvae were collected in both nets (Table 1). Consequently, only data from the DEPM survey on the *Lasker* were included in the estimation of spawning biomass of Pacific sardine. The DEPM survey from the *Lasker* employed all the usual methods for estimating sardine SSB (Lo et al. 2010), but sampling was performed outside of the standard DEPM area (Figure 1).

The 2016 sardine DEPM survey was initially designed with thirty five distinct transects in which eighteen were compulsory and seventeen were adaptive, covering the area from Newport, Oregon to Point Conception, California. The compulsory transects were positioned at forty nautical mile intervals and when adaptive transects were occupied, the spacing between transects was reduced to twenty nautical miles. Similar to the 2015 survey, the Zwolinski et al. (2011)'s habitat model forecast for April 2016 was used to determine potential optimal habitat of sardine and sampling frame of the survey. Since the northern extent of the population was not known, the ship traveled northward and began sampling on the second compulsory line (located at 43.9°N) from the northern most pre-determined transect. Because Pacific sardine eggs were encountered during operations on this transect, the ship continued sampling north until no eggs were encountered, which extended the last northern line to a position just off Lincoln Beach, Oregon. Hence, the whole DEPM survey area was located between 44.85°N and 37.84°N (Figure 1) and effectively occupied 11 compulsory and 5 adaptive lines from the north to the south. Transect spacing was reduced, as much as 20 nautical mile, whenever sardine eggs, larvae or fish were encountered. In areas with no observed eggs, fish or larvae, transect spacing was increased as much as forty nautical miles to save time and cover a broader area of the coast.

The 2016 DEPM index area for the entire survey (44.85°N latitude to CalCOFI line 56.7) was 133,489 km^2 (Figure 1). The egg production (P_0) estimate was 0.54/0.05m^2/day (CV = 0.56) in the high egg-density region and 0.07/0.05 m^2/day (CV = 0.58) for the whole survey area. These areas were computed after a 2.5 nautical mile expansion (i.e. half of the distance between CUFES samples) from survey line or station (see Dorval et al. 2017). Female spawning biomass for the whole survey area was taken as the sum of female spawning biomasses in Regions 1 and 2 (Table 2). The female spawning biomass (sum) and total spawning biomass for the DEPM whole survey area were estimated to be 5,929 mt (CV = 0.58) and 9,536 mt (CV = 0.59), respectively (Table 2).

Adult reproductive parameters for the 2016 whole survey area are presented in Table 3. The estimated daily-specific fecundity was 20.07 (number of eggs/population weight (g)/day) using the following estimates of reproductive parameters from 71 mature females collected from 6 positive trawls: mean batch fecundity (F) was 34,327 eggs/batch (CV = 0.15), fraction spawning (S) was 0.145 females spawning per day (CV = 0.20), mean female fish weight (W_f) was 148.03 g (CV = 0.098), and sex ratio of females by weight (R) was 0.598 (CV = 0.13). Since 2005, trawling has been conducted randomly or at CalCOFI stations, which resulted in sampling adult sardines in both high (Region 1) and low (Region 2) sardine egg-density areas. During the 2016 survey, 3 tows were positive for mature female sardines in Region 1 and 3 in Region 2. Additionally, during the survey one tow caught solely males and nine tows caught only immature sardines (Dorval et al. 2016). Further, batch fecundity was predicted from a regression model using data collected from the 2016 survey.

In SS, the DEPM series was taken to represent female SSB (length selectivity option ’30’) in the middle of S2 (April). Since 2009, the time series of spawning biomass was replaced by female spawning biomass for years when sufficient trawl samples were available and the total egg production for other years as inputs to the stock assessment of Pacific sardine. The 2016 DEPM estimate is much lower than in the previous few years (Tables 2 & 3; Figure 1), potentially due to: 1) continuing decline in spawning stock biomass since 2011; 2) the shift of the high egg-density area to off Oregon, a less suitable spring spawning habitat; and 3) the trawl catches were mostly dominated by young, small and immature sardines which were not producing eggs.

Table 1. Number of positive tows of sardine eggs from CalVET, yolk-sac larvae from CalVET and Bongo, eggs from CUFES and positive sardine trawls[a] in Region 1 (high, eggs/min ≥ 0.2), Region 2 (low, eggs/min < 0.2) for the *Reuben Lasker* Sardine DEPM survey in spring 2016 and the *Bell M. Shimada* CalCOFI survey. The *Lasker* whole DEPM survey area (133,488 km^2, between latitudes 44.85°N and 37.84°N) from about Lincoln Beach, Oregon to CalCOFI line 56.7 (Muir Beach, California) was all north of the standard DEPM area (CalCOFI line 60.0 to 95.0).

Gear	Tows and Sampling type	CalCOFI	DEPM		
		April 1-22, 2016 *Bell M. Shimada*	March 26 – April 22, 2016 *Reuben Lasker*		
			Region 1	Region 2	Whole
CalVET (Pairovet)	Total tows	87	18	43	61
	Total positive tows	0	10	6	16
	Positive egg tows	0	10	2	12
	Eggs	0	31	41	72
	Positive larvae tows	0	2	5	7

	Positive samples	9	39	15	54
	Eggs	15	448	32	480
Trawl	Total tows	n/a	6	35	41
	Total positive tows		3	13	16
	Total sardine		212	276	488
	Female sardine		105	107	212
	Area in km^2	354,032	12,778	120,710	133,488

[a] All sardines were captured at night; 10 trawls in Region 2 caught only male or immature sardines.
[b] Egg data from the Bongo net are not used in the daily egg production (P_0) estimation.
[c] Total sardine were those sampled and measured: including males, females, and those of unknown sex
[d] Female sardine were those sampled and measured: including mature and immature.

Table 2. The spawning biomass related parameters: daily egg production/0.05m^2 (P_0),daily mortality rate (z), survey area (km^2), two daily specific fecundities: (RSF/W), and (SF/W); s. biomass, female spawning biomass, total egg production (TEP) and sea surface temperature for 1986, 1987, 1994, 2004, 2005 and 2007-2016.

1: P_0 for the whole is the weighted average with area as the weight.

2. The estimates of adult parameters for the whole area were unstratified and RSF/W was based on original S_1 data of day-1 spawning females. For 2004, 27.03 was based on sex ratio= 0.618 while past biomass used RSF/W of 21.86 based on sex ratio = 0.5.(Lo et al. 2008).

3. The estimates of adult parameters for the whole area were unstratified. Batch fecundity was estimated with error term. For 1987 and 1994, estimates were based on S_1 using data of day-1 spawning females. For 2004, all trawls were in Region 1 and value was applied to Region 2.

4. Region 1 area is based: in 2015, on CUFES ≥ 0.3 eggs/min; in 2004-2013, on CUFES ≥1 eggs/min; and prior to 1997, from CalVET tows with eggs/0.05m^2 >0.

5: For the spawning biomass, the estimate for the whole area uses unstratified adult parameters.

6. Within southern and northern area, the survey area was stratified as Region 1 (eggs/0.05m2>0 with embedded zero) and Region 2 (zero eggs).

Table 3. Pacific sardine female adult parameters for surveys conducted in the standard daily egg production method (DEPM) sampling area off California during 1994-2014 (1994 includes females from off Mexico) and off northern California and Oregon in 2015-2016.

[a] 1994-2001 estimates were calculated using F_b = -10858 + 439.53 W_{of} (Macewicz et al. 1996), 2004 used $F_b = 356.46W_{of}$. (Lo and Macewicz 2004), 2005 used F_b = -6085 + 376.28 W_{of} (Lo and Macewicz 2006), 2006 used F_b = -396 + 293.39 W_{of} (Lo et al. 2007a), 2007 used $F_b = 279.23W_{of}$ (Lo et al. 2007b), 2008 used $F_b = 305.14W_{of}$ (Lo et al. 2008), 2009 used $F_b = -4598 + 326.78W_{of} + e$ (Lo et al. 2009), 2010 used $F_b = 5136 + 287.37W_{of} + e$ (Lo et al. 2010), 2011 used $F_b = -2252 + 347.6W_{of} + e$ (Lo et al. 2011), 2012 used $F_b = -12724 + 402.3W_{of} + e$ (Lo et al. 2013), 2013 used $F_b = -9759 + 404.24W_{of} + e$ (Dorval et al. 2014), 2014 used equation from 2013, 2015 used $F_b = -5112 + 365.85W_{of} + e$, and 2016 used $F_b = 12708 + 167.83W_{of} + e$,.

[b] Mature females include females that are active and those that are postbreeding (incapable of further spawning this season). S_1 was used for years prior to 2009 and S_{12} was used staring 2009.

[c] Active mature females are capable of spawning and have ovaries containing oocytes with yolk or postovulatory follicles less than 60 hours old.

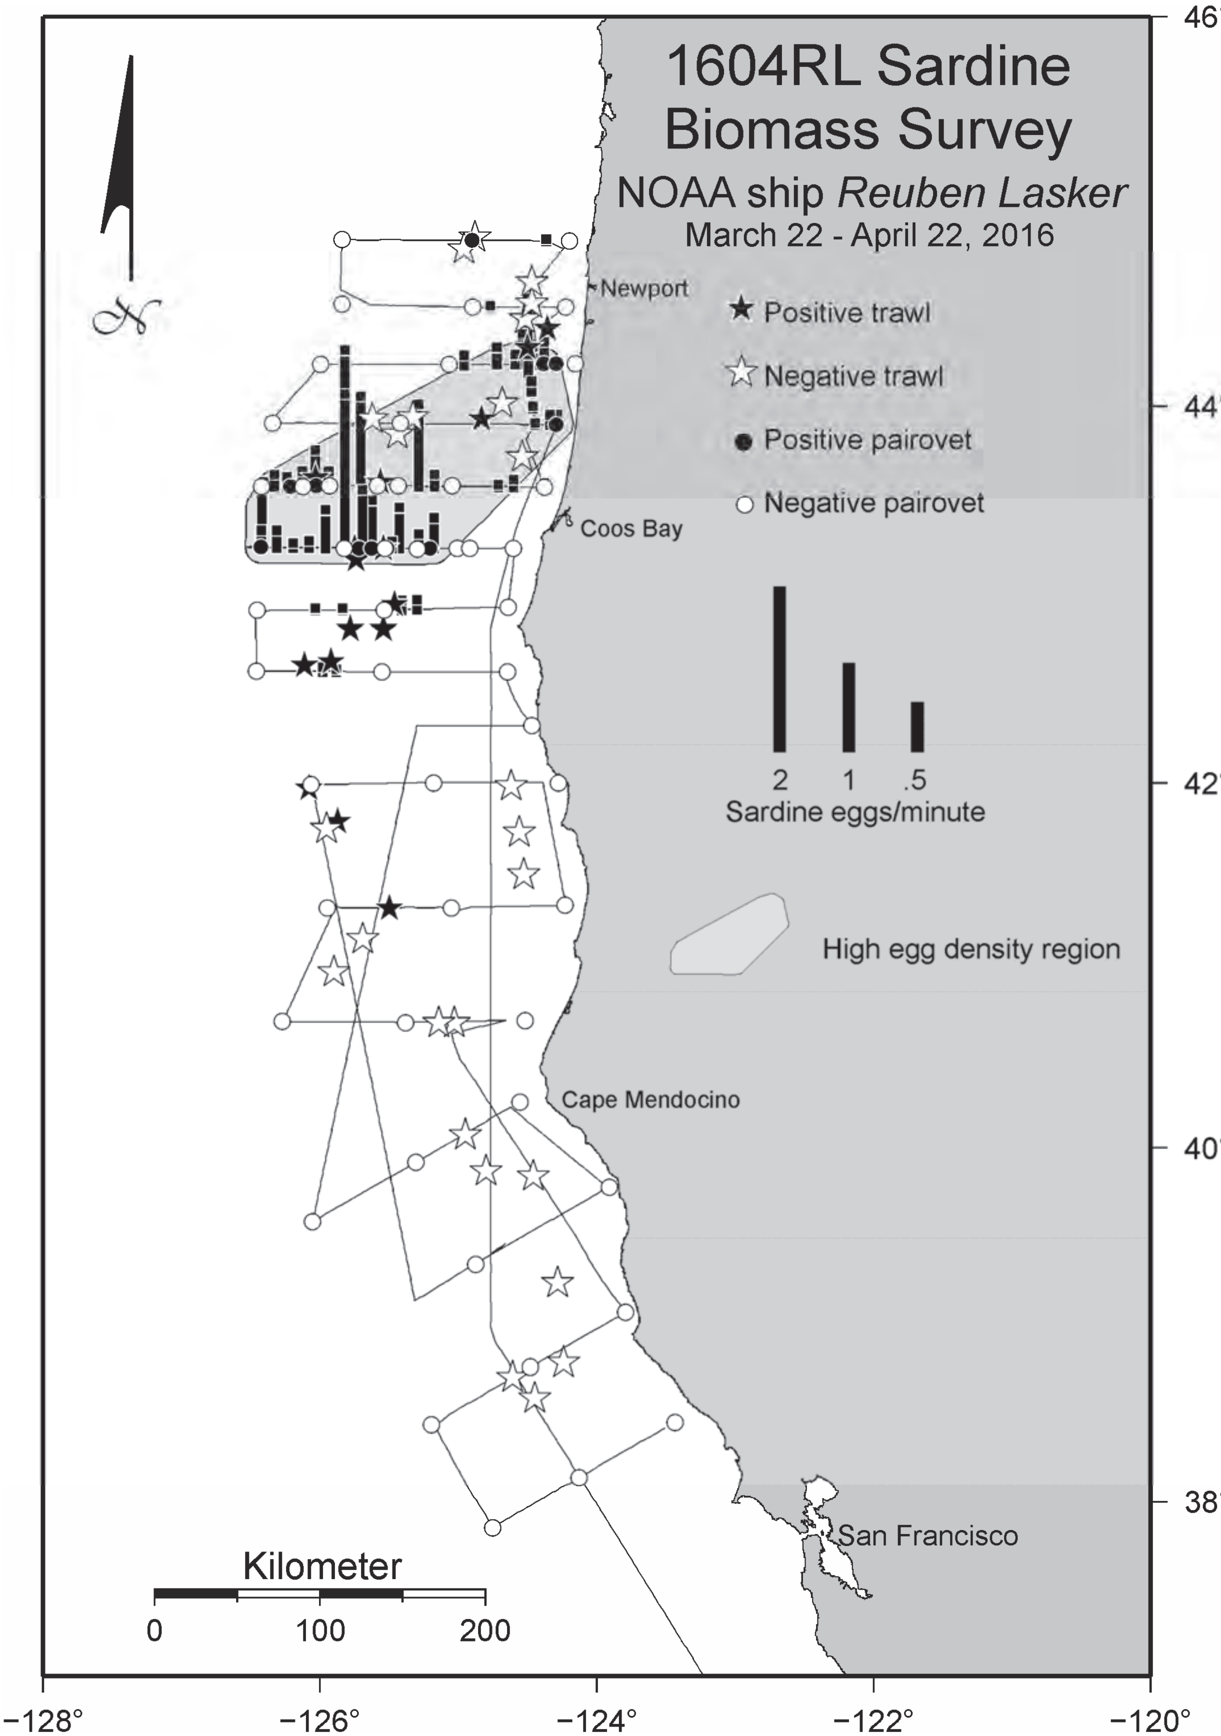

Figure 1. DEPM survey area and location of CalVET (Pairovet) and bongo tows, CUFES, and trawl locations during the 2016 survey aboard the NOAA ship *Reuben H. Lasker*.

Pacific Sardine
STAR Panel Meeting Report

NOAA / Southwest Fisheries Science Center
La Jolla, California
February 21-23, 2017

STAR Panel Members:
André Punt (Chair), Scientific and Statistical Committee (SSC), Univ. of Washington
Will Satterthwaite, SSC, Southwest Fisheries Science Center
Evelyn Brown, SSC, Lummi Natural Resources, LIBC
Jon Vølstad, Center for Independent Experts (CIE)
Gary Melvin, Center for Independent Experts (CIE)

Pacific Fishery Management Council (Council) Representatives:
Kerry Griffin, Council Staff
Diane Pleschner-Steele, CPSAS Advisor to STAR Panel
Lorna Wargo, CPSMT Advisor to STAR Panel

Pacific Sardine Stock Assessment Team:
Kevin Hill, NOAA / SWFSC
Paul Crone, NOAA / SWFSC
Juan Zwolinski, NOAA / SWFSC

1) Overview

The Pacific Sardine Stock Assessment and Review (STAR) Panel (Panel) met at the Southwest Fisheries Science Center (SWFSC), La Jolla, CA from February 21-23, 2017 to review a draft assessment by the Stock Assessment Team (STAT) for the northern subpopulation of Pacific Sardine. Introductions were made (see list of attendees, Appendix 1), and the agenda was adopted. A draft assessment document and background materials were provided to the Panel in advance of the meeting on a Council FTP site.

Drs. Paul Crone, Kevin Hill, and Juan Zwolinski presented the assessment methodology. Paul Crone first outlined the assessment philosophy, which focused on selecting an approach that made most use of the data source considered by the STAT to be most objective, i.e. the Acoustic Trawl Method (ATM) survey. The STAT provided results for two assessment approaches: (a) use of the summer 2016 ATM survey estimate and associated age-composition projected to 1 July 2017, and (b) a model-based assessment that provides an estimate of age 1+ biomass on 1 July 2017.

Juan Zwolinski described the survey-based method for estimating age 1+ biomass on 1 July 2017, which involved estimating numbers-at-age on 1 July 2016 from the summer 2016 ATM survey from numbers-at-length using an age-length key that pooled data over multiple summer surveys, and projecting these numbers forward accounting for natural mortality and growth, and adding the estimated recruitment for 2016. The recruitment for 2016 was based on the stock-recruitment relationship estimated by model ALT, and the spawning stock biomass for 2016 was estimated by back-projecting the summer 2016 numbers-at-age to 1 January 2016.

Kevin Hill and Paul Crone described the data on which the model-based assessment was based, as well the results from a draft assessment utilizing the Stock Synthesis Assessment Tool, Version 3.24aa. Model ALT differed from the model on which the 2016 update assessment was based by starting the assessment in 2005 rather than 1993, excluding the Daily Egg Production Method (DEPM) and Total Egg Production (TEP) indices, estimating rather than pre-specifying stock-recruitment steepness, pre-specifying weight-at-age rather than estimating it within the assessment, assuming that selectivity for the ATM survey is zero for age 0 and uniform for age 1 and older, estimating survey catchability (Q), assuming that selectivity is age- rather than length-based, modelling ages 0-10+yr rather than ages 0-15+yr, assuming natural mortality (*M*) is 0.6yr^{-1} rather than 0.4yr^{-1} for all age classes and fitting the catch and ATM survey age-composition data (rather than the associated length-composition data). Unlike the 2016 and earlier assessments, model ALT included additional live bait landings, which generally reflected a minor contribution to the total landings in California. However, model ALT did not include biological composition data from the live bait catches, given this fishery sector had not been regularly sampled in the past, with samples being available for only the most recent year of the time period modelled in the assessment.

The review and subsequent explorations of the assessment through sensitivity analyses were motivated primarily by the need for the survey-based method to provide an estimate of age 1+ biomass and its CV, to better understand the rationale for the changes made to the model on which the last full assessment was based that led to model ALT, and to identify the best approach for providing an estimate of age 1+ biomass on 1 July 2017. The Panel had several comments and concerns regarding the ATM survey methodology and ways in which estimates of close-to-absolute abundance can be obtained. However, this was not a review of the ATM survey, since a second Council-sponsored ATM methodology review is planned for early 2018. Therefore, comments regarding the ATM survey and how estimates of abundance from that survey are constructed are reflected primarily in the Research Recommendations section of the report.

The STAR Panel thanked the STAT for their hard work and willingness to respond to Panel requests, and the staff at the SWFSC La Jolla laboratory for their usual exceptional support and provisioning during the STAR meeting.

2) <u>Day 1 requests made to the STAT during the meeting – Tuesday, February 21</u>

Request 1: Provide documentation on the procedures used to calculate the survey age-composition data, including how age-length and age-biomass keys are constructed.

Rationale: These calculations are critical to projecting biomass after accounting for natural mortality, somatic growth, and recruitment; but the draft assessment document did not describe these calculations in sufficient detail for them to be reproduced. In addition, the age-compositions for the ATM survey in model ALT were computed using the method.

Response: Dr. Zwolinski presented written documentation and figures. The function "multinom" from the R package "nnet" fits a multinomial log-linear model using neural networks. The response is a discrete probability distribution (see Fig. 1). It is simpler to use than the alternative (sequential logistic models), and it provides a smoother transition between classes than an empirical age-at-length key. The age and lengths used for constructing the age-length key were from surveys from 2004 to the present. Due to the assumption of a July first date and its effect on ageing, the STAT built a season-specific age-length key using data pooled across time, separately for spring/summer.

The Panel agreed that aggregation across years is not appropriate if some length classes represent multiple ages, which is the case for Pacific sardine. Moreover, substantial spatial and temporal variation occurs in size-at-age, and merging the data from several years creates bias in annual estimates of age compositions of varying magnitude and direction.

Request 2: Provide full specification, including equations, of the calculations used to 1) project from the ATM survey biomass estimate to the estimated age-1+ biomass on July 1 of the following fishing year, and 2) calculate the uncertainty associated with that biomass estimate.

Rationale: The projection calculations need to be reproducible. Management advice (Overfishing Level OFL, Acceptable Biological Catch ABC, and Harvest Guideline HG) for Pacific sardine requires an estimate of age 1+ biomass (OFL, ABC, HG) and its uncertainty (ABC) on July 1, 2017.

Response: For 1), Dr. Zwolinksi walked the Panel through a spreadsheet that made these calculations and the Panel agreed that the calculations were sensible, conditional on the age-weight key. For 2), assuming independence of age 1 and age 2+ biomass, the total variance was calculated by summing the respective variances. This calculation is negatively biased because it ignores uncertainty in age-composition and weight-at-age. It was noted that the resultant coefficient of variation (CV) for age 1+biomass is lower than the CV for either component (age 1 versus age 2+) due to their assumed independence.

Request 3: Plot cohort-specific rather than year-specific growth curves (weight-at-age) for the ATM survey and overlay raw data/information on sample sizes. Make it clear which values are estimated versus inferred. Do this for the fisheries data as well.

Rationale: Cohort-specific curves are easier to interpret as growth trajectories than year-specific curves. It is important to understand how much data drives these estimates, and to understand the consequences of applying the same age-length key for all years with survey data to calculate the weight-at-age and age-composition for the ATM survey.

Response: Dr. Hill presented tables including sample sizes and estimated means for each cohort-season-age combination. The tables were formatted to highlight entries that were inferred versus estimated. Dr. Hill calculated means whenever 3 or more samples were available. However, these means were sometimes overwritten based on the assumption that animals did not shrink. The ATM data showed substantial variation in weight-at-age across years (Fig. 2), and possibly increasing size-at-age in recent years. The MexCal catch data appeared less variable overall, and it was noted that fishery sample sizes were generally larger than the ATM sample sizes. The smoothing was not applied to the PNW catch.

The Panel noted that the adopted method ended up discarding data for cohorts with unusually large mean sizes for (for example) age-0 fish by not allowing "shrinkage", whereas it may have been the age-0 means that were anomalous rather than the means calculated for older ages. The Panel also noted that in many cases, the sample sizes were very small. The weight-at-age key used within the survey-based projection did not exclude "shrinkage". Using the weight-at-age key in model ALT produced an imperceptible difference in model-estimated age 1+ biomass.

Request 4: Verify that model ALT was run with ATM survey selectivity set equal to 0 for age-0 fish. Contact Dr. Rick Methot to better understand how selectivity is being modeled under the chosen selectivity option in SS.

Rationale: The model outputs appear to indicate that the model predicts non-zero catches of age-0 fish despite the intent to specify selectivity to be zero on age-0 fish. This may have significant unintended consequences for the likelihood calculations.

Response: This question was not fully resolved. It appears that Stock Synthesis predicts some catch of nominal "age 0" even given selectivity of zero on true age-0 fish because aging error leads to the expectation that some age-1 fish will be caught and mis-categorized as age 0. Further, model runs revealed that the model was unable to converge if aging error was set to zero or made very small, but reductions in the specified aging error led to the expected reduction in the predicted age-0 catch. It was noted that surveys likely include a mix of age-1 fish mis-categorized as age-0, as well as fish that are truly age 0.

Dr. Methot also noted that Stock Synthesis had not been as thoroughly debugged for semester-based models as for strictly annual models.

See also Requests 5, 8, and 9.

Request 5: Re-run model ALT with age 0 fish removed from the input file for the ATM survey.

Rationale: Similar to Request 4, the model likelihood should not be influenced by data on age-0 fish if it is assumed selectivity on age-0 fish is zero, but the model appears to be generating non-zero predictions and comparing these against the input data.

Response: The model still predicted catch of age-0 fish in this scenario. This is consistent with the explanation suggested for this pattern under Request 4.

Request 6: Report the CV of the estimate of terminal biomass based on changes in how the compositional data are weighted.

Rationale: The weighting of composition data appeared to have little effect on the point estimate of biomass, but it is important to understand implications of alternative weighting schemes for uncertainty as well.

Response: Data weighting increased the CV by 2-3%. The base model had a CV of approximately 36%, Francis-weighting led to a CV of approximately 38%, and harmonic mean weighting led to a CV of about 39%.

Request 7: Show more outputs from T_2017 and T_2017_No_New_AT_Comp.
Rationale: These outputs would help the Panel evaluate the reasons for proposing a move away from a strict update of the previously accepted model structure, i.e. identify problems with a strict update that the new model structure addresses.
Response: Selectivity curves for the spring and summer ATM surveys were noticeably different depending on whether the two most recent survey length-compositions were included in the assessment or not (Fig. 3). These models appeared to yield acceptable fits to abundance indices, but the fits to observed length-compositions were poor. It appears that the model estimates very low selectivity on small fish for the summer survey (since selectivity does not vary across years, and very few small fish are encountered most years) such that when small fish are encountered, they are expanded to a very large number. During Panel discussion, it was noted that this unexpected behavior should not happen if selectivity were forced to be the same for the spring and summer surveys.

<u>**Day 2 requests made to the STAT during the meeting – Wednesday, February 22**</u>
Request 8: Develop a model in which selectivity for age-0 animals in the survey is time-varying.
Rationale: The availability of age-0 animals to the survey seems to be highly variable among years, but influential on the results. A selectivity function in which age-0 selectivity varies among years should "discount" the influence of occasional catches of age-0 animals.
Response: A model was presented that assumed essentially full selection on age-1+ animals, and time-varying age-0 selectivity. The model estimated nearly zero selectivity on age-0 fish in all years except 2015, when estimated selectivity on age-0 fish was nearly 1.0 (atypically large pulse of small/young fish observed in summer 2015). Fits to composition data were similar to those for model ALT, except that the spike of age-0 fish in 2015 was captured better. The estimate of age 1+biomass on 1 July, 2017 for this model was 77,845 t.

Request 9: Run a variant of model ALT in which the age-composition data are assigned to a new fleet (6) that has logistic selectivity (estimated separately for the spring and summer periods).
Rationale: Selectivity for the ATM survey is assumed to be uniform on animals aged 1 and older so age-composition data are not required for this survey. The selectivity pattern for the trawl component of the survey is not uniform on age-1+ animals (some age-0 animals are caught) and it may be possible to represent this using a logistic selectivity function.
Response: This model performed generally similar to a logistic formulation applied to the ATM survey for both age-composition and as an abundance index, but it misses the summer 2016 ATM survey estimate of biomass from above whereas the logistic fits that estimate closely. However, the logistic model had a negative log-likelihood of approximately 311, compared to 305 for this variant, and 333 for model ALT. Thus, both a model with logistic ATM selectivity and a model that assumed 1+ selectivity for ATM survey estimates and logistic selectivity for the associated age-composition data fit the data somewhat better than model ALT.

Request 10: Conduct a retrospective evaluation of how well alternative assessment methods can predict the biomass from the summer ATM surveys. For each year Y for which there is a summer ATM survey estimate for year Y and year Y+1, report predictions of year Y+1 biomass based on

(a) the estimate of biomass from the results of the ATM survey during summer of year Y, (b) the estimate of biomass based on applying the projection method to the results from the ATM survey in summer of year Y, and (c) model ALT based on data through year Y.
Rationale: The Panel wished to understand which method was able to predict the ATM survey estimate of biomass most accurately.
Response: The STAT provided results for the three selected approaches as well estimates of age 1+ biomass obtained by projecting the actual assessments used for 2012, 2013, 2014 and 2015 forward ("Past assessment" in Fig. 4) and estimates of age 1+ biomass obtained by projecting the model used for 2014, 2015 and 2016 management advice ("2014 formulation"). Model ALT generally came closest to predicting the survey biomass estimate the following year, doing so by a substantial margin for 2014. "Past assessment" was usually the worst. Model ALT had the lowest residual variance. Relative errors were a CV of 1.07 for Model ALT, 1.26 for the 2014 model formulation, 1.50 for the last survey without projection, 1.62 for the values adopted in management specifications, and 1.70 for projections from the previous ATM survey (see Appendix 2 for the specifications for the method).

Day 3 requests made to the STAT during the meeting – Thursday, February 23
Request 11: Develop a method for estimating recruitment solely from ATM data, explain how these recruitment estimates could be used to project forward from an ATM biomass estimate, and then add results for that method to the retrospective comparison described in Request 10.
Rationale: During discussion of Request 10, it was clear that much of the concern regarding the currently proposed method of projecting from the survey was its dependence on model ALT for stock-recruitment estimates for conducting the projection, resulting in its dependence on the same assumptions the STAT was hoping to avoid by moving away from an integrated assessment. It was pointed out that it could be possible to develop estimates of age 1 biomass on 1 July, 2017 strictly from the ATM data.
Response: The STAT modified the survey projection method so that projected biomass of 1-year-olds was the average over the most recent five years (see Appendix 2 for details). As desired, this approach was not tied to the model ALT. However, the residual standard deviation for this approach ("Survey projection 2"), while better than "Survey projection", was still worse than Model ALT and the 2014 model formulation (1.45) (Fig. 4).

3) Technical Merits and/or Deficiencies of the Assessment

Alternative assessment approaches
The Panel considered four ways to estimate age 1+ biomass on 1 July 2017: (a) use the estimate of biomass from the summer 2016 ATM survey, (b) project the estimate of biomass from the summer 2016 ATM survey to 1 July 2017 using the 'survey projection' model (or an alternative approach), (c) model ALT, and (d) the model on which the 2014-16 assessments were based. The Panel had concerns with, and comments on, all of these methods:

- Assuming that the 1 July 2017 biomass equals the estimate of biomass from the summer 2016 ATM survey ignores mortality (from natural causes and from fishing), growth and recruitment from July 2016 to July 2017. However, this method is simple to implement because it does not rely on a model, nor does it rely on estimates of age composition for which sample sizes are low.
- Projecting the biomass from the 2016 ATM survey to 1 July 2017 accounts for mortality, growth and recruitment from July 2016 to July 2017. However, the approach used to

convert from length composition to age composition is incorrect, and the method used to derive the CV of age 2+ biomass does not allow for uncertainty in population age composition, projected weight-at-age and maturity-at-age. In addition, the method relies heavily on model ALT because approximately half of the age 1+ biomass on 1 July 2017 consists of age-1 animals, i.e. the estimate of this biomass is based to a substantial extent on the stock-recruitment function from model ALT. Finally, the value for M of 0.6yr^{-1} has no clear justification. The version of the projection model provided initially to the Panel did not account for catches so it could not be applied were the targeted sardine fishery to be re-opened, and does not account for the limited catches during 2016.

- Model ALT has several of the problems associated with the 'survey projection' model, i.e. the age-composition data are based on a year-invariant age-length key, and the basis for M=0.6yr^{-1} lacks strong empirical justification (and indeed likelihood profiles indicate some support for lower M than the value adopted for model ALT). In addition, the model presented to the Panel predicted age-0 catch in the ATM survey even though it is assumed that age-0 animals are not selected during the ATM survey. It appears that the model predictions of age-0 animals in the ATM survey are actually model-predicted numbers of age-1 animals that are predicted to be mis-read as age-0 animals. However, examination of the ATM survey length-frequencies suggests that that some age-0 animals (or animals that were spawning earlier in the year) are encountered during the surveys (Fig. 5). Model ALT estimates Q to be 1.1, which is unlikely given some sardine are not available to the survey owing to being inshore of the survey area.
- The model on which the 2014-16 assessments were based was approved for management by the 2014 STAR Panel. However, that assessment had some undesirable features, including extreme sensitivity to the occurrence of small (<~15cm fish) in the ATM surveys, poor fits to the length-composition and survey data, and sensitivity to the initial values for the parameters (i.e. local minima). These sensitivities and the resultant high uncertainty about population scale were noted in previous reviews.

The Panel explored alternatives to the current selectivity formulation to better understand why model ALT was predicting age-0 catch when selectivity for age-0 fish was set to zero. It was noted that the results are generally robust to assuming that selectivity is a logistic function of length (but that implies that some age-1+ animals are not available to the ATM survey), allowing for time-varying age-0 selectivity, and estimating a separate selectivity pattern for ATM survey age-composition data.

The Panel noted that the 'survey projection' model and model ALT both rely on the samples from the ATM surveys to compute weight-at-age and survey age-composition data. The samples sizes for age from each survey are very small (16 – 1,051), which means that estimates of, for example, weight-at-age are highly uncertain. The procedure of ensuring that weight-at-age for a cohort does not decline over time seems intuitively correct. However, if the estimated mean weight of young fish in a cohort is anomalously high or low due to sampling errors (owing to small samples), it can impact the weight-at-age of that cohort for all subsequent ages.

Model ALT estimated steepness rather than fixing it equal to 0.8. The results were not sensitive to fixing versus estimating steepness, but the estimate of 0.36 was low.

Selection of an assessment approach

The Panel considered the merits of the various approaches. It concluded that:

- The approach on which 2014-16 management was based exhibited undesirable assessment diagnostics, and produced extremely high estimates of recruitment when large numbers of small fish were observed in the ATM survey length-frequencies. The approach also performed poorly in retrospective analysis (Fig. 4)[1]. The Panel and STAT agreed that this approach should not be used for 2017 management.
- The survey projection method (and the modified version, "Survey projection 2") seems a viable and defensible way to estimate age 1+ biomass using the ATM survey results, especially if the method could be modified to not use the results from model ALT. However, as currently formulated, this method performs no better than assuming that the age 1+ biomass in July 2017 equals the survey estimate of biomass for summer 2016 (Fig. 4). Thus, while viable, this approach requires further development and review prior to adoption.
- Estimating the biomass on 1 July of year Y+1 based on the ATM survey estimate for year Y is simple, but the Panel was concerned that this method ignored catches during year Y and may lead to additional risk. Thus, the basic approach is viable, but needs additional testing prior to adoption.

Given the current management approach that requires an estimate of age-1 biomass at the start of July, the Panel and STAT agreed that model ALT was the best approach at present for conducting an assessment for the northern subpopulation of Pacific sardine, notwithstanding the concerns listed above. The results from the assessment are robust to changes to how selectivity is modelled, the value for steepness and data weighting, but there were several concerns with this model that could not be resolved during the Panel meeting. Assuming uniform selectivity leads to lower estimates of current 1+ biomass, but this assumption reflects the expectation that all fish in the survey area are vulnerable to detection during an acoustic survey.

The final model (model ALT) incorporates the following specifications:
- catches for the MexCal fleet computed using the environmentally-based method;
- two seasons (semesters, Jul-Dec=S1 and Jan-Jun=S2) for each assessment year from 2005 to 2016;
- sexes were combined; ages 0-10+.
- two fisheries (MexCal and PacNW fleets), with an annual selectivity pattern for the PacNW fleet and seasonal selectivity patterns (S1 and S2) for the MexCal fleet;
    - MexCal fleet: age-based selectivity (one parameter per age)
    - PacNW fleet: asymptotic age-based selectivity;
    - age-compositions with effective sample sizes calculated by dividing the number of fish sampled by 25 (externally) and lambda weighting=1 (internally);
- Beverton-Holt stock-recruitment relationship with "steepness" estimated;
- *M* was fixed (0.6 yr^{-1});
- recruitment deviations estimated from 2005-2015;
- virgin recruitment estimated, and σ_R fixed at 0.75;
- initial *F*s estimated for the MexCal S1 fleet and assumed to be 0 for the other fleets;

[1] Care needs to be taken interpreting Fig. 4 given the low number of years involved and the fact the observed 1+ biomass is subject to considerable sampling error.

- ATM survey biomass 2006-2013, partitioned into two (spring and summer) surveys, with Q estimated;
    - age-compositions with effective sample sizes set to 1 per cluster (externally);
    - selectivity is assumed to be uniform (fully-selected) above age 1 and zero for age 0.

The estimate of age 1+ biomass on 1 July 2017 from model ALT is 86,586t (CV 0.363). Model ALT indicates that age 1+ biomass has rebuilt close to that in 2014, owing to a substantial increase in biomass based on the indices from the survey (Fig. 6). The estimate of age 1+ biomass is less than the estimate of age 1+ biomass on 1 July 2016 from the 2016 stock assessment (106,137t). This is a consequence of the change in assessment methodology, in particular that selectivity for the ATM survey is assumed to be uniform for fish aged 1 and older (assuming that selectivity is logistic in model ALT increases the estimate of 1+ biomass from 86,586t to 153,020t).

Future directions

The STAT strongly supports that management advice for Pacific sardine be based on the estimates of biomass from the ATM survey rather than a projection model or an integrated assessment. The Panel notes the following ways in which management could be based on the ATM survey results.

- Change the start-date of the fishery so that the time between conducting the survey and implementation of harvest regulations is minimized.
- Use Management Strategy Evaluation to evaluate the risk to the stock of basing management actions on an estimate of biomass that could be a year old at the start of the fishing season (if the fishery start date is unchanged). Review of an updated MSE would likely not require a Methodology Panel, but could instead be conducted by the SSC.

The Panel notes that there may be benefits to attempting to use both the spring and summer ATM surveys as the basis for an ATM survey-only approach and that moving to an assessment approach that relies on the most recent ATM survey (or two) may be compromised by reductions in ship time and/or problems conducting the survey. It agrees with the STAT that there is value in continuing to collect biological data and to update model ALT even if management moves to an ATM survey-only approach.

4) Areas of Disagreement

There were no major areas of disagreement between the STAT and Panel, nor among members of the Panel.

5) Unresolved Problems and Major Uncertainties

The core issues for stock assessments continue to be related to the temporal and spatial scale of the surveys and insufficient sample sizes of age-length for sardine in the ATM survey. The ability of a single boat following fixed transects along the entire sardine NSP region over a single period to sufficiently observe and sample a highly mobile schooling fish that exhibits high variability in recruitment, migratory patterns and timing, school structure, and depth distribution remains a core challenge. The relatively small sample size of sardine for biological analysis remains a concern related to acoustic expansions, population model estimates, and projection forecasts that depend on age composition and size-at-age information. A solution may require more resources than SWFSC has at its disposal so that will require Council action; resolution of this issue is outside of the ability of the Panel to address.

The Panel identified concerns with all of the proposed assessment approaches as highlighted in Section 3 of this report. In relation to model ALT, the Panel was unable to fully resolve the issue of observations of age-0 animals in the ATM survey age compositions, and how to compute age-composition and weight-at-age for the ATM survey.

6) Issues raised by the CPSMT and CPSAS representatives during the meeting

a) CPSMT issues

The CPSMT (MT) representative appreciates the substantial efforts by the STAT and the constructive Panel discussion, and offers the following comments.

The STAT proposed the ATM survey as the preferred approach over an integrated model for estimating sardine biomass. However, because the ATM survey at this time does not better estimate biomass projected to the start of the 2017-18 fishing year, the integrated model (Model ALT) was ultimately recommended. The MT representative agrees this was a reasonable approach to meet management requirements for a July 1, 2017 biomass estimate, but nevertheless also supports further consideration for shifting to the ATM survey to estimate biomass. The MT representative notes that issues of spatial and temporal coverage, and sample size remain for the survey. This has implications for the model ALT as well.

The review noted problems associated with some very small sample sizes produced by the trawl component of the ATM survey. Given that fish captured in trawls informs the species composition of the acoustic signals, as well as providing biological data, additional effort is required to refine and improve trawling operations. Additionally, more of the fish (particularly during the summer survey) that are collected need to be processed for ageing. The MT representative notes small sample size was flagged as a concern in the last full update conducted in 2014 and strongly supports the Panel recommendation that the SWFSC conduct analyses to estimate optimal sample size and to refine the survey methodology.

The lack of nearshore coverage by the ATM survey persists. Research needs to be conducted to explore possible approaches for surveying this area. Collaborative projects with industry should be encouraged to leverage their expertise. Further, emphasis should be placed on ensuring that the survey has sufficient sea-days to effectively cover the entire west coast irrespective of whether the ATM survey is used within a model or if the ATM survey is to be considered the preferred approach to inform the biomass estimate for management. The current plan to reduce the number of sea-days from 80 in 2016 to 50 in 2017 is concerning. The 50-day summer survey planned for 2017 does not include the area south of Monterey. If distance between transects were increased, the survey could possibly be extended to Point Conception, which would still not include the Southern California Bight. Fewer days at sea and the corresponding likely decrease in number of trawls also reduces the data upon which to base species composition and to produce biological data.

An MSE to evaluate the effects of using the ATM biomass estimate to inform the following year's harvest control rules is proposed as a high research priority (G). If the MSE were to find the one-year lag does create unacceptable outcomes one approach would be to develop an improved projection model. Another proposed fix would be to move the fishing year start date. While possible, the MT representative would like to highlight that the start date was adjusted beginning in 2014 to afford the STAT more time between the conclusion of field seasons and the deadline for STAR review of stock assessments. More significantly, shifting the start date can raise management issues because embedded in it is the period-based catch allocation scheme. Selecting an existing allocation period start date (January 1, July 1 and September 1) is perhaps more straightforward and would not necessarily require substantial analysis. Selecting any other starting point would likely necessitate an analysis of impacts and therefore more time to implement (i.e. two to three Council meetings). How to best accomplish aligning a shift to using only an ATM survey-derived biomass estimate with a change to the fishing year will require additional deliberation.

b) CPSAS issues

The CPSAS representative commends the Panel and STAT for their extensive and thoughtful body of work throughout the 2017 sardine STAR panel. Unfortunately, the 2017 sardine assessment again encountered the same difficulties observed in previous STAR panels. Most of the unresolved problems and major uncertainties listed in the 2011 and 2014 STAR panel reports still exist.

Earlier panels pointed out significant scaling issues. The 2017 assessment also encountered issues with ageing, notably an age-length key that was deemed incorrect. One persistent problem is the very small sample size for biological composition data obtained during ATM surveys and other sampling; another is the high variability in length-at-age observed in sardine year-to-year. As pointed out during the meeting, an age/length key averaged over seasons is not valid; it ignores differential cohort strengths. This presents a major problem in model projections, and adds another layer of uncertainty considering the current time lag between field surveys and the development of either ATM survey-based or model-based management advice for the fishery.

Assigning July 1 as the standardized birth date for sardine also presents problems, particularly in light of recent year ocean conditions that have precipitated sardine spawning earlier in the year, too early to be observed in April DEPM surveys, and producing age-0 fish assumed too small to be captured in ATM surveys. Yet an abundance of small fish exists! In fact, the 2015 summer ATM survey did encounter a spike of very small fish. A record number of pelagic juvenile sardines (and anchovies) also was found in the 2015 juvenile rockfish cruise. However, the length-composition data for the small fish were omitted from the assessment model in 2015 because the biomass estimate produced was “unrealistic.”

Ironically, none of the approaches considered at this STAR panel meeting found adequate evidence of recruitment in 2016 to boost the stock assessment “number” in 2017. In fact, the projected biomass estimate for 2017 is lower than 2016 at a time that sardines are increasing in abundance, apparently coast-wide, but certainly in California. The current report attributed this to a change in assessment methodology.

Fishermen from the Pacific Northwest and California who attended the STAR panel meeting reported that they have observed an abundance of 3-6 inch fish for the past couple of years, particularly in live bait catches. California fishermen delivered samples of these fish to the SWFSC and California Department of Fish and Wildlife (CDFW). But while the 2016 draft stock assessment did include a small number of live bait catches (now the only active non-treaty fishery for sardine on the West Coast), the corresponding biological-composition data were not aged and hence included in the assessment.

In the opinion of the fishermen, an opinion shared by this CPSAS representative, none of the four approaches considered during the panel meeting accurately reflect the biomass of sardine now in the ocean. The Panel also voiced concerns with all the methods presented; those concerns are reflected in the body of this report under **Technical Merits and/or Deficiencies of the assessment.**

The CPSAS representative highlights major concerns, including:

- The STAT now recommends the ATM survey as the most objective survey method. However, ATM surveys at present do not capture fish in the upper water column, nor a large biomass of young fish (sizes 3 inches and up) that fishermen have observed in nearshore waters since late 2014; this biomass is largely inside ATM survey tracks. But the ATM survey is assigned a catchability quotient (Q) of 1 nonetheless, meaning it "sees" all the fish. The Q for Model ALT, which is based largely on ATM survey data, is estimated at 1.1, which the STAR Panel report calls into question, given for example the unquantified volume of fish in nearshore waters.
- The summer 2016 ATM survey reported a fourfold increase in age 1+ biomass, but the biomass estimate produced is substantially lower than the estimate used for management in 2016. The STAR panel found fault with the methodology used to project the 2016 biomass to 2017. So do we – but using the 2016 ATM biomass estimate without adjusting for recruitment ignores reality.
- In addition, the proposal to simply use the biomass estimate from the summer ATM survey directly, to avoid uncertainty in model assumptions, could bypass surveying a substantial portion of the biomass if/when cruises are shortened, or disrupted. For example, the 2017 summer survey schedule is only 50 days, down from 80 days in 2016. This means the survey may not extend much below San Francisco, which will miss a substantial portion of California's historical fishing grounds.
- Also, a proposal to change the fishing season start date to more closely follow the survey, thus avoiding the need to project recruitment, is not as simple as it sounds. The current seasonal structure is tied to an allocation framework that would require serious discussion and analysis before any change could be implemented.
- At the end of the day, the STAR panel cautiously recommended proceeding with Model ALT, as the "least-worst" way to produce the age 1+ biomass estimate and CV required for management in 2017. The CPSAS hopes the SSC and Council will acknowledge all the caveats, and recognize that this is a "stop-gap" approach until the ATM methodology review can be accomplished in 2018, along with further review and improvement of Model ALT input and assumptions and potential review of other assessment indices.
- The CPSAS representative again voices concern that stock assessments appear to be gravitating toward one independent index measuring one point in time, based on ATM surveys. We strongly encourage a continuation of multiple surveys as each survey type has strengths and weaknesses. Other fishery-independent research, i.e. the juvenile rockfish survey, was informative in 2016 and should be approved to provide information for future sardine stock assessments, as this could serve as another indicator of recruitment.
- Clearly the small sample size and inadequate biological composition data are causing serious problems in assessing the sardine (and anchovy) resource. Industry has offered to help collect data, and we hope this offer will be acted upon in a way that such information can be incorporated into future stock assessments.

- As we have noted in the past, industry wants to see a sustainable resource (to the degree that environmental conditions will allow) that is in no danger of being overfished. Current sardine stock assessments and harvest policy are very precautionary. We sincerely hope that going forward we can develop a truly collaborative research program for the CPS complex.

Other recommendations:

- Please work collaboratively with industry to resolve persistent data deficiencies, including assessing the nearshore, upper water column, and the need for substantial increase in sample size and biological composition data for sardine (and other CPS), particularly ageing.
- Recognize that the 2017 assessment is "déjà vu all over again" and most of the unresolved problems and major uncertainties listed in the 2011 and 2014 STAR panel reports still exist.
- Prior panel, SSC, CPSMT and CPSAS reports have recommended a methods review of the ATM survey ASAP as a high priority research and data need. We continue to emphasize this need, and further recommend that such review also encompass review of Model ALT and other potential data collection options, including the juvenile rockfish survey, CDFW/CWPA aerial survey and any other promising data collection prospects available by the time of the scheduled ATM review in January 2018.
- We also support the STAT high-priority recommendation to address: "*technical issues related to echosounder deployment and associated signal interpretation (e.g., uncertainty surrounding species-specific target strength [TS], sonar bias related to backscatter uncertainty, and areas of the upper water column that potentially are not capable of being surveyed*)."

Dr. Zwolinski noted that target strength is currently based on "similar" fish, not Coastal Pelagic Species (CPS) found in the California Current. The STAT and Panel recognized that incorrect target strength could result in both over or under-estimation of biomass

Finally, the CPSAS representative points out that improving survey and assessment methodology to accurately reflect abundance of sardine (and other CPS) is absolutely essential: the future of the industry hangs in the balance.

7) Research Recommendations

High priority

A. Conduct an analysis of effect of fish sample size on the uncertainty in the ATM biomass estimates and model outputs. Use this information to re-evaluate and revise the sampling strategy for size and age data that includes target sample sizes for strata
B. The clusters (the Primary Sampling Units, PSUs) with age-length data should be grouped into spatial strata (post-strata, or collapsed post-strata used in ATM biomass estimators). The variance in estimates of age-length compositions can then be estimated by bootstrapping of PSUs, where age-length keys are constructed for each bootstrap replicate. The sub-sample size of fish within clusters that are measured for lengths should be increased, and length-stratified age-sampling should be implemented. This approach would likely increase coverage of age samples per length class and reduce data gaps.

C. The survey projection method should be developed further. Specifically, the survey age-composition should be based on annual age-length keys, and the uncertainty associated with population age-composition, weight-at-age and maturity-at-age needs to be quantified and included in the calculation of CVs. A bootstrapping procedure could be used to quantify the uncertainty associated with population age-composition and projected weight-at-age. Uncertainty in weight-at-age could also be evaluated using a retrospective analysis in which the difference between observed and predicted weight-at-age for past years was calculated. Ultimately, improved estimates of weight-at-age and measures of precision of such estimates could be obtained by fitting a model to the empirical data on weight-at-age.
D. The methods for estimating 1 July age 1+ biomass based on the results of the ATM survey during the previous year currently use only the results of the summer survey. Improved precision is likely if the results from the spring and summer surveys were combined. This may become more important if the number of days for surveying is reduced in future. Consideration should be given to fish born after 1 July.
E. Investigate alternative approaches for dealing with highly uncertain estimates of recruitment that have an impact on the most recent estimate of age-1+ biomass that is important for management.
F. Modify Stock Synthesis so that the standard errors of the logarithms of age-1+ biomass can be reported. These biomasses are used when computing OFLs, ABCs and HGs, but the CV used when applying the ABC control rule is currently that associated with spawning biomass and not age-1+ biomass.
G. The approach of basing OFLs, ABCs and HGs for a year on the biomass estimate from the ATM survey for the previous year should be examined using MSE so the anticipated effects of larger CVs and a possible time-lag between when the survey was conducted and when catch limits are implemented on risk, catch and catch variation statistics can be quantified.
H. The assessment would benefit not only from data from Mexico and Canada, but also from joint assessment activities, which would include assessment team members from both countries during assessment development.
I. The assessment would benefit from the availability of estimates of 1+ biomass that include quantification of the biomass inshore of the survey area and in the upper water column.
J. It is unclear how the habitat model is applied to determine survey design. Is this an *ad hoc* decision or is there a formal procedure? The next Panel should be provided with comprehensive documentation on how the habitat model is applied.
K. Consider future research on natural mortality. Note that changes to the assumed value for natural mortality may lead to a need for further changes to harvest control rules.
L. Explore the potential of collaborative efforts to increase sample sizes and/or gather data relevant to quantifying effects of ship avoidance, problems sampling near-surface schools, and currently unsampled nearshore areas.
M. Reduce aging error and bias by coordinating and standardizing aging techniques and performing an aging exchange (double blind reading) to validate aging and estimate error. Standardization might include establishing a standard "birth month" and criteria for establishing the presence of an outer annuli. If this has already been established, identify labs, years, or sample lots where there is deviation from the criteria. The outcome of comparative studies should be provided with every assessment.

Medium priority

N. Continue to explore possible additional fishery-independent data sources such as the SWFSC juvenile rockfish survey and the CDFW/CWPA cooperative efforts (additional sampling and aerial surveys). Inclusion of a substantial new data source would likely require review, which would not be easily accomplished during a standard STAR Panel meeting and would likely need to be reviewed during a Council-sponsored Methodology Review.

O. Consider spatial models for Pacific sardine that can be used to explore the implications of regional recruitment patterns and region-specific biological parameters. These models could be used to identify critical biological data gaps as well as better represent the latitudinal variation in size-at-age; this should include an analysis of age-structure on the mean distribution of sardine in terms of inshore-offshore (especially if industry partner-derived data were available).

P. Consider a model that has separate fleets for Mexico, California, Oregon-Washington and Canada.

Q. Compare annual length-composition data for the Ensenada fishery that are included in the MexCal data sets for the northern sub-population with the corresponding southern California length compositions. Also, compare the annual length-composition data for the Oregon-Washington catches with those from the British Columbia fishery. This is particularly important if a future age data/age-based selectivity model scenario is further developed and presented for review.

Low priority

R. Consider a model that explicitly models the sex-structure of the population and the catch.

S. Develop a relationship between egg production and fish age that accounts for the duration of spawning, batch fecundity, etc. by age. Using this information in the assessment would require that the stock-recruitment relationship in SS be modified appropriately.

T. Change the method for allocating area in the DEPM method so that the appropriate area allocation for each point is included in the relevant stratum. Also, apply a method that better accounts for transect-based sampling and correlated observations that reflects the presence of a spawning aggregation.

Recommendations that should be addressed during the 2018 review of the ATM survey

A. In relation to the habitat model
    a. Investigate sensitivity of the assessment to the threshold used in the environmental-based method (currently 50% favourable habitat) to further delineate the southern and northern subpopulations of Pacific sardine.
    b. Further validate the environmentally-based stock splitting method. The habitat model used to develop the survey plan and assign catches to subpopulation seems to adequately predict the spawning/egg distribution in the CalCOFI core DEPM region, but eggs were observed where they were not expected in northern California, Oregon and Washington during one of the two years when the survey extended north. It may be possible to develop simple discriminant factors to differentiate the two sub-populations by comparing metrics from areas where mixing does not occur. Once statistically significant discriminant metrics (e.g. morphometric, otolith morphology, otolith micro-structure, and possibly using more recent developments in genetic methods) have been chosen, these should be

applied to samples from areas where mixing may be occurring or where habitat is close to the environmentally-based boundary. This can be used to help set either a threshold or to allocate proportions if mixing is occurring.

c. Consider including environmental covariates in model-based approaches that would account quantitatively for environmental effects on distribution and biomass. The expertise from a survey of fishermen could be extremely useful in identifying covariates that impact the distribution of clusters.

B. The SWFSC plans to examine ship avoidance using aerial drone sampling; there is an ongoing significant effort by Institute of Marine Research in Norway to understand the same issue using sonar, and the SWFSC acoustics team should communicate and coordinate with those researchers.

C. The effect of population size affecting the number and spacing of school clusters likely affects the probability of acoustic detection in a non-linear way; this could create a negatively biased estimate at low population levels and potentially a non-detection threshold below which the stock size cannot be reliably assessed. A simulation exercise should be conducted using the current, decreased and increased survey effort over a range of simulated population distribution scenarios to explore this.

D. The consequences of the time delay and difference in diurnal period of the acoustic surveys versus trawling need to be understood; validation or additional research is critical to ensure that the fish caught in the trawls from the night time scattering layer share the same species, age and size structure as the fish ensonified in the daytime clusters.

E. The ATM survey design and estimation methods need to be more precisely specified. A document must be provided to the ATM review (and future assessment STAR Panels) that:
   - delineates the survey area (sampling frame);
   - specifies the spatial stratification (if any) and transect spacing within strata planned in advance (true stratification);
   - specifies the rule for stopping a transect (offshore boundary);
   - specifies the rules for conducting trawls to determine species composition;
   - specifies the rule for adaptive sampling (including the stopping rule); and
   - specifies rules for post-stratification, and in particular how density observations are taken into account in post-stratification. Alternative post-stratification without taking into account density should be considered.

Appendix 2
Projection of summer AT biomass 1 year into the future (Juan Zwolinski)

Given a vector of abundance-at-age from a summer survey during year *t* $\hat{\mathbf{a}}_{\mathrm{t}} = [\hat{a}_{0t}, a_{1t}, \ldots, a_{9+t}]$, with ages 0 through 9 and above, and where $\hat{a}_{0t}$ is the expected abundance of age-0 sardine estimated in one of the two possible ways described below, the abundance of sardine age 1 and older (zge-1+) at year *t+1* can be estimated by $\hat{\mathbf{a}}_{t+1} = \hat{\mathbf{a}}_{\mathrm{t}} \times e^{-(M+F)}$, where M and F are natural and fishing instantaneous mortality coefficients relative to one year, respectively. The corresponding biomass is obtained by the pointwise product $\hat{\mathbf{a}}_{\mathrm{t+1}} \times \mathbf{w}_{\mathrm{t}}$, where the empirical mean weight-at-age $\mathbf{w}_t = [w_{1t}, \ldots, w_{9+t}]$ is estimated from the survey during year *t*. If fishing mortality is expressed in catch, then $\hat{\boldsymbol{a}}_{t+1}$ can be approximated by $\hat{\boldsymbol{a}}_{t+1} = (\,\hat{\mathbf{a}}_t \times e^{-(M/2)} - \mathbf{c}_t) \times e^{-(M/2)}$, where $\hat{\boldsymbol{c}}_t = [c_{0t}, c_{1t}, \ldots, c_{9+t}]$ is the expected catch in numbers per age class.

Estimating a_{0t}

Summer AT surveys are not reliable estimators of the abundance of age-0 sardine at time *t* ($a_{0\mathrm{t}}$). Therefore, any projection of biomass from a survey at year *t* to year *t+1* requires a_{0t} to be estimated. Assuming that no fishing occurs for age-0 sardine, the expected age-0 abundance $\hat{a}_0$ can be estimated as the mean of the implied age-0 abundances calculated from *n* surveys such that:

$$E[a_0] = \hat{a}_0 = \frac{1}{\mathrm{n}} \sum_n a_1 \times e^M \, .$$

Alternatively, a_{0t} can be estimated using the stock-recruitment relationship from the most recent assessment. In order to do so, the abundance $\boldsymbol{a}_t = [a_{1t}, \ldots, a_{9+t}]$ from the summer survey has to be regressed 6 months and converted into spawning stock biomass (SSB) at *t-0.5*. Using empirical mean weight-at-age in winter $\mathbf{w}_{\mathrm{t-0.5}} = [w_{0t-0.5}, \ldots, w_{8+t}]$, and the vector of proportions of mature fish per age class $\mathbf{s}_{\mathrm{t-0.5}} = [s_{0t-0.5}, \ldots, s_{8+t}]$, $\mathrm{SSB}_{t\text{-}0.5}$ is obtained by the sum of the pointwise-product $\mathbf{a}_{\mathrm{t-0.5}} \times \mathbf{w}_{\mathrm{t-0.5}} \times \mathbf{s}_{\mathrm{t-0.5}}$, where $\mathbf{a}_{\mathrm{t-0.5}}$ can be calculated by $\hat{\mathbf{a}}_{\mathrm{t-0.5}} = \hat{\mathbf{a}}_{\mathrm{t}} \times e^{(M+F)/2}$ in case F is reasonably known. If fishing is expressed in catch, then $\hat{\mathbf{a}}_{\mathrm{t-0.5}} = (\,\hat{\mathbf{a}}_{\mathrm{t}} \times e^{(M/4)} + \mathbf{c}_{\mathbf{t-0.5}}) \times e^{(M/4)}$. There, $\mathbf{c}_{\mathbf{t-0.5}}$ is the vector of catch-at-age that occurred in the 6 months prior to the survey.

Center for Independent Experts (CIE) Independent Peer Review Report of the Pacific Sardine Stock Assessment

Executive Summary

In the US, the Pacific sardine is currently a limited entry fishery managed by the Pacific Fishery Management Council using a Harvest Control Rule where the total allowable catch for a given year is based on a forward projection estimate of age 1+ biomass (mt) from the prior year assessment. The main objective of this STAR review was to evaluate two proposed alternative assessment methods for giving quota advice for 2017: (1) the Acoustic-Trawl Method (ATM) survey, which is preferred by the SWFSC stock assessment team, and (2) Model ALT which is implemented using the Stock Synthesis Model. An alternative ATM survey projection method was also considered during the review. The relatively parsimonious Model ALT reduced the parameter space compared to a standard implementation of Stock Synthesis by estimating several parameters external to the model using empirical data, and by fixing parameters. The performance of several assessment methods under the current HCR was compared based on their ability to predict a current ATM survey estimate of age 1+ biomass in the prior year´s assessment. The ATM survey method is considered to provide the most reliable estimate of the current year 1+ biomass, but the survey methods are not sufficiently documented to assess the accuracy of the estimate, and have several issues that could lead to bias in the absolute biomass estimates and associated variance. Although the ATM survey itself will be reviewed in 2018, and was not a focus of this review, all assessment methods rely heavily on survey estimate of absolute biomass of age 1+ fish. Therefore, I discuss some possible sources of bias in this review, and provide some recommendations for reducing such biases. It is well known from the literature that post-stratification based on density values observed during the survey, as was done in the ATM survey, can result in negative bias in variance estimates. The variance estimation by bootstrapping for the ATM survey also treats the transects within post-strata as simple random. This is common practice in analysis of systematically spaced transects, and is conservative since it will likely overestimate the variance for evenly spaced transects. However, in the ATM survey the handling of the adaptive component results in variable transect spacing (unequal inclusion probability) in some post-strata, which can bias the variance estimates in unknown directions when this is ignored in the analysis. The use of seasonal fixed age-length keys based on multi-year trawl survey data from 2006 can also yield biases with varying magnitude and directions in estimates of age-compositions, and will cause negative bias in variance estimates for age-compositions, and therefore estimates of age 1+ biomass. The assumption that the ATM method provides unbiased absolute biomass estimates assumes that target strength is known, and ignores vessel avoidance, incomplete survey coverage and other factors that can cause bias. Also, as revealed during this review the current forward projection method for the ATM survey method does not perform well. As currently formulated, this method performs no better than assuming no change and applying the survey estimate of age 1+ biomass in 2016 as an estimate also for age 1+ biomass in July 2017. Thus, while viable, this approach requires further development and review prior to adoption. The review panel considered Model ALT method to perform best for the current management advice that relies on a projection estimate of 1+ biomass for 2017, even though several errors in the model were discovered during the review. Major sources of uncertainty for stock assessments under the current HCR, regardless of method, is related to highly variable recruitment, growth, and uncertainty in natural mortality, *M*. Accuracy of assessments is also highly influenced by the temporal and spatial coverage of the ATM survey, the post-stratification used for estimation, insufficient sample sizes of age-length, and the use of fixed age-length keys. The assumption of multinomial distribution of numbers at age in the ATM survey method and the ALT model is likely to be unrealistic given the highly-clustered trawl sampling, causing additional errors.

Background

The National Marine Fisheries Service's (NMFS) Office of Science and Technology coordinates and manages a contract providing external expertise through the Center for Independent Experts (CIE) to conduct independent peer reviews of NMFS scientific projects. Background material and reports (Appendix A) for the review was provided by the NMFS project contact two weeks prior to the review. A Statement of Work (Annex B) is established by the NMFS Project Contact and Contracting Officer's Technical Representative, and reviewed by the CIE for compliance with their policy for providing independent expertise that can provide impartial and independent peer review without conflicts of interest.

CIE reviewers are selected by the CIE Steering Committee and CIE Coordination Team to conduct the independent peer review of NMFS science in compliance with the predetermined Terms of Reference (ToRs) of the peer review. Each CIE reviewer is contracted to deliver an independent peer review report to be approved by the CIE Steering Committee. Further information on the CIE process can be obtained from www.ciereviews.org.

This independent reviewer was requested by the Center of Independent Exerts to participate in a stock assessment review (STAR) panel to conduct independent peer review of the 2016 draft assessment by the Stock Assessment Team (STAT) for the northern subpopulation of Pacific Sardine. The STAR Panel (Appendix C), including the two CIE Reviewers, are responsible for determining if a stock assessment or technical analysis is sufficiently complete. It is their responsibility to identify assessments that cannot be reviewed or completed for any reason.

1. Description of the Reviewer's Role in the Review Activities

A peer review meeting was held at the Southwest Fisheries Science Center (SWFSC) in La Jolla, California, from February 21-24 to review a draft assessment by the Stock Assessment Team (STAT) for the northern subpopulation of Pacific Sardine. The Stock Assessment Review (STAR) panel consisted of three members of the Scientific and Statistical Committee (SSC): Dr. André Punt (University of Washington, Chair), Dr. Will Satterthwaite (SWFSC), and Dr. Evelyn Brown (Lummi Natural Resources), and two reviewers from the Center for Independent Experts (CIE): Dr. Jon Vølstad (Norway), and Dr. Gary Melvin (Canada). The STAR panel was expertly chaired by Andre Punt.

My input in the review was particularly related to statistical survey sampling methods and propagation of errors in input data through the assessment modeling that provides biomass estimates for quota advice. I have long experience and expertise in the design, analysis, and execution of fishery-independent surveys for use in stock assessments, and have experience with demersal and mid-water trawl surveys, acoustic-trawl surveys of pelagic fishes, and in the use of aerial surveys. I also have expertise in the application of fish stock assessment methods, particularly length/age-structured modeling approaches. For comments related to technical aspects of acoustic survey methods I defer to fellow CIE reviewer Gary Melvin who specializes in acoustic methods.

By way of background, I am chief scientist and leader of the Fishery Dynamics research group at Institute of Marine Research, Bergen, Norway. My education includes a bachelor with double majors in mathematics and biology, a master degree in Fishery Biology incl. management, and a Ph.D. in quantitative fisheries biology (biometrics) from University of Bergen, Norway. My PhD studies included research as a visiting scholar at Northeast Fisheries Science Center, Woods Hole, and graduate courses in mathematical statistics at University of Bergen and at the Department of Biomathematics (now department of Statistics), Oxford University (UK), as a British Council Scholar. My dissertation was on survey design and analysis of abundance surveys. I have more than 25 years of international research experience in statistical survey methods, quantitative fisheries biology, and statistical ecology from academia, national institutes, and private industry. My research primarily focuses on the development and optimization of statistical survey techniques for assessment of fisheries resources and the environment, and the quantification of uncertainty in stock assessments.

My preparations in advance of the peer review meeting included a review of background material and reports (Appendix A) provided by the SWFSC Project Contact Dr. Dale Sweetnam (SWFSC) via email on February 7 via link to ftp-site. This was a very effective way of distributing the extensive material. All the presentations (see below) were added to the ftp site during the review meeting.

A series of very informative power point presentations were given during the review meeting by the SWFSC Stock Assessment Team. My fellow peer reviewers and I asked questions during the presentations and participated in the panel discussions on validity, results, recommendations, and conclusions. Will Satterthwaite (SSC, SWFSC) acted as rapporteur.

Drs. Paul Crone, Kevin Hill, and Juan Zwolinski presented the assessment methodology. Two alternative assessment approaches were presented:

1. Direct use of the summer 2016 Acoustic Trawl Method (ATM) survey estimate and associated age-composition projected to 1 July 2017, which is the method preferred by SWFSC, and

2. Model ALT which is a model-based assessment that provides an estimate of age 1+ biomass on 1 July 2017 based on a modified more parsimonious Stock Synthesis model where many parameters are estimated externally from empirical data.

Juan Zwolinski described the survey-based method for estimating age 1+ biomass on 1 July 2017 that involved:

- estimating numbers-at-age on 1 July 2016 from the summer 2016 ATM survey from numbers-at-length using an age-length key that pooled data over multiple summer surveys, and
- projecting these numbers forward accounting for natural mortality and growth, and adding the estimated recruitment for 2016. The recruitment for 2016 was based on the stock-recruitment relationship estimated by model ALT, and the spawning stock biomass for 2016 was estimated by back-projecting the summer 2016 numbers-at-age to 1 January 2016.

Kevin Hill and Paul Crone described the data on which the model-based assessment was based, as well the results from a draft assessment utilizing the Stock Synthesis Assessment Tool, Version 3.24aa. Model ALT differed from the model on which the 2016 update assessment was based by:

- starting the assessment in 2005 rather than 1993,
- excluding the Daily Egg Production Method (DEPM) and Total Egg Production (TEP) indices,
- estimating rather than pre-specifying stock-recruitment steepness,
- pre-specifying weight-at-age rather than estimating it within the assessment,
- assuming selectivity for the ATM survey to be zero for age 0 and uniform for age 1 and older,
- estimating survey catchability (Q), assuming selectivity to be age- rather than length-based,
- modelling ages 0-10+yr rather than ages 0-15+yr, assuming natural mortality (M) is 0.6yr-1 rather than 0.4yr-1 for all age classes and fitting the catch and ATM survey age-composition data (rather than the associated length-composition data).

Unlike the 2016 and earlier assessments, model ALT included additional live bait landings, which generally reflected a minor contribution to the total landings in California in the past. However, model ALT did not include biological composition data from the live bait catches, given this fishery sector had not been regularly sampled in the past, with samples being available for only the most recent year of the time series modelled in the assessment.

The review and request by the STAR panel for additional analysis during the meeting were motivated primarily by the need to better understand the rationale for model ALT, and to identify the best approach for providing a projection of age 1+ biomass on 1 July 2017 that is currently required by management. The Panel had several comments and concerns regarding the ATM survey methodology and ways in which estimates of close-to-absolute abundance can be obtained. However, this was not a review of the ATM survey, since a second Council-sponsored ATM methodology review is planned for early 2018. Therefore, comments in the Panel Report regarding the ATM survey and how estimates of abundance from that survey are constructed are reflected primarily in the Research Recommendations section of the report. However, since both assessment methods considered in the review strongly depends on the ATM survey, I have made several comments in the next section, and in section (3).

2. Findings by ToR

The bibliography list (Appendix A) and the Statement of Work (Appendix B) describe the documents reviewed and review activities, respectively, as part of an independent peer review completed for the Center for Independent Experts (CIE).

2.1. Acoustic Trawl Method (ATM) Survey Assessment

In the assessment approach based on the ATM survey two methods are used to project the current (2016) estimate of age 1+ biomass to an estimate of age1 biomass for 2017. The preferred approach in the Draft Stock Assessment Document projecting the biomass from the 2016 ATM survey to 1 July 2017 accounting for mortality, growth and recruitment from July 2016 to July 2017. However, the approach used to convert from length composition to age composition is incorrect, and the method used to derive the CV of age 2+ biomass does not allow for uncertainty in population age composition, projected weight-at-age and maturity-at-age. In addition, the method relies heavily on model ALT because approximately half of the age 1+ biomass on 1 July 2017 consists of age-1 animals, i.e. the estimate of this biomass is based to a substantial extent on the stock-recruitment function from model ALT. Finally, the value for M of 0.6yr-1 has no clear justification. The version of the projection model provided initially to the Panel did not account for catches so it could not be applied were the targeted sardine fishery to be re-opened, and does not account for the limited catches during 2016. An alternative assessment based on the ATM survey proposed during the review meeting assume that the 1 July 2017 biomass equals the estimate of biomass from the summer 2016 ATM survey. This “projection” ignores mortality (from natural causes and from fishing), growth and recruitment from July 2016 to July 2017. However, this method is simple to implement because it does not rely on a model, nor does it rely on highly uncertain recruitment estimates and estimates of age composition for which sample sizes are low.

The Panel had several comments and concerns regarding the ATM survey methodology and ways in which estimates of close-to-absolute abundance can be obtained. In a prior CIE review in 2011, it was concluded that there are no major problems with acoustic technique and methodology and it was the best that could be used at that time. Although this is not a review of the ATM survey, since a second Council-sponsored

ATM methodology review is planned for early 2018, I have several comments in section (3) since the ATM survey results are critical input to all assessment models being evaluated.

2.2. Model ALT Assessment

The final model (model ALT) incorporates the following specifications:

- catches for the MexCal fleet computed using the environmentally-based method;
- two seasons (semesters, Jul-Dec=S1 and Jan-Jun=S2) for each assessment year from 2005 to 2016;
- sexes were combined; ages 0-10+.
- two fisheries (MexCal and PacNW fleets), with an annual selectivity pattern for the PacNW fleet and seasonal selectivity patterns (S1 and S2) for the MexCal fleet;
  - MexCal fleet: age-based selectivity (one parameter per age)
  - PacNW fleet: asymptotic age-based selectivity;
  - age-compositions with effective sample sizes calculated by dividing the number of fish sampled by 25 (externally) and lambda weighting=1 (internally);
- Beverton-Holt stock-recruitment relationship with "steepness" estimated;
- *M* was fixed (0.6 yr^{-1});
- recruitment deviations estimated from 2005-2015;
- virgin recruitment estimated, and σ_R fixed at 0.75;
- initial *F*s estimated for the MexCal S1 fleet and assumed to be 0 for the other fleets;
- ATM survey biomass 2006-2013, partitioned into two (spring and summer) surveys, with Q estimated;
  - age-compositions with effective sample sizes set to 1 per cluster (externally);
  - selectivity is assumed to be uniform (fully-selected) above age 1 and zero for age 0.

The estimate of age 1+ biomass on 1 July 2017 from model ALT is 86,586t (CV 0.363). Model ALT indicates that age 1+ biomass has rebuilt close to that in 2014, owing to a substantial increase in biomass based on the indices from the survey.

Model ALT has several of the problems associated with the 'survey projection' model, i.e. the age-composition data are based on a year-invariant age-length key, and the basis for M=0.6yr-1 lacks strong empirical justification (and indeed likelihood profiles indicate some support for lower M than the value adopted for model ALT). In addition, the model presented to the Panel predicted age-0 catch in the ATM survey even though it is assumed that age-0 animals are not selected during the ATM survey. It appears that Stock Synthesis with the ALT parametrization predicts some catch of nominal "age 0" even when the selectivity is set to zero for age-0 fish. The STAR review panel requested several additional model runs to gain insights, because aging error could result in some age-1 fish in catches being misclassified as age 0. Furthermore, model runs revealed that the model was unable to converge if aging error was set to zero or made very small, but reductions in the specified aging error led to the expected reduction in the predicted age-0 catch. It was noted that surveys likely include a mix of age-1 fish misclassified as age-0, as well as fish that are truly age 0. Dr. Methot has also noted that Stock Synthesis had not been as thoroughly debugged for semester-based models as for strictly annual models

2.3. Evaluating the Performance of Assessment Approaches

The performance of several assessment methods under the current HCR was compared based on their ability to predict a current ATM survey estimate of age 1+ biomass in the prior year´s assessment. The

STAR review considered four methods:

a) ATM survey method using the 1+ biomass estimate from the prior year as is,
   i. This assumption ignores mortality (from natural causes and from fishing), growth and recruitment from July 2016 to July 2017.
b) ATM survey method projecting the biomass from the prior summer ATM survey estimate using the 'survey projection' model (or an alternative approach),
c) Model ALT assessment and projection, and for comparison,
d) the assessment model and projection on which the 2014-16 estimates of biomass were based.

Results are provided in Fig. 4 from the STAR Panel.

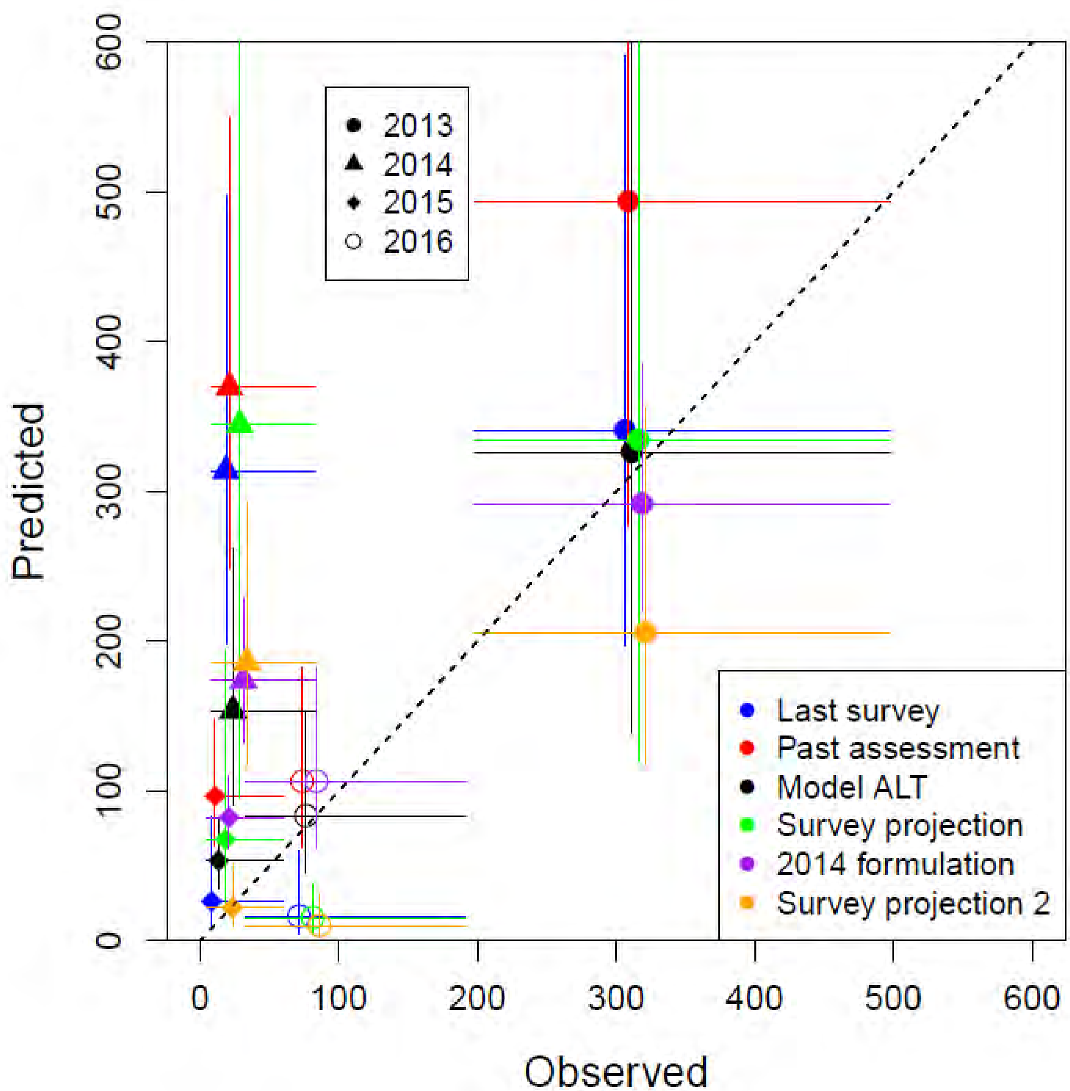

Fig. 4. (From Final Report of Sardine STAR Panel). Observed (x-axis values, ATM survey biomass estimates) and model-predicted (y-axis values) biomass on 1 July of each of 2013, 2014, 2015 and 2016. The observed values are the summer ATM survey estimates. The lines indicate 90% confidence intervals under the assumption of log-normal error. The x-axis values are jittered for ease of presentation.

The Panel had concerns with these methods. The ATM survey is considered to provide the most reliable estimate of the current year 1+ biomass, but the survey design and analysis methods are not sufficiently documented to assess the accuracy of the estimate, and have several issues that could lead to bias in the absolute biomass estimates and associated variance. Projecting the biomass from the 2016 ATM survey to 1 July 2017 (Method b) accounts for mortality, growth and recruitment from July 2016 to July 2017. However, the approach used to convert from length composition to age composition using fixed seasonal age-length keys based on data since 2006 is incorrect, and the method used to derive the CV of age 2+ biomass does not allow for uncertainty in population age composition, projected weight-at-age and maturity-at-age. In addition, the estimate of this biomass is based to a substantial extent on the stock-recruitment function from model ALT. Finally, the value for M of 0.6yr-1 has no clear justification.

Model ALT (Method c) has several of the problems associated with the 'survey projection' model, i.e. the age-composition data are based on a fixed age-length key, and the basis for M=0.6yr-1 lacks strong empirical justification. In addition, the model presented to the Panel predicted age-0 catch in the ATM survey even though it is assumed that age-0 animals are not selected during the ATM survey. Also, Model ALT estimates Q to be 1.1, which is unlikely given some sardine are not available to the survey owing to being inshore of the survey area.

The model (d) on which the 2014-16 assessments were based was approved for management by the 2014 STAR Panel. However, that assessment had some undesirable features, including extreme sensitivity to the occurrence of small (<~15cm fish) in the ATM surveys, poor fits to the length-composition and survey data, and sensitivity to the initial values for the parameters (i.e. local minima). These sensitivities and the resultant high uncertainty about population scale were noted in previous reviews.

The Panel explored alternatives to the current selectivity formulation to better understand why model ALT was predicting age-0 catch when selectivity for age-0 fish was set to zero. It was noted that the results are generally robust to the assumption that selectivity is a logistic function of length, allowing for time-varying age-0 selectivity, and estimating a separate selectivity pattern for ATM survey age-composition data.

The Panel noted that the 'survey projection' model and model ALT both rely on the samples from the ATM surveys to compute weight-at-age and survey age-composition data. These estimates are highly uncertain since the samples sizes for age from each survey are very small (16 – 1,051 fish; and VERY few trawl clusters which are the primary sampling units for the age-comps).

3. Conclusions and Recommendations

The SWFSC assessment scientists (STAT) did an outstanding job presenting the assessment results, and were very helpful throughout the review meeting by providing additional analysis upon request and answering questions related to the panel's interpretation of the available data and results. The panel members had broad and complimentary expertise that covered all the review subjects. The effectiveness of the review process was substantially enhanced by the expert leadership of the chair, Andre Punt, and the panel greatly benefited from the input from the Pacific Fishery Management Council, and representatives from the fishing industry. One criticism I have is that the stock assessment report and material provided that formed the basis for the review provided insufficient details to fully assess the quality of the input-data and model specification. I recognize that the stock assessment scientists responsible for the report may have had insufficient time to fully document the methods.

The STAR panel cautiously recommended proceeding with Model ALT, as the "least-worst" way to produce the age 1+ biomass estimate and CV required for management in 2017. Given the current

HCR, the Panel and STAT agreed that model ALT was the best approach at present for conducting an assessment for the northern subpopulation of Pacific sardine, notwithstanding the concerns listed above.   The alternative assessment approaches provided more uncertain predictions of age 1+ biomass July 1, 2017:

- The approach on which 2014-16 management was based exhibited undesirable assessment diagnostics, and produced extremely high estimates of recruitment when large numbers of small fish were observed in the ATM survey length-frequencies. The approach also performed poorly in retrospective analysis (Fig. 4). The Panel and STAT agreed that this approach should not be used for 2017 management.
- The survey projection method (and the modified version, "Survey projection 2") seems a viable and defensible way to estimate age 1+ biomass using the ATM survey results, especially if the method could be modified to not use the results from model ALT. However, as currently formulated, this method performs no better than assuming the age 1+ biomass in July 2017 equals the survey estimate of biomass for summer 2016 (Fig. 4). Thus, while viable, this approach requires further development and review prior to adoption.
- Estimating the biomass on 1 July of year Y+1 based on the ATM survey estimate for year Y is simple, but the Panel was concerned that this method ignored catches during year Y and may lead to additional risk. Thus, the basic approach is viable, but needs additional testing prior to adoption.

I agree fully with these recommendations in the STAR review report on how management could be based on the ATM survey results:

- Change the start-date of the fishery so that the time between conducting the survey and implementation of harvest regulations is minimized.
- Use Management Strategy Evaluation to evaluate the risk to the stock of basing management actions on an estimate of biomass that could be a year old at the start of the fishing season (if the fishery start date is unchanged). Review of an updated MSE would likely not require a Methodology Panel, but could instead be conducted by the SSC.

As the review Panel noted, there may be benefits in using both the spring and summer ATM surveys as the basis for the assessment. Relying an ATM survey based assessment approach that relies on an estimate for the current year may be compromised by proposed reductions in ship time and/or problems conducting the survey. Also, as pointed out by the STAT there is value in continuing to collect biological data and to update model ALT even if management moves to an ATM survey-only approach.

In the following section, I have some more comments on the STM survey, and recommendations for future documentation and analysis.

Acoustic Trawl Method Survey

The systematic design for acoustic-trawl survey is robust for covering Pacific sardine with varying patchiness and areas of occupancy, provided that the spatial coverage E-W and N-S is adequate. The acoustic survey transect design is systematic with a close to regular spacing of transects allocated in advance, and adaptive component with reduced transect spacing in some areas of expected high abundance. Abundance and biomass is estimated by treating transects as simple random samples within post-strata, and the variance is estimated by bootstrap with equal selection probability of transects. However, based on provided material, documents, and discussions during this review it is apparent that the ATM survey is not based on probabilistic sampling design where every transect (primary sampling unit, PSU) has a known probability of being selected. The adaptive sampling component where additional acoustic transects are added in areas with observed high density of Pacific sardines is not well documented, and appears to be ad-hoc. The post-stratification of transects used in the estimating abundance and biomass by age class takes are based on sampling intensity (spacing of transects) and measured density. The grouping of transects with low density into separate strata is inappropriate and likely to cause bias in the variance estimates. Also, even though SWFSC staff argued that transects within all post-strata have equal spacing (and selection probability), this is not documented and is contradicted by figures presented during the review showing post-strata and acoustic transects.

Before the upcoming 2018 review of the ATM survey, it is strongly recommended that SWFSC specify the survey design and estimation methods in sufficient details. A document should be provided to the ATM review (and future assessment STAR Panels) that:

- delineates the annual survey area (sampling frame);
- specifies the spatial stratification (if any) and transect spacing within strata planned (true stratification);
- specifies the rule for stopping a transect (offshore boundary);
- specifies the rules for conducting trawls to determine species composition;
- specifies the rule for adaptive sampling (including the start and stopping rule); and
- specifies rules for post-stratification, and how density observations are considered in post-stratification.
- alternative post-stratification without considering density should be considered.

It is particularly important that the sampling frame covers the area of occupancy, that allocation of transects be based on probabilistic methods and that biases be minimized. The systematic allocation of transects with random start, and known selection probabilities, provides unbiased estimates of means and totals provided that the estimators apply weights that consider the probabilities of selection. However, systematic sampling precludes unbiased analytical variance estimates, and if the systematic survey is treated as simple random the estimated variance is likely to be biased upwards (Cochran, 1977). The systematic transect survey can also be considered a stratified sampling design with 1 PSU (transect) in each spatial stratum. A common approach to approximate the variances in estimates of means and totals in systematic designs is to group neighboring strata to yield a pseudo design with more than one PSU per stratum that is treated as it were the actual design (Wolter, 1985; Dunn and Harrison, 1993, Korn and Graubard, 1999). The variance and the relative standard error (RSE) (Jessen, 1978) is then estimated under the assumption of simple random sampling within the collapsed strata (Fuller, 2009). See Nøttestad et al. (2017) for an application for trawl sampling of mackerel.

The sardine habitat model based on remotely sensed SST, chlorophyll, and sea-surface gradient (Zwolinski et al. 2011) is currently used to (1) develop the sampling frame, and (2) assign catches to subpopulation but not to allocate sampling effort within the survey area, which is based on an ad-hoc adaptive sampling with denser spacing of transects in areas with high density of sardine. One reason for this adaptive component, with use of post-stratification in the analysis, instead of stratifying in advance (true stratification) on habitat is that the habitat is very dynamic even within the time period of the surveys. It is strongly recommended that the best available models be used for sample allocation, and that any real-time adaptive component be conducted using methods that minimizes bias (see for example, Harbitz et al. 2009; Thomposon and Seber 2009).

Assuming we have defined the sampling frame using a model, allocation based on the model will only affect precision, and even a relatively crude model that can identify areas with higher than average density will likely give better precision than equal spacing throughout the survey area. The habitat model predicts probabilities of capture for broad categories of habitat (e.g., "optimal", "good", "unsuitable" habitat). This is fine for defining the sampling frame but for sample allocation/stratification, the distribution of model predictions should be used to create strata that are most similar within. Alternative model approaches should also be considered for stratification. Ed Weber (SWFSC) is currently working with a sardine habitat model based on a ROMS model (Wang and Chao 2004) coupled with a biological model known as CoSiNE (Carbon, Silicate, Nitrogen Ecosystem model Chai et al., 2002; Liu and Chai, 2009). He demonstrated the model to me after the review meeting. Based on simulations of historic surveys he is testing if stratification based on modeled habitat could improve the precision of acoustic surveys. Using modeled data for stratification, and to allocate more transects (with known probability) to strata that are expected to have high density and variance, instead of satellite data, appears to have a several advantages. It is mechanistic, at least to the level of secondary production. It does not suffer from data gaps due to cloud cover. It could potentially be projected into the future for short periods.

Clearly, the changes in spatial distributions over time, both horizontally and vertically, may introduce biases in acoustic indices of abundance of changing magnitudes and directions. Such biases can be caused by vessel avoidance, acoustic shadowing and depth dependent acoustic target strength (Skaret et al., 2005; Løland et al., 2007; Hjellvik et al., 2008). Random sampling errors in acoustic survey indices of abundance due to spatial sampling has been shown to be the main source of uncertainty in acoustic measurements of abundance (Rose et al. 2000). Løland et al. (2007) investigated several additional sources of error in acoustic survey estimates of the Norwegian Spring Spawning herring stock in the wintering area. They did, however, conclude that acoustic sampling error (variation among transects) was the largest contributor to the total uncertainty of the estimate. The ATM surveys at present do not capture fish in the upper water column, and appears to miss a large biomass of young fish (sizes 3 inches and up) that fishermen have observed in nearshore waters since late 2014; this biomass is largely inside ATM survey tracks. The SWFSC plans to examine ship avoidance using aerial drone sampling. There is an ongoing significant effort by Institute of Marine Research in Norway to understand the same issue using sonar, and the SWFSC acoustics team should communicate and coordinate with those researchers. The possible bias due to not detecting fish that are near the surface by acoustics could be investigated using sonar. This is currently being done in acoustic-trawl surveys for herring by Institute of Marine Research, Norway, and is addressed in a large effort to reduce uncertainty in stock assessments (REDUS project: www.redus.no).

Trawl sampling and the estimation of age-compositions

The current practice of treating data on numbers-at-age from the trawl survey as multinomial is problematic because the trawl samples are clustered, and age-samples are subsamples from trawl hauls. This is likely to result in cluster effects, resulting in correlation among age-groups (see ICES 2016a,b, 2017, and Aanes and Vølstad 2016). It is recommended that the age-data be evaluated. Ideally, it would be possible to run bootstrap resampling on the PSUs to create replicated Model ALT runs that reflect the complexity in input data. See the Norwegian Spring-spawning Herring case study under the REDUS project in ICES WKCOSTBEN (ICES 2017) for an example where the more complex error structure in input data is accounted for. The statistical assessment model XSAM (developed by Sondre Aanes, Norwegian Computing Centre) has been chosen for the assessment of Norwegian Spring Spawning Herring by ICES Benchmark assessments (2016a,b) because it can take into account the complex error structure in input-data in age-based assessment.

It is further recommended that the level of biological sub-sampling and data collections at each trawl station (or clusters of trawl stations) be evaluated through simulations to see how subsample size at the trawl stations affects the precision in estimates of numbers at age through age-length keys for the combined acoustic-trawl survey. The effective sample size for estimating age is likely to be driven by the number of transects and trawl stations sampled, and may be little affected by the sub-sample sizes of fish that are aged at each trawl station. Stewart and Hamel (2014) and Aanes and Vølstad (2015) have shown that it is sufficient to collect ~10-20 ages from each station to estimate the age distribution and that higher numbers of age-samples will only marginally improve the precision in estimates of age-composition, since the variance is driven by the number of PSUs sampled (number of trawl stations). Results in Nøttestad et al. (2017) show that for Atlantic mackerel the collections of extra length samples within trawl stations, and trawl stations with length-only samples can increased the precision in the estimates of abundance indices at age for age groups that occur in low proportions.

STAR Panel Review of the 2017-2018 Pacific Sardine Stock Assessment

February 21-24, 2017

Background

The National Marine Fisheries Service (NMFS) is mandated by the Magnuson-Stevens Fishery Conservation and Management Act, Endangered Species Act, and Marine Mammal Protection Act to conserve, protect, and manage our nation's marine living resources based upon the best scientific information available (BSIA). NMFS science products, including scientific advice, are often controversial and may require timely scientific peer reviews that are strictly independent of all outside influences. A formal external process for independent expert reviews of the agency's scientific products and programs ensures their credibility. Therefore, external scientific peer reviews have been and continue to be essential to strengthening scientific quality assurance for fishery conservation and management actions.

Scientific peer review is defined as the organized review process where one or more qualified experts review scientific information to ensure quality and credibility. These expert(s) must conduct their peer review impartially, objectively, and without conflicts of interest. Each reviewer must also be independent from the development of the science, without influence from any position that the agency or constituent groups may have. Furthermore, the Office of Management and Budget (OMB), authorized by the Information Quality Act, requires all federal agencies to conduct peer reviews of highly influential and controversial science before dissemination, and that peer reviewers must be deemed qualified based on the OMB Peer Review Bulletin standards.
(http://www.cio.noaa.gov/services_programs/pdfs/OMB_Peer_Review_Bulletin_m05-03.pdf).
Further information on the CIE program may be obtained from www.ciereviews.org.

Scope

The CIE reviewers will serve on a Stock Assessment Review (STAR) Panel and will be expected to participate in the review of Pacific sardine stock assessment. The Pacific sardine stock is assessed regularly (currently, every 1-2 years) by SWFSC scientists, and the Pacific Fishery Management Council (PFMC) uses the resulting biomass estimate to establish an annual harvest guideline (quota). The stock assessment data and model are formally reviewed by a Stock Assessment Review (STAR) Panel once every three years, with a coastal pelagic species subcommittee of the SSC reviewing updates in interim years. Independent peer review is required by the PFMC review process. The STAR Panel will review draft stock assessment documents and any other pertinent information for Pacific sardine, work with the stock assessment teams to make necessary revisions, and produce a STAR Panel report for use by the PFMC and other interested persons for developing management recommendations for the fishery. The PFMC's Terms of Reference (ToRs) for the STAR Panel review are attached in Appendix 1. The tentative agenda of the Panel review meeting is attached in Appendix 2. Finally, a Panel summary report template is attached as Appendix 3.

Requirements

Two CIE reviewers shall participate during a panel review meeting in La Jolla, California during 21-24 February, and shall conduct impartial and independent peer review accordance with the SoW and ToRs herein. The CIE reviewers shall have the expertise as listed in the following descending order of importance:

- The CIE reviewer shall have expertise in the design and execution of fishery-independent surveys for use in stock assessments, preferably with coastal pelagic fishes

- The CIE reviewer shall have expertise in the application of fish stock assessment methods, particularly, length/age-structured modeling approaches, e.g., 'forward-simulation' models (such as Stock Synthesis, SS) and it is desirable to have familiarity in 'backward-simulation' models (such as Virtual Population Analysis, VPA).
- The CIE reviewer shall have expertise in the life history strategies and population dynamics of coastal pelagic fishes.
- It is desirable for the CIE reviewer to be familiar with the design and application of fisheries underwater acoustic technology to estimate fish abundance for stock assessment.
- It is desirable for the CIE reviewer to be familiar with the design and application of aerial surveys to estimate fish abundance for stock assessment.

The CIE reviewer's duties shall not exceed a maximum of 14 days to complete all work tasks of the peer review process.

Tasks for reviewers

- Review the following background materials and reports prior to the review meeting: *Two weeks before the peer review, the NMFS Project Contact will send by electronic mail or make available at an FTP site to the CIE reviewers all necessary background information and reports for the peer review. In the case where the documents need to be mailed, the NMFS Project Contact will consult with the CIE on where to send documents. The CIE reviewers shall read all documents in preparation for the peer review, for example:*

    - *Recent stock assessment documents since 2013;*
    - *STAR Panel- and SSC-related documents pertaining to reviews of past assessments;*
    - *CIE-related summary reports pertaining to past assessments; and*
    - *Miscellaneous documents, such as ToR, logistical considerations.*

Pre-review documents will be provided up to two weeks before the peer review. Any delays in submission of pre-review documents for the CIE peer review will result in delays with the CIE peer review process, including a SoW modification to the schedule of milestones and deliverables. Furthermore, the CIE reviewers are responsible only for the pre-review documents that are delivered to the reviewer in accordance to the SoW scheduled deadlines specified herein.

- Attend and participate in the panel review meeting
    - The meeting will consist of presentations by NOAA and other scientists, stock assessment authors and others to facilitate the review, to provide any additional information required by the reviewers, and to answer any questions from reviewers
- After the review meeting, reviewers shall conduct an independent peer review in accordance with the requirements specified in this SOW, OMB guidelines, and TORs, in adherence with the required formatting and content guidelines; reviewers are not required to reach a consensus
- Each reviewer may assist the Chair of the meeting with contributions to the summary report, if required by the TORs
- Deliver their reports to the Government according to the specified milestone dates

Foreign National Security Clearance

When reviewers participate during a panel review meeting at a government facility, the NMFS Project Contact is responsible for obtaining the Foreign National Security Clearance approval for reviewers who are non-US citizens. For this reason, the reviewers shall provide requested information (e.g., first and last name, contact information, gender, birth date, passport number, country of passport, travel dates, country of citizenship, country of current residence, and home country) to the NMFS Project Contact for the purpose of their security clearance, and this information shall be submitted at least 30 days before the peer review in accordance with the NOAA Deemed Export Technology Control Program NAO 207-12 regulations available at the Deemed Exports NAO website: http://deemedexports.noaa.gov/ and http://deemedexports.noaa.gov/compliance_access_control_procedures/noaa-foreign-national-registration-system.html. The contractor is required to use all appropriate methods to safeguard Personally Identifiable Information (PII).

Place of Performance

The place of performance shall be at the contractor's facilities, and at the Southwest Fisheries Science Center in La Jolla, California.

Period of Performance

The period of performance shall be from the time of award through April 30, 2017. Each reviewer's duties shall not exceed 14 days to complete all required tasks.

Schedule of Milestones and Deliverables:

The contractor shall complete the tasks and deliverables in accordance with the following schedule.

No later than January 24, 2017	CIE sends reviewers contact information to the COTR, who then sends this to the NMFS Project Contact
No later than February 7, 2017	NMFS Project Contact sends the CIE Reviewers the pre-review documents
February 21-24, 2017	The reviewers participate and conduct an independent peer review during the panel review meeting
March 10, 2017	CIE reviewers submit draft CIE independent peer review reports to the CIE Lead Coordinator and CIE Regional Coordinator
March 31, 2017	CIE submits CIE independent peer review reports to the COTR
April 7, 2017	The COTR distributes the final CIE reports to the NMFS Project Contact and regional Center Director

Applicable Performance Standards

The acceptance of the contract deliverables shall be based on three performance standards: (1) The reports shall be completed in accordance with the required formatting and content (2) The reports shall address each TOR as specified (3) The reports shall be delivered as specified in the schedule of milestones and deliverables.

Travel

All travel expenses shall be reimbursable in accordance with Federal Travel Regulations (http://www.gsa.gov/portal/content/104790). International travel is authorized for this contract. Travel is not to exceed $10,000.

Restricted or Limited Use of Data

The contractors may be required to sign and adhere to a non-disclosure agreement.

Peer Review Report Requirements

1. The report must be prefaced with an Executive Summary providing a concise summary of the findings and recommendations, and specify whether or not the science reviewed is the best scientific information available.

2. The report must contain a background section, description of the individual reviewers' roles in the review activities, summary of findings for each TOR in which the weaknesses and strengths are described, and conclusions and recommendations in accordance with the TORs.

   a. Reviewers must describe in their own words the review activities completed during the panel review meeting, including a brief summary of findings, of the science, conclusions, and recommendations.

   b. Reviewers should discuss their independent views on each TOR even if these were consistent with those of other panelists, but especially where there were divergent views.

   c. Reviewers should elaborate on any points raised in the summary report that they believe might require further clarification.

   d. Reviewers shall provide a critique of the NMFS review process, including suggestions for improvements of both process and products.

   e. The report shall be a stand-alone document for others to understand the weaknesses and strengths of the science reviewed, regardless of whether or not they read the summary report. The report shall represent the peer review of each TOR, and shall not simply repeat the contents of the summary report.

3. The report shall include the following appendices:

   Appendix 1: Bibliography of materials provided for review
   Appendix 2: A copy of this Statement of Work
   Appendix 3: Panel membership or other pertinent information from the panel review meeting.

Appendix 1: Terms of Reference for the Peer Review of the Pacific sardine stock assessment

The CIE reviewers are one of the four equal members of the STAR panel. The principal responsibilities of the STAR Panel are to review stock assessment data inputs, analytical models, and to provide complete STAR Panel reports.

Along with the entire STAR Panel, the CIE Reviewer's duties include:

1. Reviewing draft stock assessment and other pertinent information (e.g.; previous assessments and STAR Panel reports);
2. Working with STAT Teams to ensure assessments are reviewed as needed;
3. Documenting meeting discussions;
4. Reviewing summaries of stock status (prepared by STAT Teams) for inclusion in the Stock Assessment and Fishery Evaluation (SAFE) document;
5. Recommending alternative methods and/or modifications of proposed methods, as appropriate during the STAR Panel meeting, and;
6. The STAR Panel's terms of reference concern technical aspects of stock assessment work. The STAR Panel should strive for a risk neutral approach in its reports and deliberations.

The STAR Panel, including the CIE Reviewers, are responsible for determining if a stock assessment or technical analysis is sufficiently complete. It is their responsibility to identify assessments that cannot be reviewed or completed for any reason. The decision that an assessment is complete should be made by Panel consensus. If agreement cannot be reached, then the nature of the disagreement must be described in the Panels' and CIE Reviewer's reports.

The review solely concerns technical aspects of stock assessment. It is therefore important that the Panel strive for a risk neutral perspective in its reports and deliberations. Assessment results based on model scenarios that have a flawed technical basis, or are questionable on other grounds, should be identified by the Panel and excluded from the set upon which management advice is to be developed. The STAR Panel should comment on the degree to which the accepted model scenarios describe and quantify the major sources of uncertainty Confidence intervals of indices and model outputs, as well as other measures of uncertainty that could affect management decisions, should be provided in completed stock assessments and the reports prepared by STAR Panels.

Recommendations and requests to the STAT Team for additional or revised analyses must be clear, explicit, and in writing. A written summary of discussion on significant technical points and lists of all STAR Panel recommendations and requests to the STAT Team are required in the STAR Panel's report. This should be completed (at least in draft form) prior to the end of the meeting. It is the chair and Panel's responsibility to carry out any follow-up review of work that is required.

Appendix 3: STAR Panel Summary Report (Template)

- Names and affiliations of STAR Panel members

- List of analyses requested by the STAR Panel, the rationale for each request, and a brief summary the STAT responses to each request

- Comments on the technical merits and/or deficiencies in the assessment and recommendations for remedies

- Explanation of areas of disagreement regarding STAR Panel recommendations
    - Among STAR Panel members (including concerns raised by the CPSMT and CPSAS representatives)
    - Between the STAR Panel and STAT Team

- Unresolved problems and major uncertainties, e.g., any special issues that complicate scientific assessment, questions about the best model scenario, etc.

- Management, data or fishery issues raised by the public and CPSMT and CPSAS representatives during the STAR Panel

- Prioritized recommendations for future research and data collection

Appendix 3: Panel membership or other pertinent information from the panel review meeting

STAR Panel Members:
André Punt (Chair), Scientific and Statistical Committee (SSC), Univ. of Washington
Will Satterthwaite, SSC, Southwest Fisheries Science Center
Evelyn Brown, SSC, Lummi Natural Resources, LIBC
Jon Vølstad, Center for Independent Experts (CIE)
Gary Melvin, Center for Independent Experts (CIE)

Pacific Fishery Management Council (Council) Representatives:
Kerry Griffin, Council Staff
Diane Pleschner-Steele, CPSAS Advisor to STAR Panel
Lorna Wargo, CPSMT Advisor to STAR Panel

Pacific Sardine Stock Assessment Team:
Kevin Hill, NOAA / SWFSC
Paul Crone, NOAA / SWFSC
Juan Zwolinski, NOAA / SWFSC

Other Attendees
Dale Sweetnam, SWFSC
Alan Sarich, CPSMT/Quinault Indian Nation
Emmanis Dorval, SWFSC
Chelsea Protasio, CPSMT/CDFW
Kirk Lynn, CPSMT/CDFW
Ed Weber, SWFSC
Josh Lindsay, NMFS WCR
Erin Kincaid, Oceana
Al Carter, Ocean Gold
Jason Dunn, Everingham Bros Bait
Nick Jurlin, F/V Eileen
Neil Guglielmo, F/V Trionfo
Andrew Richards, Commercial
Hui-Hua Lee, SWFSC
Bev Macewicz, SWFSC
Chenying Gao, Student
Steven Teo, SWFSC
Kevin Piner, SWFSC
Andy Blair, Commercial
Jamie Ashley, F/V Provider
John Budrick, CDFW
Steve Crooke, CPSAS
Gilly Lyons, Pew Trusts

CDFW – California Department of Fish and Wildlife
CPSAS - Coastal Pelagic Species Advisory Subpanel
CIE – Council on Independent Experts
CPSMT - Coastal Pelagic Species Management Team
CWPA – California Wetfish Producers Association

SSC - Scientific and Statistical Committee (of the Pacific Fishery Management Council)
SWFSC - Southwest Fisheries Science Center (National Oceanic and Atmospheric Administration)
WCR – West Coast Region

CIE Reviewer's Report on the STAR Panel Review of the 2017-2018 Pacific Sardine Stock Assessment

Gary D. Melvin[1]

Prepared for:

Center for Independent Experts (CIE)

[1]285 Water Street, St. Andrews, New Brunswick, Canada E5B1B8.
Phone: (506) 529-4783
e-mail: gary.lynn.melvin@gmail.com

Executive Summary

The review of the 2017-2018 Pacific Sardine Stock Assessment developed by the Southwest Fisheries Science Center (SWFSC) STAT team was conducted by a STAR Panel, at the SWFSC Torrey Pines Court Laboratory, La Jolla, CA, from 21-24 February 2017. The main objectives of the Panel were to review two new approaches to the assessment of the Northern subpopulation of Pacific sardine (NSP): the first is the acoustic trawl method which was approved by a 2011 STAR Panel to provide an estimate of absolute abundance of the NSP, and the second a revised/modified model based assessment using Stock Synthesis model Version 3.24aa with a single index of abundance. Previous assessment approaches (e.g., T_2016 update) were also examined but not really considered to provide advice on the 2017 1+ biomass.

The assessment document and all background material necessary to conduct the Panel Review was made available almost two weeks in advance, allowing plenty of time to prepare for the meeting. In general, the Panel review adhered to the agenda provided to Panel members prior to the meeting, although the Chair was flexible and allowed diversion into other subject areas when they were relevant to the discussion. Several Panel requests for additional information or clarification of procedures were made to the technical team over the first 3 days. These requests were fulfilled promptly and to the satisfaction of the Panel. Much of the success of the Panel Review can be attributed to the technical team who did an excellent job of summarizing the information and providing the available data to address the issues at hand. The Chair kept the group focused on the topic being addressed, while at the same time allowing everyone, including observers, to express their views or contribute their expert opinion. A number of the attendees also provided valuable input during the course of the meeting.

The Panel concluded that neither of the two assessment approaches presented at the 2017 Pacific Sardine stock assessment was fully acceptable. The Acoustic-Trawl survey, while all agreed was likely the better approach, did not provide a reasonable mechanism to project the 1+ biomass forward approximately 1 year to July 1, required by management. On the other hand, the model-based approach had its own issues with the treatment age 0 in the model that were not fully resolved during the review. However, the Panel concluded that based on the available information the model-based was the better approach to provide the required estimate of biomass for management of the NSP Pacific sardine resource.

Many of the issues associated with the spatial-temporal distribution of fish and sample size, identified by the last review, continue to plague the 2017 sardine assessment. The Panel again raised concerns about the survey coverage, especially in light of the fishing industry's reports of large quantities of sardines in the nearshore water not surveyed by the research vessel. The limited amount of sampling conducted by the survey vessel and the samples available for ageing in

some years was a major surprise and concern for the Panel. Development of an age length key and estimating age distribution from such few samples is problematic. Furthermore, the use of a multi-year age length key due to the lack of sufficient samples is generally frowned upon by those involved in age structured assessments. Both the distribution of sardines and sample size need to be addressed in the near future.

There is an excellent opportunity to resolve some of the issues associated with coverage and sampling. During the meeting, there were several offers from the fishing industry to assist the STAT with improving the survey coverage to areas not covered by the large vessel and to work with the survey vessel to collect additional samples. These opportunities should be explored by the STAT, and if feasible, a coordinated program developed to ensure the efficient use of vessel time and effort, as well as the integration of industry-collected data into the assessment process.

The Panel was informed that the survey vessel time for the summer survey will be reduced from the current 80 days to 50 days in 2018. This represents a significant reduction in survey time and will at a minimum increase the variance of the biomass estimates and likely impact (reduce) the survey coverage and sampling time. This is another reason to explore collaboration with the fishing industry. The effects of this change/reduction in vessel time need to be evaluated if they are to continue into the future.

The Panel’s report, to some extent summarized in this report, represents the consensus view of the STAR Panel Review of the 2017-2018 Pacific Sardine Stock Assessment and I fully concur with its content, recommendations, and conclusions. Overall, there were no major areas of disagreement between the STAT and Panel, nor among members of the Panel.

1.0 BACKGROUND

The National Marine Fisheries Service (NMFS) is mandated by the Magnuson-Stevens Fishery Conservation and Management Act, Endangered Species Act, and Marine Mammal Protection Act to conserve, protect, and manage our nation's marine living resources based upon the best scientific information available (BSIA). Under this mandate the NMFS (Office of Science and Technology) coordinates and manages a contract for providing external expertise through the Center for Independent Experts (CIE) to conduct independent peer-reviews of NMFS scientific projects. The CIE reviewers are selected by the CIE Steering Committee and the CIE Coordination Team to conduct the independent peer review of the NMFS science in compliance with the predetermined Terms of Reference (TORs) for the peer review. In this case the "Terms of Reference for the groundfish and coastal pelagic species stock assessment review process for 2017-2018", provided as background material for the meeting, describes objectives and the roles and responsibilities of the participants. Two CIE reviewers served on a five-person Stock Assessment and Review (STAR) Panel, Chaired by Andre Punt, to review the 2017-2018 Pacific Sardine Stock Assessment. The Statement of Work (SoW) described in Appendix I identified the roles, responsibilities and reporting structure for the CIE reviewer. The reviewers are chosen on their expertise to provide an impartial, independent peer review without conflicts of interest, report on methods, outcomes and recommendations of the stock assessment review.

The Pacific sardine stock is assessed regularly (currently, every 1-2 years) by SWFSC scientists and the Pacific Fishery Management Council (PFMC) uses the resulting biomass estimate to establish an annual harvest guideline (quota). The stock assessment data and models are formally reviewed by a Stock Assessment Review (STAR) Panel once every three years, with a coastal pelagic species subcommittee of the SSC reviewing updates in interim years. Independent peer review is required by the PFMC review process. The STAR Panel reviews draft stock assessment documents and any other pertinent information for Pacific sardine, works with the stock assessment (STAT) team to make necessary revisions, and produces a STAR Panel report for use by the PFMC and other interested persons for developing management recommendations for the fishery.

Each CIE reviewer is contracted to participate in the STAR Panel review meeting and to deliver an independent peer-review report to be approved by the CIE Steering Committee. This report, although generally consistent with, and similar to the STAR Panel report, is independent of the Panel report.

The specific tasks of the CIE Reviewers are to (See details in the SOW – Appendix 1):

- Review the background materials and reports prior to the review meeting
- Attend and participate in the panel review meeting
- After the review meeting, reviewers shall conduct an independent peer review in accordance with the requirements specified in this SOW, OMB guidelines, and TORs
- Assist the Chair of the meeting with contributions to the summary report, if required by the TORs
- Deliver their reports to the Government according to the specified milestone dates

1.1 Overview

A Pacific Sardine Stock Assessment and Review (STAR) Panel (Panel) was convened to review a draft assessment by the Stock Assessment Team (STAT) for the Northern Subpopulation of Pacific Sardine at the Southwest Fisheries Science Center, La Jolla, CA from February 21-24, 2017. The structure, responsibilities, goals, objectives and reporting requirements were defined under the terms of reference for the groundfish and coastal pelagic species stock assessment review process for 2017-18. In essence, the Panel reviewed three approaches for providing advice to management; two new assessment approaches and the default of updating the previous assessment. A list of attendees and the agenda are provided in the Appendices. It should be noted that because the CIE reviewer report is a standalone document, several sections of this report contain text that has been extracted almost verbatim from the STAR Panel report as the reviewer contributed to the document and feels it provides a good overview of the process and discussions.

Stock assessment team members, Drs. Paul Crone, Kevin Hill, and Juan Zwolinski presented a general overview of the assessment methodology for each of the different assessment approaches. Paul Crone first outlined the assessment history and philosophy, then moved on to focus on selecting an approach that was considered by the STAT to be most objective, i.e. the Acoustic Trawl Method (ATM) survey. In addition, because of the management schedule and fishing year, there is a requirement to provide the age 1+ biomass on July 1, 2017. The STAT provided results for two assessment approaches: (a) use of the summer 2016 Acoustic-Trawl method (ATM) survey biomass estimate and associated age-composition projected to 1 July 2017, and (b) a model-based assessment (ALT) that provides an estimate of age 1+ biomass on 1 July 2017. Both were considered as viable options for estimating biomass.

Dr. Juan Zwolinski provided a general overview of the spring (March/April) and the summer (July/September) acoustic-trawl surveys; the former concentrated in the southern USA, and the latter had broad coverage from California to Canada. Methodologies were discussed, however, because an ATM methodology review is scheduled for January 2018, only in general terms. Much of this survey approach had been reviewed and approved by a STAR Panel Review in 2011. He also described the survey-based method for estimating/projecting the age 1+ biomass on 1 July 2017. The method involved estimating numbers-at-age on 1 July 2016 from the summer 2016 ATM survey from numbers-at-length using an age-length key (pooled data over multiple summer surveys), and projecting these numbers forward under natural mortality, growth, and adding the estimated recruitment for 2016. Recruitment for 2016 was based on the stock-recruitment relationship estimated from ALT model outputs. The spawning stock biomass for 2016 was estimated by back-projecting the summer 2016 numbers-at-age to 1 January 2016.

Kevin Hill and Paul Crone presented the data on the model-based assessment, as well the results from a draft assessment utilizing the Stock Synthesis Assessment Tool, Version 3.24aa. The major differences in Model ALT from the model on which the 2016 update assessment (T_2016) were starting the assessment in 2005 rather than 1993, excluding the Daily Egg Production Method (DEPM) and Total Egg Production (TEP) indices, estimating rather than pre-specifying stock-recruitment steepness, pre-specifying weight-at-age rather than estimating it within the assessment, assuming that selectivity for the ATM survey is zero for age 0 and uniform for age 1 and older, estimating survey catchability (Q), assuming that selectivity is age- rather than length-based, modelling ages 0-10yr rather than ages 0-15yr, assuming natural mortality (*M*) is $0.6yr^{-1}$ rather than $0.4yr^{-1}$ for all age classes and fitting the catch and ATM survey age-composition data (rather than the associated length-composition data). Unlike the 2016 and earlier assessments, the model ALT included additional live bait landings, which generally reflected a minor contribution to the total landings in California and was the only active sector in the US sardine fishery. However, model ALT did not include biological composition data from the live bait catches, given this fishery sector had not been regularly sampled in the past. Samples were available for only the most recent year of the time series modelled in the assessment.

The review and subsequent explorations of the assessment through sensitivity analyses were motivated primarily by the need for the survey-based method to provide an estimate of age 1+ biomass and its CV, to better understand the rationale for the changes made to the model on which the last full assessment was based that led to model ALT. The Panel had several comments and concerns regarding the ATM survey methodology and ways in which estimates of close-to-absolute abundance can be obtained. However, it was stressed throughout the meeting that this was not a review of the ATM survey, since an ATM methodology review is planned in early 2018. Therefore, comments regarding the ATM survey and how estimates of abundance from that survey are constructed are reflected primarily in the Research Recommendations section of the report.

In the end, the Panel was not fully satisfied with either of the approaches used to estimate the age 1+ biomass on July 1, 2017. The ATM had problems with the approach used to project almost a year forward and the ALT model with the treatment age 0 in the model. These issues are discussed in more detail below; however, the Panel concluded that the ALT model was the better available approach to provide the required estimate of biomass for management of the NSP Pacific sardine resource.

The STAR Panel and the CIE reviewers thank the STAT for their hard work and willingness to respond to Panel requests, and the staff at the SWFSC La Jolla laboratory for their usual exceptional support and provisioning during the STAR meeting.

1.2 Goals and Objectives:

The specific goals and objectives for the 2017 Pacific Sardine Stock Assessment Review are those defined in the of groundfish and CPS STAR process document as follows:

1) ensure that stock assessments represent the best scientific information available and facilitate the use of this information by the Council to adopt OFLs, ABCs, ACLs, harvest guidelines (HGs), and annual catch targets (ACTs);
2) meet the mandates of the Magnuson-Stevens Fisheries Conservation and Management Act (MSA) and other legal requirements
3) follow a detailed calendar and fulfill explicit responsibilities for all participants to produce required reports and outcomes;
4) provide an independent external review of stock assessments;
5) increase understanding and acceptance of stock assessments and peer reviews by all members of the Council family;
6) identify research needed to improve assessments, reviews, and fishery management in the future; and
7) use assessment and review resources effectively and efficiently.

It is important to note that the following report to the CIE reflects my independent opinions and views on the issues and questions identified in the terms of reference, statement of work, and the above goals and objectives. The report is, however, generally consistent with the recommendations and conclusions of the other panel members and CIE reviewers. Overall, there was general consensus among the panel members with no identifiable areas of disagreement.

2.0 Description of the individual reviewers' Role

The CIE reviewers essentially served two roles on the STAR Panel Review of the 2017-2018 Pacific Sardine Stock Assessment. First, to participate as a full panel member in the review of the practices and procedures involved in the proposed assessment methods/approaches, and second to provide an independent review of the methodology and process.

To meet these requirements for the assessment of the Pacific sardine resource in 2017 a reviewer must have achieved recognition in several fisheries related fields. In this context, I am considered an expert in the assessment of small pelagic fish stocks, fisheries acoustics as applied to assessment of small and large pelagics, and their application to the management of the stocks. Currently, I am a senior Research Scientist with the Canadian Department of Fisheries and Oceans responsible for the research and assessment of large and small pelagic fish species. In addition, I am the scientist responsible for the acoustic program in my region of Canada and I have spent more than 25 years as the lead for small pelagic stock assessment program. I have a B.Sc., M.Sc., and PhD in fisheries related fields and have served on several international stock assessment review groups. Between 2010 and 2014, I was the Chair of the ICES North Sea Technical Review working group which provided quality control for all North Sea fish stocks assessed by ICES. Recently I was appointed Chair of the ICCAT western Bluefin tuna assessment working group.

My primary role was to participate in the 2017 Review as an informed expert and to contribute to the discussions and recommendations put forward by the STAT and the STAR Panel. Prior to the meeting, the stock assessment document was provided by the STAT team along with numerous background reports/documents on the fishery, methods, outputs and recommendations. The majority were read before the meeting so that well informed questions and discussions could be undertaken. Once the meeting began, my main focus was to be on the acoustic aspect of the assessment methodology; however, we were informed that because there will be a methodology review of the Acoustic –Trawl survey approach in January of 2018, much of the discussion will be deferred until. The meeting was still open to discussion on this subject, but most issues would be identified for investigation at the 2018 review.

Thereafter my focus shifted to the other areas of the review, participating in the discussions on the model-based assessment, major issues such as ageing, changes in mortality, the projection of biomass to July 1, 2017, the conclusions/

recommendations of the STAR Panel, contributions to the Panel Report and the preparation of an independent reviewer's report.

3.0 Summary of Findings for each term of Reference:

The summary presented below is an overview of the review and is generally consistent with the observations and results found in the STAR Panel Review Report. However, in several sections the text has been enhanced or is more inclusive to elaborate on specific issues. Prior to discussing the outcomes of the review associated with each TOR, I would like to make a few general comments regarding the documentation and the presentations. The stock assessment team (STAT) provided a good overview of the methodology and approaches described in the assessment document (Hill et al., 2017). The presentations by individual members of the team were informative and coherent. However, there were a number of cases where insufficient details were provided in the methods section of the assessment document for the Panel members to have a clear understanding about what or how something was done. This resulted in several extended discussions on the issue that could have been resolved with a few additional sentences in the assessment document. The STAT was very helpful in providing the details or the source of the details to the Panel where clarification was requested. Of particular concern were biological sampling protocols and the post stratification and analytical approaches used in the acoustic biomass estimation. Both involved extended discussions to clarify several areas of uncertainty.

The STAT team prepared and presented two new assessment approaches to the STAR Panel for review; One based on the outputs from an Acoustic-Trawl survey (ATM) as an absolute estimate of abundance, and the other an integrated model based method (SS3) to estimate biomass (ALT). Both methods were found to have merit but the former was obviously preferred by the STAT. The option to simply update the previous assessment (T_2016 to T2017) was not really being proposed or considered, although it was approved for management of resource by the 2014 STAR Panel. This was due to some undesirable features, such as extreme sensitivity to the occurrence of small fish in the ATM surveys, poor fits to the length-composition and survey data, as well as sensitivity to initial values for the parameters.

Although acoustic technology plays an extremely important role in the assessment, discussion on much of the acoustic methodology and assumptions was deferred. The Panel was informed that an acoustic methods meeting was scheduled for January of 2018 and that issues could, and should, be identified, but that detailed discussion of the issue would be postponed until the methods meeting. The assumption that the ATM was an acceptable approach was based on the 2011 Acoustic-Trawl Survey Method for Coastal Pelagic Species- Report of Methodology Review Panel Meeting, conclusions that: “Overall, the Panel is satisfied that the design of the acoustic-trawl surveys, as well as the methods of data collection and analysis are adequate for the provision of advice on the abundance of Pacific sardine, jack mackerel, and Pacific mackerel, subject to caveats, in particular related to the survey areas and distributions of the stocks at the times of surveying. The Panel concluded that estimates from the acoustic-trawl surveys can be included in the 2011 Pacific sardine stock assessment as “absolute estimates”.

Finally, there was a preconceived, or biased, preference of which model approach was preferred by the STAT team. While most of the Panel agreed that the simplest approach was likely the better, the text of the document only identified the merits of a survey-based assessment and the drawbacks of a model-based assessment. This somewhat unbalanced overview was discussed early during the meeting and the team agreed to provide a more balanced overview in the assessment document. Ironically, in the end, it was the model-based approach (ALT) that was selected to provide the advice to management for 2017.

One constraint in the process was the necessity for the approach to provide a mechanism for projecting a biomass estimate for the start of the fishing year, in this case 1 July 2017. As happened in this review, the STAT and the STAR Panel agreed that the ATM was the better and simpler approach for providing estimates of biomass, but because of the issues associated with the projection method proposed for the ATM the panel was left with no alternative but to recommend the use of the ALT model to provide advice to management. Both approaches provided similar biomass estimates. Several methods to provide a suitable projection approach for the ATM were investigated during the meeting but none were deemed acceptable. Alternative approaches to resolve this problem are proposed in the STAR Panel report recommendations.

The role of the STAR Panel is to conduct a detailed technical evaluation of a full stock assessment to advance the best available scientific information to the Council. The specific responsibilities of the STAR panel are to:

1) Review draft stock assessment documents, data inputs, and analytical models, along with other pertinent information (e.g., previous assessments and STAR panel reports, when available);

2) Discuss the technical merits and deficiencies of the input data and analytical methods during the open review panel meeting, work with the STATs to correct deficiencies, and, when possible, suggest new tools or analyses to improve future assessments; and

3) Develop STAR panel reports for all reviewed species to document meeting discussion and recommendations.

3.1 Review draft stock assessment documents, data inputs, and analytical models

Approximately two weeks before the STAR Panel meeting access to a web-site containing the draft Pacific Sardine Assessment Document and background material was granted. This was an excellent source on material from which to prepare for the actual review meeting. At the meeting, the SWFSC assessment team provided a good overview of the assessment approaches and the logic for their preference. Details were provided on each approach, survey design, analytical methods, and results during the meeting. This information greatly assisted the Review Panel in their review of assessment approach. When the Panel requested for a more detailed explanation or additional analysis the team generally provided the information the next day. The Panel and the CIE reviewers appreciated their efforts and acknowledge the extensive research effort to evaluate factors that may affect or bias outputs. The documented and presented information was sufficient to conduct the STAR Panel Review of the assessment and generally represents the best scientific information available at the moment. The ATM methodology Review to be held in 2018 will hopefully resolve the issues and recommendations associated with this assessment approach.

In general, the Panel review adhered to the agenda provided to attendees prior to the meeting. However, some flexibility was permitted by the chair when the discussion led into an area to be discussed later that was helpful to address the issue on-hand. Each CIE Reviewer participated in the discussion and review of the specific topics identified in the agenda and made a significant contribution to the Panel's draft summary report. The review chair collated the draft text and completed the Panel report with input from all Panel members. The review can be divided into 4 broad topics; the overview, acoustic-trawl surveys, the integrated assessment model (ALT), and conclusions/recommendations, each of which are discussed below.

3.2 Discuss the technical merits and deficiencies of the input data and analytical methods during the open review panel meeting.

The STAR Panel report provides a detailed summary of the Panel's views on the merits and deficiencies of both assessment approaches as well as suggestions to evaluated and potentially correct these deficiencies. Over the 3-day meeting, most areas of uncertainty or concern were addressed and where possible additional information or data reruns were requested to improve the Panel's understanding of procedures and processes (Section 3.3.1).

In addition, specific issues were raised and are identified below.

3.2.1 Acoustic Trawl Method (ATM) survey.

There were a number of merits and deficiencies identified during the 2017 Star Panel Review for the Acoustic Trawl Method survey. Both the STAT and the STAR Panel agreed that the ATM likely provided the better approach to assess the NSP Pacific sardine stock in term of biomass. Unfortunately, the proposed approach to project the stock forward by about 1 year was deemed circular and performed poorly to other projection methods tested during the meeting. While the detailed discussion of the acoustic methods were deferred until the 2018 methods review, several areas of weakness in the survey approach were discussed (survey coverage, biological sampling, stratification, and ageing). Factors such as TS were not investigated but could have had a significant impact on the estimated biomass (assumed to be absolute). Herein lies another example of where some additional detail in the documentation could have helped. Target strength is a function of fish length and usually expressed in terms of total length for pelagic species. Yet, the length measured during the survey was standard length. Although not requested during the meeting, a simple statement indicating the TS equation was correct for length measurement would have clarified what was actually done.

Survey Coverage:

Survey coverage has been, and continues to be, a major issue for both the spring and summer acoustic surveys in that they do not provide complete coverage of the seasonal distribution of the species. Each year the fishing industry (Captains and representatives) reports a varying amount of Pacific sardine in the inshore waters not covered by the AT surveys. According to the industry representatives present at this year's Panel, large amounts of sardines were observed inshore over the last two years during the time of the survey that would not be accounted for by the survey. If these observations can be confirmed and quantified, it would complete the survey coverage, and likely increase the 1+ biomass of the Northern Pacific stock. Even the 2011 Panel Review, which acknowledged that the survey was adequate to provide an absolute biomass estimate for the area covered, suggested that methods be explored to obtain information, particularly on the inshore and to a lesser extent on the offshore areas.

From a personal point of view, this is an excellent opportunity for the STAT team and the SWFSC to explore collaboration opportunities for surveying with the fishing industry. A major challenge for the larger research vessels is the minimum depth restrictions, imposed for safety reasons, limiting how close to shore the vessel can survey. Fishermen are general very familiar with local conditions and could, assuming a coordinated effort, provide coverage of those areas not covered by the survey vessel, thus eliminating the continuous uncertainty associated with what is and isn't in the inshore waters during the survey. Furthermore, there appears to be a sincere interest by the fishing industry to collaborate with the STAT team on surveying.

Another deficiency not directly related to spatial coverage, but the scope of the technology used to survey, is the amount of sardines distributed in the acoustic surface dead zone (10-15m below the surface). Currently, the surveys are conducted with hull mounted acoustic echo-sounders that can only detect fish directly under the vessel. Pacific sardines are commonly found very near the surface, thus any fish occurring in the dead zone would go undetected and would likely avoid the vessel, especially during the day. Recommendations have been made in previous reviews to investigate this section of the water column using sonar technology; however, no new information was presented at the review. The recommendation to use drone technology to address these and other areas of uncertainty are to be encouraged but they should not occur at the expense of more conventional technologies (e.g., sonar and aerial surveys).

Biological Sampling:

Biological Sampling appears to be another deficiency of the ATM. The current practice of surveying during the day and fishing during the night was again questioned. The assumption that fish present during the day are the same fish caught and occur with the same species composition (representative) is a major source of uncertainty. It should also be noted that a large number of the sets (Trawls) contain 0 catches (up to 50% in some years). Combine that with the pooling of sets into clusters and the actual sample size decreases substantially.

For this survey, the Primary Sampling Unit (PSU) is a cluster of sets undertaken in a general area. How the locations of the sets are determined is another area of uncertainty. It was curious to note that some clusters (multiple sets) occurred in areas where no fish were observed and no fish were caught. It was explained that because fishing occurred at night that fishing stations may or may not be in areas with fish. Given that the purpose of sampling is to determine species and size composition of the acoustic targets, fishing in areas without fish for multiple sets is somewhat futile. This practice of fishing for the sake of fishing also appears to be an inefficient use of precious vessel time. Better use of fishing time needs to be addressed and may help to improve biological sampling.

The species composition data from the sets are used to apportion the acoustic backscatter into species backscatter and subsequently into species specific biomass. Efforts should be made to improve (increase) biological sampling and reduce the uncertainty. This is another area where collaboration with the fishing industry could benefit both science and the industry. Working with the fishing industry could remove some of the uncertainty associated with day surveying and night sampling if fishing vessels were used to confirm acoustic targets. Purse seines are generally non-size selective and in many cases the entire school can be caught, permitting additional sampling with an actual biomass estimate. Additional samples would also be available for ageing.

Ageing:

The Panel discussed a number of issues associated with the number of samples aged and the development of age-length keys related to both assessment approaches being reviewed. Probably most surprising to the Panel was the limited number of otoliths collected for a given AT survey. The number of fish sampled for age ranged from 16 to 1,051 per year, but were generally less than 500, especially in the most recent years. The explanation provided by the STAT was that samples were difficult to collect during the survey as the biomass was low. The Panel expressed concern about the application of so few ages to age length keys and the implication of this on the age and weight at length used for the models. Of particular concern was the practice of pooling samples from several years to create a generic ALK that was applied to the length distributions. Most fishery scientists frown (a must not do) upon this practice as it removes the effects of all inter-annual or density dependent growth variability. The generic ALK will also have an impact on all age-related factors associated with the assessment. Several unusual patterns were noted in the weight at age figures for a number of years. The only real solution is to increase the number of samples collected and to increase the number of otoliths retained for ageing so that sufficient otoliths are collected to generate an annual ALK. This is another area that should be explored where collaboration/coordination with the fishing industry could benefit both the resource and the analysis. Fishing vessels could be utilized to sample fish during the survey or to supplement low samples in specific areas where research samples are limited.

Post survey stratification:

The method used to post stratify the AT survey into stratum was unclear in the assessment report and caused several members of the Panel to express their concern about using the presence and density of fish to post stratify the survey area. A fair amount of discussion ensued on the approach, sampling design and the potential bias of using the latter two criteria to stratify the survey observations. Eventually, the actual procedure for increasing the intensity (spacing) of transects was explained and the Panel felt more comfortable with the approach. However, there were still uncertainties associated with how things were done and what triggered a change in transect spacing. This issue will be dealt with further by the second CIE Reviewer and under the recommendations that should be addressed at the upcoming review of ATM scheduled for early 2018. Recommendation E states that the ATM survey design and estimation methods need to be more precisely specified.

3.2.2 Model-based assessment

The second assessment approach reviewed by the Panel was the model-based assessment (ALT) utilizing Version 3.24aa of the Stock Synthesis Assessment Toolbox to evaluate the status of the NSP of Pacific sardine stock. This model differs significantly in configuration and input parameters from the model used to update the assessment in 2016. Consequently, the requirement for a STAR Panel review. Changes include starting the model in 2005 (previously 1993) and excluding the Daily Egg Production Method (DEPM) and Total Egg Production (TEP) indices. Stock recruitment steepness and weight-at-age was pre-defined with the assumption that selectivity of the AT survey being 0 for age 0 and uniform for all other ages. Catchability was estimated under an age-based rather than a length-based model, ages modeled were reduced from 15 to 10 years and natural mortality increased from 0.4 to 0.6. Given that there is no directed fishery on the NSP resource so landings from the small live bait catches were included for 2015 and 2016 for the first time.

It was evident from the assessment document and presentations that the STAT team preferred the survey based method over the model-based approach to the assessment. The challenge for the preferred approach was to project forward almost a year from the last survey to the beginning of the management year. Thus, one of the key drivers in the review was to explore the method proposed by the STAT to estimate age 1+ biomass and its associated CV on July 1, 2017 from the ATM. If the proposed method was unacceptable then the Panel must identify the best approach to achieve and estimate biomass for management purposes.

Several inconsistencies, especially for age 0 were noted by the Panel in the outputs of the ALT model. A significant amount of time was spent on resolving issues associated with the ALT model. It appears that the seasonal option in the modelling (SS3) toolbox had not been fully tested and that it was producing unusual outputs related to the Age 0 fish. Several requests were made to the STAT team to try to resolve/understand these problems. Although not fully resolved to the satisfaction of the Panel, a work around process was established and projections for the 1+ biomass was available for the ALT model. Several approaches to estimate age 1+ biomass were explored by the Panel and are described below.

The first was to assume that the 1 July 2017 biomass equals the estimate of biomass from the summer 2016 ATM survey; simply ignoring mortality (natural causes and fishing), growth and recruitment from July 2016 to July 2017. This method was considered as the simplest approach and the easiest to implement because it does not rely on a model or estimates of age composition for which sample sizes are low.

The second approach was to project the biomass from the 2016 ATM survey to 1 July 2017 taking into account mortality, growth and recruitment between July 2016 and July 2017. Unfortunately, the approach used to convert from length-composition to age-composition was incorrect, and the method used to derive the CV of age 2+biomass did not allow for uncertainty in the population age-composition, projected weight-at-age and maturity-at-age. In addition, the method relied heavily on model ALT because approximately half of the age 1+ biomass on 1 July 2017 consisted of age-1 animals. As such, the estimate of biomass is based to a substantial extent on the stock-recruitment function from model ALT. Finally, the value for M of 0.6yr-1 has no clear justification. The version of the projection model provided initially to the Panel did not account for catches, meaning that the procedure could not be applied in the future when the targeted sardine fishery re-opened. Furthermore, it did not account for the limited catches during 2016.

The third approach was to use the ALT model projections. The ALT Model has similar problems associated with the ‘survey projection’ model, i.e. the age-composition data are based on a year-invariant age-length key, and the basis for M=0.6yr-1 lacks strong empirical justification (and indeed likelihood profiles indicate some support for lower M than the value adopted for model ALT). In addition, the model presented to the Panel predicted age 0 catch in the ATM survey even though it is assumed that age-0 animals are not selected during the ATM survey. It appears that the model predictions of age-0 animals in the ATM survey are actually model-predicted numbers of age-1 animals that are predicted to be mis-read as age-0 animals. However, examination of the ATM survey length-frequencies suggests that that some age-0 animals (or animals that were spawning earlier in the year) are encountered during the surveys. The Model ALT also estimates Q to be 1.1, which is unlikely given some sardine are not available to the survey owing to being inshore of the survey area.

Finally, projections from the previous assessment model were examined. The model on which the 2014-16 assessments were based was approved for management by the 2014 STAR Panel. However, that assessment had some undesirable features, including extreme sensitivity to the occurrence of small (<~15cm fish) in the ATM surveys, poor fits to the length-composition and survey data, and sensitivity to initial values for the parameters (i.e. local minima) as noted in previous reviews. The Panel explored alternatives to the current selectivity formulation to better understand why model ALT was predicting age 0 catch when selectivity for age-0 fish was set to zero. It was noted that the results were generally robust assuming that selectivity is a logistic function of length (but that implies that some age-1+ animals are not available to the ATM survey), allowing for time-varying age 0 selectivity, and estimating a separate selectivity pattern for ATM survey age-composition data.

The Panel noted that the 'survey projection' model and model ALT both rely on the samples from the ATM surveys to compute weight-at-age and survey age-composition data. The sample sizes for age from each survey were very small which means that estimates of, for example, weight-at-age are highly uncertain. The procedure of ensuring that weight-at-age for a cohort does not decline over time seems intuitively correct. However, if the estimated mean weight of young fish in a cohort is anomalously high owing to small samples, it can impact the weight-at-age of that cohort for all subsequent ages. When Model ALT steepness was estimated rather than fixing it equal to 0.8, the results were not sensitive to fixing versus estimating steepness, but the estimate of 0.36 was low.

In the end the Panel considered four ways to meet the management requirement to estimate age 1+ biomass on 1 July 2017: (1) the simple approach of using the of biomass estimate from the summer 2016 ATM survey without projecting forward, (2) projecting biomass from the 2016 ATM survey (summer) to 1 July 2017 using the proposed 'survey projection' model (and/or an alternative approach), (3) model ALT, and (4) the model on which the 2014-16 assessments were based. The Panel concluded that although neither method was fully acceptable that option 3, the ALT model, was likely the best available approach to meet the management needs.

3.3 Develop STAR panel reports for all reviewed species to document meeting discussion and recommendations.

This section summarizes the discussion and recommendations that form an integral part of the STAR Panel report. As a full member of the panel, I made a significant contribution to the preparation and editing of the final report. Consequently, I see no merit in rewording the sections related to requests for additional information, the recommendations and conclusions of the STAR panel report so I have extracted the appropriate sections and included them in my report. Although I fully agree with the content, there are a few areas where I have enhanced the text to complement that contained in the Panel report.

3.3.1 Requests made to the STAT (Taken Directly from the STAR Panel Report)

Day 1– Tuesday, February 21:

***Request 1*:** Provide documentation on the procedures used to calculate the survey age-composition data, including how age-length and age-biomass keys are constructed.

Rationale: These calculations are critical to projecting biomass after accounting for natural mortality, somatic growth, and recruitment; but the draft assessment document did not describe these calculations in sufficient detail for them to be reproduced. In addition, the age-compositions for the ATM survey in model ALT were computed using the method.

Response: Dr. Zwolinski presented written documentation and figures. The function "multinom" from the R package "nnet" fits a multinomial log-linear model using neural networks. The response is a discrete probability distribution (see Fig. 1). It is simpler to use than the alternative (sequential logistic models), and it provides a smoother transition between classes than an empirical age-at-length key. The age and lengths used for constructing the age-length key were from surveys from 2004 to the present. Due to the assumption of a July first date and its effect on ageing, the STAT built a season-specific age-length key using data pooled across time separately for spring/summer.
The Panel agreed that aggregation across years is not appropriate if some length-classes represent multiple ages, which is the case for Pacific sardine. Moreover, substantial spatial and temporal variation occurs in size-at-age, and smoothing this out by merging the data from several years creates bias in annual estimates of age compositions of varying magnitude and direction.

Request 2: Provide full specification, including equations, of the calculations used to 1) project from the ATM survey biomass estimate to the estimated age 1+ biomass on July 1 of the following fishing year, and 2) calculate the uncertainty associated with that biomass estimate.

Rationale: The projection calculations need to be reproducible. Management advice (Overfishing Level OFL, Acceptable Biological Catch ABC, and Harvest Guideline HG) for Pacific sardine requires an estimate of age 1+ biomass (OFL, ABC, HG) and its uncertainty (ABC) on July 1, 2017.

Response: For 1), Dr. Zwolinksi walked the Panel through a spreadsheet that made these calculations and the Panel agreed that the calculations were sensible, conditional on the age-weight key. For 2), assuming independence of age- 1 and age- 2+ biomass, the total variance was calculated by summing the respective variances. This calculation is negatively biased because it ignores uncertainty in age-composition and weight-at-age. It was noted that the resultant coefficient of variation (CV) for age 1+biomass is lower than the CV for either component (age- 1 versus age- 2+) due to their assumed independence.

Request 3: Plot cohort-specific rather than year-specific growth curves (weight-at-age) for the ATM survey and overlay raw data/information on sample sizes. Make it clear which values are estimated versus inferred. Do this for the fisheries data as well.

Rationale: Cohort-specific curves are easier to interpret as growth trajectories than year-specific curves. It is important to understand how much data drives these estimates, and to understand the consequences of applying the same age-length key for all years with survey data to calculate the weight-at-age and age-composition for the ATM survey.

Response: Dr. Hill presented tables including sample sizes and estimated means for each cohort-season-age combination. The tables were formatted to highlight entries that were inferred versus estimated. Dr. Hill calculated means whenever three or more samples were available. However, these means were sometimes overwritten based on the assumption that animals did not shrink. The ATM data showed substantial variation in weight-at-age across years (Fig. 2), and possibly increasing size-at-age in recent years. The MexCal catch data appeared less variable overall, and it was noted that fishery sample sizes were generally larger than the ATM sample sizes. An error was discovered in the weight-at-age data for the PNW catch, which could not be resolved during the Panel meeting.

The Panel noted that the adopted method ended up discarding data for cohorts with unusually large mean sizes for age-0 fish by not allowing "shrinkage", whereas it may have been the age-0 means that were anomalous rather than the means calculated for older ages. The Panel also noted that in many cases, the sample sizes were very small. The weight-at-age key used within the survey-based projection did not exclude "shrinkage". Using the weight-at-age key in model ALT produced an imperceptible difference in model-estimated age 1+ biomass.

Request 4: Verify that model ALT was run with ATM survey selectivity set equal to 0 for age-0 fish. Contact Dr. Rick Methot to better understand how selectivity is being modeled under the chosen selectivity option in SS.

Rationale: The model outputs appear to indicate that the model predicts non-zero catches of age-0 fish despite the intent to specify selectivity to be 0 zero on age-0 fish. This may have significant unintended consequences for the likelihood calculations.

Response: This question was not fully resolved. It appears that Stock Synthesis predicts some catch of nominal "age- 0" even given selectivity of zero on true age-0 fish because aging error leads to the expectation that some age-1 fish will be caught and miscategorized as age- 0. Further model runs revealed that the model "blew up" if aging error was set to zero or made

very small, but reductions in the specified aging error led to the expected reduction in the predicted age-0 catch. It was noted that surveys likely include a mix of age-1 fish miscategorized as age-0, as well as fish that are truly age-0.
Dr. Methot also noted that Stock Synthesis had not been as thoroughly debugged for semester-based models as for strictly annual models.
See also Requests 5, 8, and 9.

Request 5: Re-run model ALT with age- 0 fish removed from the input file for the ATM survey.

Rationale: Similar to Request 4, the model likelihood should not be influenced by data on age-0 fish if it is assumed selectivity on age-0 fish is zero, but the model appears to be generating non-zero predictions and comparing these against the input data.

Response: The model still predicted catch of age-0 fish in this scenario. This is consistent with the explanation suggested for this pattern under Request 4.

Request 6: Report the CV of the estimate of terminal biomass based on changes in how the compositional data are weighted.

Rationale: The weighting of compositional data appeared to have little effect on the point estimate of biomass, but it is important to understand implications of alternative weighting schemes for uncertainty as well.

Response: Data weighting increased the CV by 2-3%. The base model had a CV of approximately 36%, Francis-weighting led to a CV of approximately 38%, and harmonic mean weighting led to a CV of about 39%.

Request 7: Show more outputs from T_2017 and T_2017_No_New_AT _Comp

Rationale: These outputs would help the Panel evaluate the reasons for proposing a move away from a strict update of the previously accepted model structure, i.e. identify problems with a strict update that the new model structure addresses.

Response: Selectivity curves for the spring and summer ATM surveys were noticeably different depending on whether the two most recent survey length-compositions were included in the assessment or not (Fig. 3). These models appeared to yield acceptable fits to abundance indices, but the fits to observed length-compositions were poor. It appears that the model estimates very low selectivity on small fish for the summer survey (since selectivity does not vary across years, and very few small fish are encountered most years) such that when small fish are encountered, they are expanded to a very large number. During Panel discussion, it was noted that this unexpected behavior should not happen if selectivity were forced to be the same for the spring and summer surveys.

Day 2 – Wednesday, February 22

Request 8: Develop a model in which selectivity for age-0 animals in the survey is time-varying.

Rationale: The availability of age-0 animals to the survey seems to be highly variable among years, but influential on the results. A selectivity function in which age-0 selectivity varies among years should “discount” the influence of occasional catches of age-0 animals.

Response: A model was presented that assumed essentially full selection on age-1+ animals, and time-varying age-0 selectivity. The model estimated nearly zero selectivity on age-0 fish in all years except 2015, when estimated selectivity on age-0 fish was nearly 1.0. Fits to compositional data were similar to those for model ALT, except that the spike of age-0 fish in 2015 was captured better. The estimate of age 1+biomass on 1 July, 2017 for this model was 77,845 t.

Request 9: Run a variant of model ALT in which the age-compositions are assigned to a new fleet (6) that has logistic selectivity (estimated separately for the spring and summer periods).

Rationale: Selectivity for the ATM survey is assumed to be uniform on animals aged 1 and older so age-composition data are not required for this survey. The selectivity pattern for the trawl component of the survey is not uniform on age-1+ animals (some age-0 animals are caught) and it may be possible to represent this using a logistic selectivity function.

Response: This model performed generally similarly to a double-logistic formulation applied to the ATM survey for both age-composition and as an abundance index, but it misses the summer 2016 ATM survey estimate of biomass from above, whereas the double-logistic fits that estimate closely. The double-logistic model had a negative log-likelihood of approximately 311, compared to 305 for this variant and 333 for model ALT. Thus, both a model with logistic ATM selectivity and a model that assumed 1+ selectivity for ATM survey estimates and logistic selectivity for the associated age-composition data fit the data somewhat better than model ALT.

Request 10: Conduct a retrospective evaluation of how well alternative assessment methods can predict the biomass from the summer ATM surveys. For each year Y for which there is a summer ATM survey estimate for year Y and year Y+1, report predictions of year Y+1 biomass based on (a) the estimate of biomass from the results of the ATM survey during summer of year Y, (b) the estimate of biomass based on applying the projection method to the results from the ATM survey in summer of year Y, and (c) model ALT based on data through year Y.

Rationale: The Panel wished to understand which method was able to predict the ATM survey estimate of biomass most accurately.

Response: The STAT provided results for the three selected approaches as well as the estimates of age 1+ biomass obtained by projecting the actual assessments used for 2012, 2013, 2014 and 2015 forward ("Past assessments" in Fig. 4) and estimates of age 1+ biomass obtained by projecting the model used for 2014, 2015 and 2016 management advice ("2014 formulation"). Model ALT generally came closest to predicting the survey biomass estimate the following year, doing so by a substantial margin for 2014. "Past assessment" was usually the worst. Model ALT had the lowest residual variance. Relative errors were a CV of 1.07 for Model ALT, 1.26 for the 2014 model on which 2014, 2015 and 2016 management advice was based on formulation, 1.50 for the last survey without projection, 1.62 for the values adopted in management specifications, and 1.70 for projections from the past previous ATM survey (see Appendix 2 for the specifications for the method).

Day 3 – Thursday, February 23

Request 11: Develop a method for estimating recruitment solely from ATM data, explain how these recruitment estimates could be used to project forward from an ATM biomass estimate, and then add results for that method to the retrospective comparison described in Request 10.

Rationale: During discussion of Request 10, it was clear that much of the concern regarding the currently proposed method of projecting from the survey was its dependence on model ALT for inputs, resulting in its dependence on the same assumptions the STAT was hoping to avoid by moving away from an integrated assessment. It was pointed out that it could be possible to develop estimates of age 1 biomass on 1 July, 2017 strictly from the ATM data.

Response: The STAT modified the survey projection method so that projected biomass of 1-year-olds was the average over the most recent five years. As desired, this approach was not tied to the model ALT. However, the residual standard deviation for this approach ("Survey projection 2"), while better than "Survey projection", was still worse than Model ALT and the 2014 model formulation (1.45) (Fig. 4).

4.0 Recommendation and Conclusions

One of the primary objectives of the stock assessment process and the STAR Panel Review was to provide advice to management on 2017-2018 NSP Pacific sardine resource using the best available information/data. The Panel reviewed multiple options, described above and concluded for 2017 that, given the current management approach requires an estimate of age-1 biomass at the start of July, model ALT was the best approach at present for conducting this assessment notwithstanding the concerns listed above. The results from the assessment are robust to changes in how selectivity is modelled, the value for steepness and data weighting, but there were several concerns with this model that could not be resolved during the Panel meeting. Assuming uniform selectivity leads to lower estimates of current 1+ biomass, but this assumption reflects the expectation that all fish in the survey area are vulnerable to detection during an acoustic survey.

The STAT strongly recommends that management advice for Pacific sardine be based on the estimates of biomass from the ATM survey rather than a projection model or an integrated assessment. The STAR Panel is in general agreement with this approach and notes the following ways in which management could be based on the ATM survey results given the July 1 biomass estimate requirement. The first would be to change the start-date of the fishery so that the time between conducting the survey and the implementation of harvest regulations is minimized. And, secondly to use Management Strategy Evaluation to evaluate the risk to the stock of basing management actions on an estimate of biomass that could be a year old at the start of the fishing season (if the fishery start date is unchanged). Review of an updated MSE would likely not require a Methodology Panel, but could instead be conducted by the SSC.

The Panel further notes that there may be benefits to attempting to use both the spring and summer ATM surveys as the basis for an ATM survey-only approach and that moving to an assessment approach that relies on the most recent ATM survey (or two) may be compromised by reductions in ship time and/or problems conducting the survey. From the CIE Reviewer perspective, the reduction of vessel time will have implications for the AT survey and at a minimum will increase the variance estimates of biomass and the uncertainty about survey coverage.

The Panel agrees with the STAT that there is value in continuing to collect biological data and to update model ALT even if management moves to an ATM survey-only approach.

4.1 Research Recommendations:

The Panel identified a number of research recommendations that have been prioritized in three categories: High, medium and low.

High priority

A. Conduct an analysis of effect of fish sample size on the uncertainty in the ATM biomass estimates and model outputs. Use this information to re-evaluate and revise the sampling strategy for size and age data that includes target sample sizes for strata.
B. The clusters (the Primary Sampling Units, PSUs) with age-length data should be grouped into spatial strata (post-strata, or collapsed post-strata used in ATM biomass estimators). The variance in estimates of age-length compositions can then be estimated by bootstrapping of PSUs, where age-length keys are constructed for each bootstrap replicate. The sub-sample size of fish within clusters that are measured for lengths should be increased, and length-stratified age-sampling should be implemented. This approach would likely increase coverage of age samples per length class and reduce data gaps.
C. The survey projection method should be developed further. Specifically, the survey age-composition should be based on annual age-length keys, and the uncertainty associated with population age-composition, weight-at-age and maturity-at-age needs to be quantified and included in the calculation of CVs. A bootstrapping procedure could be used to quantify the uncertainty associated with population age-composition and projected weight-at-age. Uncertainty in weight-at-age could also be evaluated using a retrospective analysis in which the difference between observed and predicted weight-at-age for past years was calculated. Ultimately, improved estimates of weight-at-age and measures of precision of such estimates could be obtained by fitting a model to the empirical data on weight-at-age.
D. The methods for estimating 1 July age 1+ biomass based on the results of the ATM survey during the previous year currently use only the results of the summer survey. Improved precision is likely if the results from the spring and summer surveys were combined. This may become more important if the number of days for surveying is reduced in the future. Consideration should be given to fish born after 1 July.
E. Investigate alternative approaches for dealing with highly uncertain estimates of recruitment that have an impact on the most recent estimate of age-1+ biomass that is important for management.
F. Modify Stock Synthesis so that the standard errors of the logarithms of age-1+ biomass can be reported. These biomasses are used when computing OFLs, ABCs and HGs, but the CV used when applying the ABC control rule is currently that associated with spawning biomass and not age-1+ biomass.
G. The approach of basing OFLs, ABCs and HGs for a year on the biomass estimate from the ATM survey for the previous year should be examined using MSE so the anticipated effects of larger CVs and a possible time-lag

between when the survey was conducted and when catch limits are implemented on risk, catch and catch variation statistics can be quantified.

H. The assessment would benefit not only from data from Mexico and Canada, but also from joint assessment activities, which would include assessment team members from both countries during assessment development.
I. The assessment would benefit from the availability of estimates of 1+ biomass that include quantification of the biomass inshore of the survey area and in the upper water column.
J. It is unclear how the habitat model is applied to determine survey design. Is this an *ad hoc* decision or is there a formal procedure? The next Panel should be provided with comprehensive documentation on how the habitat model is applied.
K. Consider future research on natural mortality. Note that changes to the assumed value for natural mortality may lead to a need for further changes to harvest control rules.
L. Explore the potential of collaborative efforts to increase sample sizes and/or gather data relevant to quantifying effects of ship avoidance, problems sampling near-surface schools, and currently un-sampled nearshore areas.
M. Reduce aging error and bias by coordinating and standardizing aging techniques and performing an aging exchange (double blind reading) to validate aging and estimate error. Standardization might include establishing a standard “birth month” and criteria for establishing the presence of an outer annuli. If this has already been established, identify labs, years, or sample lots where there is deviation from the criteria. The outcome of comparative studies should be provided with every assessment.

Medium priority

N. Continue to explore possible additional fishery-independent data sources such as the SWFSC juvenile rockfish survey and the CDFW/CWPA cooperative efforts (additional sampling and aerial surveys). Inclusion of a substantial new data source would likely require review, which would not be easily accomplished during a standard STAR Panel meeting and would likely need to be reviewed during a Council-sponsored Methodology Review.
O. Consider spatial models for Pacific sardine that can be used to explore the implications of regional recruitment patterns and region-specific biological parameters. These models could be used to identify critical biological data gaps as well as better represent the latitudinal variation in size-at-age; this should include an analysis of age-structure on the mean distribution of sardine in terms of inshore-offshore (especially if industry partner-derived data were available).
P. Consider a model that has separate fleets for Mexico, California, Oregon-Washington and Canada.

Q. Compare annual length-composition data for the Ensenada fishery that are included in the MexCal data sets for the northern sub-population with the corresponding southern California length compositions. Also, compare the annual length-composition data for the Oregon-Washington catches with those from the British Columbia fishery. This is particularly important if a future age data/age-based selectivity model scenario is further developed and presented for review.

Low priority

R. Consider a model that explicitly models the sex-structure of the population and the catch.
S. Develop a relationship between egg production and fish age that accounts for the duration of spawning, batch fecundity, etc., by age. Using this information in the assessment would require that the stock-recruitment relationship in SS be modified appropriately.
T. Change the method for allocating area in the DEPM method so that the appropriate area allocation for each point is included in the relevant stratum. Also, apply a method that better accounts for transect-based sampling and correlated observations that reflects the presence of a spawning aggregation.

4.2 Recommendations that should be addressed during the 2018 review of the ATM survey

The Panel was informed that a methodology review of the ATM approach was scheduled for January 2018. Because of this, a number of issues and detailed discussions regarding this approach were deferred until the review. However, the Panel did make several recommendations, listed below, that should be considered for the 2018 review.

A. In relation to the habitat model:

a. Investigate sensitivity of the assessment to the threshold used in the environmental-based method (currently 50% favourable habitat) to further delineate the southern and northern subpopulations of Pacific sardine.
b. Further validate the environmentally-based stock splitting method. The habitat model used to develop the survey plan and assign catches to subpopulation seems to adequately predict the spawning/egg distribution in the CalCOFI core DEPM region, but eggs were observed where they were not expected in northern California, Oregon and Washington during one of the two years when the survey extended north. It may be possible to develop simple discriminant factors to differentiate the two sub-populations by comparing metrics from areas where mixing does not occur. Once statistically significant discriminant metrics (e.g. morphometric, otolith morphology, otolith micro-structure, and possibly using more recent developments in genetic methods) have been chosen,

these should be applied to samples from areas where mixing may be occurring or where habitat is close to the environmentally-based boundary. This can be used to help set either a threshold or to allocate proportions if mixing is occurring.

c. Consider including environmental covariates in model-based approaches that would account quantitatively for environmental effects on distribution and biomass. The expertise from a survey of fishermen could be extremely useful in identifying covariates that impact the distribution of clusters.

B. The SWFSC plans to examine ship avoidance using aerial drone sampling; there is an ongoing significant effort by Institute of Marine Research in Norway to understand the same issue using sonar, and the SWFSC acoustics team should communicate and coordinate with those researchers.

C. The effect of population size affecting the number and spacing of school clusters likely affects the probability of acoustic detection in a non-linear way; this could create a negatively biased estimate at low population levels and potentially a non-detection threshold below which the stock size cannot be reliably assessed. A simulation exercise should be conducted using the current, decreased and increased survey effort over a range of simulated population distribution scenarios to explore this.

D. The consequences of the time delay and difference in diurnal period of the acoustic surveys versus trawling need to be understood; validation or additional research is critical to ensure that the fish caught in the trawls from the night time scattering layer share the same species, age and size structure as the fish ensonified in the daytime clusters.

E. The ATM survey design and estimation methods need to be more precisely specified. A document must be provided to the ATM review (and future assessment STAR Panels) that:

- delineates the survey area (sampling frame);
- specifies the spatial stratification (if any) and transect spacing within strata planned in advance (true stratification);
- specifies the rule for stopping a transect (offshore boundary);
- specifies the rules for conducting trawls to determine species composition;
- specifies the rule for adaptive sampling (including the stopping rule); and
- specifies rules for post-stratification, and in particular how density observations are taken into account in post-stratification. Alternative post-stratification without taking into account density should be considered.

STAR Panel Review of the 2017-2018 Pacific Sardine
Stock Assessment
February 21-24, 2017

Background

The National Marine Fisheries Service (NMFS) is mandated by the Magnuson-Stevens Fishery Conservation and Management Act, Endangered Species Act, and Marine Mammal Protection Act to conserve, protect, and manage our nation's marine living resources based upon the best scientific information available (BSIA). NMFS science products, including scientific advice, are often controversial and may require timely scientific peer reviews that are strictly independent of all outside influences. A formal external process for independent expert reviews of the agency's scientific products and programs ensures their credibility. Therefore, external scientific peer reviews have been and continue to be essential to strengthening scientific quality assurance for fishery conservation and management actions.
Scientific peer review is defined as the organized review process where one or more qualified experts review scientific information to ensure quality and credibility. These expert(s) must conduct their peer review impartially, objectively, and without conflicts of interest. Each reviewer must also be independent from the development of the science, without influence from any position that the agency or constituent groups may have. Furthermore, the Office of Management and Budget (OMB), authorized by the Information Quality Act, requires all federal agencies to conduct peer reviews of highly influential and controversial science before dissemination, and that peer reviewers must be deemed qualified based on the OMB Peer Review Bulletin standards.
(http://www.cio.noaa.gov/services_programs/pdfs/OMB_Peer_Review_Bulletin_m05-03.pdf).
Further information on the CIE program may be obtained from www.ciereviews.org.

Scope

The CIE reviewers will serve on a Stock Assessment Review (STAR) Panel and will be expected to participate in the review of Pacific sardine stock assessment. The Pacific sardine stock is assessed regularly (currently, every 1-2 years) by SWFSC scientists, and the Pacific Fishery Management Council (PFMC) uses the resulting biomass estimate to establish an annual harvest guideline (quota). The stock assessment data and model are formally reviewed by a Stock Assessment Review (STAR) Panel once every three years, with a coastal pelagic species subcommittee of the SSC reviewing updates in interim years. Independent peer review is required by the PFMC review process. The STAR Panel will review draft stock assessment documents and any other pertinent information for Pacific sardine, work with the stock assessment teams to make necessary revisions, and produce a STAR Panel report for use by the PFMC and other interested persons for developing management recommendations for the fishery. The PFMC's Terms of Reference (ToRs) for the STAR Panel review are attached in Appendix 1. The tentative agenda of the Panel review meeting is attached in Appendix 2. Finally, a Panel summary report template is attached as Appendix 3.

Requirements

Two CIE reviewers shall participate during a panel review meeting in La Jolla, California during 21-24 February, and shall conduct impartial and independent peer review accordance with the SoW and ToRs herein. The CIE reviewers shall have the expertise as listed in the following descending order of importance:

- The CIE reviewer shall have expertise in the design and execution of fishery-independent surveys for use in stock assessments, preferably with coastal pelagic fishes.
- The CIE reviewer shall have expertise in the application of fish stock assessment methods, particularly, length/age-structured modeling approaches, e.g., ‘forward-simulation’ models (such as Stock Synthesis, SS) and it is desirable to have familiarity in ‘backward-simulation’ models (such as Virtual Population Analysis, VPA).
- The CIE reviewer shall have expertise in the life history strategies and population dynamics of coastal pelagic fishes.
- It is desirable for the CIE reviewer to be familiar with the design and application of fisheries underwater acoustic technology to estimate fish abundance for stock assessment.
- It is desirable for the CIE reviewer to be familiar with the design and application of aerial surveys to estimate fish abundance for stock assessment.

The CIE reviewer's duties shall not exceed a maximum of 14 days to complete all work tasks of the peer review process.

Tasks for reviewers

- Review the following background materials and reports prior to the review meeting: *Two weeks before the peer review, the NMFS Project Contact will send by electronic mail or make available at an FTP site to the CIE reviewers all necessary background information and reports for the peer review. In the case where the documents need to be mailed, the NMFS Project Contact will consult with the CIE on where to send documents. The CIE reviewers shall read all documents in preparation for the peer review, for example:*

- *Recent stock assessment documents since 2013;*
    - *STAR Panel- and SSC-related documents pertaining to reviews of past assessments;*
    - *CIE-related summary reports pertaining to past assessments; and*
    - *Miscellaneous documents, such as ToR, logistical considerations.*

Pre-review documents will be provided up to two weeks before the peer review. Any delays in submission of pre-review documents for the CIE peer review will result in delays with the CIE peer review process, including a SoW modification to the schedule of milestones and deliverables. Furthermore, the CIE reviewers are responsible only for the pre-review documents that are delivered to the reviewer in accordance to the SoW scheduled deadlines specified herein.

- Attend and participate in the panel review meeting • The meeting will consist of presentations by NOAA and other scientists, stock assessment authors and others to facilitate the review, to provide any additional information required by the reviewers, and to answer any questions from reviewers

    - After the review meeting, reviewers shall conduct an independent peer review in accordance with the requirements specified in this SOW, OMB guidelines, and TORs, in adherence with the required formatting and content guidelines; reviewers are not required to reach a consensus
- Each reviewer may assist the Chair of the meeting with contributions to the summary report, if required by the TORs
- Deliver their reports to the Government according to the specified milestone dates

Foreign National Security Clearance

When reviewers participate during a panel review meeting at a government facility, the NMFS Project Contact is responsible for obtaining the Foreign

National Security Clearance approval for reviewers who are non-US citizens. For this reason, the reviewers shall provide requested information (e.g., first and last name, contact information, gender, birth date, passport number, country of passport, travel dates, country of citizenship, country of current residence, and home country) to the NMFS Project Contact for the purpose of their security clearance, and this information shall be submitted at least 30 days before the peer review in accordance with the NOAA Deemed Export Technology Control Program NAO 207-12 regulations available at the Deemed Exports NAO website: http://deemedexports.noaa.gov/ and http://deemedexports.noaa.gov/compliance_access_control_procedures/noaa-foreign-national-registration- system.html. The contractor is required to use all appropriate methods to safeguard Personally Identifiable Information (PII).

Place of Performance

The place of performance shall be at the contractor's facilities, and at the Southwest Fisheries Science Center in La Jolla, California.

Period of Performance

The period of performance shall be from the time of award through April 30, 2017. Each reviewer's duties shall not exceed 14 days to complete all required tasks.

Schedule of Milestones and Deliverables

The contractor shall complete the tasks and deliverables in accordance with the following schedule.

No later than January 24, 2017	CIE sends reviewers contact information to the COTR, who then sends this to the NMFS Project Contact
No later than February 7, 2017	NMFS Project Contact sends the CIE Reviewers the pre-review documents
February 21-24, 2017	The reviewers participate and conduct an independent peer review during the panel review meeting
March 10, 2017	CIE reviewers submit draft CIE independent peer review reports to the CIE Lead Coordinator and CIE Regional Coordinator
March 31, 2017	CIE submits CIE independent peer review reports to the COTR
April 7, 2017	The COTR distributes the final CIE reports to the NMFS Project Contact and regional Center Director

Applicable Performance Standards

The acceptance of the contract deliverables shall be based on three performance standards:
(1) The reports shall be completed in accordance with the required formatting and content (2) The reports shall address each TOR as specified (3) The reports shall be delivered as specified in the schedule of milestones and deliverables.

Travel

All travel expenses shall be reimbursable in accordance with Federal Travel Regulations (http://www.gsa.gov/portal/content/104790). International travel is authorized for this contract. Travel is not to exceed $10,000.

Restricted or Limited Use of Data

The contractors may be required to sign and adhere to a non-disclosure agreement.

Annex I: Review Panel Agenda

Revised AGENDA

2017 Pacific Sardine Stock Assessment Review

Southwest Fisheries Science Center
8901 La Jolla Shores Dr., La Jolla, CA 92037
La Jolla, CA 92037
858-334-2800

This is a public meeting, and time for public comment may be provided at the discretion of the meeting Chair. This is a work session for the primary purpose of reviewing the current Pacific sardine stock assessment, under the Pacific Fishery Management Council's (Council) terms of reference for the CPS stock assessment reviews. The Stock Assessment Review Panel will review the assessment and produce a report to the full SSC, in advance of the April 2017 Council meeting in Sacramento, California. The assessment will be used for setting sardine harvest specifications and management measures for the July 1, 2017 – June 30, 2018 fishery.

TUESDAY, FEBRUARY 21, 2017 – 10 A.M.

A. Call to Order, Introductions, Approval of Agenda — André Punt, Chair
(10 a.m., 15 minutes)

B. Terms of Reference for CPS Stock Assessment Review Process — Kerry Griffin
(10:15 a.m., 15 minutes)

C. Pacific Sardine Stock Assessment Team Presentation Overview — Paul Crone, Kevin Hill
(10:30 a.m., 15 minutes)

D. Acoustic-Trawl Survey — Juan Zwolinski
(10:45 a.m., 45 minutes)

E. Pacific Sardine Stock Assessment Team Presentation — Kevin Hill, Paul Crone
(11:30 p.m., 1 hour 30 minutes)

LUNCH
(1 p.m. – 3p.m., 2 hours)

NOTE: The Pacific Room is needed for another purpose from 1 p.m. until 3 p.m. The STAR Panel and attendees can move to Stenella Meeting room during this time.

E. Pacific Sardine Stock Assessment Team Presentation (continued if needed) Kevin Hill
(3:00 p.m., 30 minutes) Paul Crone

F. Discussion and Requests Panel
(3:30 p.m., 1 hour 30 minutes)

WEDNESDAY FEBRUARY 22, 2017

G. Work Session – STAT and STAR Panel All
(8 a.m., 2 hours)

H. Public Comment
(10 a.m., 0.5 hours)

I. Response to Requests Kevin Hill
(10:30 a.m., 1.5 hours)

LUNCH

J. Initial Report Writing and STAT Work Session Panel
(1 p.m., 2.5 hours)

K. Discussion and Requests Panel
(3:30 p.m., 1 hour)

L. Public Comment André Punt
(4:30 p.m., 0.5 hours)

THURSDAY FEBRUARY 23, 2017

M. Response to Requests Kevin Hill
(8 a.m., 2 hours)

BREAK

N. Discussion and Requests Panel
(10:30 a.m., 1.5 hours)

LUNCH

O. Response to Requests Kevin Hill
(1 p.m., 1 hour)

P. Public Comment
(2 p.m., 0.5 hours)

BREAK

Q. Report Writing and STAT Work Session
(3 p.m., 2 hours)

FRIDAY FEBRUARY 24, 2017

R. Response to Comments (If Necessary) — Kevin Hill
(8 a.m., 1 hour)

S. Discussion – Next Steps and Deadlines — André Punt
(9 a.m., 1 hour) — Kerry Griffin

BREAK

T. Finalize Report Assignments — André Punt
(10:30 a.m., 1.5 hours)

U. Work Session as Necessary and Meeting Wrap Up — André Punt
(12:00 p.m.)

ADJOURN

Appendix III: List of Participants

STAR Panel Members:
André Punt (Chair), Scientific and Statistical Committee (SSC), Univ. of Washington
Will Satterthwaite, SSC, Southwest Fisheries Science Center
Evelyn Brown, SSC, Lummi Natural Resources, LIBC
Jon Vølstad, Center for Independent Experts (CIE)
Gary Melvin, Center for Independent Experts (CIE)

Pacific Fishery Management Council (Council) Representatives:
Kerry Griffin, Council Staff
Diane Pleschner-Steele, CPSAS Advisor to STAR Panel
Lorna Wargo, CPSMT Advisor to STAR Panel

Pacific Sardine Stock Assessment Team:
Kevin Hill, NOAA / SWFSC
Paul Crone, NOAA / SWFSC
Juan Zwolinski, NOAA / SWFSC

Other Attendees
Dale Sweetnam, SWFSC
Alan Sarich, CPSMT/Quinault Indian Nation
Emmanis Dorval, SWFSC
Chelsea Protasio, CPSMT/CDFW
Kirk Lynn, CPSMT/CDFW
Ed Weber, SWFSC
Josh Lindsay, NMFS WCR
Erin Kincaid, Oceana
Al Carter, Ocean Gold
Jason Dunn, Everingham Bros Bait
Nick Jurlin, F/V Eileen
Neil Guglielmo, F/V Trionfo
Andrew Richards, Commercial
Hui-Hua Lee, SWFSC
Bev Macewicz, SWFSC
Chenying Gao, Student
Steven Teo, SWFSC
Kevin Piner, SWFSC
Andy Blair, Commercial
Jamie Ashley, F/V Provider
John Budrick, CDFW
Steve Crooke, CPSAS
Gilly Lyons, Pew Trusts

Agenda Item G.5.b
Supplemental SSC Report
April, 2017

SCIENTIFIC AND STATISTICAL COMMITTEE REPORT ON FINAL ACTION ON SARDINE ASSESSMENT, SPECIFICATIONS, AND MANAGEMENT MEASURES

The Scientific and Statistical Committee (SSC) reviewed the 2017 stock assessment of the northern subpopulation of Pacific sardine. Drs. Kevin Hill and Paul Crone (Southwest Fisheries Science Center) presented the results of the stock assessment and Dr. André Punt (SSC) provided an overview of the Stock Assessment Review (STAR) Panel report. The SSC appreciates the effort put forth by the stock assessment team to improve the assessment model in response to previous full and update assessment concerns.

The SSC endorses the 2017 Pacific sardine base case assessment model (termed model ALT in the assessment document) as the best available science for use in managing the northern subpopulation of Pacific sardine. The base case model uses an integrated assessment approach to estimate age-1+ biomass at the start of the 2017/2018 fishing year (July 1, 2017). This model is more stable, shows improved fit to recent surveys, and has improved retrospective patterns and thus is an improvement over the 2014 full assessment model and subsequent update assessments. Major differences include starting the assessment in 2005 rather than 1993, excluding the Daily Egg Production Method and Total Egg Production indices, and changing model specifications for natural mortality, weight-at-age, survey selectivity, catchability, and steepness of the stock-recruitment relationship.

There is no direct information on the size of the 2016 year-class, so it is estimated from the stock-recruitment relationship. As a result, there is considerable uncertainty associated with the estimate of age-1+ biomass in 2017. A substantial proportion of total biomass will be from that incoming cohort of uncertain size, especially when the stock size is estimated to be low, as it is presently. There are additional key uncertainties associated with natural mortality, weight-at-age, survey selectivity, and catchability.

The estimate for total age-1+ biomass on July 1, 2017, is 86,586 mt. The SSC recommends an overfishing limit (OFL) of 16,957 mt and that the base model be considered a category 1 assessment with a default sigma (σ) of 0.36 to be used in determining the acceptable biological catch.

The SSC reiterates that the assessment and OFL are only for the northern subpopulation of Pacific sardine, although some portion of the U.S. catch in each year is likely from the southern subpopulation.

There may be benefits to the survey-based approach advocated by the stock assessment team, and the planned early 2018 review of this survey could provide further information on the suitability of this approach. There would be less uncertainty in the calculation of the OFL when using a survey-based approach if the time-lag between conducting the survey and the start of the fishing year was minimized. Further evaluation of a survey-based assessment approach through a management strategy evaluation would be beneficial.

PFMC
04/08/17

COASTAL PELAGIC SPECIES MANAGEMENT TEAM REPORT ON FINAL ACTION ON SARDINE ASSESSMENT, SPECIFICATIONS, AND MANAGEMENT MEASURES

The Coastal Pelagic Species Management Team (CPSMT), Coastal Pelagic Species Advisory Subpanel (CPSAS) and Scientific and Statistical Committee (SSC) jointly received a presentation from Drs. Kevin Hill and Paul Crone concerning the Pacific sardine full stock assessment conducted in 2017. The CPSMT recommends that the Pacific Fishery Management Council (Council) adopt the Alternative Stock Assessment (ALT) model within the full assessment for management of the 2017-2018 sardine fishery (Agenda Item G.5.a, Stock Assessment Report). The age 1^+ biomass estimated from this assessment for July 1, 2017 is 86,586 metric tons (mt).

Similar to the 2016-2017 biomass estimate of 106,137 mt, the 2017-2018 biomass estimate of 86,586 mt is below the CUTOFF value of 150,000 mt. Accordingly, the Fishery Management Plan dictates a closure of the primary directed fishery for Pacific sardine for the upcoming fishing year (July 1, 2017 - June 30, 2018). This closure, however, does not preclude the allowance for incidental catch in other CPS and non-CPS fisheries as well as directed live bait, recreational and tribal harvest fisheries.

Harvest Specifications for 2017-2018
Table 1 (below) contains the overfishing limit (OFL) and a range of acceptable biological catch (ABC) values based on various P* (probability of overfishing) values. The CPSMT recommends use of a P* value of 0.40, consistent with previous sardine management specifications. The SSC designated the 2017 assessment as a Tier 1. The P* value of 0.40 applied to the 2016-2017 OFL of 16,957 mt, using a Tier 1 sigma of 0.36, produces an acceptable biological catch (ABC) of 15,479 mt.

During the 2015-2016 fishing season, the CPSMT evaluated the potential needs for incidental allowances for other CPS fisheries when the primary directed sardine season is closed (April 2015 Agenda item G.1.b, Supplemental CPSMT Report). That evaluation considered the historical levels of incidental sardine catch under a range of species and fishery dynamics. Consistent with that evaluation, the CPSMT again recommends an annual catch limit (ACL) of 8,000 mt (Table 2) to allow other fisheries to proceed. The CPSMT also recommends the same accountability measures as 2016-2017, presented following Table 2.

The Quinault Indian Nation request of 800 mt, the live bait fishery, and other minimal sources of mortality, such as recreational take, will be accounted for against the ACL. Coastwide incidental non-tribal landings for the 2016-2017 season through March 30, 2017 total 358 mt, while the Quinault Indian Nation reports 85 mt.

Table 1. Pacific sardine harvest formula parameters for 2017-2018.

Harvest Control Rule Formulas									
OFL = BIOMASS * E_{MSY} * DISTRIBUTION; where E_{MSY} is bounded 0.00 to 0.25									
$ABC_{P\text{-}star}$ = BIOMASS * $BUFFER_{P\text{-}star}$ * E_{MSY} * DISTRIBUTION; where E_{MSY} is bounded 0.00 to 0.25									
HG = (BIOMASS - CUTOFF) * FRACTION * DISTRIBUTION; where FRACTION is E_{MSY} bounded 0.05 to 0.20									
Harvest Formula Parameters

$ABC_{Tier 2}$ =	15,490	14,130	12,849	11,625	10,434	9,251	8,040	6,739	5,188
HG =	**0**								

Table 2. 2017-2018 Calculated OFL, ABC and CPSMT-Recommended ACL.

Biomass	86,586 mt
OFL	16,957 mt
P* buffer	0.4
$ABC_{0.4}$	15,479 mt
ACL	8,000 mt

List of CPSMT-Recommended Accountability Measures

The following would be automatic in season actions for CPS fisheries:

- An incidental per landing allowance of 40 percent Pacific sardine in non-treaty CPS fisheries until a total of 2,000 mt of Pacific sardine are landed.
- When the 2,000 mt is achieved the incidental per landing allowance would be reduced to 20 percent until a total of 5,000 mt of Pacific sardine have been landed.
- When 5,000 mt have been landed, the incidental per landing allowance would be reduced to 10 percent for the remainder of the 2017-2018 fishing year.

A 2 mt incidental per landing allowance in non-CPS fisheries.

COASTAL PELAGIC SPECIES ADVISORY SUBPANEL REPORT ON FINAL ACTION ON SARDINE ASSESSMENT, SPECIFICATIONS, AND MANAGEMENT MEASURES

The Coastal Pelagic Species Advisory Subpanel (CPSAS) heard a presentation by Dr. Kevin Hill on the Assessment of the Pacific Sardine Resource in 2017 for U.S. Management in 2017-18 (Agenda Item G.5.a, Stock Assessment Report), given at the Science and Statistical Committee (SSC) meeting. CPSAS members also heard a summary review of the Pacific Sardine Stock Assessment Review (STAR) Panel Meeting Report (Agenda Item G.5.a, STAR Panel Report) by Dr. Andre Punt. CPSAS members reviewed both documents prior to the SSC meeting.

A majority of the CPSAS remains extremely frustrated that this STAR panel review found the same unresolved problems as in prior assessments. As noted in the STAR Panel Report under Unresolved Problems and Major Uncertainties (page 9), "***The core issues for stock assessments continue to be related to the temporal and spatial scale of the surveys and insufficient sample sizes of age-length for sardine in the ATM survey.***"

The STAR Panel Report expressed concerns with all the assessment approaches offered, but reviewers were asked to recommend the "least worst" option for the Council to set management measures for the 2017 sardine fishery. Model ALT turned out to be marginally better than the biomass estimated in the summer Acoustic Trawl Method (ATM) survey proposed by the Stock Assessment Team (STAT). Following discussion, the SSC ultimately approved this approach for 2017, recognizing this as the basis for two years of update assessments before the next full assessment review.

A majority of the CPSAS ask the Council to heed fishermen who are reporting a large biomass of sardines (as well as anchovy) in waters inshore of the current ATM survey area. We agree with the concerns expressed in the CPSAS representative's statement in the STAR Panel Report. Quoting from that statement: *"ATM surveys at present do not capture fish in the upper water column, nor a large biomass of young fish (sizes 3 inches and up) that fishermen have observed in nearshore waters since late 2014; this biomass is largely inside ATM survey tracks. But the ATM survey is assigned a catchability quotient (Q) of 1 nonetheless, meaning it "sees" all the fish. The Q for Model ALT, which is based largely on ATM survey data, is estimated at 1.1, which the STAR Panel report calls into question, given for example the unquantified volume of fish in nearshore waters.*

The summer 2016 ATM survey reported a fourfold increase in age 1+ biomass, but the biomass estimate produced is substantially lower than the estimate used for management in 2016. The STAR panel found fault with the methodology used to project the 2016 biomass to 2017. So do we – but using the 2016 ATM biomass estimate without adjusting for recruitment ignores reality."

A majority of the CPSAS also express concern that stock assessments seem to be gravitating to only one independent index, ATM surveys, which measure only one point in time. In our view this is a big problem, based on the following:

- The current trawl speed (4 knots or less) likely results in under sampling larger sardines.
- The nearshore area (where young sardines are often concentrated) is not sampled.

- ATM surveys have not been able to estimate recruitment.
- Q is assumed to be 1 – and in Model ALT, Q freely estimated is 1.1, which the STAR panel questioned. Clearly, current ATM surveys do not "see" all the fish, and thus biomass estimates must be considered to be negatively biased.
- In fact, the projected biomass estimate for 2017 is lower than 2016 at a time that sardines are increasing in abundance, apparently coast-wide, but certainly in California. The STAR Panel Report attributed the reduction in biomass to a change in assessment methodology.

Nevertheless, this assessment is a recipe for disaster, and the impact is being felt coastwide. Fishermen are having a hard time finding schools of CPS with a mix of less than 40 percent sardines.

The majority of the CPSAS ask the Council to consider the following recommendations:

- Assessments should be based on more than one survey index. The 2015 and 2016 juvenile rockfish surveys were informative as evidence of recruitment and should be considered in future stock assessments.
- Please support cooperative research with industry to survey nearshore waters now missed in National Oceanic and Atmospheric Administration acoustic surveys.
- The Terms of Reference (TOR) for stock assessments should be revised to provide more flexibility, particularly in update years, to incorporate new findings and data into assessments that more accurately reflect ocean conditions. The TOR should also provide for a process to reopen a fishery based on new lines of evidence as soon as possible, rather than the current requirement to wait for the next full assessment. Without flexibility to adaptively manage dynamic CPS stocks, industry is forced to sit idle for the better part of one or two years, or even more –which may be beyond its economic tipping point.

Management Measures

The majority of the CPSAS recommends continuing the management measures approved by the Council in 2016, including:
Annual Catch Limit (ACL) 8,000 mt
Automatic in-season actions:

- An incidental per landing allowance of 40 percent Pacific sardine in non-Treaty CPS fisheries until a total of 2,000 mt of Pacific sardine are landed.
- When the 2,000 mt is achieved, the incidental per landing allowance would be reduced to 20 percent, until a total of 5,000 mt of Pacific sardine have been landed.
- When 5,000 mt have been landed, the incidental per landing allowance would be reduced to 10 percent for the remainder of the 2017-2018 fishing year.

In addition, the Council should adopt a 2 mt incidental per landing allowance in non-CPS fisheries.

Conservation representative statement:

The conservation representative of the CPSAS recommends setting incidental catch for Pacific sardine at a precautionary level that both protects the spawning stock while not unduly constraining other fisheries, including other CPS fisheries. Of an 8,000 mt ACL for the current season, approximately 1,000 mt in sardine landings have been recorded so far, suggesting that the current ACL on its own is not having a constraining effect on other fisheries. Given that the July 2017 projected biomass for Pacific sardine is lower than the estimated biomass from the past two years, and the overfishing limit and acceptable biological catch for the coming season will necessarily be reduced from the 2016-2017 specifications, the Council could consider and adopt an ACL for 2017-2018 that is commensurately reduced from last year's ACL. The conservation representative suggests that a high level of precaution is appropriate in setting incidental catch, given Pacific sardine's continued low abundance and its essential role as forage in the California Current Ecosystem. Finally, the conservation representative echoes the majority of the CPSAS's support for cooperative research to improve the capacity of acoustic surveys to survey inshore waters.

PFMC
4/10/17

Decision Summary Document
Pacific Fishery Management Council

April 7-11, 2017

Council Meeting Decision Summary Documents are highlights of significant decisions made at Council meetings. Results of agenda items that do not reach a level of highlight significance are typically not described in the Decision Summary Document. For a more detailed account of Council meeting discussions, see the Council meeting record and voting logs or the Council newsletter.

Habitat

Current Habitat Issues

The Council directed staff to communicate with the Federal Energy Regulatory Commission and California Department of Water Resources to express Council concerns about thermal regulation at Oroville Dam, to ask for clarity on specific issues related to those concerns, and to invite representatives of the two agencies to present to the Council and/or Habitat Committee (HC) in June. The Council directed staff to work with California Department of Fish and Wildlife staff to identify those specific concerns. The Council may send a follow-up letter in the future.

In addition, the Council directed staff to send the HC's letter to the U.S. Army Corps of Engineers on the Permit Renewal and Expansion on the Coast Seafoods project with edits outlined in the Supplemental California Dept. of Fish and Wildlife Report and further edited by the Council.

The Council also requested both an update from the HC and a draft letter commenting on the Environmental Protection Agency's National Pollution Discharge Elimination System general permit for the June Briefing Book.

Salmon Management

Sacramento River Winter Chinook Harvest Control Rule

The Council reviewed the progress of the ad hoc Sacramento River Winter Chinook Workgroup since their last report in September 2016. The Council provided feedback on the initial analysis and is tentatively scheduled to provide preliminary recommendations for control rules at the September 2017 Council meeting and final recommendations at the November 2017 Council meeting.

Methodology Review Preliminary Topic Review

The Council supported the list of items for review submitted by the Scientific and Statistical Committee (SSC) and the Model Evaluation Workgroup (MEW) that included: 1) Complete the documentation of the development of the new Chinook Fishery Regulation Assessment Model (FRAM) base period including algorithms, and 2) review and update the FRAM documentation and User Manual that is currently on the Council website.

The Council is scheduled to adopt the final list of topics at the September Council meeting and any final methodology changes/updates at the November Council meeting.

Final Action on 2017 Salmon Management Measures

The Council adopted management measures for 2017 ocean salmon fisheries. Detailed management measures and a press release are posted on the Council's webpage.

Groundfish Management

Final Action on Electronic Monitoring of Non-whiting Midwater and Bottom Trawl Fisheries Regulations and Update on Exempted Fishing Permit (EFP)

The Council received an update on ongoing EFPs and modified several of the preferred alternatives they had adopted in September 2014 for the non-whiting midwater trawl and bottom trawl fisheries. A complete list of final alternatives is available on the Council website. The Council also directed:

- NMFS, in consultation to the Council, to develop a process that does not require rulemaking to adjust the discard species list;
- NMFS to maintain the current practice of having Pacific States Marine Fisheries Commission (PSMFC) perform video review responsibilities, but develop protocols for transferring financial responsibility for the video review from NMFS to the industry. The Council would like NMFS to examine the feasibility of using a sole provider (PSMFC) model indefinitely;
- NMFS and Council staff work with the Groundfish Electronic Monitoring Policy Advisory Committee/Technical Advisory Committee, Groundfish Management Team (GMT), and other appropriate Council advisory bodies to develop a process for reducing the level of video review to the minimum level necessary to audit logbooks, and to develop new discard mortality rates for halibut when vessels use electronic monitoring (EM); and
- Revisions to the draft regulations to include:

    1. Changes in the final preferred alternatives adopted by the Council;

    2. A requirement for self-enforcing agreement groups to submit an annual report to the Council;

    3. Deep-sea sole, sanddabs, and starry flounder in the list of species that can be discarded. Deep-sea sole and sanddabs would be counted as individual fishing quota (IFQ) species, if mixed with IFQ species; and

4. A provision to allow state-managed species to be landed when using EM, but prohibit sale or use of those fish, and include a landing limit of 150 pounds for California halibut.

Salmon Endangered Species Act (ESA) Consultation Recommendations

The Council provided guidance to NMFS on the proposed action that will be the basis for ESA section 7 consultation on the take of listed salmonids in the Pacific Coast groundfish fishery. The recommendations include:

- A description of groundfish fisheries including the likely future distribution of fishing, range of directed catch volumes, and range of Chinook salmon bycatch rates, which can be used to estimate amount and stock composition of Chinook take.
- Chinook salmon bycatch thresholds of 11,000 for the whiting fishery, 5,500 for all other groundfish fisheries, and a 3,500 reserve to be used for additional bycatch in either of the two fisheries. The sum of these three thresholds, 20,000 Chinook, equals the sum of the bycatch thresholds specified in the current biological opinion.
- Considering additional bycatch mitigation measures as part of the 2019-2020 biennial harvest specifications and management measures process.

NMFS intends to request Council recommendations on a draft incidental take statement at the September 2017 meeting, prior to completing the biological opinion.

Trawl Catch Shares and Intersector Allocation Progress Reports and Cost Recovery Report

Catch Share Program Review: Review document will be made available as early as possible to facilitate public review.

Intersector Allocation Review: The Council identified issues requiring additional information and proposed a process involving a public review draft adopted at the June Council meeting and final action taken in the fall. The Council directed that the next draft of the intersector allocation review document:

- address the recommendations in the GMT report and the GAP report;
- include approaches for addressing the sablefish management line and related allocation issues;
- focus on set-asides in the non-trawl sectors for a select number of the species identified as trawl-dominant (i.e., darkblotched rockfish, Pacific ocean perch, petrale sole, and longspine thornyhead north of 40º 10’ N. latitude);
- evaluate species that may be constraining the non-trawl fishery while not being fully attained in the trawl fishery (e.g., lingcod south of 40º 10’ N. latitude); and,
- discontinue development of the yellowtail rockfish cap issue.

C**ost Recovery**: Council and NMFS staff will meet to discuss ways to address transparency concerns such as those raised by the GAP report.

Groundfish Non-Salmon Endangered Species Workgroup Report

The Groundfish Endangered Species Workgroup (Workgroup) reports to the Council biennially on estimated bycatch of Endangered Species Act- (ESA) listed marine mammals, sea turtles, eulachon, green sturgeon, and seabirds subject to a 2013 biological opinion on the continued operation of the Pacific Coast groundfish fishery. The Workgroup found that recent take of subject species did not warrant consideration of additional mitigation measures by the Council. The Workgroup noted that new biological opinions will be completed in 2017 for eulachon and short-tailed albatross. Based on the Workgroup Report, the Council made the following recommendations:

- Conduct a risk analysis of humpback whale takes in the groundfish fixed gear fishery and work with the fleet to reduce the risk of such takes;
- GMT work with NMFS to better estimate eulachon take in the groundfish fishery;
- Complete the new seabird biological opinion and report to the Council at the June or September 2017 meeting to allow development of additional mitigation measures, as appropriate, through the 2019-2020 groundfish biennial harvest specifications and management measures process; and,
- Facilitate greater engagement by industry representatives in future Workgroup meetings.

Final Action on Inseason Adjustments

The Council recommended increasing the open access fixed gear trip limits for sablefish north of 36° N. latitude limits to 300 pounds per day, or one landing per week of up to 1,000 pounds, not to exceed 2,000 pounds per two months because effort and landings are tracking behind recent years.

Klamath Chinook salmon, a bycatch species in the groundfish trawl fisheries, will not meet escapement goals for 2017 by a historically large margin. The Council recommended the whiting fleet voluntarily move north to avoid Chinook salmon, recognizing there could be increased interactions with Pacific ocean perch (POP), especially given the historically high whiting quotas. Therefore, the Council also recommended that NMFS reallocate 3.5 mt of POP from the incidental open access off-the-top deduction to the mothership sector and 3.5 mt to the catcher-processor sector as soon as possible.

The Council also directed the GMT to develop alternatives for potentially distributing the POP, darkblotched, and canary rockfish buffers later in the year and report back at the June Council meeting in Spokane, Washington.

Updated Coordinates for the 125 Fathom (fm) Rockfish Conservation Area Line in California

The Council adopted revised coordinates for the 125 fm line at Usal and Noyo canyons in California for public review, as shown in Table 1 of the CDFW Report. These modifications are intended to provide access to canyons that were previously open when the 150 fm line was in effect (2003-2016). The Council is scheduled to take final action on the updated coordinates at the June 2017 Council meeting. The modifications for Delgada, Point Ano Nuevo, Cordell Banks contained in the CDFW Report and any other proposed modifications will be forwarded for consideration in the 2019-2020 harvest specifications and management measures process at the September 2017 Council meeting.

Sablefish Electronic Ticket Reporting Requirements

The Council directed its Enforcement Consultants and Groundfish Advisory Subpanel to meet together at the June Council meeting, discuss non-regulatory possibilities for resolving concerns about the 24-hour reporting requirement associated with electronic fish tickets, and report to the Council.

Coastal Pelagic Species Management

Central Subpopulation of Northern Anchovy (CSNA) Overfishing Limit (OFL) Process

The SSC will further review methods for developing an OFL for the central subpopulation of northern anchovy, evaluate the results of the January 2018 acoustic-trawl survey methodology review as it could apply to anchovy biomass and F_{msy} estimates, and report to the Council in April 2018.

Methodology Review Planning

The Council approved a proposed methodology review of the SWFSC's acoustic-trawl survey, tentatively scheduled for January 2018, and directed that the review address recommendations included in the SSC report. The Council will consider a proposed Terms of Reference for the review at its September 2017 meeting.

Small-Scale Fishery Management Final Action

The Council adopted Coastal Pelagic Species (CPS) Fishery Management Plan Amendment 26 allowing for small-scale directed fishing on CPS finfish stocks that are otherwise closed to directed fishing. The amendment will allow for landings up to one metric ton per day, with a limit of one trip per day. The Coastal Pelagic Species Management Team will provide an update on the small-scale fishery at its April 2018 meeting.

Final Action on Sardine Assessment, Specifications, and Management Measures

The Council adopted the 2017 sardine stock assessment report and the following harvest specifications and management measures, as described in the Supplemental CPSMT Report:

Biomass	**86,586 mt**
OFL	**16,957 mt**
P* buffer	**0.4**
$ABC_{0.4}$	**15,479 mt**
ACL	**8,000 mt**

They adopted the following automatic inseason actions for CPS fisheries:

- An incidental per-landing allowance of 40 percent Pacific sardine in non-treaty CPS fisheries until a total of 2,000 mt of Pacific sardine are landed.
- When the 2,000 mt is achieved, the incidental per-landing allowance would be reduced to 20 percent until a total of 5,000 mt of Pacific sardine have been landed.
- When 5,000 mt have been landed, the incidental per-landing allowance would be reduced to 10 percent for the remainder of the 2017-2018 fishing year.

The Council also adopted a 2 mt incidental per-landing allowance in non-CPS fisheries, and acknowledged a letter from the Quinault Indian Nation stating their intent to harvest up to 800 mt of sardine. Tribal landings would be accounted for within the ACL.

Pacific Halibut Management

Final Incidental Landing Restrictions for the 2017-2018 Salmon Troll Fishery

The Council adopted final incidental landing restrictions May 1, 2017 through December 31, 2017 and April 1-30, 2018 as follows: license holders may land no more than one Pacific halibut per two Chinook, except one Pacific halibut may be landed without meeting the ratio requirement, and no more than 35 halibut landed per trip. Limits may be modified by inseason action.

Administrative Matters

Legislative Matters

The Council approved the requested letter to Rep. Jaime Herrera-Beutler commenting on H.R. 200, the Strengthening Fishing Communities and Increasing Flexibility in Fisheries Management Act (a Magnuson-Stevens Act reauthorization bill) with minor edits.

Membership Appointments and Council Operating Procedures

The Council adopted revisions to Council Operating Procedure (COP) 1 regarding the submission of supplemental written public comments at Council meetings and COP 20 regarding the deadline for submission of exempted fishing permits for Highly Migratory Species.

Additionally, the Council is currently soliciting nominations for a vacant California seat on the Ecosystem Advisory Subpanel. The deadline for submitting nominations is May 11, 2017. See the Council web page for further information.

18 Ocean pout

Susan Wigley

This assessment of the ocean pout (Zoarces americanus) stock is an operational assessment of the 2015 operational assessment (NEFSC 2015). Based on the 2015 assessment, the stock was overfished but overfishing was not occurring. This assessment updates commercial fishery catch data, research survey indices and the exploitation ratios through 2016. There are no stock projections.

State of Stock: Based on the current assessment, the ocean pout (*Zoarces americanus*) stock is overfished and overfishing is not occurring (Figures 86-87). Retrospective adjustments were not made to the model results. Biomass proxy (B) in 2016 was estimated to be 0.223 (kg/tow) which is 5% of the biomass target (B_{MSY} *proxy* = 4.94; Figure 86). The 2016 fully selected fishing mortality was estimated to be 0.221 which is 29% of the overfishing threshold proxy (F_{MSY} *proxy* = 0.76; Figure 87).

Table 52: Catch and model results table for ocean pout. Catch weights are in (mt), survey biomass is in (kg/tow), and the relative exploitation ratio is the total catch / NEFSC 3 year average spring biomass index. Model results are from the current updated index assessment. Note: A 2014 landings database correction was made.

	2007	2008	2009	2010	2011	2012	2013	2014	2015	2016
Data										
US Commercial discards	164	118	165	125	76	94	68	74	63	49
US Commercial landings	4	7	3	0	0	0	0	0	0	0
Other landings	0	0	0	0	0	0	0	0	0	0
Catch for Assessment	167	126	168	126	77	90	68	74	63	49
Model Results										
NEFSC 3 yr average Spring Survey	0.475	0.513	0.479	0.44	0.343	0.298	0.357	0.29	0.317	0.223
Relative Exploitation Ratio	0.352	0.245	0.35	0.286	0.224	0.302	0.191	0.256	0.197	0.221

Table 53: Comparison of reference points estimated in an earlier assessment and from the current updated assessment. For ocean pout, median NEFSC 3 year average Spring survey biomass and median exploitation ratio during 1977-1985 are used as B_{MSY} and F_{MSY} proxies, respectively.

	2015	2017
F_{MSY} *proxy*	0.76	0.76
B_{MSY} *proxy* (kg/tow)	4.94	4.94
MSY (mt)	3,754	3,754
Overfishing	No	No
Overfished	Yes	Yes

Projections: The index-based assessment approach does not support catch projections; catch advice for ocean pout has been based on the target exploitation rate and the most recent centered 3-year average biomass index from the NEFSC spring survey.

Special Comments:

- What are the most important sources of uncertainty in this stock assessment? Explain, and describe qualitatively how they affect the assessment results (such as estimates of biomass, F, recruitment, and population projections).
  An important source of uncertainty is the stock has not responded to low catch as expected.

- Does this assessment model have a retrospective pattern? If so, is the pattern minor or major? (A major retrospective pattern occurs when the adjusted SSB or F_{Full} lies outside of the approximate joint confidence region for SSB and F_{Full}; see Table 8).
  The model used to estimate status of this stock does not allow estimation of a retrospective pattern.

- Based on this stock assessment, are population projections well determined or uncertain? If this stock is in a rebuilding plan, how do the projections compare to the rebuilding schedule?
  N/A

- Describe any changes that were made to the current stock assessment, beyond incorporating additional years of data and the effect these changes had in the assessment and stock status.
  A database correction was made to the 2014 ocean pout landings. This change had a negligible effect on the assessment. Recreational landings were updated and were found to be negligible (time series average of recreational landings to total catch was less than 1%) and therefore not included in this assessment.

- If the stock status has changed a lot since the previous assessment, explain why this occurred.
  Ocean pout stock status has not changed since the previous assessment.

- Provide qualitative statements describing the condition of the stock that relate to stock status.
  Discards comprise most of the catch since the no possession regulation was implemented in May 2010. The NEFSC survey indices remain at near-record low levels; there are few large fish in the population. The ocean pout stock remains in poor condition.

- Indicate what data or studies are currently lacking and which would be needed most to improve this stock assessment in the future.
  The ocean pout assessment could be improved with studies that explore why this stock is not rebuilding as expected.

- Are there other important comments?
  Biological reference points are based on catch; the estimated discards used in the catch are based on a mix of direct (1989 onward) and indirect (1988 and back) methods. The catch

used to determine MSY is based on indirect methods. Minimum estimates of scientific research removals of ocean pout ranged between 0.2 and 24.9 mt, with an average of 3 mt between 1963 and 2016. The NEFSC bottom trawl surveys, Massachusetts Division of Marine Fisheries inshore surveys, Atlantic States Marine Fisheries Commission summer shrimp surveys, and various Cooperative Research surveys (e.g., such as Industry-based surveys for cod and for yellowtail flounder) and gear studies have contributed to scientific research removals.

18.1 Reviewer Comments: Ocean pout

Assessment Recommendation:

The panel concluded that the operational assessment was acceptable as a scientific basis for management advice.

Alternative Assessment Approach:

Not applicable

Status Recommendation:

Based on the operational assessment, the panel agrees with the conclusion that the ocean pout stock is overfished and overfishing is not occurring. Discards comprise most of the catch since the no possession regulation was implemented in May 2010. The National Marine Fisheries Service survey indices remain at near-record low levels, and there are few large fish in the population. The ocean pout stock remains in poor condition.

Key Sources of Uncertainty:

An important source of uncertainty is that the stock size has not increased as a result of catch reductions. The majority of catch is comprised of discards, which are estimated using both direct and indirect methods. There are questions over whether the current perspective of the stock is due to environmental drivers influencing stock abundance.

Research Needs:

The ocean pout assessment could be improved with studies that explore why this stock is not rebuilding, in particular an exploration of whether fishing mortality, biological dynamics, or environmental drivers may be causing this issue.

Table of Contents

Foreword to the NE Data Poor Stocks Report

The Northeast Regional Stock Assessment Workshop (SAW) process has three parts: preparation of stock assessments by the SAW Working Groups and/or by ASMFC Technical Committees/Assessment Committees; peer review of the assessments by a panel of outside experts who judge the adequacy of the assessment as a basis for providing scientific advice to managers; and a presentation of the results and reports to the Region's fishery management bodies. Council and Commission teams (e.g., Plan Development Teams, Monitoring and Technical Committees) formulate management advice, after an assessment has been accepted by the peer review panel.

Reports that are produced following peer review meetings typically include: an *Assessment Report* – a detailed account of the stock assessment; and the review panel report – a summary of the reviewer's opinions and recommendations. Assessment reports are available online at http://www.nefsc.noaa.gov/nefsc/publications/series/crdlist.htm. Review panel reports as well as assessment reports can be found at http://www.nefsc.noaa.gov/nefsc/saw/.

The Northeast "Data Poor Stocks" Working Group (DPWG) was formed in 2007, as part of the SAW process, to perform stock assessments of species that are difficult to assess due to lack of critical data or severe modeling problems. Monkfish was the first stock addressed by DPWG in 2007. The current report describes new work performed in 2008 by the DPWG on the NE skate species complex, deep sea red crab, Atlantic wolffish, scup, black sea bass, and weakfish. The DPWG met in October and November, 2008, and had an integrated peer review meeting during December 8-12, 2008 in Woods Hole at the Northeast Fisheries Science Center.

This Foreword contains a brief summary of the integrated peer review meeting, Terms of Reference, a list of reviewers, the December meeting agenda, and a list of meeting attendees (Tables 1-4). Maps of the Atlantic coast of the USA and Canada are also provided (Figures 1-3).

Summary of Peer Review Meeting (December 8-12, 2008):

The Working Group (DPWG) that did the analyses was comprised of NEFSC assessment scientists, and staff from NERO, NEFMC, MAFMC, and ASMFC. There was also participation by scientists from NOAA's SWFSC and SEFSC.

The Peer Review Panel examined working papers that were focused on Biological Reference Points (BRP) of Northeast skate species, deep sea red crab, Atlantic wolffish, scup, and black sea bass. The Review Panel also provided guidance for scientists to use in future weakfish assessments.

In addition to reviewing BRPs for each stock (with the exception of weakfish), the panel was asked to make a recommendation on the utility of the analyses for stock assessment. In particular the panel was asked to determine if the analyses and amount of peer review were sufficient to make a determination about stock status. If not, the panel was asked to recommend the process for further analyses and review.

The Review Panel accepted new assessment models for red crab, wolffish, scup and black sea bass. This resulted in new BRP recommendations and new estimates of those parameters. New BRPs were not recommended for the skates. However, the Panel generally advocated updating the estimates of skate biomass targets and thresholds (with the exception of Barndoor skate) to include data from recent surveys. Some changes in stock status are implied by the outcome of this peer review. The review panel report can be found at *http://www.nefsc.noaa.gov/nefsc/saw/.*

Table 1. Background and Terms of Reference for the DPWG developed by the Northeast Regional Coordinating Committee (NRCC).

Draft Terms of Reference
Data Poor Stocks Working Group
(written: 10-11-07, updated: 5-9-08**)**

Background

Data poor stocks are problematic for managers because traditional measures of status (biomass and fishing mortality) are not available. A variety of *ad hoc* metrics have been developed to address these issues but a synoptic evaluation of the problem has not been conducted in the Northeast. The term "data poor" will be used to categorize assessments limited by either data or lack of contrast in time series. Fisheries stock assessments require the integration of multiple sources of data including commercial and recreational landings, discards from multiple fleets, fishery independent survey indices, and measures of fishing effort. For some species, one or more of these data sources may not be available or have such low precision that it is not possible to use them in a conventional application within an assessment.

Objectives

1. Constitute and convene a Working Group comprising NEFSC assessment scientists, and staff from NERO, NEFMC, MAFMC, and ASMFC to:
    a. Recommend biological reference points (BRPs) and measurable BRP and maximum sustainable yield (MSY) proxies for the following data poor stocks: Black sea bass; Deep-sea red crab; Scup; Skates; Atlantic wolffish.
    b. Provide advice about scientific uncertainty and risk for Scientific and Statistical Committees (SSCs) to consider when they develop fishing level recommendations for these stocks.
    c. Consider developing BRPs for species groups for situations where the catch or landings can not be identified to species. Work on this objective will depend on, and needs to be consistent with, final guidance on implementing the Reauthorized Magnuson-Stevens Act, whenever that guidance becomes available.
    d. Comment on what can be done to improve the information, proxies or assessments for each species.
2. For weakfish, provide guidance/suggest methodologies for scientists to use in future assessments.

Participants

The Working Group (WG) will consist of representatives from the staffs of the NEFMC (2), MAFMC (2), ASMFC (2), NERO (3), and NEFSC (5).

Products

The WG product will be a document providing: (a) proposed BRPs and measurable BRP and MSY proxies for the five Northeast stocks/species groups listed in 1(a) above; (b) advice for SSCs to consider when they develop fishing level recommendations for these stocks; (c) advice on what to do about species with identification problems; (d) comments on what is needed to improve the proxies and/or assessments for each species and (e) suggested methodologies for conducting future weakfish stock assessments. Although it is expected that significant uncertainties will be associated with the proposed BRPs, MSYs, and their proxies, the intention is that the recommended values will represent the best available science.

During (or after) the WG's activities, a peer review of some type will be undertaken to ensure that the WG's recommendations and technical approaches are sound.

Table 2. Peer Reviewers of the December 8-12, 2008 "Northeast Data Poor Stocks" Working Group Meeting (See Table 4 for a list of meeting attendees).

Chairman:
Dr. Thomas Miller, Univ. of Maryland Center for Environmental Science, Chesapeake Biological Laboratory

Panelists :
Dr. Robert Muller, Florida Fish and Wildlife Commission
Mr. Robert O'Boyle, Beta Scientific Consulting Inc.
Dr. Andrew Rosenberg, Dept. Natural Resources, Univ. of New Hampshire

Northeast Data Poor Stocks Working Group Meeting
Woods Hole, MA
December 8-12, 2008

Executive Summary

The seven species in the Northeast Region (Maine to Virginia) skate complex are: little skate (*Leucoraja erinacea*), winter skate (*L. ocellata*), barndoor skate (*Dipturus laevis)*, thorny skate (*Amblyraja radiata*), smooth skate (*Malacoraja senta*), clearnose skate (*Raja eglanteria*), and rosette skate (*L. garmani*). Landings have generally been increasing since 2000 and the 2007 reported commercial landings of 19,000 mt were the highest on record. Discard estimates from SAW/SARC 44 in 2006 were revised in this assessment based on Standardized Bycatch Reporting Methodology. Most differences were due to inclusion of more trips from the last few years (e.g., Special Access Programs, etc.).

The landings estimates were not disaggregated to skate species in previous assessments because identification of skates is uncertain in the Domestic Observer Program (NEFSC 2007). Alternative methods to estimate landings by species were developed, each of which has strengths and weaknesses. The Review Panel concluded that progress had been made and future efforts should be encouraged, but that the Panel had insufficient time to explore the alternative methods in detail. Therefore, these approaches will be used in future modeling efforts, and will serve as an indication of the uncertainty in the catch of skates. Discards were also disaggregated to skate species using one method.

Survey indices by species were updated through 2007/2008 and aggregate indices were developed by area. These were used along with the catch data in An Index Method (AIM). Attempts to use this model were unsuccessful. Another model, SEINE (Survival Estimation in Non-Equilibrium Situations Model), was attempted to estimate fishing mortality. While the model estimated fishing mortality, it did so over a very long time period, but was not useful for producing annual estimates.

SPR-based reference points for three skate species, barndoor, winter, and thorny, were derived from life-history parameters and fitted Beverton-Holt stock recruit relationships. Future assessments might determine stock status by comparing these depletion levels either with depletion in the surveys or from a stock assessment model that incorporates information about maturity. These results were not accepted for reference points at this time.

Until new models are constructed using the new catch by species information, the existing overfishing definitions, updated through 2007/2008 will remain the best available. For barndoor skate, the current (i.e., non-updated) definition will be retained. Stock status with respect to the updated estimates is described. For skates in general, no new measurable stock status definitions were identified.

Terms of Reference

The following Terms of Reference were provided to the Data Poor Stocks Working Group for peer review in December 2008:

a. Recommend biological reference points (BRPs) and measurable BRP and maximum sustainable yield (MSY) proxies for the following data poor stocks: Black sea bass; Deep-sea red crab; Scup; Skates; Atlantic wolffish.

b. Provide advice about scientific uncertainty and risk for Scientific and Statistical Committees (SSCs) to consider when they develop fishing level recommendations for these stocks.

c. Consider developing BRPs for species groups for situations where the catch or landings can not be identified to species. Work on this objective will depend on, and needs to be consistent

with, final guidance on implementing the Reauthorized Magnuson-Stevens Act, whenever that guidance becomes available.
d. Comment on what can be done to improve the information, proxies or assessments for each species.

Introduction

The seven species in the Northeast Region (Maine to Virginia) skate complex are distributed along the coast of the northeast United States from near the tide line to depths exceeding 700 m (383 fathoms). The species are: little skate (*Leucoraja erinacea*), winter skate (*L. ocellata*), barndoor skate (*Dipturus laevis)*, thorny skate (*Amblyraja radiata*), smooth skate (*Malacoraja senta*), clearnose skate (*Raja eglanteria*), and rosette skate (*L. garmani*).

In the Northeast region, the center of distribution for the little and winter skates is Georges Bank and Southern New England. The barndoor skate is most common in the Gulf of Maine, on Georges Bank, and in Southern New England. The thorny and smooth skates are commonly found in the Gulf of Maine. The clearnose and rosette skates have a more southern distribution, and are found primarily in Southern New England and the Chesapeake Bight. Skates are not known to undertake large-scale migrations, but they do move seasonally in response to changes in water temperature, moving offshore in summer and early autumn and returning inshore during winter and spring. Members of the skate family lay eggs that are enclosed in a hard, leathery case commonly called a mermaid's purse. Incubation time is 6 to 12 months, with the young having the adult form at the time of hatching (Bigelow and Schroeder 1953).

The first stock assessment for the skate complex was conducted in 1999 at SARC/SAW 30 (NEFSC 2000). At that time there was no Fishery Management Plan (FMP) in place. The National Marine Fisheries Service had been petitioned to list barndoor skate as endangered based on a paper published by Casey and Myers (1998) and was also asked to assess the other species in the complex. SARC 30 found no cause to list barndoor as endangered but recommended that the species remain on the candidate species list as well as to put thorny skate on the candidate species list. Biomass reference points were developed for all seven species and four were listed as overfished. Fishing mortality reference points were developed for winter and little skate and overfishing was occurring for winter skate.

An FMP was developed following SARC 30 by the New England Fishery Management Council (NEFMC) when they were informed of the overfished status of thorny and barndoor (winter and smooth biomass increased in the 1999 autumn survey and were no longer considered overfished). The FMP was implemented in September of 2003 with a primary requirement for mandatory reporting of skate landings by species by both dealers and vessels. Possession prohibitions of barndoor and thorny skate as well as smooth skate in the Gulf of Maine were also provisions of the FMP. A trip limit of 10,000 lbs was implemented for winter skate with a Letter of Authorization for the bait fishery (little skate) to exceed the trip limit. The biomass reference points developed at SARC 30 were maintained, but new fishing mortality reference points were developed.

The last stock assessment for the skate complex was conducted in 2006 at SARC/SAW 44 (NEFSC 2007). Several methods were attempted to develop fishing mortality estimates and biological reference points. These included the Gedamke-Hoenig length-based mortality estimator, length-based yield-per-recruit, spawner-per-recruit, and a length-tuned model. None of these methods were accepted, although some had promise. SARC 44 did not change the biological reference points.

Commercial Fishery Landings

Skates have been reported in New England fishery landings since the late 1800s. However, commercial fishery landings, primarily from off Rhode Island, never exceeded several hundred metric tons until the advent of distant-water fleets and the industrial fishery during the 1950s and 1960s. Skate landings reached 9,500 mt in 1969, but declined quickly during the 1970s, falling to 800 mt in 1981 (Table 1, Figure 1). Landings then increased substantially; partially in response to increased demand for lobster bait, and more significantly, to the increased export market for skate wings. Landings increased to 12,900 mt in 1993 and then declined somewhat to 7,200 mt in 1995. Landings increased again and the 2007 reported commercial landings of 19,000 mt were the highest on record (Table 1, Figure 1).

United States landings of skates are reported in all months (Table 2). There is a relatively even distribution of landings across months, but the summer months do show a slightly higher percentage, probably due to the increased demand for lobster bait during those months.

Skate landings are primarily from Massachusetts and Rhode Island (mainly New Bedford and Point Judith) with 85-95% of the landings occurring in those two states (Table 3). Landings from other states did occur back through time and the table somewhat reflects better reporting as more states reported in the NMFS database. Also, the difference in total landings between Table B1.1 and B1.3 is likely the result of landings from the industrial fishery not included in the Weighout database. These landings were sampled during the 1960s and 1970s for species composition and prorated. Skates accounted for about 10% of those landings.

Otter trawls are the primary gear used to land skates in the United States, with some landings coming from sink gill nets (Table 4). In the last couple of years, landings from longline gear have increased slightly in importance. The increase in other gear reflects the new reporting system implemented in 2004.

Landings historically were taken from the Georges Bank and Southern New England during the early 1960s as the industrial fishery operated mainly out of Point Judith and the distant-water fleet fished mainly on Georges Bank (Table 5). Landings from Mid-Atlantic increased through the early 2000s while landings from Georges Bank in 2007 were the highest on record.

Landings are generally not reported by species, with over 99% of the landings reported as “unclassified skates” until the FMP was implemented in September of 2003 (Table 6). Wings are most likely taken from winter and thorny skates, the two species currently known to be used for human consumption. Bait landings are presumed to be primarily from little skate, based on areas fished and known species distribution patterns. Landings of barndoor and thorny skate are being reported by the dealers even though there is a possession prohibition for those two species. There are also wings reported for rosette, little and smooth which are known to be too small for wings. The distribution of skate landings by state and species also shows that some species are landed in areas that they do not occur (Table 7). For example, in 2004, barndoor were landed in Virginia which is too far south for barndoor skate.

Commercial Fishery Discards

Discard estimates from SAW/SARC 44 were revised in this assessment. The ratio-estimator used in this assessment is based on the methodology described in Rago et al. (2005)

and updated in Wigley et al 2007. It relies on a d/k ratio where the kept component is defined as the total landings of all species within a “fishery”. A fishery is defined as a homogeneous group of vessels with respect to gear type (longline, otter trawl, shrimp trawl, sink gill net, and scallop dredge), quarter (months 1-4, 5-6, 7-8, 9-12), and area fished (GOM, GB, SNE, MA). Mesh size was not used to split out otter trawl trips or sink gill net trips. All trips were included if they occurred within this stratification regardless of whether or not they caught skates.

The discard ratio for skates in stratum h is the sum of discard weight over all trips divided by sum of kept weights over all trips:

$$\hat{R}_h = \frac{\sum_{i=1}^{n_h} d_{ih}}{\sum_{i=1}^{n_h} k_{ih}} \qquad (1)$$

where d_{ih} is the discards for skates within trip i in stratum h and k_{ih} is the kept component of the catch for all species. R_h is the discard rate in stratum h. The stratum weighted discard to kept ratio is obtained by weighted sum of discard ratios over all strata:

$$\hat{R} = \sum_{h=1}^{H} \left(\frac{N_h}{\sum_{h=1}^{H} N_h} \right) \hat{R}_h \qquad (2)$$

The total discard within a strata is simply the product of the estimate discard ratio R and the total landings for the fishery defined as stratum h, i.e., $D_h=R_hK_h$.

Missing cells were inputed using averages of existing cells. If information existed in the same area fished, the annual average discard ratio was applied in the missing cells. If the information was missing in the area fished, but available in the region (i.e. SNE and MA or GOM and GBK), then the annual average for that region was applied. There were some cases for the longline fishery in which the entire year was averaged for all areas or for a span of 12 years (1993-2004). The details of the imputation are given in Appendix 1.

To hindcast the discard estimates back to 1964, a three-year average (the earliest three years of data) of the discards of skates/landings of all species was used. The sensitivity of this estimate was examined using a five-year average and a time-series average (Figure 2). The trends in the total estimates are similar, with the time-series average giving the lowest estimate and the three-year average the highest estimates. Using the three estimates in any future modeling efforts will give some idea of the uncertainty in the data.

Estimated discards by fishery, region and half year for 1964-2007 are summarized in Tables 8-10. The new estimated discards are different than those estimated in SARC/SAW 44 (Figure 3). There are two main reasons for these differences. First, missing cells were imputed in the new method. This should lead to higher values in general. Second, the data for any Special Access Programs for 2005 -2007 were included in the new estimates. These trips showed a higher discard ratio than those outside the closed areas. These should be placed in a separate stratum, however, there is no easy way to determine if a trip in the dealer database was fishing in an SAP. The coefficients of variation for the otter trawl are generally reasonable, while the scallop dredge estimates are highly variable (Table 11). Alternative stratification schemes were examined to determine if this had any impact on the magnitude of the discard estimates (Appendix 2). When all trips were included the estimates were all fairly similar.

The estimates from 1992-2007 were hind-cast using the first three years of the time series to compare actual estimates and hind-cast estimates (Figure 4). For years when the regulations were similar (mid-1990s), the hind-cast estimates were comparable to the actual estimates. In more recent years, management has changed and the estimates are not and probably should not be comparable.

Recreational Fishery Catch

Aggregate recreational landings of the seven species in the skate complex are relatively insignificant when compared to the commercial landings, never exceeding 300 mt during the 1981-1998 time series of Marine Recreational Fishery Statistics Survey (MRFSS) estimates. Little and clearnose skates are the most frequently landed species of the complex. For little skate, total landings varied between <1000 and 56,000 fish, equivalent to <1 to 15 mt, during 1981-1998. For clearnose skate, total landings varied between 2,000 and 145,000 fish, equivalent to 2 to 232 mt, during 1981-1998. The number of skates reported as released alive averages an order of magnitude higher than the reported landed number. Party/charter boats have historically been undersampled compared to the private/rental boat sector that accounts for most of the recreational catch, and may have a different discard rate. The recreational fishery release mortality rate of skates is unknown, but is likely comparable to that for flounders and other demersal species, which generally ranges from 10-15%. Assuming a 10-15% release mortality rate would suggest that recreational fishery discard mortality is of about the same magnitude as the recreational landings. Data from 1999 through 2005 were similar in magnitude.

Landings by Species Estimation

The landings estimates were not dis-aggregated to skate species in previous assessments because identification of skates is uncertain in the Domestic Observer Program (NEFSC 2007). Alternative methods to estimate landings by species were developed, each of which has both strengths and weaknesses. Therefore, both sets of estimates were chosen to be used in any future modeling efforts as an indication of the uncertainty in the catch of skates.

The first method used the observer lengths of the kept component of the catch directly. In order to split the data into the bait (whole) and wing components of the fishery, a length cutoff of 60 cm was used, since there is no direct way of determining the disposition of the landings until recently. This seemed justified, since the maximum size in the bait fishery was instituted to also be close to the minimum accepted length for the wing fishery. Examination of the samples by the two main gear types also showed two groups of fish with a trough at about 60 cm (Figure 5). The data were apportioned into two regions, Gulf of Maine to Georges Bank (GOMGBK – Divisions 51 and 52), and Southern New England to Mid-Atlantic (SNEMA – Divisions 53 and Subarea 6). The number of fish measured in these regions was barely sufficient (Table 12) so no further areal division was attempted. Pooling over years within a region was still required to get an adequate number of fish (Figure 6). An average skate length-weight equation was applied to the samples and used to estimate the landings numbers at length for each market category (Figure 7).

Length compositions for each species for the two regions (GOMGBK – Offshore strata 13-30, 36-40, and Inshore strata 56-66; SNEMA – Offshore strata 1-12, 61-76, and Inshore strata 1-55) were estimated. The species length-weight equations were then applied to determine weight-at-length by species. The proportions at length by species for both number and weight were applied to the commercial landings-at-length to estimate landings-at-length by species. The lengths had to be grouped into 5 cm intervals to avoid zero cells in the survey and all fish greater than 112 cm were set to be barndoor skate.

For the second method, a selectivity ogive was estimated for observed hauls in each skate fishery compared to the applicable surveys during 2004-2007. The data were fit using a three parameter logistic curve via Millar's (1992) SELECT model. Results of these logistic model fits are given in Table 13 and in Figures 8-11. In most cases where the parameters could be estimated, the L50s for winter and little skates were similar to the overall fit for all skate species (with a notable exception of little skates observed in the retained fraction of gillnet catches). Also the ogives by region were very similar to one another within each fishery and gear type. As a result, pooled selectivity ogives for each gear and skate fishery were used to determine the exploitable species composition at size in each survey stratum. In the following table, the L50s for the newly estimated ogives are compared with the PDT's assumed knife edge selectivity ogive.

Fishery	**L50 for selectivity ogive applied to survey weight per tow data**	**PDT assumed knife edge selectivity**
Trawl wing	66.9 cm	> 40 cm
Trawl whole/bait	44.4 cm and < 59 cm	< 59 cm
Gillnet	54.9 cm	> 65 cm

Average proportional weight per tow by three digit statistical area was re-estimated by determining an average stratum weight per tow and then computing an area-weighted average for the sampled strata within each three digit statistical area. While this approach does not readily allow estimation of variance (like a domain estimator), the averages computed in this way satisfy the conditions of the stratified random survey design. These average proportions of survey catch by skate species were then applied to the VTR data by gear type, fishery (product form), and trimester (corresponding to the spring, fall, and winter surveys).

Comparison of the two methods generally shows higher amounts of winter, clearnose, and rosette skate in method one (length composition) compared to the second method (selectivity ogive) and lower amounts of little, smooth, and thorny skate (Tables 14-15; Figures 12-14). Barndoor skate are generally comparable. The length composition method uses the annual length data when possible, but may be ignoring some sub-regional differences due to the low sample sizes. The selectivity ogive method, on the other hand, uses the sub-regional data while assuming that the length composition of the survey, once the skates are fully selected, reflects the length composition of the fishery. The two methods give a range of values and will both be used in any future modeling efforts.

Discards by Species Estimation

The discard estimates were not dis-aggregated to skate species in previous assessments because identification of skates is uncertain in the Domestic Observer Program (NEFSC 2007).

The observer lengths of the discarded component of the catch were used by gear type. The data were apportioned into two regions, Gulf of Maine to Georges Bank (GOMGBK – Divisions 51 and 52), and Southern New England to Mid-Atlantic (SNEMA – Divisions 53 and Subarea 6). The number of fish measured in these regions was barely sufficient (Table 16) so no further areal division was attempted. Pooling over years, sometimes over the entire time series, within a region was still required to get an adequate number of fish (Figure 15). For longline gear, all samples were used for both regions. An average skate length-weight equation was applied to the samples and used to estimate the discard numbers at length by gear category (Figure 16).

Length compositions for each species for the two regions (GOMGBK – Offshore strata 13-30, 36-40, and Inshore strata 56-66; SNEMA – Offshore strata 1-12, 61-76, and Inshore strata 1-55) were estimated. The species length-weight equations were then applied to determine weight-at-length by species. The proportions at length by species for both number and weight were applied to the commercial landings-at-length to estimate landings-at-length by species. The lengths had to be grouped into 5 cm intervals to avoid zero cells in the survey and all fish greater than 112 cm were set to be barndoor skate. The estimates by gear type and species are given in Table 17.

Research Survey Data- Total Stock Biomass

Indices of relative abundance have been developed from NEFSC bottom trawl surveys for the seven species in the skate complex, and these form the basis for most of the conclusions about the status of the complex. The NEFSC trawl survey has been conducted in the autumn from the Gulf of Maine to Southern New England since 1963 (Azarovitz 1981) and the Mid-Atlantic was added in 1967. A spring survey was started in 1968 with stations <= 27 m added in 1975. All statistically significant NEFSC gear, door, and vessel conversion factors were applied to little, winter, and smooth skate indices when applicable (Sissenwine and Bowman, 1978; NEFC 1991). Juvenile little and winter skates are not readily distinguished in the field. The numbers of juveniles were split between the two species based on the abundance of the adults in the same tow.

For the aggregate skate complex, the spring survey index of biomass was relatively constant from 1968 to 1980, then increased significantly to peak levels in the mid to late 1980s. The index of skate complex biomass then declined steadily until 1994, but increased until 2000 and has since decreased (Figure 17). If the species in the complex are divided into large (barndoor, winter, and thorny) and small sized skates (little, clearnose, rosette, and smooth), it is evident that the large increase in skate biomass in the mid to late 1980s was dominated by winter and little skate (Figure 17). The biomass of large sized skates steadily declined from the mid-1980s to the mid-1990s and has since been stable. The increase in aggregate skate biomass from the mid-1990s to 2000 was due to an increase in little skate and the subsequent decline is also due to little skate (Figure 17).

Indices were also derived for the aggregate skate complex by region. The index of skate biomass in the Gulf of Maine (Offshore strata 26-30, 36-40) was steady through the mid-1970s, started to decline and is currently among the lowest on record (Figure 18). The index for the Georges Bank region (Offshore strata 13-25) was relatively low at the start of the time series, increased to high levels in the 1980s and has since declined to low levels (Figure 18). For the Southern New England region (Offshore strata 1-12), the index either increased over time (the spring survey) or was stable (the fall survey) (Figure 19). The index for the Mid-Atlantic (Offshore strata 61-76) region has increased over time (Figure 19).

Indices of relative abundance for some of the species have also been developed from MADMF and CTDEP research surveys. Data are also available from the Maine-New Hampshire inshore survey, the ASMFC shrimp trawl survey, the monkfish survey, and the VIMS trawl survey but have not been developed into indices at this time.

The bootstrap methodology of Smith (1997) was continued from the previous SARC and also applied to the MADMF survey but the complete results are not shown. The data are shown to demonstrate what may be available for future modeling work.

Winter skate

In the NEFSC spring survey offshore strata (1968-2008), the annual total catch of winter skate has ranged from 160 fish in 1976 to 1,891 fish in 1985. In the NEFSC autumn survey offshore strata (1963-2007), the annual total catch of winter skate has ranged from 115 fish in 1975 to 1,187 fish in 1984. Calculated on a per tow basis, these spring survey catches equate to maximum stratified mean number per tow indices for the GOM-MA offshore strata of about 7.9 fish, or 16.4 kg, per tow during 1985; autumn maximum catches equate to indices of 3.7 fish, or 13.3 kg, per tow in 1984 (Tables 18-19).

The catchability of winter skate in the NEFSC winter bottom trawl survey (which substitutes a chain sweep with small cookies for the large rollers used in the spring and autumn surveys, to better target flatfish) is significantly higher than in the spring and autumn series, especially for smaller winter skates. NEFSC winter survey (1992-2007) annual catches of winter skate have ranged from 841 fish in 1993 to 4,055 fish in 1996, equating to a maximum stratified mean catch per tow of 43.5 fish, or 25.2 kg, per tow in 1996 (Table 20). The winter survey is focused in the Southern New England and Mid-Atlantic offshore regions, with a limited number of samples on Georges Bank, and no sampling in the Gulf of Maine and has been discontinued.

Indices of winter skate abundance and biomass from the NEFSC spring and autumn surveys were stable, but below the time series mean, during the late 1960s and 1970s (Figure 20). Winter skate indices increased to the time series mean by 1980, and then reached a peak during the mid 1980s. Winter skates indices began to decline in the late 1980s. Current NEFSC indices of winter skate abundance are below the time series mean, at about the same value as during the early 1970s. Current NEFSC indices of winter skate biomass are about 20% of the peak observed during the mid 1980s (Figure 20).

The NEFSC scallop dredge survey, as with the winter survey also catches winter skates mostly on Georges Bank and also does not sample in the Gulf of Maine and on the very shallowest portions of Georges Bank. However, the trends in abundance are similar to the trends in the spring and autumn surveys (Figure 21).

Indices of abundance for winter skate are available from the Massachusetts Division of Marine Fisheries (MADMF) spring and autumn research trawl surveys in the inshore waters of Massachusetts for the years 1978-2008. MADMF biomass indices of winter skate were moderate to high from 1981 through 1987. Thereafter, both spring and autumn indices declined to time series lows in 1989-1991. The spring index rebounded to moderate levels during 1992-1996 before dropping again to low values in the late 1990s and remaining low through 2008 (Figure 22). The autumn index is more erratic, but generally shows the same pattern.

Indices of abundance for winter skate are available from the Connecticut Department of Environmental Protection (CTDEP) spring and autumn finfish trawl surveys in Long Island Sound for the years 1984-2008 (1992 and later only for biomass). Annual CTDEP survey catches have ranged from 0 to 115 skates. CTDEP survey indices suggest that after increasing to a time series high from 1984 through 1989, winter skate in Long Island Sound has declined slightly (Figure 23).

Little skate

In the NEFSC spring surveys (1976-2008), the annual total catch of little skate has ranged from 2,271 fish in 2006 to 16,406 fish in 1999 (Table 21). In the NEFSC autumn surveys (1975-2007), the annual total catch of little skate has ranged from 1,124 fish in 1993 to 6,523 fish in 2003 (Table 22). Calculated on a per tow basis, these spring survey catches equate to maximum stratified mean number per tow indices for the GOM-MA inshore and offshore strata of about 28 fish, or 10 kg, per tow during 1999; autumn maximum catches equate to indices of 18 fish, or 7.7 kg, per tow in 2003 (Tables 21-22).

The catchability of little skate in the NEFSC winter bottom trawl survey (which substitutes a chain sweep with small cookies for the large rollers used in the spring and autumn surveys, to better target flatfish) is significantly higher than in the spring and autumn series. NEFSC winter survey (1992-2007) annual catches of little skate have ranged from 8,870 fish in 2003 to 18,418 fish in 1992, equating to a maximum stratified mean catch per tow of 170 fish, or 66 kg, per tow in 1992 (Table 23). The winter survey is focused in the Southern New England and Mid-Atlantic offshore regions, with a limited number of samples on Georges Bank, and no sampling in the Gulf of Maine and has been discontinued.

Indices of little skate abundance and biomass from the NEFSC spring and autumn surveys were stable, but below the time series mean, during the 1970s. Little skate spring survey indices began to increase in 1982, reached a peak in 1999, and declined thereafter (Figure 24). Autumn survey indices have been relatively stable over the duration of the time series, with a slight increase in recent years (Figure 24). The application of the NEFSC gear conversion factors to spring survey indices decreased the indices in 1981 and earlier years by 75 percent. This may account for some of the mis-match between the spring and autumn surveys.

The NEFSC scallop dredge survey, as with the winter survey also catches little skates in all areas and also does not sample in the Gulf of Maine, on the very shallowest portions of Georges Bank, and parts of Southern New England. However, the trends in abundance are similar to the spring and autumn surveys with the indices showing little trend over the time series (Figure 25).

Indices of abundance for little skate are available from the Massachusetts Division of Marine Fisheries (MADMF) spring and autumn research trawl surveys in the inshore waters of Massachusetts for the years 1978-2008 (Figure 26). MADMF biomass indices of little skate declined through the 1980's to time series lows in 1989 (autumn) and 1991 (spring). Biomass indices quickly rose to high levels in the early 1990's, and have since fluctuated without trend.

Indices of abundance for little skate are available from the Connecticut Department of Environmental Protection (CTDEP) spring and autumn finfish trawl surveys in Long Island Sound for the years 1984-2008 (1992 and later only for biomass). Little skate are the most abundant species in the skate complex in Long Island Sound, with annual CTDEP survey catches ranging from 142 to 837 skates. CTDEP survey indices suggest an increase in abundance of little skate in Long Island Sound through 1996 followed by a decline (Figure 27).

Barndoor skate

In the NEFSC spring surveys (1968-2008), the annual total catch of barndoor skate has ranged from 0 fish (several years during the 1970s and 1980s) to 325 fish in 2007 (Table 24). In the NEFSC autumn surveys (1963-2007), the annual total catch of barndoor skate has ranged from 0 fish (several years in the 1970s and 1980s) to 120 fish in 1963 (Table 25). Calculated on a per tow basis, the autumn survey catches equate to maximum stratified mean number per tow indices for the GOM-SNE offshore strata of about 0.8 fish, or 2.6 kg, per tow in 1963 while the spring maximum is 1.5 fish, or 6.8 kg, per tow in 2007 (Tables 24-25). The spring survey index was driven mainly by one large tow (277 fish; >1500 kg).

The catchability of barndoor skate in the NEFSC winter bottom trawl survey (which substitutes a chain sweep with small cookies for the large rollers used in the spring and autumn surveys, to better target flatfish) is significantly higher than in the spring and autumn series and may be particularly higher for smaller skates as in winter skates. NEFSC winter survey (1992-2007) annual catches of barndoor skate have ranged from 0 fish in 1992 to 355 in 2006, equating to a maximum stratified mean catch per tow of 3.2 fish, or 3.0 kg, per tow in 2006 (Table 26). The winter survey is focused in the Southern New England and Mid-Atlantic offshore regions, with a limited number of samples on Georges Bank, and no sampling in the Gulf of Maine and has been discontinued.

Indices of barndoor skate abundance and biomass from the NEFSC spring and autumn surveys were at their highest values during early to late 1960s, and then declined to 0 fish per tow during the early 1980s. Since 1990, both spring and autumn survey indices have steadily increased, with the spring survey at the highest value and the autumn survey nearing the peak values found in the 1960s (Figure 28).

The NEFSC scallop dredge survey, as with the winter survey also catches winter skates mostly on Georges Bank and also does not sample in the Gulf of Maine, on the very shallowest portions of Georges Bank, and parts of Southern New England. However, the trends in abundance are similar to the trends in the spring and autumn surveys showing a large increase since 1992 while the biomass is much noisier (Figure 29).

Thorny skate

In the NEFSC spring surveys (1968-2008), the annual total catch of thorny skate has ranged from 29 fish in 2006 to 574 fish in 1973 (Table 27). In the NEFSC autumn surveys (1963-2007), the annual total catch of thorny skate has ranged from 36 fish in 2005 to 874 fish in 1978 (Table 28). Calculated on a per tow basis, these spring and autumn survey catches equate to maximum stratified mean number per tow indices for the GOMSNE offshore strata of about 2 to 3 fish, or about 6.0 kg, per tow during the early 1970s (Tables 27-28).

NEFSC spring and autumn survey indices for thorny skate have declined continuously over the last 40 years. Indices of thorny skate abundance and biomass from the NEFSC spring and autumn surveys were at a peak during the early 1970s, reaching 2.9 fish per tow (5.3 kg per tow) in the spring survey and 1.8 fish per tow (5.9 kg per tow) in the autumn survey. Kulka and Mowbray (1998) indicated a similar period of high abundance for thorny skate in Canadian waters. NEFSC indices of thorny skate abundance have declined steadily since the late 1970s, reaching historically low values by 2005-2007 that are less than 10% of the peak observed in the 1970s (Figure 30).

The NEFSC scallop dredge survey also catches thorny skates primarily on the edges of Georges Bank and a sharp decline followed by no trend (Figure 31). The scallop survey also does not sample in the Gulf of Maine, on the very shallowest portions of Georges Bank and parts of Southern New England.

Indices of abundance for thorny skate are available from the Massachusetts Division of Marine Fisheries (MADMF) spring and autumn research trawl surveys in the inshore waters of Massachusetts for the years 1978-2008. MADMF indices of thorny skate biomass have been variable over the time series, but there is a decreasing trend evident in both the spring and autumn time series. The spring index has stabilized around the median of 0.2 kg/tow throughout the 2000's, while the autumn index has been below the median of 0.6 kg/tow since 1994 except for 2001 and 2002 (Figure 32).

Smooth skate

In the NEFSC spring surveys (1968-2008), the annual total catch of smooth skate has ranged from 12 fish in 1996 to 179 fish in 1973 (Table 29). In the NEFSC autumn surveys (1963-2007), the annual total catch of smooth skate has ranged from 10 fish in 1976 to 130 fish in 1978 (Table 30). Calculated on a per tow basis, these spring and autumn survey catches equate to maximum stratified mean number per tow indices for the GOM-MA offshore strata of 0.6 to 1.6 fish, or about 0.6 to 0.9 kg, per tow during the 1970s (Tables 29-30).

Indices of smooth skate abundance and biomass from the NEFSC surveys were at a peak during the early 1970s for the spring series and the late 1970s for the autumn series (Figure 33). NEFSC survey indices declined during the 1980s, before stabilizing during the early 1990s at about 25% of the autumn and 50% of the spring survey index values of the 1970s.

The NEFSC scallop dredge survey also catches smooth skates primarily on the edges of Georges Bank and the indices have slightly increased (Figure 34). The scallop survey also does not sample in the Gulf of Maine, on the very shallowest portions of Georges Bank and parts of Southern New England.

Clearnose skate

In the NEFSC spring surveys (1976-2008), the annual total catch of clearnose skate has ranged from 9 fish in 1979 to 136 fish in 1993 (Table 31). In the NEFSC autumn surveys (1975-2007), the annual total catch of clearnose skate has ranged from 19 fish in 1983 to 221 fish in 2001 (Table 32). Calculated on a per tow basis, these spring and autumn survey catches equate to maximum stratified mean number per tow indices for the Mid-Atlantic offshore and inshore strata set of 1.2-1.6 fish, or about 0.8-0.9 kg, per tow during the mid 1990s and 2000s (Tables 31-32).

The catchability of clearnose skate in the NEFSC winter bottom trawl survey (which substitutes a chain sweep with small cookies for the large rollers used in the spring and autumn surveys, to better target flatfish) is significantly higher than in the spring and autumn series. NEFSC winter survey (1992-2007) annual catches of clearnose skate have ranged from 343 fish in 1999 to 3,086 fish in 1996, equating to a maximum stratified mean catch per tow of 12 fish or 15 kg per tow in 1996 (Table 33). The winter survey is focused in the Southern New England and Mid-Atlantic offshore regions, with a limited number of samples on Georges Bank, and no sampling in the Gulf of Maine, and has been discontinued.

NEFSC spring and autumn survey indices for clearnose skate increased from the mid-1980s through 2000, declined to about average values, and increased slightly in the last few years (Figure 35).

Indices of abundance for clearnose skate are available from the Connecticut Department of Environmental Protection (CTDEP) spring and autumn finfish trawl surveys in Long Island Sound for the years 1984-2008 (1992 and later only for biomass). The CTDEP survey had caught very few clearnose skate, with annual catches ranging from 0 to 20 skates through 1998, but the indices have increased in Long Island Sound over the times series with 100 caught in 2005 (Figure 36).

Rosette skate

In the NEFSC spring surveys (1968-2008), the annual total catch of rosette skate has ranged from 0 fish, in 1970 and1984, to 70 fish in 1977 (Table 34). In the NEFSC autumn surveys (1967-2005), the annual total catch of rosette skate has ranged from 1 fish, most recently in 1982, to 46 fish in 1999 (Table 35). Calculated on a per tow basis, these spring survey catches equate to maximum stratified mean number per tow indices for the Mid-Atlantic offshore strata set of about 0.6 fish, or about 0.1 kg, per tow during 1977 (Tables 34-35).

The catchability of rosette skate in the NEFSC winter bottom trawl survey (which substitutes a chain sweep with small cookies for the large rollers used in the spring and autumn surveys, to better target flatfish) is significantly higher than in the spring and autumn series. NEFSC winter survey (1992-2007) annual catches of rosette skate have ranged from 143 fish in 1993 to 1029 fish in 2003, equating to a maximum stratified mean catch per tow of 2.8 fish or 0.7 kg per tow in 2003 (Table 36). The winter survey is focused in the Southern New England and Mid-Atlantic offshore regions, with a limited number of samples on Georges Bank, and no sampling in the Gulf of Maine and has since been discontinued.

Indices of rosette skate abundance and biomass from the NEFSC surveys were at a peak during 1975-1980, before declining through 1986. NEFSC survey indices for rosette skate increased from 1986 through 2001, declined slightly and recent indices are near the peak values of the late 1970s (Figure 37).

Research Survey Data- Spawning Stock Biomass

Maturity information was available in some form for all species to split the survey length information into mature and immature animals (Table 37). The series chosen for each species was the same as chosen for reference points at SARC30. There is a protracted spawning as females likely lay eggs year round so there is no need to pick a season based on spawning time. The autumn survey was used for all species except little as it is generally the longest. For little skate, the spring series from 1982 on was used to avoid gear conversion issues.

Winter skate SSB generally follows the pattern of the autumn total biomass index with very low values in the 1970s followed by the large expansion of the size composition in the 1980s (Table 38; Figure 38). The index of SSB declined in the mid- to late 1990s, increased slightly, and is currently at low values. Little skate SSB has been fairly stable through the time series with slightly higher values from 1999-2004 than in the 1980s and early 1990s (Table 38; Figure 38). The pattern in barndoor skate SSB indices is much the same as that of total biomass with high values in the early 1960s, followed by very low to nonexistent values in the 1970s and 1980s, and then a consistent increase in the 1990s and 2000s (Table 38; Figure 38). The decline in thorny skate SSB indices is more pronounced than for the total biomass index (Table 38; Figure 38). Smooth skate SSB indices are very variable, but exhibit a slight decline over the time series (Table 38; Figure 38). Clearnose skate SSB has increased over the time period (Table 38; Figure 38). Rosette skate SSB has been variable but has generally increased (Table 38; Figure 38).

Fishing Mortality Estimates

Gedamke and Hoenig (2006) developed a method to estimate mortality from mean length data in nonequilibrium situations, now called Survival Estimation in Non-Equilibrium Situations Model (SEINE, available at http://nft.nefsc.noaa.gov/). It is an extension of the Beverton-Holt length-based mortality estimator that assumes constant recruitment throughout the time series and mortality at fixed levels for certain periods within the time series. The approach allows for the transitory changes in mean length to be modeled as a function of mortality rate changes. After an increase in mortality, mean length will gradually decrease due to larger animals being less prevalent in the population. After a decrease in mortality, mean length will increase slowly due to growth of the fish in the population. The rates of change in both cases depend on the von Bertalanffy growth parameters and the magnitude of change in the mortality rates. Since the method requires only a series of mean length above a user defined minimum size and the von Bertalanffy growth parameters, it can be applied in many data poor situations. Gedamke and Hoenig (2006) demonstrated the utility of this approach using both simulated data and an application to data for goosefish caught in the NEFSC fall groundfish survey.

Most of the information for the six species suggests that there is one break-point in the time series. This is not useful in monitoring the species on an annual basis. Further modeling efforts are required to estimate fishing mortality.

Biological Reference Points

Current Reference Points

The existing biomass reference points were developed at SARC 30 (NEFSC 2000) and maintained at SARC 44 (NEFSC 2007) with B_{MSY} Proxy formulated as the 75th percentile of the given time series of each species, except barndoor (Table 39) and half that value for $B_{threshold}$. It was assumed that all species had at some time passed through B_{MSY} at some point in the time series. For barndoor skate, the mean of the first four years of the autumn survey were used instead, given that biomass had been extremely low during most of the time series. To reduce the variability in the survey estimates, a three-year moving average of the survey indices was proposed to evaluate stock status for all species (Table 40).

The fishing mortality reference points developed at SARC 30 were not accepted by the NEFMC and a different method for evaluating fishing mortality was developed by the Plan Development Team (PDT). The thresholds for fishing mortality are based on annual percentage declines of the three-year average of the NEFSC trawl survey time series chosen for the biomass reference points. The percentages are specified for each species individually based on historical variation within the survey. The thresholds also include what is termed a precautionary "backstop" that indicates that overfishing is occurring if the trawl survey mean weight per tow declines for three consecutive years. The main part of the definition is that overfishing is occurring when the three-year moving average of the given survey biomass index declines by more than the average CV of the time series. The resulting overfishing status determinations are shown in Table 41.

Extension of time series

One alternative biomass reference point is to use the 75th percentile of the series, but to add the nine years of survey data since the last SARC (Table 42). This gives slightly lower estimates of B_{target} for winter, thorny, and smooth, a much lower estimate for barndoor, and higher estimates for little, clearnose, and rosette.

An Index Method (AIM)

An Index Method (AIM, available at http://nft.nefsc.noaa.gov/) was attempted for all seven species using both spring and autumn surveys. For this method, the replacement ratios, defined as the biomass index in the current year divided by the average biomass indices from the previous 5 years was calculated. Autumn and spring survey biomass indices and total landings and total catch were used to compute the relative exploitation rates, defined as the catch in the current year divided by the 3 year average survey biomass index for the current year and the previous and following years. These relative exploitation rates (or relative F) may be considered a proxy for F. The relationship between replacement ratios and relative F was evaluated by a linear regression of the Log_e replacement ratio on Log_e relative F. None of the relationships were significant and some were actually positive. This method was also attempted for the aggregate skate landings/catch for the four regions. These model runs were also unsuccessful.

SPR- Based Reference Points

SPR-based reference points for three skate species, barndoor, winter, and thorny, were derived from life-history parameters and fitted Beverton-Holt stock recruit relationships (Appendix 3). Estimated overfishing reference points for these three species are $F_{25\%}$, $F_{37\%}$, and $F_{46\%}$, respectively. Future assessments could estimate comparable F's from mean length models (SEINE, e.g.), or from age-specific assessment models provided discards and landings could be disaggregated to species level. Estimates of overfished reference points are also SPR based, and are defined in terms of depletion, i.e. the proportion of spawners relative to unexploited levels. For barndoor, winter, and thorny skates, the depletion reference points are 0.20, 0.27, and 0.32, respectively. Future assessments could determine stock status by comparing these depletion levels either with depletion in the surveys or from a stock assessment model that incorporates information about maturity. There are several important caveats for the methods used in this working paper, namely, that a fixed value of M was assumed for all ages, that the errors in variables problem was ignored in fitting the stock recruit relationship (*status quo*), and that no fishing is assumed to occur prior to the age of recruitment. The sensitivity to the assumed M value is addressed by exploring alternative values. If any fishing were to occur prior to the age of recruitment, then the estimated slope at the origin (*a* in the Beverton-Holt function) would be biased low, leading to an SPR reference point having a positive bias.

Reference Point Recommendation

In general for skates, no new measurable alternative BRPs were identified or recommended. Until new models are constructed using the new catch by species information, the existing overfishing definitions, using information updated through 2007/2008 (except for barndoor skate), will remain in place (Table 43; Figure 39). For barndoor skate, the reference point estimates will not be updated through 2007/2008 because barndoor skate survey indices were extremely low during most of the time series and have been increasing recently (Table 40).

Under the current definition, a stock of skates is designated as overfished when the three year moving average of the NEFSC survey index is less than $B_{THRESHOLD}$. For each of the skate stocks, estimates of the three year moving average survey index are provided in Table 40.

Overfished status determinations can be made by comparing the survey index estimates (Table 40) to the recommended biomass-based reference points (Table 43).

The overfishing status determinations are shown in Table 41 (See additional description in the earlier section labeled "Current Reference Points".

Research Recommendations

1) Given the new information on catch by species, efforts should be made to use a more complex model such as Stock Synthesis.
2) The identification of the species composition of the skate catch should be improved.
3) Age and growth studies, for all seven species in the complex, should be continued.
4) Fecundity studies, for all seven species in the complex, are needed. Use of life history models requires these data, and may prove useful in establishing biological reference points for the skate species.
5) Estimates of commercial and recreational fishery discard mortality rates, for different fishing gears and coastal regions and/or bottom types, for all seven species in the complex, are needed.
6) Studies of the stock structure of the species in the skate complex are needed to identify unit stocks. Stock identification studies, especially for barndoor, thorny, winter, and little skate, are needed.

Table 18. Abundance and biomass from NEFSC spring surveys for winter skate for the Gulf of Maine to Mid-Atlantic region (offshore strata 1-30,33-40,61-76). The mean index, 95% confidence intervals, individual fish weight, minimum, mean, and maximum length, 5th, 50th, and 95th percentiles of length, number of nonzero tows, and number of fish caught are presented for 1968-2008.

Table 20. Abundance and biomass from NEFSC winter surveys for winter skate for the Georges Bank to Mid-Atlantic region (offshore strata 1-3,5-7,9-11,13-14,16,61-63,65-67,69-71,73-75). The mean index, 95% confidence intervals, individual fish weight, minimum, mean, and maximum length, 5th, 50th, and 95th percentiles of length, number of nonzero tows, and number of fish caught are presented for 1992-2007. Stratum 16 not sampled in 1993, 2000, 2002-2007. Strata 13 and 14 not sampled in 2003 and 2007. Stratum 63 not sampled in 1993. Stratum 14 not sampled in 2005 and 2007.

Table 25. Abundance and biomass from NEFSC autumn surveys for barndoor skate for the Gulf of Maine to Southern New England region (offshore strata 1-30, 33-40). The mean index, 95% confidence intervals, individual fish weight, minimum, mean, and maximum length, 5th, 50th, and 95th percentiles of length, number of nonzero tows, and number of fish caught are presented for 1963-2007.

Table 30. Abundance and biomass from NEFSC autumn surveys for smooth skate for the Gulf of Maine to Southern New England region (offshore strata 1-30,33-40). The mean index, 95% confidence intervals, individual fish weight, minimum, mean, and maximum length, 5th, 50th, and 95th percentiles of length, number of nonzero tows, and number of fish caught are presented for 1963-2007.

Table 36. Abundance and biomass from NEFSC winter surveys for rosette skate for the Georges Bank to Mid-Atlantic region (offshore strata 1-3,5-7,9-11,13-14,16,61-63,65-67,69-71,73-75). The mean index, 95% confidence intervals, individual fish weight, minimum, mean and maximum length, 5th, 50th, and 95th percentiles of length, number of nonzero tows, and number of fish caught are presented for 1992-2007. Stratum 16 not sampled in 1993, 2000, 2002-2007. Strata 13 and 14 not sampled in 2003 and 2007. Stratum 63 not sampled in 1993. Stratum 14 not sampled in 2005 and 2007.

Table 37. Estimates of size at 50% maturity, length-weight parameters (Wigley et al 2003) and Von Bertalanffy Parameter estimates used to estimate SSB and to calculate Hoenig (1987) mortality estimates. Smooth skate data in parentheses are female values. Clearnose data in parentheses are in disk width.

Species (Study)	L50	ln(a)	b	Linf	K	t0 (L0)

MEMORANDUM

DATE: **December 11, 2008**

TO: Data Poor Assessment Workshop

FROM: Andrew Applegate

SUBJECT: **Discard estimation**

During the Data Poor Assessment Workshop (DPWS), new skate discard estimates were presented which differed substantially (see Figure 1) from those estimated during SAW44 and updated by the Skate PDT during the development of Amendment 3. Most of the differences were thought to be associated with filling unmatched trips with average DK (live weight ratio of observed discarded skates to the observed kept of all species). Like the SAW44 estimate, a three level stratification was applied to observed trips and dealer landings (obtained from the area allocation "AA" tables). The stratification included gear (longline, limited access scallop dredge, general category scallop dredge, shrimp trawl, sink gillnet, and fish trawl), region (Gulf of Maine, Georges Bank, Southern New England, Mid-Atlantic) and quarter (1-4).

The new estimates had the same trend as the previous ones through 2002, but differed substantially from 2003 to 2006 (Figure 1). Most filled DK rations, however, were concentrated in earlier years (Figures 4-7), the largest difference arising from longline gear in 1991 and 1992 and trawl gear in 1998. The cause of the differences for 2003-2006 were not apparent. These more recent discard estimates are critically important because the Council uses the last three years of the discard time series (2004-2006) to reduce the allowable catch limits and set landings targets. Based on the earlier estimates, it was believed that discards had declined substantially due to regulatory effects. The new estimated discards do not show this decline.

To explore the source of these important differences the sea sampling and dealer data were analyzed independently using a different stratification schema to potentially reduce the effects of oversampling of the US/CA area, access area, and special access program trips which are distributed in special areas. Also mesh categories were also introduced to account for DK differences that might be caused by small (< 5.5 inches), large (5.5 to 8 inches), and very large mesh (> 8 inches) for trawl and sink gillnets. A seasonal stratification was also applied (fall 07-10, spring 03-06, and winter 11-02) to comport with the three annual finfish NMFS trawl surveys so that the aggregate discard estimates could be allocated by species. A four level stratification was applied to both data sets: gear (longline, scallop dredge, scallop trawl, sink gillnet, fish trawl, shrimp trawl, and other), sub-region (Delmarva, E. Georges Bank, E. Gulf of Maine, NY Bight, Offshore, S. Channel, Southern New England, and Other), season (see above), and mesh (see above). Dealer data that matched observed DK ratios from observed trips accounted for about 65-75% of total landings. Where DK matches did not exist, the DK ratio for a two level stratification (gear and sub-region) was applied. Together, the combined matches accounted for 95-99% of total landings. The remaining unmatched trips were for combinations that generally seemed to be associated with low skate discards and the DK ratios were assumed to be zero. No general linear modeling was applied (see analysis below for further discussion) at the time of these discard estimates.

Similar to the NEFSC estimates, the ratio of sums (DK) were applied to total live weight landings of all species on the dealer reports. A simplified method was also applied which discards are the multiplicative product of the observed skate discards per trip times the number of trips landed by dealers. For both, discard 95% confidence levels were computed by bootstrapping the trips (10% of trips in 100 iterations) to obtain a standard deviation for the DK mean by gear. The discard estimates in each 'cell' were then calculated over 1000 iterations with a log normal distribution on DK with a mean μ and a standard deviation σ.

The alternative discard estimates (Figure 2) tend to agree reasonably well with the NEFSC estimates since 1999, and particularly well for estimates since 2003. Before 1998, the discard estimates diverge due to low sample size, but generally all estimates show a declining trend from 1996-1999.

These discard estimates did not however reveal the source of the error in the SAW44 discard estimates. Further exploration of the discard rates was conducted to try to understand why skate discards do not appear to be declining despite more restrictive groundfish regulations during the recent period. For vessels using trawls, skate discards per haul, trip, and kept landings increased from 2000 to 2008 (Figure 9). A similar pattern was observed for vessels using sink gillnets (Figure 10). Observed skate discard rates declined for vessels using scallop dredges (Figure 11). In all three cases, the trends could be caused by oversampling trips in special access programs that could have skate discard rates that differ from regular trips.

Skate discards for vessels landing more than 1000 lbs. of skates (live weight) also increased since 2001 (Figure 12), but appear to level off since 2005 and possible decline in 2008 (a partial year). Skate discard rates for vessels fishing in the Gulf of Maine (Figure 14) and the Mid-Atlantic (Figure 16) appeared to vary without trend (Figure 13) at very low levels particularly since 1999, either per trip or per lb. kept. There appears to be a moderate upward trend in discards in Southern New England (Figure 15) since 2000. Skate discard rates on Georges Bank appear to have trended upward since 2001 (Figure 14), mimicking the overall trend.

When broken out by management program, skate discard rates for regular trawl trips in the Georges Bank region varied without trend from 1989 to 2000, then increased in 2001 and varied at a higher level since that time. In the more recent period, discards averaged 0.3 to 0.6 lbs. of skates per pound kept. In contrast, skate discards on oversampled US/CA area trips were much higher, averaging 0.6 to 0.8 lbs. of skate discards per pound kept.

During the comparison of the discard estimates during the DPWS, it was determined that the SAW44 estimates did not include the US/CA area, scallop access area, and groundfish special access program observed trips. It seems plausible that this omission may have contributed to the estimated declining trend in skate discards that was previously estimated. On the other hand, the high skate discard rates in the US/CA trips may also in some cases be inappropriately applied to non-US/CA area trips, but there is no field in the dealer data to determine trip type. Some post-stratification of DK rates and dealer landings by sub-region and time could reduce this undue influence on the discard estimation.

Also during the DPWS, it was suggested that a General Linear Model (GLM) analysis should be conducted to determine which type of stratification of observed trips would be better a better model to follow. All three stratifications were analyzed via GLM, plus the NEFSC stratification with only regular management program trips (excluding US/CA area, scallop access area, Multispecies Category B DAS, and special access program trips). All models were significant and one stratification wasn't clearly superior to the other, except that simpler models (i.e. less independent variables) explained a significant amount of the DK variance, but all models had relatively low predictive capability (low R).

More detailed information about the GLM analyses are shown in Tables 2-5. For model 1 (Table 2), the MSE for all independent variables except quarter were significant. Holding the effects of the other independent variables constant, the least squares means increased from 2001 to 2007. Trawl DK rates were substantially higher than other gears and higher in the Southern New England region than the others. Similar trends were observed for a GLM applied to only regular management program observed trips (Table 3).

For model 3 (Table 4), which was applied to unmatched trips in this analysis, all independent variables (year, gear, sub-region) were significant and explained a significant fraction of the DK variation. DK trends for year and gear were similar to those for models 1 and 2. DK rates were high for the E. Georges Bank, NY Bight, and Southern New England sub-regions. All independent variables in model 4 (which was used in this analysis to estimate discards on matched trips) were significant (Table 5), except for season which was retained to comport with the survey data to be used to allocate aggregate discards to species. Holding the effects of the other independent variables constant, the least squares means showed a similar trend for year, but the discard rate for trawls was lower than the other model formulations which did not use mesh as an independent variable. Somewhat counter intuitively, the DK rate was highest for large mesh trawls and gillnets, and lowest for small mesh trawls and gillnets. This may be related to the lower amount of kept for other species compared to the discard of skates for vessels using large mesh. It also suggests that vessels using mesh larger than 8 inches may have a lower skate discard rate – or simply catch more of the target species relative to the amount of skates discarded.

Draft Working Paper for pre-dissemination peer review only.

Skate Complex
Methodology to determine overfished and overfishing reference points
Appendix 3

Data Poor Stocks Working Group Meeting
Woods Hole, MA
December 8-12, 2008

This Working Paper was distributed for pre-dissemination peer review at the NE Data Poor Stocks Peer Review Meeting, December 8-12, 2008. It does not represent any final NOAA agency determination or policy. Some comments in the Peer Review Panel's Report of the Data Poor Stock Working Group are in response to this WP.

Executive Summary

SPR-based reference points for three skate species, Barndoor, Winter, and Thorny, were derived from life-history parameters and fitted Beverton-Holt stock recruit relationships. Estimated overfishing reference points for these three species are $F_{25\%}$, $F_{37\%}$, and $F_{46\%}$, respectively. Future assessments could estimate comparable F's from mean length models (SEINE, e.g.), or from age-specific assessment models provided discards and landings could be disaggregated to species level. Estimates of overfished reference points are also SPR based, and are defined in terms of depletion, i.e. the proportion of spawners relative to unexploited levels. For Barndoor, Winter, and Thorny skates, the depletion reference points are 0.20, 0.27, and 0.32, respectively. Future assessments could determine stock status by comparing these depletion levels either with depletion in the surveys (provided information is available to estimate depletion for the first year in the survey) or from a stock assessment model that incorporates information about maturity. The same approach to derive reference points was attempted for Clearnose skate, however the parameter estimates from stock recruit curve were unrealistic.

There are several important caveats for the methods used in this working paper, namely, that a fixed value of M was assumed for all ages, that the errors in variables problem was ignored in fitting the stock recruit relationship (*status quo*), and that no fishing is assumed to occur prior to the age of recruitment. The sensitivity to the assumed M value is addressed by exploring alternative values. If any fishing were to occur prior to the age of recruitment, then the estimated slope at the origin (*a* in the Beverton-Holt function) would be biased low, leading to an SPR reference point having a positive bias.

Introduction

Determination of stock status requires a set of reference points that are measured in the same units as estimates of current stock levels. The *de facto* target reference points are associated with Maximum Sustainable Yield (MSY), with limit reference points being some fraction of the target, typically one-half of the target. When MSY estimates can't be obtained, reference points based on spawning potential ratio (SPR) are a common proxy. There is abundant literature exploring the use of SPR (Goodyear 1977; Gabriel et al. 1989; Goodyear 1993; Mace 1993) and recommending appropriate levels of SPR (Clark 1991; Mace and Sissenwine 1993). Brooks et al. (*in prep.*) suggest that the appropriate level depends on species-specific characteristics, and that the level can be derived analytically from life-history parameters. The ability to express the reference point explicitly in terms of survival, maturity, and fecundity allows the proxy SPR level to be tailored to the species of interest. The appropriateness of the SPR level can be evaluated by inspection of the individual components to determine whether they are biologically realistic, and sensitivity to assumed rates can be calculated directly.

As is discussed in this WP, skate landings are not disaggregated to the species level, and there is uncertainty in the species identification of observed skate discards. The lack of species specific catch poses a major problem to conducting stock assessment analyses. The methods proposed in this working paper for deriving biological reference points use only data from the research surveys conducted by the Northeast Fisheries Science Center, thereby avoiding the potential problems associated with disaggregating the commercial catches.

Methods

Overfishing and overfished reference points are derived in terms of the SPR level that achieves maximum excess recruitment (MER, Goodyear 1980). MER differs from MSY in that it solves for the maximum yield in numbers rather than in weight. By comparison, $SPR_{MER}<SPR_{MSY}$ because the F that achieves MER is greater. This is due to the fact that MSY is achieved by allowing more fish to survive to older, hence heavier, ages. MER reference points are expressed in terms of maximum lifetime reproduction, $\hat{\alpha}$ (Myers et al., 1997, 1999), where

$$(1) \qquad \hat{\alpha} = a \sum_{age=r}^{A\max} p_{age} E_{age} \prod_{j=1}^{age-1} e^{-M_j} \ .$$

In (1), r is the age of recruitment, p_{age} is the proportion mature at age, E_{age} is the number of eggs produced at age, M is natural mortality, and a is the slope at the origin in the Beverton-Holt equation

$$(2) \qquad R = \frac{aS}{1 + S/K} .$$

The level of SPR corresponding to MER is given by

$$(3) \qquad SPR_{MER} = \frac{1}{\sqrt{\hat{\alpha}}} .$$

After calculating $\hat{\alpha}$, the resulting SPR_{MER} could be used to determine the overfishing target by calculating $F_{\%SPR}$. An overfished target could similarly be calculated from $\hat{\alpha}$ as

$$(4) \qquad \frac{SSB_{MER}}{SSB_0} = \frac{\sqrt{\hat{\alpha}} - 1}{\hat{\alpha} - 1} .$$

The calculated value in (4) gives a target depletion level, against which current estimates of spawner depletion could be compared.

In order to calculate the reference points, the components of $\hat{\alpha}$ are needed. First, the slope at the origin, a, was obtained by fitting Beverton-Holt curves to NEFSC fall bottom trawl survey data following Gedamke et al. (2009). Annual estimates of mean number of spawners per tow were derived by assuming knife-edged maturity at L_{50}. To obtain a time series of recruitment, the length corresponding to age of full vulnerability to the gear (L_{Crit}) was determined, and this was converted to a mean age from von Bertalanffy growth curves (Table 1).

The stratified mean number of fish per tow above L_{50} (spawners) and for the year class corresponding to L_c (recruits) was then estimated for all years. The vector of mean number of spawners per year was then paired with the vector of mean number of recruits given the appropriate lag (Table 2). For instance, if recruitment was determined to occur at age 4, then a lag of 5 years was taken to account for the additional year spent as an egg. Years with missing data in these lagged pairs were dropped from the analysis. We emphasize that we used spawning number rather than spawning biomass. This is a more realistic approach for elasmobranchs, because they typically produce a few large eggs sacks (or pups, in the case of live bearers).

Counting the number of spawners reflects the fact that there is a finite capacity for egg production and internal storage, whereas using spawning biomass as a proxy implies that fecundity increases by a power function with age. The fall survey was used because it is a longer time series and was more likely to reflect a wider range of observed stock sizes (NEFSC 2000).
Beverton-Holt curves were fit in ADMB (Otter Research, Ltd. 2004) assuming log-normal error in recruitment. We note that while the observations of spawners are not measured without error, the errors in variable problem is ignored (*status quo*).

The estimate of *a* obtained from the Beverton-Holt fits is a compound term that expresses survival from the egg stage (S_{egg}) to the age of recruitment (S_{r-1}) as well as the number of eggs produced per spawner (*E*), which is assumed to be a constant for all ages:

(5) $$a = ES_{egg}S_0S_1 \cdots S_{r-1}.$$

Given the definition of $\hat{\alpha}$ in (1), the remaining term depends only on the natural mortality rate (*M*) assumed:

(6) $$\hat{\alpha} = a\sum_{age=r}^{A\max} p_{age} \prod_{j=1}^{age-r} e^{-M_j} = ae^{-(Amat-r)*M} \sum_{age=Amat}^{A\max} e^{-(age-Amat)*M} = a\frac{e^{-(Amat-r)*M}}{1-e^{-M}}.$$

The final term above is the closed form solution for the sum of a geometric series, which results for very large *Amax*, the maximum age. If Amax is 30 years or greater, then the difference between the finite sum and the infinite sum is small (Appendix 1). Estimates of an age-constant natural mortality (M) were calculated using four different methods based on life-history parameters: Pauly (1980), Hoenig (1983), and the Jensen (1996) age at maturity and k methods. Estimates ranged from 0.09 to 0.17 yr^{-1}, 0.15 to 0.18 yr^{-1}, and 0.17 to 0.25 yr^{-1} for winter, thorny and barndoor skates, respectively. The base case values used for these three species were 0.15, 0.18, and 0.18, respectively. For the clearnose skate, an M of 0.15 was used based on similarity with the other skates. Note that an estimate of water temperature is required for the Pauly (1980) estimator and we used 8.5 C as reported by Myers et al. (1997).

The reasonableness of the estimate of *a* can be evaluated by dividing *a* by *E*, the total number of eggs produced by a female in a year. The term remaining from this division is the cumulative survival from egg stage to the age of recruitment, $S_{egg}S_0S_1 \ldots S_{r-1}$. Assuming that survival is constant at each of these pre-recruit stages, then the annual survival can be calculated as $(S_{egg}S_0S_1 \ldots S_{r-1})^{1/r}$.

The sensitivity of $\hat{\alpha}$ and SPR based reference points was explored for a reasonable range of alternative M values that bracketed the estimates discussed above (0.10-0.25). The resulting SPR_{MER} and the level of F that would produce SPR_{MER} were calculated for each of the possible M values. Uncertainty in the reference points arising from uncertainty in *a* was evaluated with MCMC in AD Model Builder (Otter Research, Ltd, 2004). Two independent chains of length 1E+06 were simulated, with a thinning rate of 1/50. The first 35% of each chain was dropped (burn-in), and the remaining values were retained for analysis.

Results

The results of fitting Beverton-Holt relationships to the observed spawner and recruit data were evaluated by examination of diagnostic plots (Figures 1-4). For Barndoor, Thorny, and Winter skate, the diagnostics are acceptable, and the estimated parameters are reasonable (Table 3). However, for Clearnose skate, the residuals show unacceptable time trends (Figure 4) and the estimates are not reasonable (Tables 3 and 4; steepness of about 0.96).

The estimated precision for the reference points only reflects the precision of the estimated stock-recruit parameters (*a* and *K*). Sensitivity of the estimated reference points and the associated fishing mortality rate for alternative values of M are given in Tables 5-7. For higher M, SPR_{MER} and depletion at MER are also higher, which equates to a lower F. This may initially seem counterintuitive, for one often finds that assuming a higher M leads to a higher estimate of F_{MSY} in a typical stock assessment. However, in this case, the result of a higher M producing a lower $F_{\%SPR}$ is due to the direct impact of M on the unexploited calculation of spawners per recruit (Table 8). It is this parameter that scales *a* to yield $\hat{\alpha}$, from which the reference points are estimated.

Barndoor skate

There were 14 observations of (S_y, R_y) for Barndoor skate from the fall NEFSC bottom trawl survey (Table 2). The estimated slope at the origin was 5.78, which gives a maximum lifetime reproduction of 15.61 ($\hat{\alpha}$, Table 3). From equations (3) and (4) above, SPR_{MER}=0.25 and the depletion of spawners at MER (S_{MER}/S_0) is 0.20. The estimated fishing mortality that achieves an SPR of 0.25 is $F_{25\%}$= 0.18. The implied annual survival during the pre-recruit stage is 0.27/year for three years (egg stage to age 2, Table 3). The long right tail in the posterior distribution of the slope at the origin (*a*) reflects the poorer precision of that parameter (CV=50%). By comparison, the reference points were twice as precise.

Winter skate

There were 36 observations of (S_y, R_y) for Winter skate from the fall NEFSC bottom trawl survey (Table 2). The estimated slope at the origin was 2.94, which gives a maximum lifetime reproduction of 7.39 ($\hat{\alpha}$, Table 3). From equations (3) and (4) above, SPR_{MER}=0.37 and the depletion of spawners at MER (S_{MER}/S_0) is 0.27. The estimated fishing mortality that achieves an SPR of 0.37 is $F_{37\%}$=0.08. The implied annual survival during the pre-recruit stage is 0.43/year for five years (egg stage to age 4, Table 3). As was the case with barndoor skate, the estimated CV for the slope at the origin (*a*) was twice that of the reference points (0.39 for *a* versus 0.19 and 0.14 for SPR_{MER} and depletion at MER).

Thorny skate

There were 40 observations of (S_y, R_y) for Thorny skate from the fall NEFSC bottom trawl survey (Table 2). The estimated slope at the origin was 2.71, which gives a maximum lifetime reproduction of 4.67 ($\hat{\alpha}$, Table 3). From equations (3) and (4) above, SPR_{MER}=0.46 and the depletion of spawners at MER (S_{MER}/S_0) is 0.32. The estimated fishing mortality that achieves an SPR of 0.46 is $F_{46\%}$=0.07. The implied annual survival during the pre-recruit stage is 0.44/year for five years (egg stage to age 4, Table 3). As was the case with barndoor skate, the estimated CV for the slope at the origin (*a*) was twice that of the reference points (0.31 for *a* versus 0.16 and 0.11 for SPR_{MER} and depletion at MER).

Clearnose skate

There were 28 observations of (S_y, R_y) for Clearnose skate from the fall NEFSC bottom trawl survey (Table 2). The estimated slope at the origin was 101.10, which gives a maximum lifetime reproduction of 15.61 ($\hat{\alpha}$, Table 3). The diagnostics were not acceptable, and the parameter estimates were unrealistic (steepness=0.96, Table 4); therefore, the estimated reference points are considered inappropriate for management advice. No MCMC simulations were conducted for this species based on the poor initial model fit.

Conclusions

Assessment of skate species has proven to be difficult, due to the aggregated nature of commercial landings and the lack of data on discards for much of the time series. The difficulty applies equally to the estimation of reference points for skates. The methodology of Gedamke et al. (2008) provided a method to estimate the slope at the origin for Beverton-Holt stock recruit relationships. Management reference points are strongly dependent on the stock recruitment curve, and the slope parameter is a key component in determining appropriate reference points. Combining the slope with other biological parameters, the analytic solutions for SPR_{MER} were derived from results in Brooks et al. (2008, *in preparation*).

Data were sufficient to attempt fitting stock recruit curves to four skate species: Barndoor (14 data points), Thorny (40 data points), Winter (36 data points), and Clearnose skate (28 data points). The diagnostics were acceptable for all but Clearnose skate, and the parameter estimates for the remaining three species appear reasonable. The resulting reference point estimates are on a scale that would be compatible with existing assessment methodology. For example, models such as SEINE (2008; NMFS Toolbox module based on Gedamke and Hoenig, 2006) , or other mean length based models, could provide estimates of fishing mortality, provided the lengths examined included only those above the full vulnerability to the gear. These assessment-based estimates of F could then be compared to the $F_{\%SPR}$ estimated in this working paper to determine the overfishing status. The overfished status could be determined by examining the implied depletion of spawners, for example by examining the final point in the scaled index of mean spawners/tow ($S_y/S_{y=1}$). The scaled index of spawners would be depletion from an unexploited state if it was appropriate to assume that the stock was unexploited in year $y=1$. If that is not the case, then the index could be multiplied by a scalar, *d*, which reflects a measure (or expert opinion) of the level of depletion in year $y=1$. Alternatively, if algorithms to dissociate the landings and to hindcast discards are developed and agreed upon, then traditional stock assessment methods could be applied to estimate current levels of fishing mortality and stock size.

These SPR reference points were bounded by considering sensitivity across a reasonable range of natural mortality (M) levels.

Beverton-Holt curves were fit, but no Ricker curves were attempted because there is no obvious mechanism that would lead to overcompensation, nor is there data available that would suggest it.

As is common in most stock-recruit curve fitting exercises, the error in observed spawners per tow is ignored. Walters and Ludwig (1981) suggest that the estimation performance from ignoring error in the 'independent' variable is worse if the observations all come from a period where the stock was already heavily exploited. As the time series used in fitting Beverton-Holt curves extends back to the 1960s, it may be that a fairly broad range of spawning stock sizes is reflected in the observations.

Northeast Data Poor Stocks Working Group Meeting
Woods Hole, MA
December 8-12, 2008

***Editor's Note: The authors of this red crab report added italicized text to this chapter, summarizing the Peer Review Panel Report (that full report is available at http://www.nefsc.noaa.gov/nefsc/saw/).**

Executive summary

Deep sea red crabs in the northwest Atlantic represent a data-poor stock because they inhabit deep water, are rarely caught in NMFS bottom trawl surveys, require targeted surveys to collect data on abundance, and little is known about their life history. Data from related species has been considered to make assumptions about the life history. Targeted surveys were conducted in 1974 (Wigley et al. 1975) and during 2003-2005 (Wahle et al. 2008). Two stock assessments have been completed for red crabs (Serchuk 1977; NEFSC 2006a).

This male-only fishery began in the late 1970's. Quality of commercial landings data is variable. The most recent targeted survey (2003-2005) found that there had been a significant reduction in abundance of large male crabs since 1974. In 1974 the minimum acceptable marketable size was 114 mm carapace width (CW). In 2008 the minimum market size of landed crabs was less than 90 mm. The size distribution of the females did not change, indicating that the change in male size frequency was due to harvesting. The male red crab carries the female during mating, and the male must be larger than the female for successful mating. The reduction in large males in the population could reduce mating success. Females might not find males of the right size and sperm shortage might occur.

The deep sea red crab fishery management plan (FMP) was implemented in 2002. The FMP set an MSY (2830 mt) based on the biomass of male red crabs over 102 mm in carapace width. Overfishing is considered to be occurring if catch>MSY, or a proxy thereof. The B_{MSY} calculated for the FMP is 18,867 mt of males, and if biomass goes below ½ B_{MSY} then the stock is considered overfished.

Three options for updating B_{MSY} were considered. The first was status quo (i.e., the value in the FMP), the second was to use an updated MSY (provided there was one) to calculate a B_{MSY} proxy, and the third option was to use the biomass of fishable males from the more recent survey as a B_{MSY} proxy. The review panel did not recommend a new B_{MSY} or B_{MSY} proxy, but they were concerned with the change in size of harvested crabs over time. B_{MSY} for red crabs will remain at the default level of 18,867 mt of males.

Several options for updating MSY for red crab were considered. Two models were used, the depletion corrected average catch model (DCAC) (A. MacCall, pers. comm.) and a 2-point boundary model. Runs made over a range of assumed M values (0.05 to 0.15) estimated sustainable catches from 1785-2004 mt. The long-term average catch (1775 mt) was also suggested as a possible MSY proxy. It was also suggested that MSY could be calculated with an updated version of Gulland's (1970) equation with an F_{MSY} to M ratio of 0.8 and the same range of M values, which gave estimates of 549-1740 mt. MSY values from the new options were smaller than the status quo value of 2830 mt.

The panel rejected the current estimate of MSY (2830 mt) as too high, based on observed changes in population size structure since the beginning of the fishery. Based on congruence between average landings and results from the DCAC model, the panel concluded that MSY ranges from 1700-1900 mt of males.

The review panel did not change the overfishing definition for red crab (i.e. overfishing occurs if catch of males >MSY).

Terms of reference (TOR)

a) Recommend biological reference points (BRPs) and measurable BRP and maximum sustainable yield (MSY) proxies.

b) Provide advice about scientific uncertainty and risk for Scientific and Statistical Committees (SSCs) to consider when they develop fishing level recommendations for these stocks.
c) Consider developing BRPs for species groups for situations where the catch or landings can not be identified to species. Work on this objective will depends on, and needs to be consistent with, final guidance on implementing the Reauthorized Magnuson-Stevens Act, whenever that guidance becomes available. (This TOR not applicable to red crab)
d) Comment on what can be done to improve the information, proxies or assessments for each species.

Biological characteristics[1]

Information in this section is summarized primarily from Steimle et al. (2001) and Wahle et al. (2008). Deep-sea red crabs (*Chaceon quinquedens*) are a brachyuran crab (family Geryonidae) inhabiting the edge of the continental shelf and slope from Emerald Bank, Nova Scotia, the Gulf of Maine, and south through the mid-Atlantic Bight and into the Gulf of Mexico. According to Weinberg et al. (2003), genetic differences between deep-sea red crabs from southern New England and the Gulf of Mexico indicate that crabs in the two areas belong to different biological populations (figure 1). Red crabs in Southern New England and the Mid-Atlantic Bight (south of Georges Bank) and the Gulf of Maine (north of Georges Bank) are assumed to be the same stock although fishing occurs primarily off Southern New England. Red crabs in the Gulf of Maine are smaller and the bottom is rough so little fishing for red crab occurs there.

Deep-sea red crabs live at depths of 200–1800 m, where temperatures are between 5 and 8 ^{o}C. Adult crabs are segregated incompletely by sex. Adult females generally inhabit shallower water than adult males, and juveniles tend to be deeper than adults, suggesting a deep-to-shallow migration as the crabs mature.

Information on the growth, longevity and mortality of red crabs is scarce. Natural mortality rates were assumed to be 0.2 y^{-1} in Serchuk (1977) and 0.15 y^{-1} in the current Fishery Management Plan (FMP) for Deep-Sea Red Crab. An assumed longevity of 30 or more years corresponds approximately to $M = 0.1\ y^{-1}$ (see below).

On the basis of limited laboratory data, red crabs are believed to require 5–6 years to attain a size of 114 mm carapace width (CW). Male red crabs are estimated to mature at about 75 mm CW and to reach a maximum size of about 180 mm CW. Females begin to mature at somewhat smaller sizes and reach a smaller maximum size of about 136 mm CW.

As in other brachyuran crabs, the mating male is larger than the female and forms a protective “cage” around the female while she molts and becomes receptive to copulation. The protective copulatory period may last as long as 2–3 weeks in red crabs. The minimum size of males relative to females required for successful mating is unknown. Information about sperm storage is not available for female red crabs.

Fishery and management

Red crabs in the US waters outside the Gulf of Mexico are managed as a single stock located primarily in the Mid-Atlantic Bight to Gulf of Maine region, although red crabs in the Gulf of Maine are not considered in calculation of reference points, biomass estimates or other management analyses.

[1] Based on Steimle et al. (2001) and Wahle et al. (2008).

A small experimental fishery for red crabs was established in the early 1970s. Before the initial targeted survey for red crabs (Wigley et al. 1975), fishery catches were small and sporadic. In the 1980s and 1990s, fishing effort was inconsistent due to market demand. A directed fishery for male red crabs and consistent markets developed in the mid-1990s.

The current US fishery for male red crabs has limited entry and as of 2006 consisted of four or fewer vessels 30+ m long. The fishery uses specially designed traps almost exclusively, although small catches are taken also in lobster traps. Fishing occurs year round and catches are made mainly along the continental shelf from the Canadian border (Hague Line), at the eastern end of Georges Bank, to Cape Hatteras, NC, USA, in depths ranging from 400 to 800 m.

Annual US commercial landings of red crabs during the period 1982–2005 ranged from 466 mt (1996) to 4000 mt (2001); there was no fishery in 1994. Since 2002, when the FMP was implemented, landings have been stable at about 2000 t per year. The current fishery is authorized to operate with a target TAC of 2688 mt, and an effort allocation of 780 days at sea. There is no recreational fishery for the species.

Minimum market sizes and fishery size selectivity have decreased since the early 1970s. The minimum market size for male deep sea red crabs in 1974 was 114+ mm CW. The minimum market size for male deep sea red crabs in recent years is about 85 mm CW. Fishery size selectivity has been estimated for the current fishery during 2004-2005 (L_{50}=92 mm CW) but no selectivity estimates are available for earlier years.

Based on limited log book, sea- and port sample information, discards of female and undersize male red crabs appear to average about 30% of total catch but can range from about 10% to 69% of total red crab catch. Discard mortality from being brought to the surface and handled on deck averages about 5%. (Tallack 2007). Bycatch of red crab in fisheries directed at other species is minor.

The major fishery related uncertainties for red crab are discards, discard mortality, as well as historical and recent fishery size composition. In addition, the expected response of the stock to fishing in terms of growth and recruitment is uncertain.

The infrequency of stock assessments is another key uncertainty. Only two stock assessments have been completed for deep-sea red crab off Southern New England (Serchuk 1977; NEFSC 2006a). Both were based on camera/trawl surveys completed just prior to the assessment.

Data availability

The principle fishery data for red crab are landings data from dealer reports starting in 1973, logbooks that start in 1994, size composition data for marketable males from routine port samples, and sea sample data for females and all males from a pilot program involving one vessel during 2004-2005. Landings data from dealer reports for years prior to 1982 are less reliable than data for later years. Landings per unit effort data are available from logbooks and dealer reports but are difficult to interpret. The fishery occurs off south of Georges Bank and virtually no fishery data are available for the Gulf of Maine. As described above, discard estimates based on limited sea-, port and logbook data are available and size selectivity estimates for the recent commercial fishery are available from comparison of sea- and port sample data.

The principle fishery independent data for red crab are from camera sled/bottom trawl surveys conducted during 1974 and 2003-2005 on red crab habitat between Maryland and the eastern tip of Georges Bank (excluding the Gulf of Maine). Camera data provide information about red crab density and bottom tow data provide information and sex- and size composition. The survey data for 2003-2005 are generally combined and treated as one survey. Data from a variety of research bottom trawl surveys are of limited use for red crab because catches are very low. The NMFS Cooperative Monkfish Survey may provide some useful information about red crab in the Gulf of Maine.

Camera and trawl tows in the 1974 and recent surveys were generally from the same or similar sites and sample locations. The two sets of surveys used bottom trawls of the same design and the same trawling protocols, although different vessels were used. Efforts were made to make camera data from the two surveys as comparable as possible but there is uncertainty about the effective area sampled (and therefore red crab density) by images collected during the 1974 survey. Density estimates from the recent survey are believed to be biased low because crab densities were significantly lower in the foreground (close to the camera sled) than in the background of the sampled area suggesting crabs were avoiding the camera, but the extent of the potential bias is unknown. The most reliable survey data are bottom trawl size compositions from both sets of surveys and density estimates from the most recent surveys.

Current stock status

Information in this section is summarized from NEFSC (2006a). The most recent assessment concluded that overfishing was not occurring because red crab landings during 2005 (2013 mt) were less than an MSY proxy (2830 mt, see below). Recent fishing mortality estimates were available but not used to determine overfishing because no F based reference point or proxy for F_{MSY} was available.

Based on the most recent assessment, average fishing mortality rate (landings / fishable biomass) on male red crabs was estimated to be F=0.055 (SE 0.008) y^{-1} during 2003-2005. This estimate is probably an underestimate because it does not consider potential mortality due to discarding of undersized male crabs and completely omits mortality due to discarding of females. Fishing mortality estimates are calculated using biomass estimates from surveys during 2003-2005, which are relatively certain but possibly biased low due to avoidance of the camera sled. Red crab biomass is appreciable but catches are currently near zero in the Gulf of Maine.

Alternate fishing mortality estimates including discards and based on best available discard estimates for sea- and port samples are given below (Table 1) for males only, females only and males plus females. Results indicate that total fishing mortality (including discards) during 2003-2005 were $F \leq 0.08$ y^{-1} for both sexes and for the sexes combined. The alternative estimates are “worse-case” scenarios because they assume that 50% of discarded red crabs die, whereas the current best estimate of discard mortality indicate that about 5% of discarded red crabs die from being brought to the surface and handled on deck (Tallack 2007). Discard rates (discard/total catch) were from sea- and port samples during 2003-2004 (Table D4.5 in NEFSC 2006a). In this exercise, fishing mortality for red crab was approximated as catch (landings + discards) divided by total biomass and catch divided by 90+ CW biomass (the approximation for F are relatively precise because mortality rates are low). Calculations using total biomass may understate fishing mortality because total biomass includes small size groups probably not taken in traps although potential bias may be small because small crabs have low weight. Calculations using 90+ CW biomass may overstate fishing mortality because red crabs of sizes smaller than 90+ CW make up the bulk of the discard.

Based on the most recent assessment (Table 2), fishable red crab biomass during 2003-2005 was about 36,000 mt. Overfished status was not determined for lack of an adequate B_{MSY} estimate or proxy (see below).

Comparisons of biomass estimates from the two surveys are uncertain due to uncertainty about the effective area sampled by cameras during 1974. However, biomass estimates from the two sets of surveys (table 2) indicate that male fishable biomass (based on current fishery selectivity) increased by about 20% during 1974 to 2003-2005. Female biomass (total, 90+ and 114+ CW) increased substantially by 150%-250%. In contrast, total male biomass increased by only 75% and biomass of large (114+ CW) males decreased by about 43%. Size composition data from the surveys indicates that both male and female red crabs have benefitted from recruitment in recent years (figure 2). The loss of large (114+ CW) male biomass and relatively modest increase biomass of males 90+ mm CW can probably be attributed to size-selective fishing (Weinberg and Keith 2003).

Red crab overfishing definitions

The Magnuson-Stevens act includes the requirement that all FMPs "specify objective and measurable criteria for identifying when the fishery to which the plan applies is overfished." The National Standard Guidelines (NSGs) require the specification of "status determination criteria" (63 FR 24212). These criteria are to be "expressed in a way that enables the Council and Secretary to monitor the stock or stock complex and determine annually whether overfishing is occurring and whether the stock or stock complex is overfished."

The National Standard Guidelines define overfished stock conditions and overfishing. According to the NSGs, an overfished stock is one "whose size is sufficiently small that a change in management practices is required in order to achieve an appropriate level and rate of rebuilding." A stock is considered overfished when its size falls below the minimum stock size threshold (MSST). The Magnuson-Stevens Act requires a rebuilding plan for stocks that are overfished. According to the NSGs, overfishing "occurs whenever a stock or stock complex is subjected to a rate or level of fishing mortality that jeopardizes the capacity of a stock or stock complex to produce MSY on a continuing basis." Overfishing is considered to occur if the maximum fishing mortality threshold (MFMT) is exceeded for one year or more.

Reference point approaches for red crab do not establish a fixed metric or approach to measuring stock biomass or exploitation. Based on the current FMP, overfished stock status and overfishing for red crab should be defined in terms of the best available measures of stock biomass and exploitation or fishing mortality relative to the value of the measures under MSY conditions. Choice of the particular measure or proxy depends on best available data and circumstances but a list of potential proxies and conditions is described in the FMP. In particular, based on the FMP, the red crab stock will be considered to be in an overfished condition if one of the following three conditions is met:

Condition 1 -- The current biomass of red crab is below ½ B_{MSY} in the New England Council's management area (excluding the Gulf of Maine).

Condition 2 -- The annual fleet average CPUE, measured as marketable crabs landed per trap haul, continues to decline below a baseline level for three or more consecutive years.

Condition 3 -- The annual fleet average CPUE, measured as marketable crabs landed per trap haul, falls below a minimum threshold level in any single year.

Similarly two potential approaches or proxies for identifying overfishing are described:

Proxy #1: F / F_{MSY} -- It is common for data sparse stocks to estimate trends in fishing mortality as an exploitation ratio, i.e., landings or catch divided by an index of abundance, usually from a survey. As a proxy for F_{MSY}, Councils in the past have selected an exploitation level that existed during a time with no trend in biomass at an intermediate biomass level.

Proxy #2: Landings / MSY – In the absence of other information, overfishing can be defined as catches in excess of an estimate of MSY. Although crude, provides an indication of current fishing effort relative to MSY conditions.\

The FMP describes a default control rule (figure 3) that could be used by managers, although this has proved impractical due to lack of biomass, exploitation, natural mortality and reference point estimates.

Current reference points

Information in this section is summarized from NEFSC (2006b). The reference point used as a fishing mortality threshold is MSY = 2,830 mt (6.24 million pounds).
The reference point used as a biomass target is B_{MSY} = 18,867 mt (41.6 million pounds) of male red crabs 102+ mm CW (4" CW). The reference point used as a biomass threshold reference point ½ B_{MSY} = 9,434 mt. A suggested CPUE baseline (presumably for use as a target) is 26-29 market-size crabs per trap, before adjustment for an equivalent number of 102 mm (4") CW market-size crabs.

Logic and justifications

In view of survey data limitations and infrequency of stock assessments for red crab, a landings-based BRP (e.g. estimate of MSY) for overall exploitation is appropriate for use as a threshold for exploitation rates in deep-sea red crab.

Serchuk's (1977) original MSY estimate (1,247 mt or 2.75 million lbs) assumed an underlying Schafer surplus production model, and used estimated biomass for male red crabs 114+ mm CW from the 1974 camera/trawl survey as an estimate of virgin biomass B_0 (114 mm CW was the minimum marketable size at that time). Based on the Schaefer surplus production model, MSY= $\frac{1}{2}MB_0$ and it was assumed that $F_{MSY} \cong M$. For the original red crab estimate, M=0.2 y^{-1} and B_0=24,948 mt of male red crabs 114+ mm CW.

The MSY estimate (2,903 mt) currently used by managers was made using the same formula and revised values for M and B_0. The revised value for natural mortality M=0.15 y^{-1} was thought to be a better estimate than M=0.2 y^{-1} for red crab. The original B_0 value was adjusted downward to account for part of the survey being in Canadian waters, adjusted upward to include male crabs 102 mm (4") CW and larger, as compared to the 1974 marketable size of 114 mm (4.5") CW, and adjusted upward again to account for the fact that the area fished is larger than the area surveyed. The adjustments took away biomass which now belongs to Canada, and added biomass to account for the area of the fishery south of the survey boundary to Cape Hatteras.

Reference point weaknesses

In the most recent stock assessments (NEFSC 2006) the current MSY and B_{MSY} estimates for red crabs were criticized and judged unreliable due to uncertainty about biological parameters and the model used to calculate MSY. New estimates were not developed due to lack of information about growth, longevity and trends in abundance.

Relatively little new information has become available since the last assessment. However, limited data for related species (*Geryon maritae*; Mellville-Smith 1989) suggest that M may be as low as 0.1 y^{-1}, which is lower than the previous estimates (0.15 and 0.2 y^{-1}).

The assumption that $F_{MSY}=M$ has been criticized recently. Walters and Martell (2004) suggest that F_{MSY} is lower and approximately 0.8M for many species.
The assumption that B_{MSY} = ½B_0 (Schaefer surplus production curve) is reasonable if the underlying spawner-recruit relationship is a Ricker curve. However, $B_{MSY}<$ ½B_0 if the underlying spawner-recruit relationship is a Beverton-Holt curve. Beverton-Holt recruitment dynamics are more likely for red crab because there is no known biological mechanism that might result in maximum recruitment at intermediate spawning biomass levels.

The current B_{MSY} estimate of 18,867 mt in the FMP is for male red crabs 102+ mm CW (4") which is not representative of current fishery conditions. The current fishery lands male red crabs 80+ mm and the L50 for current fishery selectivity is 92 mm CW.

The survey biomass for 1974 may be a poor estimate of B_0 because of statistical variance in the estimate (variances are not available for the estimate), uncertainty about effective area sampled by the camera sled, or because some fishing had already taken place prior to 1974. The total biomass for male red crabs during 2003-2005 (56,443 mt) exceeds the estimate for 1974 (32,190 mt) despite consistent fishing indicating that the estimate for 1974 is a poor estimate of B_0.

The fishery appears to have substantially reduced the abundance of the largest male red crabs. Smaller male crabs may not be able to mate with large females. There is concern that reduced abundance of large male crabs may lead to sperm limitation and reduced levels of egg production if there are no males left in the population to mate with the larger females.
Landings per unit of fishing effort data (LPUE) are mentioned in the FMP as a baseline stock biomass indicator for red crab but LPUE data have proven difficult to interpret, particularly as long time series (NEFSC 2006a).

Options and recommendations

This section outlines a range of options for exploitation and biomass based biological reference points to be used managing deep-sea red crab in the management area outside the Gulf of Maine.
The exploitation BRPs described here are thresholds specified in terms of landed weight (yield). Yield based approaches are the only practical approach for red crab because the only fishery dependent or fishery independent data routinely available for red crabs are landings. The options for yield based BRPs are intended as proxies for landings at F_{MSY}.

Options outlined below emphasize the most reliable information sources for red crab, which are landings since 1982 and biomass, abundance and size composition data the most recent camera/trawl survey conducted during 2003-2005, and size composition data from the original camera/trawl survey conducted during 1974. Biomass estimates from 1974 are less reliable and more uncertain because of questions about the effective area sampled by cameras in that survey. Uncertainty about biomass estimates makes trend analysis uncertain. Size composition data from 1974 are more reliable and are comparable to size composition data from 2003-2005 because bottom trawls and towing protocols used in 1974 were well documented and because trawls and protocols used in later years were the same.

Fishing for females

All options outlined in this report assume a male only fishery for deep-sea red crab. None are applicable to fishery involving female red crabs. If a female red crab fishery is ever established, then all yield- and biomass based BRPs should be revaluated.

Marketable sizes and fishery selectivity

In laying out options for BRPs, we assume that fishery selectivity in the future will be the same as during 2003-2005. As described above, fishery selectivity for red crab has changed over time. Marketable size males were 114+ mm CW during the late 1970s. Based on the last stock assessment, the selectivity pattern in the current fishery follows a steeply increasing logistic pattern with selectivity near 0% at 80 mm CW, 50% selectivity at 92 mm CW and nearly 100% at 120 mm CW. If fishery selectivity changes, then all yield- and biomass based BRPs should be reevaluated.

OPTIONS for a Gulf of Maine stock

The management area for red crab excludes the Gulf of Maine and this situation complicates the development of biomass based BRPs. Red crabs in the Gulf of Maine (where little or no fishing occurs) and red crabs in the Southern New England and the Mid-Atlantic regions where (fishing occurs) are considered to be a single US stock. It is possible that depletion of red crabs south of Georges Bank might be "hidden" by including some level of unfished biomass in the Gulf of Maine as part of the stock as a whole, to the detriment of the entire stock and the fishery. Thus, the separation of red crabs into one management area and an area with no active management complicates specification and probably reduces the potential benefits of BRPs.

Under these conditions, it may be advisable to manage the areas north (Gulf of Maine) and south (Southern New England and Mid-Atlantic areas) as separate stocks. Red crab are a demersal species that migrate ontogenetically and seasonally from shallow to deep but there is no evidence of strong migratory movement of juveniles and adults along the coast. Thus, localized depletion may occur in red crabs due to continuous fishing in areas south of Georges Bank. The shallow waters and geography of Georges Bank effectively separate the Gulf of Maine from other habitat areas along the US coast. Red crabs in the Gulf of Maine appear to be smaller than red crabs in southern areas where the fishery is occurring, suggesting differences in growth rates and other biological characteristics. However, it is unlikely that red crabs in different areas off the northeast coast of the US differ genetically. It is also likely that recruitment is linked to some extent along the entire US coast due to transport of larvae in currents.

Two options are proposed.

Option 1: Continue to manage a single US stock of red crabs. The main advantages of this option are minimization and simplicity of regulations. The main disadvantages are loss or potential benefits from BRPs.

Option 2: Manage red crab in the Gulf of Maine and areas south of Georges Bank (Southern New England and Mid-Atlantic regions) as separate stocks.

Under this option, the exploitation BRP used to define overfishing for the Gulf of Maine stock would be F_{MSY} or the best available proxy. BRPs used to define the biomass target and biomass threshold for the Gulf of Maine would be B_{MSY} and $\frac{1}{2}B_{MSY}$ or the best available proxies. F_{MSY} and B_{MSY} for the Gulf of Maine are currently unknown and would have to be determined if interest in a Gulf of Maine red crab fishery develops. One or more special surveys designed to target red crabs would likely be required.

The main disadvantages of this option are increased regulations and complexity although any increases would be modest. The main advantage would be increased benefits of BRPs for red crab in the area were fishing occurs.

The second option (separate stocks) is recommended because the hypothesis of two stocks is scientifically credible, in view of restricted adult movement around Georges Bank and smaller red crabs in the Gulf of Maine, and because the potential utility of BRPs for the fished and unfished stock areas is increased. Under current legislation, BRPs used to define overfishing and overfished stock conditions must apply to entire stocks. Overfishing definitions for parts of stocks, such as the current management area for red crab, are apparently not allowed. Therefore, meaningful BRPs that address only red crab in the current management area appear impractical. *The review panel did not discuss management of deep sea red crabs in the Gulf of Maine.*

OPTIONS to regulate minimum legal size for male red crabs

Minimum size regulations may be desirable and should be evaluated for use in the red crab fishery. Minimum size regulations are used with some success in many crab and lobster fisheries. It is much easier to recommend biomass based reference points once the fishable stock (including minimum size) is clearly established and BRPs for a specified fishable stock are likely to be more meaningful and useful. Moreover, none of the options for exploitation and biomass based BRPs in this report deal effectively with concerns that sperm limitation may result from removal of large males by fishing. Exploitation and biomass based BRPs are indirect approaches to dealing with these potential issues.

Because marketable sizes, fishery selectivity and potential sperm limitation are important, three options for regulating minimum marketable sizes are presented for consideration by managers. Detailed analysis of this topic is an important area for research which should be carried out as soon as possible under any option because the full range of cost and benefits to the stock and fishery have not bet identified.

Option 1: No action. The main advantage is minimal impact on the fishery and minimal management costs. There is no evidence of serious problems in the fishery so no actions to regulate minimum legal size may be necessary. Minimum legal size regulations could be implemented in the future if required. The main disadvantage is the potential for changes in marketable sizes that tend to make BRPs for deep-sea red crabs moot. It is also possible that shifts in marketable sizes could exacerbate loss of large males which may be important for successful reproduction.

Option 2: Implement a minimum legal size for red crab that would leave some larger males in the population yet allow for a significant portion of crabs currently landed to remain marketable. This option would prohibit landings of male red crabs less than a specified CW. This minimum legal size should be close to the current minimum marketable size, such as 85-90 mm CW, to minimize fishery impacts yet large enough to leave males suitable for mating with newly mature females. With this option in place further losses of large males and the potential for sperm limitation in the population might be minimized. BRPs for red crabs would be more meaningful and useful if the fishable stock is defined.

Option 3: Defer minimum legal size regulations until more analysis is carried out to determine the optimum minimum legal size from the fishery and biological perspectives. This option is basically a combination of options 1 and 2.

Option 2 is recommended to increase potential benefits of BRPs and to help avoid potential problems with loss of large males. Impacts on the current fishery would be minimal.

The review panel did not discuss minimum legal size for male red crabs.

Biomass based biological reference points

As described above, biomass based reference points can be outlined for red crabs but data limitations and infrequent assessments will probably undermine their utility. Exploitation (yield-based) reference points are likely to be more important in a practical sense for deep-sea red crabs.

Some MSY analyses and estimates described in this report for red crab assume virgin or near virgin biomass conditions during 1974. Many are basically trend analyses which assume that biomass estimates for 1974 and 2003-2005 are directly comparable. The results of these analyses are uncertain to the extent that biomass estimates for 1974 are uncertain because of questions about the area of the sea floor the camera sled was able to illuminate and photograph clearly during the 1974 survey. Biomass estimates from more recent 2003-2005 surveys are better understood, better documented and the area covered by the cameras is well defined. Recent estimates were affected by some avoidance behavior that resulted in negative bias and some underestimation of stock biomass. Avoidance behavior may affect 1974 estimates as well but uncertainty about the effective area of the camera is most important. Biomass estimates for 1974 are also uncertain because biomass estimates for all but large male crabs were substantially higher for 2003-2005 than for 1974, despite substantial fishery removals during 1974-2003.

OPTIONS for biomass based BRPs

Terms of Reference and NSGs require biomass based BRPs that describe target and threshold biomass levels. It is possible to define biomass based BRPs for red crabs but they are likely to be of little use because of lack of stock assessments, lack of useful survey data and difficulties in interpreting fishery catch rates (LPUE). None of the proposed options for biomass BRPs involve commercial catch rates (LPUE) because they have proven difficult to interpret for red crab (NEFSC 2006).

Three proposed options for B_{MSY} estimates that could be used as target BRPs for red crabs are described below. In each case, the threshold BRP would be ½ of the B_{MSY} estimate or proxy.

Option	B_{MSY} (males only)
1	18,867 mt 102+ mm CW
2	16,904 mt fishable sizes
3	36,253 mt fishable sizes

Option 1: Status quo or no action (Listed in red crab FMP, 2002, Section 3.6.4). This gives a biomass based target B_{MSY} =18,867 mt of male red crabs 102+ mm CW, developed from the approximation $MSY = ½MB_0$ where B_0 was the estimated biomass of male red crabs during 1974 with adjustments for male

biomass at size and for areas not sampled in the survey. The biomass threshold that defines an overfished stock biomass is ½B_{MSY} = 9,434 mt. Weaknesses with Option 1 are described in earlier section of this report "Reference Point Weaknesses". Weaknesses are related to underlying assumptions about the spawner recruit curve, what B_0 represents in terms of virgin biomass, and M.

Option 2: Use the updated estimate of MSY (to be selected, see below) and current fishable biomass from the most recent assessment to estimate B_{MSY}. The biomass threshold that defines overfished stock biomass conditions is ½ B_{MSY}.

The main advantage of Option 2 is ensuring that biomass BRPs are consistent with exploitation based BRPs. If virgin biomass is very uncertain, then it may be better to base biomass reference points on the MSY proxy or estimate of sustainable catch. The main disadvantage is that it necessitates additional information about stock productivity. In addition, it may provide a poor estimate of B_{MSY} if the F_{MSY} proxy is inaccurate or the estimate of sustainable yield is substantially different from MSY.

In particular, assume $F_{MSY} = cM$ where c=0.7 (see below) and the natural mortality rate M= 0.15 y^{-1} (see below), then MSY= F_{MSY} B_{MSY} = 0.7(0.15) B_{MSY} = 0.105 B_{MSY} and B_{MSY} = MSY / 0.105 = 9.52 MSY. For example, if MSY= 1775 mt (the long term average catch and within the range of sustainable yield and MSY proxy options given below), then the biomass target B_{MSY} = 9.52 x 1775 = 16,904 mt fishable biomass and the biomass threshold B_{MSY} /2 = 8,452 mt fishable biomass.

Option 3: Use the most recent estimate of fishable biomass from the last assessment (36,247 mt) as B_{MSY}. The biomass threshold that defines overfished stock biomass conditions is ½ B_{MSY}.

The main advantage of Option 3 is that it is based on the relatively reliable 2003-2005 biomass estimate. As described above, uncertainties about the 1974 biomass estimate for red crab may preclude its use in estimating virgin biomass. The stock shows signs of fishing down (reduction in abundance of large males) expected under fishing at MSY levels. Current fishing mortality rates appear to be relatively low (F=0.055 y^{-1} in the managed stock area ignoring discards and no more than 0.1 y^{-1} including discards). These fishery induced mortality estimates are comparable to the range of F_{MSY} levels (F_{MSY} =0.6 M to 0.8 M, with M=0.1-0.2 y-1) that might be considered for red crabs and potentially sustainable. The main disadvantage is the possibility that current biomass is substantially larger or smaller than B_{MSY}.

Option 2 (use the updated estimate of MSY to specify B_{MSY}) is recommended by the Working Group because virgin biomass is uncertain. Option 1 is not recommended because it involves poor approximations to F_{MSY} and B_{MSY}. Option 3 is not recommended because it implies MSY= F_{MSY} B_{MSY} levels of about 0.7 (0.1) * 36,253 = 2,538 mt per year. This estimate is substantially larger than the long term average catch which has a pronounced effect on the relative abundance of large males.

The Peer Review Panel recommended Option 1 for B_{MSY}. The Panel did not recommend changing B_{MSY} or the B_{MSY} proxy for red crab, due to concerns about the shifting size of *marketable crabs and fishery-induced size frequency changes in the population. A simple biomass-based B_{MSY} proxy would not be reliable under the present circumstances of the fishery.*

Options for exploitation based BRPs

All of the options for exploitation based BRPs in this report are specified in terms of landings (yield) because landings are the only data consistently available for the fishery. Landings based BRPs are also desirable for red crabs because they are simple and easy for managers to use outside the formal stock assessment process and without extensive review.

Ideally, all exploitation BRPs for red crabs based on landings would be MSY estimates or proxies to be used as thresholds that define overfishing. In principal, these BRPs are not used as targets. In particular, current NSGs indicate that managers may specify any annual catch limit (ACL) as long as exploitation is below the exploitation threshold BRP. In other words, managers are expected to consider uncertainties and risks in setting ACLs in addition to not exceeding the threshold reference point. In this report, we focus primarily on uncertainties about the reference points themselves and ignore many of the uncertainties managers face in setting ACLs.

A number of the methods used to calculate potential exploitation based BRPs are estimators for “sustainable” catch levels, rather than estimates or proxies for MSY. There is no guarantee that sustainable catch levels calculated for red crab are near MSY. Sustainable yield estimates are often estimates of average catch with or without adjustments for unsustainable “windfall” catches that may occur as virgin stock is fished down towards B_{MSY}. MSY is the maximum sustainable catch level at biomass levels usually less than ½ virgin biomass.

A number of the methods used in this report to calculate potential exploitation based BRPs are equilibrium estimators that assume constant recruitment, growth and mortality over the period of years in the model. Equilibrium estimators are often used in data poor circumstances but they tend to perform poorly in non-equilibrium situations. Size composition data from surveys during 1974 and 2003-2005 indicate changes in recruitment because small male and female red crabs were abundant during the latter survey. Changes in growth and recruitment would, in fact, be expected as the near virgin stock in 1974 was fished down over several decades. Results of the equilibrium estimators are uncertain to the extent that equilibrium assumptions may have been violated.

We used 4 methods to estimate MSY or proxies thereof:

1) Long-term average catch. We can make the argument that if CPUE in pounds per day at sea has been relatively stable and the biomass of currently marketable red crabs hasn’t changed much from 1974 to 2005, then the level of fishing on the population since the 1970s must be sustainable. If summed recorded landings from 1973-2007 (35 years) equal 62,132mt, then the mean annual take of red crab has been 1,775mt, which is slightly less than mean landings since 2002.

2) Updated yield equation. The equation used to calculate MSY for the FMP was Y = (0.5)(M)(B_0) = (0.5)(0.15)(B_0 of males >114mm). However, $B_{MSY} < ½B_0$ if the underlying spawner-recruit relationship is a Beverton-Holt curve. Beverton-Holt recruitment dynamics are more likely for red crab because there is no known biological mechanism that might result in maximum recruitment at intermediate spawning biomass levels. Secondly, the ratio of F_{MSY} to M at maximum sustainable yield has been found to be less than one for most fisheries (Walters and Martell 2004). A coefficient c should be applied to M that is often 0.8 but for stocks more

vulnerable to overfishing can be as low as 0.5. To update the equation to match the conditions of the current red crab fishery, the B_0 must be for males smaller than the >114mm CW it was originally calculated for. So that leaves the equation Y = (0.4)(*c*)(*M*)(B_0 fishable males). We used a range of *M* values and calculated MSYs based on both the 1974 and 2003-2005 survey biomass of fishable males.

3) Depletion-corrected average catch (DCAC) model. The addition of a second survey allowed us to run two models which use length frequency or abundance data from two points in time to look at potential sustainable yields. The DCAC model input consists of summed annual landings, an estimate of *M*, an estimate of the F_{MSY} to *M* ratio, the amount of depletion between the two surveys and the number of years between them. It calculates a sustainable yield of a population after accounting for the "windfall" which occurs at the beginning of a fishery. We ran the model using several different estimates of *M*. For model details see appendix 2.

4) Two-point boundary model. This approach also uses abundance data from 2 points in time, and was run using various values of *M*. Estimates of median recruitment of males and females of various sizes, average *F*, and catch at equilibrium were derived for male and female red crabs from the 1974 and 2003-2005 surveys, and landings from 1974 to 2003. For model details see appendix 3.

Most of the yield based reference points presented in this report (Table 3) are lower than the current estimate of MSY (2830 mt) and target TAC (2688 mt). Most are lower than the observed catches during some years. Most of the estimates are reasonably consistent, possibly because they are based on average landings or because they assume fishable stock biomass levels were similar during 1974 and 2003-2005. The similarity of many of the new MSY estimates (figure 4) to the long-term average catch (from 1973 to 2007, 1775 mt) supports the idea that this level of landings is sustainable. Recent catches from 2002 to 2007 (mean 1853 mt) have been in this range, yet declining over the last few years. We recommend a catch limit that mimics both recent and long term mean annual landings, and suggest the current MSY of 2830 mt is not sustainable.

The review panel agreed that the MSY calculated for the FMP (2,830 mt) is not reliable. If the assumption that the changes in red crab population structure were caused by fishing is true, then previous higher catches have not been at sustainable MSY levels. The review panel concluded that, using the best available scientific information, estimates of MSY for male crabs only was in the range of 1700-1900 mt. The depletion corrected average catch model (DCAC), which estimated MSY to be very similar to the long-term mean catch, was deemed an acceptable model for this rarely-surveyed resource. The panel found no reason to change the overfishing definition of catch>MSY.

The panel noted that the change in the size distribution of landed male crabs over time may introduce uncertainty in the DCAC model. Even though the data were standardized to the same size structure, it is unclear how the removal of smaller and smaller male crabs over time may affect the model estimates of BRPs.

The review panel suggested that BRPs based on size and sex ratio may be useful in the future due to the importance of preventing sperm limitation in the red crab population. Unfortunately, that would require regular surveying, since fishery-dependent data does not give an accurate picture of the whole population as large males are targeted and the crabs are generally segregated by sex.

Since there is evidence the red crab fishery may be moving southward into previously lightly-fished areas as large males are depleted in the traditional fishing areas, the review panel noted the estimated BRPs are for the current area being fished and/or the extent of the surveys.

Scientific risks and uncertainties

Risks and uncertainties regarding BRPs for deep-sea red crabs are described below which are important in the context of choosing among BRP options, and in setting ACLs once BRPs are chosen. Risks to the stock due to overharvest and to the fishery due to foregone harvest are described in general terms but have not been quantified (no formal risk analyses were carried out).

Biomass based BRPs are difficult to evaluate for red crabs at this time due to lack of routinely available information about biomass levels and trends, and infrequent stock assessments. Therefore, risks and uncertainties regarding exploitation based BRPs are particularly important.

The following key uncertainties are listed in approximate order of importance.

a) There is a great deal of uncertainty about fundamental life history parameters in red crab, including longevity and natural mortality, growth and maturity, and reproductive biology. There is also uncertainty about whether red crabs have a terminal molt and the extent to which females can store sperm.
b) There is no available information about the spawner-recruit pattern and recruitment variability in red crab. There is uncertainty about the potential productivity of red crab due to uncertainty about fundamental life history parameters and recruitment.
c) Minimum marketable sizes and fishery size selectivity have changes since the early 1970s and processors now accept smaller male red crabs. There are no management measures regulating minimum size. Thus future fishery selectivity patterns are uncertain.
d) Based on the last stock assessment (NEFSC 2006a; 2006b), there is no evidence of serious problems in the red crab population (fishery induced mortality rates are $< 0.1\ y^{-1}$) and recruitment was apparently occurring during 2003-2005. However, survey size composition data from 1974 and 2003-2005 show reduced abundance of large males (114+ CW) probably due to fishing. There is little uncertainty about reductions in occurrence of large males. There are questions about the potential importance of large males in spawning. In particular, loss of large males may affect reproductive capacity of the red crab stock. These questions have a sound logical basis but have not been fully investigated.
e) Discards of undersize males and females are thought to be about 30% of total catch but the estimates are uncertain. Mortality of discarded crabs was relatively low in a recent study (~5%) but the estimate is uncertain and may be higher during routine fishing.
f) Some of the methods used to calculate biological reference points in this report rely heavily on landings data collected during a period when exploitation levels were relatively low. Historical catches may understate MSY to the extent that fishing mortality has been less than F_{MSY} during recent years. Thus, there is appreciable risk that reference points in this report will result in unnecessarily foregone catches.
g) Some of the methods used to calculate biological reference points in this report involved equilibrium assumptions that may not be justified for red crab. The potential effects of the equilibrium assumptions are uncertain.

h) As noted above, biomass estimates from the camera/trawl survey during 1974 are uncertain because of questions about the effective area searched by camera. Uncertainty in the 1974 biomass estimate increases uncertainty in BRP calculations that evaluate long term biomass trends or use the 1974 survey to characterize virgin or near-virgin stock levels.
i) Recent red crab biomass estimates from surveys during 2003-2005 have a negative bias due to a statistically significant level of red crab avoidance behavior. The magnitudes of red crab avoidance behavior and bias have not been evaluated.
j) There is uncertainty about whether new NEFSC bottom trawl surveys will provide useful information about red crabs. Available data from comparative fishing experiments provide little evidence one way or the other in this regard.
k) Changes in fishing locations have occurred during recent years, presumably due to localized depletion.

The review panel, in their report under "advice about scientific uncertainties" emphasized what they thought were the most significant sources of uncertainty. Under "observation uncertainty", they listed aspects of the biology, the survey and the fishery for red crab. Regarding red crab biology, the most significant sources of uncertainty were the lack of basic knowledge of life history, especially maximum age, growth per molt, intermolt period, and the occurrence of a terminal molt. Seasonal changes in distribution were also noted as a source of possible uncertainty.

Uncertainties involving the surveys exist because only two have been conducted (30 years apart). Also, there are concerns about comparability of the two surveys because of uncertainty about how crab counts from the illuminated area in the first survey were expanded and extrapolated to estimate the number of crabs in the entire region.

There is also uncertainty surrounding the fishery and the distribution of effort both spatially and temporally, and whether the distribution of the crabs was affecting the behavior of the fishery. The panel noted that an assumption of all the red crab analyses was that the pattern of harvest was from a stationary population.

In terms of "process uncertainty", the panel emphasized several possible sources. The first was that there is no knowledge of the influence of male to female ratios, in both number and size, on reproductive potential. The removal of a significant portion of the large males over time may have significant consequences on the population as males must be larger than females to mate. Other process uncertainties are the fact that the fishery may be changing its distribution and thus changing availability patterns, and the unreliability of the VTR discard data.

Research recommendations

a) Establish a regular schedule for surveys that provide useful information about deep-sea red crab. This is the most important research recommendation for red crabs.
b) Develop practical survey approaches for red crab in deep water. Recent cooperative work indicates that towed body video surveys are accurate and useful for sea scallops. It is likely that the same equipment and approaches would be useful for deep-sea red crab.
c) Evaluate the importance of large male red crabs in reproduction considering the size distribution and molting cycle of females, sperm storage, length of the mating season, duration of copulation and other key parameters.
d) Studies to refine estimates of growth parameters, longevity, natural mortality and reproductive parameters are needed.

e) Place scientific observers on board fishing vessels during routine fishing trips to collect data about discards.

The review panel recommended several additional research needs and general suggestions which would reduce the uncertainties in the BRPs:

a) Consider additional fishery-independent surveys, with continued industry support and involvement. These cooperative surveys might include standardized trap-based sampling or HABCAM (cameara) surveys. The panel noted that the industry is already supporting a sizeable tagging program.

b) Additional information on relative sizes of mating pairs and its consequences on reproductive potential (sperm limitation) would allow for the inclusion of additional size-based BRPs

i) Consider simulation modeling to explore the response of the population sex ratio to different exploitation patterns to determine whether sex ratios may serve as a tool to inform management on current catch rates. The review team noted that such an approach would only work if knowledge of the population wide sex ratio was indexed.

c) Studies of brood production, incubation period, and pattern of sperm storage would be helpful.

d) Studies to refine growth (intermolt period and growth per molt) and longevity estimates would improve understanding of stock dynamics.

e) Assessment of whether females, in particular, exhibit a terminal molt would help development of growth models.

f) Information on movement and behavior of crabs within their range would be of utility.

g) Abundance-habitat relationships.

h) Role of economic factors in crab and other fisheries may alter distribution and interpretation of fishing effort.

Red crab size composition analysis

Based on the ratio of minimum mature size, and ratio of mean size in 1974, we assume that males must be at least 25% larger than females to mate successfully (alternative assumptions could be explored). This analysis examines the impact of the fishery on the size structure of the population, specifically with regard to the ratio of number of males to the number of females small enough for the males to fertilize.

Direct analysis of survey results has the benefit of being able to explore the sex ratio in terms of observed densities of crabs, but lacks the ability to interpret those results in terms of a reference point of no fishing. It may be possible to interpret the 1974 survey as representing size distributions under light fishing, so that 1974 could serve directly as a reference distribution.

Direct analysis of survey densities

Table 1a shows summary statistics of mature red crabs from the 1974 and 2003-2005 surveys. Females are assumed to mature at 70mm, and males at 90mm. The densities of mature male crabs per 30-minute tow declined slightly, but the density of female crabs increased substantially in the later survey. This poses some difficulty for interpretation, with the main hypotheses being that it is due to imprecision (including differences in survey locations—all this needs to be explored), or alternatively that it is due to exploitation effects on a population that otherwise would have been more abundant in the later period. If the 1974 ratio of males to females is applied to the density of females in 2003-2005, the expected male density would have been approximately 30, in which case the relatively low observed value of 15 is presumably due to exploitation effects. Mean size of females is similar in the two surveys, but mean size of males declined as would be expected from exploitation effects including a shift of minimum marketable size from 114mm to 90mm. By tabulating the sum of densities of females smaller than the minimum sized female each male size class is capable of mating with, table 1a below shows the mean number of females available to the males, weighted by the size frequency of males. In order to maintain a similar level of fertilization, the average male in 2003-2005 must mate with 2.33 times the number of females that it did in 1974. If the1974 size composition already showed exploitation effects, the population impact is greater than is shown in table 1a.

Table 1a. Summary of size composition analysis.

Survey date	1974		2003-2005	
	males	females	males	females
Size at maturity (mm)	90	70	90	70
total density (n per 30-min tow)	17.2	17.8	15.0	31.3
mean size of mature crabs (mm)	113.8	94.1	105.7	95.1
mean ratio of size-dependent available females to males	25.3		58.9

Depletion-Adjusted Average Catch Model

Alec MacCall, NMFS/SWFSC/FED (draft 9/6/07)

Unlike the classic fishery problem of estimating MSY, data-poor fishery analysis must be content simply to estimate a yield that is likely to be sustainable. While absurdly low yield estimates would have this property, they are of little practical use. Here, the problem is to identify a moderately high yield that is sustainable, while having a low chance that the estimated yield level greatly exceeds MSY and therefore is a dangerous overestimate that could inadvertently cause overfishing and potentially lead to resource depletion before the error can be detected in the course of fishery monitoring and management.

Perhaps the most direct evidence for a sustainable yield would be a prolonged period over which that yield has been taken without indication of a reduction in resource abundance.

The estimate of sustainable yield would be nothing more than the long-term average annual catch over that period. However, it is rare that a resource is exploited without some change in underlying abundance. If the resource declines in abundance (which is necessarily the case for newly-developed fisheries), a portion of the associated catch stream is derived from that one-time decline, and does not represent potential future yield supported by sustainable production. If that non-sustainable portion is mistakenly included in the averaging procedure, the average will tend to overestimate the sustainable yield. This error has been frequently made in fishery management. Based on these concepts, we present a simple method for estimating sustainable catch levels when the data available are little more than a time series of catches. The method needs extensive testing, both on simulated data and on cases where reliable assessments exist for comparison. So far, test cases indicate that it may be a robust calculation.

The Windfall/Sustainable Yield Ratio

The old potential yield formula Ypot = 0.5*M* $B_{UNFISHED}$ (Alverson and Pereyra, 1969; Gulland, 1970) is based on combining two approximations: 1) that B_{MSY} occurs at 0.5*$B_{UNFISHED}$, and 2) that F_{MSY} = M. In this and the following calculations fishing mortality rate (F) and exploitation rate are treated as roughly equivalent.

However, it is possible to take the potential yield rationale one step farther, and calculate the ratio of the one-time “windfall” harvest (W) due to reducing the abundance from $B_{UNFISHED}$ to the assumed B_{MSY} level. After that reduction in biomass has occurred, a tentatively sustainable annual yield Y is given by the potential yield formula. So we have the following simple relationships:

$Y = 0.5*M* B_{UNFISHED}$, and

$W = 0.5* B_{UNFISHED}$.

Under the potential yield assumptions, the ratio of one-time windfall yield to sustainable yield is the windfall/sustainable yield ratio (or simply the “windfall ratio”) W/Y = 1/M. For example, if M = 0.1, the windfall is equal to 10 units of annual sustainable yield.

An Update

The assumptions underlying the potential yield formula are out-of-date, and merit reconsideration. Most stock-recruitment relationships indicate that MSY of fishes occurs somewhat below the level of 0.5*

$B_{UNFISHED}$. We replace the value of 0.5 with a value of 0.4 as a better approximation of common stock-recruitment relationships.

The F_{MSY} = M assumption also requires revision, as fishery experience has shown it tends to be too high, and should be replaced by a F_{MSY} = c*M assumption (Deriso, 1982; Walters and Martell, 2004). Walters and Martell suggest that coefficient c is commonly around 0.8, but may be 0.6 or less for vulnerable stocks. Figure 1 shows the distribution of c values for West Coast groundfish stocks assessed in 2005. The average of c for those West Coast species is 0.62, but there is a substantial density of lower values. Because the risk is asymmetrical (ACLs are specifically intended to prevent overfishing), use of the average value is risk-prone. Consequently, we have used a value of c=0.5 in the following calculations.

The yield that is potentially sustainable under these revised assumptions is

$Y = 0.4^* B_{UNFISHED} {}^*c^*M$,

or for c = 0.5,

$Y = 0.2^* B_{UNFISHED} {}^*M$.

The windfall is based on the reduction in abundance from the beginning of the catch time series to the end of the series,

$W = Bbegin - Bend = DELTA^* B_{UNFISHED}$,

where DELTA is the fractional reduction in biomass from the beginning to the end of the time series, relative to unfished biomass. The analogous case to the potential yield formula is Bbegin = $B_{UNFISHED}$, and Bend = 0.4* $B_{UNFISHED}$, in which case DELTA = 0.6. In practice, Bbegin is rarely $B_{UNFISHED}$, and DELTA is unlikely to be known explicitly. Although data may be insufficient for use of conventional stock assessment methods, an estimate (or range) of DELTA based on expert opinion is sufficient for this calculation. The windfall ratio is now

$W/Y = DELTA/(0.4^*c^*M)$,

or in the case of c=0.5,

$W/Y = DELTA/(0.2^*M)$.

For example, in the case of fishing down from $B_{UNFISHED}$ to near B_{MSY} where DELTA=0.6, if c = 0.5, W/Y = 3/M. Thus the revised calculation gives a much larger estimate of the windfall ratio. For the previous example of M = 0.1, the windfall ratio is now estimated at 30 units of sustainable annual yield.

A Sustainable Yield Calculation

Assume that in addition to the windfall associated with reduction in stock size, each year produces one unit of annual sustainable yield. The cumulative number of annual sustainable yield units harvested from the beginning to the end of the time series is n + W/Y, where n is the length of the series. In this calculation it should not matter when the reduction in abundance actually occurs in the time series because assumed production is not a function of biomass. Of course, in view of the probable domed shape of the true production curve, the temporal pattern of exploitation may influence the approximation.

The estimate of annual sustainable yield (Ysust) is

Ysust = sum(C)/(n + W/Y).
In the special case of no change in biomass, DELTA = 0, W/Y = 0, and Ysust is the historical average catch. If abundance increases, DELTA is negative, W/Y is negative, and Ysust will be larger than the historical average catch.

Examples

The widow rockfish fishery began harvesting a nearly unexploited stock in 1981 and for the first three years, fishing was nearly unrestricted (Table 1). Reliable estimates of sustainable yield based on conventional stock assessments were not available for many years afterward. By the mid-1990s, stock assessments were producing estimates of sustainable yield ca. 5000 mtons, with indications that abundance had fallen to 20-33% of $B_{UNFISHED}$.

Application of depletion-corrected catch averaging indicates good performance of the method within a few years of the beginning of the fishery. Two alternative calculations are given in Table 1. The first calculation assumes M = 0.15, c = 0.5, and that biomass was near B_{MSY} at the end of the time period, so that DELTA = 0.6. The second calculation is closer to the most recent stock assessment (He et al., 2007) and assumes M = 0.125, c = 0.5, DELTA = 0.75 (ending biomass in year 2000 is about 25% of $B_{UNFISHED}$).

Other examples would be worth exploring, especially were they can be compared with "ground truth" from a corresponding formal stock assessment.

Low biomasses

The yields given by these calculations can only be sustained if the biomass is at or above B_{MSY}. If the resource has fallen below B_{MSY}, the currently sustainable yield (Ycurrent) is necessarily smaller. A possible approximation would be based on the ratio of Bcurrent to B_{MSY},

Ycurrent = Ysust*(Bcurrent/ B_{MSY}) if Bcurrent< B_{MSY}

Implementation

This method is most useful for species with low natural mortality rates; stocks with low mortality rates tend to pose the most serious difficulties in rebuilding from an overfished condition. As natural mortality rate increases (M > 0.2), the windfall ratio becomes relatively small, and the depletion correction has little effect on the calculation.

The relationship between F_{MSY} and M may vary among taxonomic groups of fishes, and among geographic regions, and would be a good candidate for meta-analysis. Uncertainty in parameter values can be represented by probability distributions. A Monte Carlo sampling system such as WinBUGS can easily estimate the output probability distribution resulting from specified distributions of the inputs.
With minor modifications, this method could also be applied to marine mammal populations. Although estimation of sustainable yields is not a central issue for marine mammals nowadays, the method would be especially well suited to analysis of historical whaling data, for example.

2-point boundary model

Estimation of Average Recruitment, Biomass Weighted F, and Equilibrium Catch

Two quantitative surveys of red crab abundance and long-term record of landings provide an opportunity to estimate the average recruitment necessary to support the observed time series of catch. This is accomplished by using a simple mass balance equation with boundary conditions defined as the initial and final survey values.

Process Equation

Let B_t represent the biomass at time t and specify the boundary conditions B_0 and B_T. The biomass at time t+1 can be expressed as

$$B_{t+1} = (B_t - C_t + R_t)S \qquad (1)$$

Where C_t is the total catch and R_t is total recruitment of biomass to the population. The parameter S can be thought of as either the survival rate = e^{-M} or the difference between the instantaneous rate of growth G and M or $S=e^{-(G-M)}$. For this application it was assumed that increments to population biomass via growth are included in the Rt term; therefore $S=e^{-M}$ No information is available to estimate the annual recruitment to the population but Eq. 1 can be simplified by let R_t equal a constant, say R.

$$B_{t+2} = (B_{t+1} - C_{t+1} + R)S \qquad (2)$$

Substituting Eq. 1 into 2 recursively leads to

$$B_{t+2} = ((B_t - C_t + R)S - C_{t+1} + R)S$$

$$B_{t+3} = (B_{t+2} - C_{t+2} + R)S$$

$$B_{t+3} = (((B_t - C_t + R)S - C_{t+1} + R)S - C_{t+2} + R)S$$

….

$$B_{t+T} = B_t S^{T-1} + \sum_{j=1}^{T-1} S^j R - \sum_{j=1}^{T-1} C_j S^{T-j} \qquad (3)$$

If we let B_t=B(0), B_{t+T}=B(T) and assume S then it is possible to estimate R as the average recruitment necessary to satisfy Eq. 3.

$$R = \frac{B(T) - B(0)S^{T-1} + \sum_{j=1}^{T-1} C_j S^{T-j}}{\sum_{j=1}^{T-1} S^j} \qquad (4)$$

Given the average recruitment R, the year-specific F_t can be estimated as

$$\hat{F}_t \approx \frac{C_t}{B_t + R} \qquad (5)$$

The estimates of year specific F_t are unreliable since they depend on the average recruitment estimate R. However, the average F over the period can be estimated as

$$\overline{F} = \sum_{j=1}^{T-1} \frac{\hat{F}_j}{T-1} \qquad (6)$$

The average catch sufficient to maintain the population at its current size can be estimated by setting $B_{T+1}=B_T$ in Eq. 1 and solving for C as

$$\begin{aligned} B_T &= \left(B_T - \overline{C}_{EQ} + R\right)S \\ \overline{C}_{EQ} &= R - \frac{B_T(1-S)}{S} \end{aligned} \qquad (7)$$

Eq. 4, 6 and 7 can now be used to estimate the average recruitment necessary to support the total removals between time t and t+T, the average biomass weighted F experienced by the population, and the average catch necessary to maintain the population at its current value of B_T.

Incorporating the Uncertainty in Population Size

The uncertainty in initial and final population sizes has important implications for the uncertainty in the average R, Fbar and C_{EQ}. This uncertainty can be approximated by convolving the distribution of initial population size with the final population size. Assume that the survey mean estimates are normally distributed. Let $B_t \sim N(\mu_t\ \sigma_t^2)$, $B_{t+T} \sim N(\mu_{t+T}\ \sigma_{t+T}^2)$ and $\Phi(.)$ define the cdf of the normal distribution. The inverse of the normal cdf, say $\Phi^{-1}(.)$, can be used to define population estimates for equal probability intervals

$$\begin{aligned} B_{t,\alpha} &= \Phi^{-1}\left(\mu_t, \sigma_t^2, \alpha\right), \quad \alpha = \alpha_{\min}, \ldots \alpha_{\max} \\ B_{T,\beta} &= \Phi^{-1}\left(\mu_T, \sigma_T^2, \beta\right), \quad \beta = \beta_{\min}, \ldots \beta_{\max} \end{aligned} \qquad (8)$$

Define $R_{\alpha,\beta}$ as the average recruitment obtained by substituting $B_{t,\alpha}$ and $B_{T,\beta}$ in Eq. 4 for B(0) and B(T) respectively. The sampling distribution of R and by extension, Fbar and Cbar, can now be obtained by simply matching all possible values of α with all possible values of β. More economically, one can define a small step size, say δ and evaluate $R_{\alpha,\beta}$ for equal increments between the minimum and maximum values of the cdf. The sampling distribution of R, Fbar, and Ceq is just the collection of discrete estimates since all estimates $R_{\alpha,\beta}$ have equal probabilities of occurrence = δ^2 and the sum of all δ^2 's is one.

Application to Red Crab

Estimates of R, Fbar, and C_{EQ} were derived for male and female red crab from the 1974 and 2004 fishery independent surveys (Table A3-1) and landings from 1974 to 2003 (Table A3-2). The distributions of R, Fbar and CEQ were based on convolution of 51 equal probability cut points representing a 95% confidence interval for the initial and final year biomass estimates. The convolution distribution was based on 2601 (i.e. 51 x 51) evaluations of Eq. 4. Annual survival for the base runs was assumed to be 0.86 (i.e., M=0.15)

Model results suggest that the median male recruitment is about 8500 mt per year. Historical average F between 1974 and 2004 was about 0.04 (Table A3-3). Given the population size in 2004, catches of 2,060 mt would keep the population at its current size of about 36,000 mt. This is about 16% higher than the average catch between 1973 and 2007 but 10% less than landings since 2000.

Between 1974 and 2004 the female population (>90 mm CW) increased nearly four-fold from 15 kt to 55 kt. Under the assumption that fishing mortality on the females was essentially zero, the estimated median recruitment was 9837 mt. The confidence intervals for median recruitment levels for males and females overlap which suggest comparable rates of biomass recruitment. The parameters for average recruitment and survival are confounded and the small differences in average recruitment estimates between male and female recruitment could be due to slightly different mortality rates or growth rates between sexes. For example, assuming an M=0.13 for females results in a median R of 7,810 mt that is about the same as the median R for males when M=0.15.

The sensitivity of the R, Fbar and C_{EQ} to changes in M are illustrated in Tables A3-4 to A3-6. Estimated average recruitment increases about three-fold as M increases (or S declines) from 0.05 to 0.20. The estimated equilibrium catch is relatively unchanged remaining at about 2,000 mt. Figures A3-1 and A3-2 demonstrate that as S approaches 1 the long-term catch equals the estimated average recruitment.

Table A3-1. Estimated survey biomass of male and female red crab, 1974 and 2004.

Category	Initial Biomass (SE)	Final Biomass (SE)
Fishable Biomass of Males	30,302 (6,363)	36,247 (4,612)
Female Biomass (>90 mm CW)	15,654 (3,719)	55,279 (7,033)

Atlantic Wolffish: Explanation of Corrections/Revisions in this Report

During the course of assessing Atlantic wolffish for the Northeast Data Poor Stocks Working Group Meeting, December 8-12, 2008, an incorrect conversion factor was applied to the NEFSC commercial fisheries database resulting in lower than expected commercial landings. Specifically, Atlantic wolffish landings data were extracted from the database as pounds and converted into kilograms. The landings data were then imported into a spreadsheet where it was mistakenly multiplied by 0.45359237, the conversion factor for pounds to kilograms, reducing the overall magnitude of the landings data by approximately 45%. Table 1A shows the original and corrected datasets. An example using 1964 shows corrected landings as 114.32 mt and the originally reported landings as 51.86 mt, which is 45% of the corrected amount.

Recreational catch and commercial discard data were not affected by this miscalculation. NEFSC survey indices were also unchanged. However, total catch, which is composed primarily of commercial landings and is a key component in many analyses presented in this report, was affected. Analyses that needed to be updated included the Statistical Catch at Length model (SCALE), exploitation ratios, Depletion Corrected Average Catch model (DCAC), and An Index Method model (AIM).

The SCALE model was accepted by the Peer Review Panel in December 2008 as the basis for determining biological reference points and stock status for Atlantic wolffish. The changes to commercial landings and total catch of Atlantic wolffish had mixed effects on SCALE model results. Newly estimated values of Initial Recruitment, MSY, SSB_{MSY}, and SSB_{2007}, have approximately doubled from original values, while F_{MSY}, YPR, and SSB/recruit remained mostly unchanged. The status determinations that were reported in the original version of this report still hold, and were not altered by making corrections to the commercial landings. Atlantic wolffish remains overfished (assuming a $B_{THRESHOLD}$ of ½ B_{MSY}) and overfishing status continues to be uncertain. For comparison, the original and updated (i.e., with corrected input data) estimates of Initial Recruitment, MSY, SSB_{MSY}, $SSB_{2007,}$ F_{MSY}, YPR, SSB/recruit and status determination are listed in Table 2A. In the updated section of Table 2A, inputs to SCALE model Runs 2 and 3 are the same, but Runs 2 and 3 give results corresponding to two different F_{MSY} proxies ($F_{40\%}$ and $F_{50\%}$).

Corrections were also made to catch per unit of effort indices based on observer data. Fishing effort (days fished) was double counted in the original analysis when both kept and discarded wolffish were reported by an observer. As a result of decreasing the observed effort, the magnitude of the estimated CPUE increased while the overall declining trend in CPUE remained the same. A table comparing revised and original values can be seen in Table 3A.

Corrections were made to the document with the intent to make them as seamless as possible and much of the text, figures, and tables remain unchanged. However some figures and tables were eliminated and values modified as a result of the updated analyses. A comprehensive list of changes is presented in Table 4A.

Table 1A. Differences between the originally reported NEFSC commercial fisheries database landings for Atlantic wolffish and corrected landings. Values are metric tons unless otherwise noted. The MRFSS and Discard data were not changed.

Executive Summary

Atlantic wolffish in the Gulf of Maine and Georges Bank regions inhabit the southern edge of the species distribution. Analyses herein were limited to the stock component completely within United States waters, which excluded some historically important transboundary portions of Georges Bank. There is currently no fishery management plan for the Atlantic wolffish in U.S. waters. Wolffish are associated with rough topography. Catchability of wolffish is low in NEFSC trawl surveys due to this habitat preference. Atlantic wolffish are long-lived (22 years), late maturing, and of low fecundity. Males guard the eggs in nests in the fall. Larger wolffish are caught in the spring survey compared to the fall, perhaps due to nest guarding behavior. All fishery independent survey indices show a declining trend in abundance over the time series. The commercial catch has also declined steadily since 1983. However there is no size truncation in the catch over the time series. A wolffish growth study from the 1980s in the Gulf of Maine and Georges Bank region was done by Nelson and Ross (1992). The DCAC model, AIM model, and simple exploitation ratios were examined for this assessment and presented to the Data Poor Stocks Peer Review Panel. A forward projection model, Statistical Catch At Length (SCALE), which tunes to size and age data from trawl survey recruitment and adult indices, total catch, and catch size distributions along with overall growth information, was developed for this assessment. This model was accepted by the Peer Review Panel as a basis for determining the biological reference points (BRPs) for Atlantic wolffish. The SCALE model had difficulty estimating selectivity due to the sparse data. Two different selectivity regimes were chosen to determine BRPs and their influence on stock status, using $F_{40\%}$ as a proxy for F_{MSY}. The maturation schedule of wolffish in U.S. waters is uncertain and this influences BRPs derived from the SCALE model. The sensitivity of these non-parametric BRPs was tested with a range of knife edge maturity cutoffs. Early Data-Poor Stocks Working Group meetings indicated that, given the wolffish life history, $F_{50\%}$ may be an appropriate proxy for F_{MSY} and this was presented as a third option to the Panel. Based on all SCALE model runs, the stock in 2007 is at a low biomass level (26% to 45% of B_{MSY}) and is overfished (*assuming a $B_{THRESHOLD}$ of ½ B_{MSY}). The Peer Review Panel concluded that $F_{40\%}$ is a reasonable F_{MSY} proxy and that its value is probably <0.35. The overfishing status is uncertain, and the ratio of F_{2007} to F_{MSY} falls in the range of 50% to 123%. MSY is likely in the range of 278-311 mt and SSB_{MSY} is likely in the range of 1,747-2,202 mt.

*(*Editor's note: This assumption about the definition of $B_{THRESHOLD}$ was confirmed with the Chairman of the Peer Review Panel after the December meeting.)*

Section 1. Provide the current exact, legal definitions for overfished and overfishing given in the FMP (if the definition was revised with an official FMP amendment, then give that def.). (NEFSC staff should consult with appropriate RO and Council staff that is on the DPWG to get this info).

NONE

Section 2. List the current Biological Reference Points (parameters and values). (e.g., the proxy for B_{MSY} is the 3-yr average of survey catch per tow from years 19xx to 19yy. The estimate is zzz kg/tow). Include the targets and thresholds for both overfishing and overfished, if those definitions exist.

NONE

Section 3. Explain the logic/justification for why the current definitions were adopted.
NA

Section 4. Explain weaknesses with the current definitions (e.g., not easily measured, not logical, outdated, etc.). If they are OK, say so.
NA

Section 5. (If a change to the BRPs is being recommended by the WG:) Recommend biological reference points (BRPs) and measurable BRP and MSY proxies. Provide justification for the recommendation. Be as specific as possible. If something might be proposed that is not yet measurable, then make that clear and explain what is needed to make it measurable.

A range of biological reference points were available to the Data Poor Stocks Review Panel via the forward projecting SCALE model under various model scenarios. Non-parametric biological reference points (BRP) were developed for both the selectivity L_{50} = 90 run (Run 1) and the slope = 0.15 run (Run 2) within the SCALE model using $F_{40\%}$ as a proxy for F_{MSY}. A range of knife edge maturity values were used in estimating the BRPs. Maturity as 40+ cm, a 65+ cm and 75+ cm cutoffs were used as bounds taken from NEFSC survey results and literature. The Data Poor Working Group suggested $F_{50\%}$, may be an appropriate proxy for a species which is long lived, late maturing and has low fecundity. $F_{50\%}$ BRPs were then developed for the slope =0.15 scenario. SCALE Run 2 was accepted by the Data Poor Stocks Peer Review Panel as an appropriate range of values for Atlantic wolffish biological reference points.

Section 6. Provide supporting information for Section 5.

Basic Biology and Ecology

Geographic Range

Atlantic wolffish (*Anarhichas lupus*) can be found in northern latitudes of the eastern and western North Atlantic Ocean (Figure 1). In the north and eastern Atlantic they range from eastern Greenland to Iceland, along northern Europe and the Scandinavian coast extending north and west to the Barents and White Sea's. In the northwest Atlantic they are found from Davis

Straits off of western Greenland, along Newfoundland and Labrador and continue southward through the Canadian Maritime Provinces to Cape Cod, USA. They are found infrequently in southern New England to New Jersey (Rountree, R.A. 2002). Northeast Fishery Science Centers Bottom Trawl surveys have only encountered 1 fish southwest of Martha's Vineyard, Massachusetts since 1963.

Habitats

Atlantic wolffish are demersal and prefer complex habitats with large stones and rocks which provide shelter and nesting sites (Pavlov and Novikov 1993). They are occasionally seen in soft sediments such as sand or mud substrate and likely forage for food sources in these habitats (Rountree, R.A. 2002; Falk-Petersen and Hansen 1991). They are believed to be relatively sedentary and populations localized. Tagging studies from Newfoundland, Greenland and Iceland indicate that most individuals were recaptured within short distances, ~8km, of the original tagging sites (Templeman 1984; Riget and Messtorff 1988; Jonsson 1982). Three significantly longer migrations were reported in Newfoundland ranging from 338 – 853 km (Templeman 1984).

Atlantic wolffish occupy varying depth ranges across its geographic range. In the Gulf of Maine they inhabit depths of 40 – 240 m, in Greenland and Newfoundland 0 – 600 m, in Iceland 8 – 450 m and in Norway and the Barents Sea from 10 – 215 m (Riget and Messtorff 1988; Albikovskaya 1982; Templeman 1984; Jonsson 1982; Falk-Petersen and Hansen 1991). In U.S. waters, abundance appears to be highest in the southwestern portion of the Gulf of Maine, from Jefferies Ledge to the Great South Channel, corresponding to the 100 m depth contour (Nelson and Ross 1992). Similarly, abundance is highest in the Browns Bank, Scotian shelf and northeast peak of Georges Bank areas in the Canadian portion of the Gulf of Maine (Nelson and Ross 1992). Atlantic wolffish in Newfoundland and Icelandic waters were identified as most abundant in depths 101 – 350 m and 40 - 180 m, respectively (Albikovskaya 1982; Jonsson 1982).

Temperature ranges where Atlantic wolffish occurs also deviate slightly with geographic region. Historically in the Gulf of Maine they have been associated with temperatures ranging from 0 – 11.1°C (Bigelow and Schroeder 1953). Bottom temperatures collected from NEFSC bottom trawl surveys where wolffish were encountered range from 0 – 10°C in spring and 0 – 14.3°C in fall. In Newfoundland wolffish thermal habitat ranged from -1.9 – 11.0 °C, Norway from -1.3 - 11 °C and in Iceland and Northern Europe -1.3 – 10.2 °C (Rountree, R.A. 2002; Falk-Petersen and Hansen 1991; Jonsson 1982). Laboratory studies indicate wolffish can survive a wide span of temperatures -1.7 – 17.0°C and that feeding is negatively correlated with the higher temperature extremes (Hagen and Mann 1992; King et al. 1989).

Reproduction

In general Atlantic wolffish are solitary in habit, except during mating season when bonded pairs form in spring/summer depending on geographic location (Rountree, R.A. 2002; Keats et al 1985; Pavlov and Novikov 1993). Spawning is believed to occur in September through October in the Gulf of Maine but is likely to depend on temperature and possibly photoperiod (Rountree, R.A. 2002; Pavlov and Moksness 1994). Spawning is reported to occur from August – September in Nova Scotia, during autumn in Newfoundland, September – October in Iceland, July – October in Norway, and late summer – early autumn in the White Sea (Keats et al. 1985; Templeman 1986; Jonsson 1982; Falk-Petersen, Hansen 1991; Pavlov, Novikov 1993). In the Gulf of Maine there is weak indication of a seasonal migration as wolffish may travel from shallow to deep in autumn and then deep to shallow in spring (Nelson and Ross 1992). Similar migrations occur in Iceland and the White Sea where wolffish migrate to colder temperatures before the spawning season (Pavlov and Novikov 1993; Jonsson 1982). Atlantic wolffish have the lowest fecundity compared to their relatives, the spotted wolffish (*Anarhichas minor*) and the northern wolffish (*Anarhichas denticulus*). Fecundity is related to fish size and body mass in this species and increases exponentially with length. Newfoundland mean fecundity estimates, combined from several NAFO statistical areas, range from 2,440 eggs at 40 cm to 35,320 eggs at 120 cm (Templeman 1986). In Norway a female at 60 cm produces approximately 5,000 eggs while a female 80-90 cm will lay 12,000 eggs (Falk-Petersen and Hansen 1991). Potential fecundity of wolffish in Iceland was measured between 400 and 16,000 eggs for fish at lengths of 25 and 83 cm respectively (Gunnarsson et al. 2006). Mature eggs are large measuring 5.5 – 6.8 mm in diameter (Rountree, R.A. 2002). Male Atlantic wolffish have small testes and produce small amounts of sperm peaking during late summer and autumn. These data along with morphological development of a papilla on the urogenital pore during spawning suggest internal fertilization (Pavlov and Novikov 1993; Pavlov and Moksness 1994, Johannessen et al 1993). Males have been observed guarding egg clusters for several months but it is not certain if they continue until hatching (Keats et al. 1985; Rountree, R.A. 2002). Hatching may take 3 to 9 months depending on temperature (Rountree, R.A. 2002).

Food Habits

The diet of Gulf of Maine and Georges Bank wolffish consist primarily of bivalves, gastropods, decapods and echinoderms (Nelson. Ross 1992). Wolffish possess specialized teeth, including protruding canine tusks (hence its name) and large rounded molars, which allow for removal of organisms from the sea floor and crushing of hard shelled prey (Rountree, R.A. 2002). Due to diet teeth are replaced annually (Albikovskaya 1983; Rountree, R.A. 2002). Fish have also been reported as an important food source in other regions along with amphipods and euphausiid shrimp for smaller individuals, 1 – 10 cm (Rountree, R.A. 2002; Albikovskaya 1983; Bowman et al. 2000). Travel between shelters and feeding grounds occurs during feeding periods as evidenced by crushed shells and debris observed in the vicinity of occupied shelters (Rountree, R.A. 2002; Pavlov and Novikov 1993). Fasting does occur for several months while replacing teeth, spawning and nest guarding occurs (Rountree, R.A. 2002).

Size

In the Gulf of Maine and Georges Bank regions individuals may attain lengths of 150 cm and weights of 18 kg (Goode 1884; Idoine 1998). Northeast Fishery Science Center bottom trawl surveys have captured animals ranging in size from 3 – 137 cm in spring and 4 – 120 cm in fall and with a maximum weight of 11.77 kg.

Age and Growth

Mean length at age for Atlantic wolffish in the Gulf of Maine was determined to be 22 years at 98 cm and 0 years at 4 cm (Nelson, Ross 1992). Fish over 100 cm were not sampled extensively in this study, 10 fish from 100-118 cm. Ages in the Gulf of Maine are comparable to wolffish ages in other regions, such as 21 years in east Iceland and 23 years in Norway (Gunnarsson et al. 2006; Falk-Petersen and Hansen 1991). Age 0 fish grow quickly in Icelandic waters and may reach 10.5 cm in the first year (Jonsson 1982). Gulf of Maine wolffish growth rates are faster than wolffish in Iceland, but grow fastest in the North Sea region (Nelson and Ross 1992; Liao and Lucas 2000). Growth in the Gulf of Maine for both male and female wolffish was best estimated using a Gompertz growth function, $L\infty = 98.9$ cm, $K = 0.22$ and $t_0 = 4.74$ (Nelson and Ross 1992). Female growth from Iceland has been modeled using a logistic growth function and coefficients estimated using non-linear optimization (Gauss-Newton method), results from the east and west regions were: $L\infty$ = 90.919, K = 0.230 and t_0 = 8.837 and $L\infty$ = 70.046, K = 0.378 and t_0 = 4.691, respectively (Gunnarsson et al. 2006). Von Bertalanffy growth parameters for the North Sea population of wolffish were $L\infty$ = 111.2, K = 0.12 and t_0 = -0.43 and $L\infty$ = 115.1, K = 0.11 and t_0 = -0.39, for males and females respectively (Liao and Lucas 2000).

Maturity

In the Gulf of Maine individuals are believed to reach maturity by age 5-6 when they reach approximately 47 cm total length (Nelson, Ross 1992; Templeman 1986). Size at fifty percent maturity (L_{50}) of females varies latitudinally which is likely due to the effects of temperature. Templeman (1986) showed that northern fish mature at smaller sizes than faster growing southern fish in Newfoundland. L_{50} was reported as 51.4 cm in the northern area, 61.0 cm in the intermediate region and 68.2 cm in the south. In a study somewhat contradictory to Templeman 1986, Atlantic wolffish in east Iceland, where water temperatures are colder, had larger L_{50} values than fish in the relatively warmer waters of east Iceland (Gunnarsson et al. 2006). Authors indicate that maturity may be difficult to determine using visual methods in females because of large eggs size in this species. Second generation eggs are visible in young, immature fish when the reach the cortical alveolus stage but they may not be able to spawn for several more years (Gunnarsson et al. 2006; Templeman 1986).

The US Fishery

Landings and Total Catch

NMFS Commercial Fishery Databases contain historical and current catch and effort information of Atlantic wolffish, 1963 - 2007. Data presented here are only from fishery statistical reporting areas that are completely or almost entirely within US territorial waters throughout the time series (Figure 2). The International Court of Justice in 1984 established the maritime boundary in the Gulf of Maine, known as the Hague Line, which divided US and Canadian Exclusive Economic Zones (ICJ 1984). In 1985 fishery statistical areas 523 and 524, which overlapped the US/Canada boundary in the Georges Bank region, were separated into distinct areas 551, 552, 561 and 562 (Figure 2). Disaggregating United States and Canadian landings data in areas 523 and 524 prior to 1985 was not possible so they are not reported here. Also not reported are landings in the newly created areas in US waters because they do not span the entire time frame.

US landings increased until it peaking in 1983 at 1,100 metric tons (mt) and then decline steadily until 2007, the latest complete year available, where landings were 63.32 mt (Figure 3 and Table 1). In the US, Atlantic wolffish are taken primarily as bycatch in the otter trawl fishery. Over all years, percent commercial landings of wolffish were dominated by otter trawl gear (90.83%), followed by fixed gillnets (4.33%) and bottom tending longlines (3.3%) (Figure 4). However, otter trawls have decreased in importance over time as evidenced by increased reported landings of gillnets and longlines (Appendix 1). Otter trawl gear accounted for a minimum of 73.2% to a maximum of 97.8% of the wolffish landings from 1964 to 2007 (Appendix 1). Fixed gill nets and bottom tending longline fisheries account for the majority of remaining landings. Trends in commercial landings are likely to be highly influenced by fisheries management for other groundfish species.

Reported US commercial wolffish landings come primarily from fishery statistical areas 513, 514, 515, 521 and 522 (Figure 5 and Table 2). Landings have fluctuated between statistical areas over time and spatial differences may be difficult to interpret due to management actions, such as permanent closures and rolling time closures, in the Gulf of Maine.

Commercial fishery discards from the Northeast Fisheries Observer Program database were estimated for the period 1989-2007 from US only statistical areas based on the Standardized Bycatch Reporting Methodology combined ratio estimation (Wigley et al 2007). Discards appear to be a small component of the overall catch of Atlantic wolffish (Figure 7 and Table 1). The maximum estimated discards in any one year are 26.98 mt, 1989 (Table 3). Otter trawls account for 98.3% of the total discarded wolffish from all years. Discards appear to be increasing in the gillnet sector, which reported approximately 17% of the total wolffish discarded for 2007 (Table 3).

Recreational catch data was retrieved from the MRFSS database (Figure 6 and Table 4). Landings are reported in total number of fish and total weight per year. Landings include both A and B1 fish, these are fish permanently removed from the population. B2 fish are discarded live and are assumed to have survived. Adjusted landings were developed because average weight of an individual wolffish was highly variable. Average weight (kg) was calculated based on the reported numbers of landed fish (A + B1) divided by the reported landed weight (kg). A grand mean was calculated from average weights and used in the new adjusted landings values. Adjusted landing are less variable than the original reported values and are likely to describe the recreational portion of total catch. Recreational catches have become more significant in recent years as commercial landings have steadily declined (Figure 7 and Table 1). Recreational catch makes up approximately 16% of the total catch and is 1/5 as large as the commercial landings for 2007 (Table 1).

Total Catch is comprised of reported landings, estimates of commercial discards from the primary fishery sectors and recreational catch from US waters as previously described (Figure 7 and Table 1). Recreational catches begin in 1981 and discard estimates begin in 1989. Total US catch peaked in 1983 with 1,111.83 mt and has decreased steadily reaching a low of 77.03 mt in 2007.

Commercial Lengths Data and CPUE

Fishery observers collect length samples at sea opportunistically providing information on the size structure of the population. Observer lengths have been collected since 1989. Sample sizes from early in the time series are low but have exceeded 100 samples per year during 2003-2007 (Table 5). Median length has been variable over time but increased slightly during the 2003-2007 period indicating that larger fish are being harvested (Figure 8). Differences in length composition by commercial gear types were also plotted (Figure 9). Sample sizes are small in all gears except for otter trawl and gillnet, where size distributions and median values are similar (Table 6).

Commercial lengths from port samples have been taken irregularly during the span of the commercial fishery. A significant amount of samples were collected during 1982 – 1985 and have also been taken consistently since 2001. Commercial port sample length distributions were plotted by year (Figure 10). An increase in median length can be seen during the 2001 – 2007 time period. The median has increased from 75 cm in 2001 to 84 cm in 2007 (Table 7). This data suggests that size in the commercial fishery may be increasing as the 95% confidence intervals from the 2001-2003 period do not overlap with the 2004-2007 period. Differences were then examined to see if the increase could be explained by major gear type since longlines, and gill nets have become a larger component of the fishery (Figure11). Slight differences were observed in the size compositions of the various gears but this may be an artifact of low sample size of commercial gears other than otter trawls (Table 8). Commercial length samples were also plotted by statistical area to determine if any geographic trend in size could be seen (Figure 12). The primary fishery areas, 512-522, show similar length distributions. Areas 526 and 537 had anomalous length distributions but also had low sample sizes (Table 9).

Indices of catch per unit of effort (CPUE) were calculated from fishery observer trips and self reported Vessel Trip Reports (VTRs) in party and charter boat sectors for Atlantic wolffish. Observer CPUE was estimated for 1989-2007 in the longline, gillnet and otter trawl fisheries for US statistical areas 512-515, 521-522, 525-526 and 537 (Table 10). CPUE was calculated based on the ratio: sum of kept wolffish per year / sum of days fished per year. Observer CPUE has declined in the 3 fishing sectors reviewed (Figure 13). Atlantic wolffish CPUE for the longline fishery is plotted on the second y-axis as it is significantly higher than the otter trawl and gillnet sectors.

Party and Charter boat CPUE have also declined (Figure 14; Table 11). These indices were calculated from the number wolffish reported landed on VTRs and angler days fished. Angler days fished was estimated by number anglers * hours fished / 24 per year for all party and charter trips in areas 514 and 515.

Research Vessel Survey Data

Survey Length, Weight and Maturity

Atlantic wolffish catches were grouped by decade to reduce data gaps in length frequency plots. Distributions were plotted using proportion at length and number at length (Figures 15 and 16). The numbers at length graphs show an overall reduction in numbers by decade across the length range of Atlantic wolffish. The proportion at length graphs indicate that different size fish are available to the bottom trawl gear in spring and fall. In general, spring survey encounters larger individuals (>= 50 cm) and the fall survey captures smaller individuals ranging from 10-30 cm. The spring survey also captures a unique distribution of small individuals, less than or equal to 7 cm, and may be used as a juvenile index.

Length weight relationships were developed for Atlantic wolffish from NEFSC bottom trawl survey data. Spring and fall survey data were combined to create one relationship for both male and female fish as no differences were found between seasons or sexes (Figure 17). Linear regression of log transformed data provided a good fit, $R^2 = 0.996$.

A logistic maturity ogive was developed for female Atlantic wolffish based on spring and fall survey vessel data (Figure 18). L_{50} was estimated at approximately 35 cm from these data. This L_{50} for female wolffish is lower than estimates reported in Newfoundland and Iceland where females containing second generation eggs were considered immature (Templeman 1986; Gunnarsson et al. 2006). NEFSC maturity data is based on visual inspection of the reproductive organs. Fish are classified into 1 of 7 stages of maturity (Burnett et al 1989). Fish classifications for females include immature, developing, ripe, eyed (unique for redfish), ripe and running, spent and resting. This analysis considered fish that were in the developing through resting stages as a mature and immature were those fish that contained no visible eggs. Size at maturity may be difficult to interpret for wolffish from these data as they may have an additional developing stage, or a set of second generation eggs which may last for several years, where fish are reproductively immature (Gunnarsson et al. 2006). These immature fish would likely be classified as developing in NEFSC surveys and were considered mature in the ogive thereby reducing the size at 50% mature.

Biomass and Abundance

Atlantic wolffish are encountered infrequently on NEFSC bottom trawl surveys. Strata used in wolffish analyses were limited to offshore areas completely or almost completely within US waters (Figure 19). Some historically important strata were excluded from this analysis, specifically on the Canadian portion of Georges Bank, but due to the sedentary nature of this fish it is believed to have not affected the estimation of the indices or overall trends in US waters (Figures 20 &21). Sampling effort per survey stratum in the Gulf of Maine has remained relatively consistent over most of the time series (Figure 22). The timing of the surveys in the Gulf of Maine has also been consistent during the spring and fall. Inshore sampling did not commence until the mid 1970's and was therefore not used. Higher sampling intensity did occur in portions of the 1970's and 1980's in select survey stratum but elevated abundance and biomass are not likely due to increased sampling effort (Figure 23).

In general the NEFSC spring and fall bottom trawl survey indices show abundance and biomass of Atlantic wolffish has declined over the last two to three decades (Figure 24.). The spring survey typically encounters higher abundance and biomass than the fall survey and was considered by the Data Poor Working Group to be optimal for assessing resource trends (Table 1). Survey differences may be attributed to wolffish being less available to the sampling gear while nest guarding in the fall (Rountree, R.A. 2002). Inter-annual variability among both surveys is high.

The spring biomass index averaged 0.786 kg/tow and ranged between 0.38 and 1.44 kg/tow from 1968 to 1988. Since the mid to late 1980's the resource has steadily declined. The average spring biomass index for 1989-2007 was 0.143 kg/tow, only 18% of the 1968-1988 average, and ranged from 0.0 kg/tow to 0.42 kg/tow. The fall biomass index shows little trend over time and is relatively low over most of the time series (Figure 24). A large anomalous peak in biomass appears in 1981 but is not seen again in subsequent years. Since the mid 1990's wolffish biomass has fluctuated with a slightly declining trend.

Abundance indices in both surveys show a decline in stratified mean number per tow since the mid 1990's. 3 year centered moving average plots of abundance and biomass removes the inter-annual variability within the indices and depicts an overall declining trend in the resource (Figure 25).

Spring and fall percent positive Atlantic wolffish catch was plotted by year (Figure 26). This type of index for species rarely captured can be a good indicator of how frequently rare events occur over time. These indices indicate that the number of survey tows catching at least one wolffish has decreased with time in both the spring and fall. The spring index shows an almost continuous declining trend since the late 1970's/early 1980's, averaging around 12% and dropping to approximately 2%. The fall index appears relatively stable from the mid 1960's through the early 1990's, fluctuating around 6 %. It then declines quickly from 1993 to 1996 and becomes relatively stable again near 2 % until 2007 where it reaches zero.

The spatial distribution of Atlantic wolffish has contracted according to the spring and fall bottom trawl surveys. Data were grouped by decade and survey catch in numbers were displayed using GIS (Figures 27 and 28). The spring survey shows high catch along Jefferies Ledge, Stellwagen Bank National Marine Sanctuary and off outer Cape Cod through the Great South Channel during the 1970's and 1980's. Catches in the 1990's extend across a similar area but appear with less abundance and frequency. Highest catches during the 2000's are limited to Stellwagen Bank region. A similar pattern emerges from fall survey catches and the resource appears to be more concentrated within the Jefferies Ledge and Stellwagen Bank regions. During the 1990's and 2000's catches are smaller and appear less frequently in the fall.

Modeling Results

SCALE Model

Incomplete or lack of age-specific catch and survey indices often limits the application of a full age-structured assessment (e.g. Virtual Population Analysis and many forward projecting age-structured models). Stock assessments will often rely on the simpler size/age aggregated models (e.g. surplus production models) when age-specific information is lacking. However the simpler size/age aggregated models may not utilize all of the available information for a stock assessment. Knowledge of a species growth and lifespan, along with total catch data, size composition of the removals, recruitment indices and indices on numbers and size composition of the large fish in a survey can provide insights on population status using a simple model framework.

The Statistical Catch At Length (SCALE) model, is a forward projecting age-structured model tuned with total catch (mt), catch at length or proportional catch at length, recruitment at a specified age (usually estimated from first length mode in the survey), survey indices of abundance of the larger/older fish (usually adult fish) and the survey length frequency distributions (NOAA Fisheries Toolbox 2008a). The SCALE model was developed in the AD model builder framework. The model parameter estimates are fishing mortality and recruitment in each year, fishing mortality to produce the initial population (Fstart), logistic selectivity parameters for each year or blocks of years and Qs for each survey index.

The SCALE model was developed as an age-structured model that does NOT rely on age-specific information on a yearly basis. The model is designed to fit length information, abundance indices, and recruitment at age which can be estimated by using survey length slicing. However the model does require an accurate representation of the average overall growth of the population which is input to the model as mean lengths at age. Growth can be modeled as sex-specific growth and natural mortality or growth and natural mortality can be model with the sexes combined. The SCALE model will allow for missing data.

Model Configuration

The SCALE model assumes growth follows the mean input length at age with predetermined input error in length at age. Therefore a growth model or estimates of mean length at age are essential for reliable results. The model assumes static growth and therefore population mean length/weight at age are assumed constant over time. A depiction of model assumed population growth at age using the input mean lengths at age and variation can be seen in table 12 and figure 29.

The SCALE model estimates logistic parameters for a flattop selectivity curve at length in each time block specified by the user for the calculation of population and catch age-length matrices or the user can input fixed logistic selectivity parameters. Presently the SCALE model can not account for the dome shaped selectivity pattern.

The SCALE model computes an initial age-length population matrix in year one of the model as follows. First the estimated populations numbers at age starting with age-1 recruitment get normally distributed at one cm length intervals using the mean length at age with the assumed standard deviation. Next the initial population numbers at age are calculated from the previous age at length abundance using the survival equation. An estimated fishing mortality (Fstart) is also used to produce the initial population. This F can be thought of as the average fishing mortality that occurred before the first year in the model. Now the process repeats itself with the total of the estimated abundance at age getting redistributed according to the mean length at age and standard deviation in the next age (age+1).

This two step process is used to incorporate the effects of length specific selectivities and fishing mortality. The initial population length and age distribution is constructed by assuming population equilibrium with an initial value of F, called F_{start}. Length specific mortality is estimated as a two step process in which the population is first decremented for the length specific effects of mortality as follows:

$$N^*_{a,len,y_1} = N_{a-1,len,y_1} e^{-\left(PR_{len}F_{start}+M\right)}$$

In the second step, the total population of survivors is then redistributed over the lengths at age *a* by assuming that the proportions of numbers at length at age *a* follow a normal distribution with a mean length derived from the input growth curve (mean lengths at age).

$$N_{a,len,y_1} = \pi_{len,a} \sum_{len=0}^{L_\infty} N^*_{a,len,y_1}$$

where

$$\pi_{len,a} = \Phi\left(len+1 \mid \mu_a, \sigma_a^2\right) - \Phi\left(len \mid \mu_a, \sigma_a^2\right)$$

where

$$\mu_a = L_\infty \left(1 - e^{-K(a-t_0)}\right)$$

Mean lengths at age can be calculated from a von Bertalanffy model from a prior study as shown in the equation above or mean lengths at age can be calculated directly from an age-length key. Variation in length at age a = σ_s^2 can often be approximated empirically from the growth study used for the estimation of mean lengths at age. If large differences in growth exist between the sexes then growth can be input as sex-specific growth with sex-specific natural mortality. However catch and survey data are still fitted with sexes combined.

This SCALE model formulation does not explicitly track the dynamics of length groups across age because the consequences of differential survival at length at age a do not alter the mean length of fish at age a+1. However, it does more realistically account for the variations in age-specific partial recruitment patterns by incorporating the expected distribution of lengths at age.

In the next step the population numbers at age and length for years after the calculation of the initial population use the previous age and year for the estimate of abundance. Here the calculations are done on a cohort basis. Like in the previous initial population survival equation the partial recruitment is estimated on a length vector.

$$N^*_{a,len,y} = N_{a-1,len,y-1} e^{-\left(PR_{len}F_{y-1}+M\right)}$$

second stage

$$N_{a,len,y} = \pi_{len,a} \sum_{len=0}^{L_\infty} N^*_{a,len,y}$$

Constant M is assumed along with an estimated length-weight relationship to convert estimated catch in numbers to catch in weight. The standard Baranov's catch equation is used to remove the catch from the population in estimating fishing mortality.

$$C_{y,a,len} = \frac{N_{y,a,len}\, F_y\, PR_{len}\left(1 - e^{-\left(F_y PR_{len} + M\right)}\right)}{(F_y \;\; PR_{len}) + M}$$

Catch is converted to yield by assuming a time invariant average weight at length.

$$Y_{y,a,len} = C_{y,a,len} W_{len}$$

The SCALE model results in the calculation of population and catch age-length matrices for the starting population and then for each year thereafter. The model is programmed to estimate recruitment in year 1 and estimate variation in recruitment relative to recruitment in year 1 for each year thereafter. Estimated recruitment in year one can be thought of as the estimated average long term recruitment in the population since it produces the initial population. The residual sum of squares of the variation in recruitment $\sum(\text{Vrec})^2$ is than used as a component of the total objective function. The weight on the recruitment variation component of the objective function (Vrec) can be used to penalize the model for estimating large changes in recruitment relative to estimated recruitment in year one.

The model requires an age-1 recruitment index for tuning or the user can assume relatively constant recruitment over time by using a high weight on Vrec. Usually there is little overlap in ages at length for fish that are one and/or two years of age in a survey of abundance. The first mode in a survey can generally index age-1 recruitment using length slicing. In addition numbers and the length frequency of the larger fish (adult fish) in a survey where overlap in ages at a particular length occurs can be used for tuning population abundance. The model tunes to the catch and survey length frequency data using a multinomial distribution. The user specifies the minimum size (cm) for the model to fit. Different minimum sizes can be fit for the catch and survey data length frequencies.

The number of parameters estimated is equal to the number of years in estimating F and recruitment plus one for the F to produce the initial population (Fstart), logistic selectivity parameters for each year or blocks of years, and for each survey Q. The total likelihood function to be minimized is made up of likelihood components comprised of fits to the catch, catch length frequencies, the recruitment variation penalty, each recruitment index, each adult index, and adult survey length frequencies:

$$\text{L}_{\text{catch}} = \sum_{years}\left(l\,\text{n}(Y_{\text{obs,y}} + 1) - \ln\left(\sum_a \sum_{len} \text{Y}_{\text{pred,len,a,y}} + 1 \right)\right)^2$$

$$L_{catch\_lf} = -N_{eff} \sum_{y} \left(\sum_{inlen}^{L_\infty} \left((C_{y,len}+1) \ln\left(1 + \sum_{a} C_{pred,y,a,len} \right) - \ln(C_{y,len}+1) \right) \right)$$

$$\text{L}_{\text{vrec}} = \sum_{y=2}^{Nyears} (Vrec_y)^2 = \sum_{y=2}^{Nyears} (R_1 - R_y)^2$$

$$\sum L_{rec} = \sum_{i=1}^{Nrec} \left[\sum_{y}^{Nyears} \left(\ln(I_{rec_i,inage_i,y}) - \ln\left(\sum_{len}^{L_\infty} N_{y,inage_i,len} * q_{rec\,i} \right) \right)^2 \right]$$

$$\sum L_{adult} = \sum_{i=1}^{Nadult} \left[\sum_{y}^{Nyears} \left(\ln(I_{adult_i,inlen+_i,y}) - \left(\sum_{a} \sum_{inlen_i}^{L_\infty} \ln(N_{pred,y,a,len} * q_{adult\,i}) \right) \right)^2 \right]$$

$$\sum L_{lf} = \sum_{i=1}^{Nlf} \left[-N_{eff} \sum_{y} \left(\sum_{inlen_i}^{L_\infty} \left((I_{lf_i,y,len}+1) \ln\left(1 + \sum_{a} N_{pred,y,a,len} \right) - \ln(I_{lf_i,y,len}+1) \right) \right) \right]$$

In equation L_{catch_lf} calculations of the sum of length are made from the user input specified catch length to the maximum length for fitting the catch. Input user specified fits are indicated with the prefix "in" in the equations. LF indicates fits to length frequencies. In equation L_{rec} the input specified recruitment age and in L_{adult} and L_{lf} the input survey specified lengths up to the maximum length are used in the calculation.

$$Obj\ \ fcn = \sum_{i=1}^{N} \lambda_i L_i$$

Lambdas represent the weights to be set by the user for each likelihood component in the total objective function.

Wolffish SCALE Model Configuration and results

Mean lengths at age and variation in mean length at age were based on fish collected during the 1980s from Nelson and Ross (1992). A Gompertz relationship had the best fit using all ages. We have re-estimated a von Bertalanffy relationship using data limited to fish older than 4 with L-infinity fixed at 110 cm (Figure 30). The mean lengths from Nelson and Ross's Gompertz relationship for fish younger than age 5 were also used in the SCALE model. The mean lengths from the younger fish do not have a large effect on the SCALE model results. In the final growth model we fixed L-infinity (110) at a slightly higher value than what was estimated by the Gompertz (98.9) model because few larger and older fish exist in Nelson and

Ross's study and the SCALE model had difficultly predicting larger fish that are in seen in the catch length frequency distributions. A North Sea wolffish growth study estimated L-infinity at 111 for males and 115 for females (Liao and Lucas, 2000). Figure 31 shows the predicted catch length distribution under low Fs (F=0.001) assuming different L-infinities. A standard deviation of 6 was used for fish older then age-7. The assumed variation around the mean lengths at age can be seen in Table 12 and Figure 29. Nelson and Ross's oldest fish was 22 years. The age matrix was dimensioned from ages 1 to 30 with an assumed natural mortality of 0.15.

Only one recruitment index exists in the SCALE model (Figure 32). The spring NEFSC survey shows a distinct mode between 1 and 7 cm. This index was tuned to age-1. The recruitment index suffers from zero catches in many years and at times in blocks of several years. A 40+ cm index was developed from the NEFSC spring, NEFSC fall and the MDMF spring survey (Figure 33). All three surveys show declining trends in abundance with the indices also suffering from zero catches at the end of the time series. The survey length frequency distributions are limited due to the low numbers of wolffish caught in the surveys. There is concern that biomass may have fallen below detection in the surveys. Preliminary evidence suggests the Bigelow survey may also suffer from the same low catchablility issue. Survey indices were scaled using the approximate area of survey coverage divided by the average coverage of a survey tow (Table 13). The area swept estimates can provide some insight from estimated survey efficiencies using the estimated Qs in the SCALE model.

Zero catches were set to missing in the SCALE model. Setting zeros to the smallest value in the time series appears to have a large unsubstantiated influence on the model results. The age-1 recruitment series was given a relatively low weight (Table 14). Setting the weight to high on the recruitment index will force SCALE to fit the recruitment index very closely but the model is less constrained in estimating recruitment for years where recruitment information is missing which can produce unrealistic results. The age-1 index was used more as a guide with setting the penalty on recruitment variation. The penalty on recruitment variation was set high enough to produce recruitment variation within the bounds of what was observed in the recruitment index. The model has to estimate a declining trend in recruitment to fit the decline in the 40+ cm indices and the declining trend in the catch since 1983. The recruitment index was used as guidance on whether recruitment failure has occurred for the wolffish stock. Sensitivity of the model to the weighting on the recruitment index and the penalty on variation in recruitment can be seen in Figures 34 through 37.

The catch length frequency distributions are an important component of the SCALE model. Observer trawl kept length sampling and port samples where combined to characterize the catch size distributions. Catch length frequency information exists from 1982 to 1985 and from 2001 to 2007. A single selectivity block over the time series was used due to the lack of a distinct shift in the size distribution and due to the lack of size information in many years. There is no indication of size truncation in the catch length frequency distributions over time.

The lack of data prevents the SCALE model from estimating a reliable logistic selectivity curve. The SCALE model estimates a very flat selectivity curve that produces a L-50 at very large sizes. There is a tradeoff in the SCALE model between the estimated selectivity and fishing mortality rates. Two different selectivity regimes were chosen to determine its influence of stock status determination (Figure 38). Run one had a relativity flat selectivity curve which was allowed to hit the L-50 bound of 90 cm. Run two was setup to hit the slope parameter bound of 0.15 which produces a steeper selectivity function with a lower L-50 estimate. Results of the two selectivity runs are summarized in Figures 39-42 and Table 14.

The SCALE model time series starts in 1968 with the beginning of the NEFSC spring index. The SCALE model estimates virgin conditions at the beginning of the time series with a low Fstart estimate (0.001) in 1968 when the catch was low. A strong retrospective pattern did not exist with the Slope = 0.15 run (Figure 43). The sensitivity of the assumed L-infinity for growth on the model estimated Fs and recruitment can be seen in Figure 44.

Non-parametric biological reference points (BRP) were developed for both the selectivity L-50 = 90 run (Run 1) and the slope = 0.15 run (Run 2) within the SCALE model using $F_{40\%}$ as a Proxy for F_{MSY} (Table 15). A range of knife edge maturities values were used in estimating the BRPs. Maturity as 40+ cm fish was used to correspond to NEFSC survey maturity results, a 65+ cm and 75+ cm cutoffs were used as bounds taken from the Gunnarsson et al (2006) and Templeman (1986). Templeman found maturation occurring at larger sizes in lower latitudes. However Gunnarsson et al (2006) found maturation occurring at larger sizes in the colder waters on the eastern side of Iceland compared to the western side. The Data Poor Stocks Working Group suggested that $F_{50\%}$ may be a better proxy of F_{MSY} for a species that is long lived, late maturing, and has low fecundity. $F_{50\%}$ BRPs were developed for the Slope = 0.15 run (Table 15 and Figure 45). Based on all SCALE model runs, the wolffish stock in 2007 is at a low biomass (26% to 45% of B_{MSY}) and is overfished (*assuming a $B_{THRESHOLD}$ of ½ B_{MSY}). The overfishing status determination was more uncertain with F_{2007} to F_{MSY} ratios ranging from 50% to 123%. The Peer Review Panel concluded that $F_{40\%}$ is reasonable and justifiable and that the F_{MSY} proxy < 0.35 is most probable. Therefore, MSY is likely in the range of 278-311 mt and SSB_{MSY} are likely between 1,750-2,200 mt.

*(*This assumption was confirmed by the Chairman of the Peer Review Panel after the December meeting.)*

Exploitation Ratios

Exploitation indices were created from reported wolffish catch and spring and fall biomass estimates (Figures 46; Table 1). Exploitation appears to have increased and could indicate this species is being over harvested even at low level commercial catches. Due to low survey catches some values cannot be shown on the chart. The spring exploitation index peaks at a value of 4,169.42 in 2004 and fall exploitation index contains 2 high points at approximately 42.64 in 1998 and 62.94 in 2006. Exploitation ratios were informative to the Review Panel but were considered to be highly variable.

DCAC Model

The DCAC model input consists of summed annual catch, an estimate of M, an estimate of the F_{MSY} to M ratio, the ratio of catch depletion over time and the number of years being analyzed (NOAA Fisheries Toolbox 2008b). It calculates a sustainable yield of a population after accounting for the “windfall” which occurs at the beginning of a fishery. When natural mortality is high, the DCAC model is the same as calculating the average landings. We conducted a sensitivity analysis of the delta depletion parameter over several time blocks to look at potential sustainable yields (Figure 47; Table 16). All of the time blocks cover the majority of the fishery and include high, moderate and low catch levels. The depletion-corrected average catch was significantly lower than the uncorrected average catch in each time block. Time block did not affect the DCAC but the delta depletion ratio has strong influence. DCAC results ranged from 297.4 mt to 378.0 mt and the Data Poor Stocks Review Panel believed were comparable to and supportive of the MSY values derived from the SCALE model.

AIM – An Index Method

The relationship between total catch of Atlantic wolffish and the spring biomass was explored using the An Index Method (AIM) model (NEFSC 2002 and NOAA Fisheries Toolbox 2008c). Both catch and the survey index have been declining over time with little response of the spring index to declining catches (Figure 48). The linear regression between the log_e replacement ratio and log_e relative F was not significant in a randomization test, critical value -0.387 and a significance level of 0.128 (Figure 49). Therefore this model was considered insufficient for providing results on Atlantic wolffish by the Review Panel.

Section 7. Provide advice about scientific uncertainty and risk for Scientific and Statistical Committees (SSCs) to consider when they develop fishing level recommendations for these stocks.

Major sources of uncertainty include:

1. Life history – size at maturity, age composition, $L\infty$ within the Gulf of Maine
2. Catchability in NEFSC bottom trawl surveys
3. Commercial length compositions and impacts to SCALE Model
4. Interpretation of 0 catches in recent years – modeling implications
5. Discard information from commercial fisheries
6. Habitat association is poorly known

The Data Poor Stocks Review Panel expanded upon this list of uncertainties. They included natural mortality, maximum age, fecundity and the connectivity of populations on Georges Bank and in the Gulf of Maine for important biological uncertainties. They included scientific uncertainty of the survey indices because populations are at the southern extent of the species range and may exhibit wide changes in distribution. Uncertainties from fisheries data include unknown harvest by foreign fleets and the extent of unreported catches and discards. The Review Panel believed that process uncertainty resulted from the lack of size truncation in commercially harvested fish, which indicated that fishing effort alone may not be responsible for changes in abundance. They suggest lack of preferable habitat may be considered as a viable alternative hypothesis. Model uncertainties include high survey catchability coefficients for pre and fully recruited sizes and the sensitivity of BRPs to maturity ogives and fishery selectivity curves. The Review Panel concluded that stock projections would be unreliable and should not be conducted because of the interpretation of zero catches in the survey data.

Section 8. If applicable, consider developing BRPs for species groups
NA

Section 9. Comment on what can be done to improve the information, proxies or assessments for each species.

Much work could be done to improve information on the basic biology of Atlantic wolffish in the Gulf of Maine. Age and growth data from both commercial and fishery independent sources needs to be collected to improve life history information, specifically L infinity. Conduct a maturity study based on egg size or first generation eggs in female wolffish to improve size at maturity estimates. Estimate fecundity for Gulf of Maine wolffish. Conduct tagging studies to confirm populations are sedentary and localized. Collect fishery observer data from more fishery sectors including the offshore lobster fishery. Comparative studies on wolffish catchability in multiple habitats, including complex rock habitat, with NEFSC survey gear and commercial gear types. A fishery independent index for wolffish should be developed for assessing potential biomass located in rocky habitats.

The Review Panel prioritized a list of research recommendations, including those mentioned above, to reduce uncertainty surrounding the biology, population dynamics and biological reference points of Atlantic wolffish.

1. Exploration of the relationship between survey catch per tow and habitat complexity and environmental signals should continue. These studies will aid understanding of the relationship between survey estimates and population abundance.
2. Age and growth studies for wolffish in the NE/GOM region should be conducted to refine estimates of L∞.
3. Maturity ogive data are currently based on simple presence of eggs in females, and do not account for functional maturity which requires presence of larger eggs. The review team believed the current approach is inadequate. Regional maturity ogives should be developed.
4. The review team recommended that a fixed gear survey be considered to assess abundance in non trawlable habitats.
5. Tagging studies should be conducted to explore and quantify the vagility of wolffish to help improve understanding of population structure and connectivity.

Scup:
Stock Assessment and
Biological Reference Points for 2008

by

Mark Terceiro
NOAA Fisheries
Northeast Fisheries Science Center
166 Water St.
Woods Hole, MA 02543

Northeast Data Poor Stocks Working Group Meeting
Woods Hole, MA
December 8-12, 2008

Executive Summary

The current biomass reference point for scup relies on the index of Spawning Stock Biomass (SSB) from the NEFSC spring trawl survey. Previous reviews of the stock assessment have indicated that while this index may be the most reliable fishery independent index of scup SSB, it is subject to a relatively high degree of inter-annual variability that reduces its utility as an indicator of stock status. Managers, scientists, and other stakeholders indicated a desire for a more reliable way to monitor the status of scup and support the annual specification of fishery regulations. The December 2008 Northeast Data Poor Stocks Peer Review Panel accepted a revised stock assessment using a statistical catch at age model (ASAP) as the basis for biological reference points and status determination for scup. The new model of scup population dynamics and the recommended reference points represent a more stable approach for monitoring stock status and specifying annual fishery regulations, compared with the current single index-based model. The new model integrates a broad array of fishery and survey input data and should be less sensitive to inter-annual changes in any single data component than the current model.

The Peer Review Panel recommended $F_{40\%}$ as the proxy for F_{MSY}, and the corresponding $SSB_{F40\%}$ as the proxy for SSB_{MSY}. The $F_{40\%}$ proxy for F_{MSY} = 0.177, the proxy estimate for SSB_{MSY} = 92,044 mt, and the proxy estimate for MSY = 16,161 mt (13,134 mt of landings, 3,027 mt of discards). The stock biomass threshold of ½ SSB_{MSY} = ½ $SSB_{F40\%}$ = 46,022 mt = 101.461 million lbs.

The 2007 SSB estimate of 119,343 mt is 30% above SSB_{MSY} = 92,044 mt, indicating the stock was not overfished. The F_{2007} estimate of 0.054 is 31% of F_{MSY} = 0.177, indicating overfishing was not occurring. Total catch (landings plus discards) was 7,867 mt in 2007, about 49% of MSY. The revised status determination represents a significant change from the recent biomass status update conducted in July 2008, which indicated that the stock was overfished in 2007, although not experiencing overfishing. While the accepted long-term MSY estimate appears feasible given historical evidence from the fishery, managers may wish to take an adaptive approach to the specification of fishery quotas in the short-term. Total fishery landings over the last five years (2003-2007) have averaged 6,214 mt (13.7 million lbs). If the stock is fished at $F_{40\%}$ = 0.177 over the long-term, the corresponding annual total MSY landings would be 13,134 mt (29.0 million lbs), more than double the recent five year average. The Peer Review Panel recommended that "…rapid increases in quota to meet the revised MSY would be unwarranted given uncertainties in recruitments. A more gradual increase in quotas is a preferred approach reflective of the uncertainty in the model estimates and stock status."

Term of Reference

The following components of the Terms of Reference for the Northeast Data Poor Stocks Working Group are relevant for scup:

1. Constitute and convene a Working Group comprising NEFSC assessment scientists, and staff from NERO, NEFMC, MAFMC, and ASMFC to:

    a. Recommend biological reference points (BRPs) and measurable BRP and maximum sustainable yield (MSY) proxies for Scup.

b. Provide advice about scientific uncertainty and risk for Scientific and Statistical Committees (SSCs) to consider when they develop allowable biological catches (ABCs) for these stocks.
c. Comment on what can be done to improve the information, proxies or assessments for each species.

Introduction

Scup (*Stenotomus chrysops*) is a schooling continental shelf species of the Northwest Atlantic that is distributed primarily between Cape Cod and Cape Hatteras (Morse 1978). Scup undertake extensive migrations between coastal waters in summer and offshore waters in winter. Scup migrate north and inshore to spawn in spring, with larger scup (age 2 and older) tending to arrive in spring first, followed by smaller scup (Neville and Talbot 1964; Sisson 1974). Larger scup are found during the summer near the mouth of larger bays and in the ocean within 20-fathoms, and often inhabit rough bottom areas. Smaller scup are more likely to be found in shallow, smooth bottom areas of bays during summer (Morse 1978). Scup migrate south and offshore in autumn as the water temperature decreases, arriving in offshore wintering areas by December (Hamer 1970; Morse 1978). Spawning occurs from May through August and peaks in June. About 50% of age-2 scup are sexually mature (about 17 cm total length; Morse 1978), while nearly all scup of age 3 and older are mature. Scup reach a maximum fork length of at least 41 cm and a maximum age of at least 14 years, with a likely maximum of 20 years (Dery and Rearden 1979). Tagging studies (e.g., Neville and Talbot 1964; Cogswell 1960, 1961; Hamer 1970, 1979) have indicated the possibility of two stocks of scup, one in Southern New England waters and another extending south from New Jersey waters. However, the lack of definitive locations for tag return data coupled with distributional data from the NEFSC bottom trawl surveys support the concept of a single unit stock extending from Cape Hatteras north to New England (Mayo 1982).

Overfished and Overfishing Definitions

The Mid-Atlantic Fishery Management Council (MAFMC) and the Atlantic States Marine Fisheries Commission (ASMFC) manage scup under Amendment 8 (1997) to the Summer Flounder, Scup, and Black Sea Bass (SFSCBSB) Fishery Management Plan (FMP). The FMP management unit includes all scup from Cape Hatteras, NC northward to the US-Canada border.

Amendment 8 also established a recovery plan for scup under which exploitation rates were to be reduced to 47% (F=0.72) during 1997-1999, to 33% (F=0.45) during 2000-2001, and to 21% (F=0.26) during 2002-2007. These goals were to be attained through implementation of a Total Allowable Catch (TAC) that included a commercial quota and recreational harvest limit, and other regulations including commercial fishery minimum net mesh, trap vent and fish sizes, closed areas, and recreational fishery minimum fish sizes, possession limits, and open seasons.
Amendment 12 (1998) to the FMP established a biomass threshold (a proxy for one-half BMSY) for scup based on the three-year moving average of the NEFSC spring bottom trawl survey index of Spawning Stock Biomass (SSB) during 1977-1979, which was perceived to be a period when the stock was near one-half BMSY (2.77 SSB kg per tow). The scup stock is overfished when the spawning stock biomass index falls below this value. Amendment 12 defined overfishing for

scup to occur when the fishing mortality rate exceeds the threshold fishing mortality of Fmax = 0.26 (proxy for FMSY).

Broad scale Gear Restricted Areas (GRAs) for scup were implemented in November 2000 under the framework provisions of the FMP as a measure to reduce discards of scup in the small mesh fisheries for *Loligo* squid and silver hake. The regulations restricted the use of small mesh trawl gear in areas with high concentrations of small scup during the late fall and winter months. Two Northern Areas off Long Island were implemented for November through January, while a Southern Area off the mid-Atlantic coast was implemented for January through April. The size and boundaries of the GRAs were modified in December 2000 and again in 2005 in response to commercial fishing industry recommendations.

Amendment 14 (July 2007) to the FMP defined the biomass target and implemented a stock rebuilding plan for scup. The stock must be fully rebuilt to the biomass target by January 1, 2015. The proxy for BMSY is two times the 3-year moving average of the NEFSC spring index of SSB during 1977-1979, or 2*2.77 = 5.54 SSB kg per tow. A constant fishing mortality rate (F) of 0.10 (9% exploitation rate) is to be applied in each year of a 7 year rebuilding period; 2008 was year 1 of rebuilding and F=0.10 was applied as the target F. Total Allowable Catch (TAC) of 4,491 mt (9.90 million lbs) and corresponding Total Allowable Landings (TAL) of 3,329 mt (7.34 million lbs) were established for 2008 to achieve the target F.

The current overfished and overfishing definitions are based on revisions to the SFSCBSB FMP through Framework 7 (October 2007), currently use the values established in Amendments 12 (1998) and 14 (July 2007), and are as follows:

AThe maximum fishing mortality threshold for each of the species under the FMP is defined as FMSY (or a reasonable proxy thereof) as a function of productive capacity, and based upon the best scientific information consistent with National Standards 1 and 2. Specifically, FMSY is the fishing mortality rate associated with MSY. The maximum fishing mortality threshold (FMSY) or a reasonable proxy may be defined as a function of (but not limited to): total stock biomass, spawning stock biomass, total egg production, and may include males, females, both, or combinations and ratios thereof which provide the best measure of productive capacity for each of the species managed under the FMP. Exceeding the established fishing mortality threshold constitutes overfishing as defined by the Magnuson-Stevens Act.@

AThe minimum stock size threshold for each of the species under the FMP is defined as one-half BMSY (or a reasonable proxy thereof) as a function of productive capacity, and based upon the best scientific information consistent with National Standards 1 and 2. The minimum stock size threshold (one-half BMSY) or a reasonable proxy may be defined as a function of (but not limited to): total stock biomass, spawning stock biomass, total egg production, and may include males, females, both, or combinations and ratios thereof which provide the best measure of productive capacity for each of the species managed under the FMP. The minimum stock size threshold is the level of productive capacity associated with the relevant one-half MSY level. Should the measure of productive capacity for the stock or stock complex fall below this minimum threshold, the stock or stock complex is considered overfished. The target for rebuilding is specified as BMSY (or reasonable proxy thereof) at the level of productive capacity associated with the relevant MSY level, under the same definition of productive capacity as specified for the minimum stock size threshold.@

Current Biological Reference Points

The current Biological Reference Points for scup are defined as follows in SFSCBSB FMP Amendment 12:

AOverfishing for scup is defined to occur when the fishing mortality rate exceeds the threshold fishing mortality rate of FMSY. Because FMSY cannot be reliably estimated, Fmax is used as a proxy for FMSY. Fmax is 0.26 under current stock conditions. The maximum value of the spring survey index based on a three year moving average (2.77 kg/tow) would serve as a biomass threshold. BMSY cannot be reliably estimated for scup.@ The original definition under Amendment 12 did not explicitly provide the time frame for the biomass threshold calculation. However, the specifics of the definition were provided in the discussion of the National Standards in another section of Amendment 12 as follows: AY 3-year moving average of the NEFSC spring survey catch per tow of spawning stock biomass (1977-1979 average = 2.77 kg/tow).@

Amendment 14 to the SFSCBSB FMP defined a proxy for BMSY for scup as follows:
AThe current minimum biomass threshold is the NEFSC spring SSB 3-year index value (1977-1979) of 2.77 kg/tow. Assuming the minimum biomass threshold is a proxy for 2 BMSY, doubling that index value would be a proxy for BMSY. Specifically, NEFSC spring 3-year index value of 5.54 kg/tow would be a proxy for BMSY. A

Background and Justification for Current Biological Reference Points

The last peer-reviewed assessment to include an analytical model was accepted in 1995 by SAW 19 (NEFSC 1995). The assessment featured a Virtual Population Analysis (VPA) modeled in the ADAPT framework (Conser and Powers 1990), included commercial and recreational landings and discards at age estimates, and used state and NEFSC abundance indices for calibration. The 1995 SAW 19 assessment indicated that the instantaneous fishing mortality rate (F) in 1993 was 1.3, and spawning stock biomass was 4,600 mt. A yield per recruit (YPR) analysis indicated that Fmax = 0.236.

The VPA was updated through 1996 and reviewed by SAW 25 (NEFSC 1997), but due to concerns over the low intensity of fishery sampling in the 1990s, uncertainty about the magnitude of commercial discards in the late 1990s, and the ongoing variability of survey indices, the VPA was not accepted as a basis for management decisions. Assessment conclusions were therefore based primarily on trends in NEFSC and state agency survey indices and catch curve analyses using those survey data. The 1997 SAW 25 was able to conclude that in 1996 scup were Aover-exploited and near record low abundance levels.@

The scup assessment was next updated through 1997 and reviewed by SAW 27 (NEFSC 1998). Several configurations of a surplus production model (ASPIC; Prager 1994) were reviewed in addition to an updated VPA, but like the VPA, the ASPIC model results were not accepted due to concerns over the validity of the input fishery and survey data. An updated YPR analysis was accepted and indicated that F_{max} = 0.26. SAW 27 concluded that AA VPA or other analytical model formulation for scup will not be feasible until the quality of the input data, particularly the precision of discard estimates, is significantly improved.@ The 1998 SAW 27 also concluded the scup was Aover exploited and at a low biomass level.@

The 1998 SAW27 Panel recommended the scup assessment be based on the long-term time series of NEFSC trawl survey indices and fishery catches. The Panel noted that commercial landings were sustained near 19,000 mt annually during the mid-1950s to mid-1960s, and concluded that the stock was likely near BMSY during that period (Figure 1). The nearest subsequent peak in NEFSC survey indices occurred in the late 1970s. Commercial and total fishery catches in the late 1970s were about one-half of those in the 1950s to 1960s, and so the late 1970s were identified as a period when the stock was likely to be near one-half of BMSY (Figures 1-2). The Panel considered the NEFSC spring survey series to be most representative of spawning stock biomass, since older ages were better represented in the age structure than in the NEFSC fall survey or other state agency surveys. The 1998 SAW27 Panel recommended that the three-year moving average of the NEFSC spring bottom trawl survey index of Spawning Stock Biomass (SSB) during 1977-1979 (2.77 SSB kg per tow) be used as the proxy biomass threshold (one-half BMSY) and that Fmax = 0.26 be used as the proxy fishing mortality threshold (FMSY). Those recommendations were subsequently adopted for the BRPs in FMP Amendment 12.

The scup assessment was next updated through 1999 and reviewed by SAW 31 (NEFSC 2000). The assessment continued to be based on trends in research survey indices and fishery catches and indicated that the stock was Aoverfished@ (the NEFSC spring SSB index was much lower than the biomass threshold specified in FMP Amendment 12) and that Aoverfishing@ was occurring (catch curve analyses indicated that F exceeded 1.0, much greater than the FMP Amendment 12 threshold of Fmax = 0.26).

The most recent peer-reviewed assessment of scup included fishery data through 2001 and was reviewed by SAW 35 (NEFSC 2002). The assessment was again based on trends in research survey indices and fishery catches, but indicated that the stock was no longer Aoverfished@ (the NEFSC spring SSB index was above the biomass threshold specified in FMP Amendment 12), although the SAW 35 Panel concluded that Astock status with respect to the overfishing definition cannot currently be evaluated,@ due to the uncertainty of F estimates derived from research survey catch curve calculations. The 2002 SAW 35 Panel found sufficient evidence to conclude that AThe relative exploitation rates have declined in recent years...@ and that ASurvey observations indicated strong recruitment and some rebuilding of age structure.@

Since 2002, the status of the stock has been monitored by the MAFMC Monitoring Committee using trends in research survey indices and fishery catches. A Relative Exploitation Index (REI) based on the annual total fishery landings and the NEFSC spring three-year average SSB index has been used as a proxy for F to monitor status with respect to overfishing and provide guidance to the specification of annual TACs. A projection of the NEFSC spring survey SSB index using assumptions about maturity, partial recruitment to the survey, and the level of future recruitment as indexed by the NEFSC spring survey at age 1 was used in FMP Amendment 14 to forecast stock rebuilding and set the Frebuild target for 2008-2105.

An update to the status monitoring metrics was completed in July 2008 to aid in the specification of fishery regulations for 2009. The update indicated that while the stock was overfished in 2007 (NEFSC spring SSB three-year average index = 1.16 kg per tow, 21% of the biomass target of 5.54 kg per tow), the exploitation rate was at the rebuilding target rate (9%, or about F = 0.10), suggesting that overfishing was not occurring in 2007. However, the stock rebuilding rate was slower than indicated by the Amendment 14 projection, with the NEFSC spring 2007 SSB index (three-year average = 1.16 kg per tow) at only 56% of the forecast 2007 index (2.08 kg per tow).

Need for Revision of the Current Biological Reference Points

The current stock biomass reference point relies on the index of SSB from the NEFSC spring trawl survey. Previous reviews of the scup stock assessment have indicated that while this index may be the most reliable fishery independent metric of scup SSB, it is subject to a relatively high degree of inter-annual variability and the possibility that positive and negative Aavailability@ events will reduce the utility of the index in monitoring the status of the stock for any given year, in spite of the three-year smoothing protocol (Figure 2). An example of this phenomenon took place in 2002, when an unusually high value of the NEFSC spring SSB index was recorded that did not seem to result from high abundance in 2001, nor translate into a correspondingly high value in 2003. Subsequent reviews concluded that the high 2002 index resulted mainly from an increased availability of fish to the survey, rather than due to a true increase in abundance of the recorded magnitude. However, the high 2002 index lead to a change in official stock status to Anot overfished@ when incorporated into the three-year average SSB index calculation, and then a change back to Aoverfished@ when the 2002 index passed out of the three-year average in 2005 (Figure 2), with accompanying volatility in the annual specification of fishery regulations.

The last four peer reviews of the assessment have rejected analytical models for scup, and indicated that estimates of F based on research survey catch curve analyses are not valid. The Relative Exploitation Index (REI; total fishery landings divided by the NEFSC spring three-year SSB index) used as a proxy for F is also volatile and potentially unreliable if inter-annual changes in the SSB index are suspected to be biologically unrealistic. Finally, the NEFSC survey series using NOAA Ship *Albatross IV* sampling, on which the stock status monitoring is based, ended in November 2008. While efforts are underway to calibrate the *Albatross IV* indices to new indices collected by the NOAA Ship *Henry B. Bigelow*, those efforts may not provide a reliable basis for stock monitoring in the short term. Managers, scientists, and other stakeholders have therefore indicated a desire for a more reliable way to monitor the status of the scup stock and support the annual specification of fishery regulations.

Proposed Biological Reference Points

The following section details the sequence of work that was performed in the series of Data Poor Stocks Working Group meetings during the fall of 2008 to develop the analytical model that is the basis for the accepted BRPs. The section details the two analytical modeling approaches for scup that were pursued. The first was a relatively simple approach, the AIM model, which fits relationships between single abundance index time series and fishery catch time series. The second was a statistical catch at age model incorporating many data components, ASAP. Because the accepted model requires the use of significantly more complex input fishery and research survey data than the current BRPs, a description of those data precedes the model descriptions.

Commercial Landings

US commercial landings averaged over 18,000 mt per year from 1950 to 1965 (peaking at over 22,000 mt in 1960) and declined to less than 10,000 mt per year in the late 1960s. Landings fluctuated between about 5,000 and 10,000 mt from 1970 to the early 1990s and then declined to about 1,200 mt in 2000, less than 6% of the peak observed in 1960. Commercial landings have since increased to average about 4,200 mt during 2003-2007 (Figure 1).

About eighty percent of the commercial landings of scup for the period 1979-2007 were in Rhode Island (38%), New Jersey (26%), and New York (16%; Table 1). The otter trawl is the principal commercial fishing gear, accounting for about 75% of the total catch during 1979-2007 (Table 2). The remainder of the commercial landings is taken by floating trap (11%) and hand lines (7%), with paired trawl, pound nets, and pots and traps each contributing between 1 and 4%.

Commercial Discards

The NEFSC Observer Program has collected information on landings and discards in the commercial fishery for 1989-2007. Northeast Region (ME-VA) discard estimates were raised to account for North Carolina landings. A discard mortality rate of 100% was assumed because there are no published estimates of scup discard mortality rates. This assumption is based on limited observations and is an important element of uncertainty in the assessment. Past SAW panels have recommended that research be conducted to better characterize the discard mortality rate of scup in different gear types in order to more accurately quantify the absolute magnitude of scup discard mortality (NEFSC 1995, 1997, 1998, 2000, 2002; see also Section 7 of this report AResearch Recommendations@).

Quantifying discards from the commercial fishery is necessary for a reliable scup assessment, but low sample sizes in the past have resulted in uncertain estimates. Concern regarding the uncertainty of discard estimates due to inadequate observer sampling has been expressed in at least five previous SAW reviews of the scup assessment, and those reviews have recommended increases in sampling intensity to increase the accuracy and precision of discard estimates (NEFSC 1995, 1997, 1998, 2000, 2002). Despite the uncertainty of the discard data, recent SAW panels have concluded that commercial discarding of scup has been high during most of the last 20 years, generally approaching or exceeding commercial landings (i.e., about 50% or more of the total commercial catch). Since the implementation of GRAs in 2000, estimated discards as a proportion of the total commercial catch have decreased, averaging about 35%.

Given the uncertainty associated with estimating commercial discards for scup, three different methods for calculating discard estimates have been considered in assessments since 1998:

1) Geometric Mean Discards-to-Landings Ratio (GMDL): Ratios of discards to landings by trip landings level (for trip landings < 300 kg [661 lbs], the Abycatch fishery@; or => 300 kg, the Adirected fishery@) and half year period were calculated and multiplied by the corresponding observed landings from the NEFSC Dealer Report database to provide estimates of discards. Geometric mean rates (re-transformed, uncorrected, mean ln-transformed Discards to Landings [D/L] per trip) were used because the distributions of landings and discards and the ratio of discards to landings on a per-trip basis in the scup fishery are highly variable and positively skewed. Observed trips with both scup landings and discard were used to calculate the per trip discard to landings ratios. Only trips with both non-zero landings and discards could be used for this approach to avoid division by zero. The number of trawl gear trips used to calculate geometric mean discard-to-landings ratios (GMDL) by half year for 1997-2007 ranged from 1 to 104 for trips < 300 kg and from 1 to 35 for trips =>300 kg, with the best sampling occurring since 2003. No trawl gear trips were available for half year two in 1997 and 1999 for trips < 300 kg and for half year two in 1997-2001 for trips => 300 kg. The GMDL calculated for half year one was used to estimate discards for half year two when no trawl gear trips were available in half year two. The GMDL ratios ranged from 0.03 in 2004 (half year two, trips => 300 kg) to 121.71 in 1998 (half year one, trips => 300 kg; Table 3).

The large 1998 Adirected fishery@ discard ratio and subsequent very high annual discard estimate (111,973 mt) was based on one trawl gear trip. About 93% of the discard from that trip was attributable to a single tow in which an estimated 68.2 mt (150,000 lbs) of scup were captured. This tow was not lifted from the water and the captain of the vessel estimated the weight of the catch. There has been debate concerning the validity of the catch weight estimate and whether or not it was representative of other vessels or trips in the fishery. However, the observation was reported by a trained NEFSC observer and was therefore included in the initial calculation of the GMDL estimate of scup discards (Tables 3-4).

2) Aggregate Discards-to-Landings Ratio (AGDL): The second approach for estimating discards considered aggregate discards to landings ratios (summed D/summed L for all trips catching scup in stratum). As in the GMDL method, trips are stratified by trip landings level and half year period. The number of trawl gear trips used to calculate AGDL by half year for 1997-2007 ranged from 14 to 254 for trips < 300 kg and from 1 to 35 for trips => 300 kg, with the best sampling occurring since 2003. There are more trips available for the AGDL calculation for trips < 300 kg than in the GMDL approach, since trips with zero landings can be used. The lowest AGDL ratio calculated was 0.00 in 2001 (no discard observed in 4 trips, half year two, trips => 300 kg). The highest AGDL was 121.71 in 1998 (half year one, trips => 300 kg), the same as that calculated in the GMDL method. The AGDL approach generally provides higher annual estimates of scup discards, with greater inter-annual variability, than the GMDL approach.

3) Mean Differences between Landings and Discards (DELTA): Mean differences (kg) between landings and discard (D = landings - discard, per trip) were also calculated using the same strata as for the other methods. Observed trips in the stratum were used to calculate the mean difference in stratum, which was then applied to the scup landings of trips in the NEFSC Dealer Report database to calculate a discard for each trip (discard = landings -(D)). Calculating differences allows use of trips that had discards but no landings, whereas D/L ratios cannot be calculated in these situations (i.e. zero in the denominator). When discards exceed landings, the difference (D) is negative. As the magnitude of discards is of primary interest, the absolute values of D are used. The number of trawl gear trips used in the DELTA method calculations ranged from 6 to 254 for trips < 300 kg and from 1 to 35 for trips => 300 kg, with the best sampling occurring since 2003. The magnitude of the DELTA values ranged from 10.7 in 2001 (half year two, trips < 300 kg) to 72707 in 1998 (half year one, trips => 300 kg). As before, this large discard estimate is the result of one large discarding event in the Adirected fishery@ that was discussed above. The DELTA approach generally provides lower estimates of scup discards for the Adirected fishery @ but slightly higher estimates for the Abycatch fishery@ compared to the GMDL approach.

Since 2002 the GMDL approach discard estimates have been adopted by the MAFMC Monitoring Committee to monitor trends in fishery catch and evaluate the status of the stock, since the year-to-year trends among the three approaches differed in magnitude but followed similar trends. The large discard event in 1998 affected calculations from each method, resulting in extremely high D/L rates and subsequent discard estimates in 1998 for each approach. The DELTA method yielded estimates that were fairly consistent with the GMDL rates, while the AGDL estimates exhibited generally higher discard estimates with more variability. Previous SAW Working Groups and review panels have expressed most confidence in the estimates produced using the GMDL approach and considered the estimates to be supported by the DELTA rates. The GMDL estimates were used for all subsequent modeling approaches considered in the assessment. The 1998 estimates from all 3 computational methods was considered infeasible, and replaced by the mean of the 1997 and 1999 GMDL estimates (3,331 mt) in subsequent tabulations of catch and in subsequent modeling (Tables 3-5, and 9).

Recreational Catch

Scup is an important recreational species, with the greatest proportion of catches taken in the states of Massachusetts, Rhode Island, Connecticut and New York. Estimates of the recreational catch in numbers were obtained from the NMFS Marine Recreational Fishery Statistics Survey (MRFSS) for 1981-2007. These estimates were available for three categories: type A - fish landed and available for sampling, type B1 - fish landed but not available for sampling, and type B2 - fish caught and released alive. The estimated recreational landings (types A and B1) in weight during 1981-2007 averaged about 2,000 mt per year (Table 5). Since 1981, the MRFSS data indicate that the recreational landings have averaged 29% of the commercial and recreational landings total.

The estimated recreational discard in weight during 1984-2007 ranged from 6 mt in 1999 to a high of 185 mt in 2006, while averaging about 72 mt per year (Table 5). The weight of discards has been directly calculated only for those years (1984 and later) for which recreational catch at age has been compiled. In compilations of total fishery catch for earlier years, the recreational discards was assumed to be approximately 2% of the estimated recreational landings, based on the mean discard percentage for 1984-1996 (directly calculated discard weights for years prior to implementation of FMP regulations). No length frequency samples of the scup discard were collected under the MRFSS program before 2005, so recreational discards were assumed to be fish aged 0 and 1, in the same relative proportions and with the same mean weight as the landed catch less than state regulated minimum fish sizes. An inspection of discard length frequency samples from the New York recreational fishery for 1989-1991 indicated that this assumption was reasonable. Since 2005, length samples of the recreational fishery discard have been collected in the MRFSS For Hire Survey sampling. The mortality rate due to discarding in the recreational fishery has been reported to range from 0-15% (Howell and Simpson 1985) and from 0-13.8% (Williams, pers. comm.). Howell and Simpson (1985) found mortality rates were positively correlated with size, due mainly to the tendency for larger fish to take the hook deep in the esophagus or gills. Williams more clearly demonstrated increased mortality with depth of hook location, as well as handling time, but found no association with fish size. Based on these studies, a discard mortality rate in the recreational fishery of 15% appears reasonable and has been used in previous and the current assessments.

Commercial Fishery Landings at Length and Age

The intensity of commercial fishery biological sampling is summarized in Table 6. Annual sampling intensity varied from 27 to 687 mt per 100 lengths, with sampling exceeding the informal threshold criterion of 200 mt per 100 lengths sampled since 1994. For this assessment, commercial fishery landings at age beginning in 1984 have been updated through 2007, with samples generally pooled by market category (pins/small, medium, large/mix, jumbo, and unclassified) and half year period (January-June, July-December), with market category samples pooled on a quarterly basis for 2004-2007. Estimates of commercial fishery landings at age (Figure 3) and mean weights at age are presented in Tables 7-8.

Commercial Fishery Discards at Length and Age

The intensity of length frequency sampling of discarded scup from the NEFSC Observer Program declined in 1992-1995 relative to 1989-1991 (Table 9). Sampling intensity ranged from 489 to 335 mt per 100 lengths sampled in 1992-1995, failing to meet the informal criterion of 200 mt per100 lengths sampled. Sampling intensity improved to 100 mt per 100 lengths in 1996, but then declined to over 200 mt per 100 lengths in 1997-1999. Sampling intensity has generally met the 200 mt per 100 length threshold since 1999. The mean weight of the discard was estimated from length frequency data and a length-weight equation, with the total numbers discarded then estimated by dividing total discard weight by mean fish weight, and the numbers at length then calculated from the length-frequency distribution. Discards at length were aged using a combination of commercial and survey age-length keys, with discards at age dominated by fish aged 0, 1, or 2, depending on the year under consideration. Estimates of commercial fishery discards at age (Figure 4) and mean weights at age are presented in Tables 10-11.

Recreational Fishery Landings at Length and Age

In the recreational fishery, landings sampling intensity varied from 45 to 471 mt per 100 lengths. Sampling in all years except one (1984) during 1981-1987 failed to satisfy the above criterion, but since 1987 the criterion has been met except for 1999-2000 (Table 12). Numbers at length for recreational landings were determined based on available recreational fishery length frequency samples pooled by half year period over all regions and fishing modes, and were converted to numbers at age by applying half year period age-length keys constructed from NEFSC commercial and survey samples. Age-length keys from spring surveys and first and second quarter commercial samples were applied to numbers at length from the first half of the year, while age-length keys from fall surveys and third and fourth quarter commercial samples were applied to numbers at length from the second half of the year. Estimates of recreational fishery landings at age (Figure 5) and mean weights at age are presented in Tables 13-14.

Recreational Fishery Discards at Length and Age

As noted earlier, no length frequency distribution data on scup discard are routinely collected under the MRFSS program prior to 2005, so recreational discards were assumed to be fish less than state minimum sizes, in the same relative proportions at age as the landed catch less than the respective state minimum sizes (i.e., sub-legal fish of ages 0 and 1). This assumption for the coastwide fishery is supported by discard length frequency samples from the New York recreational fishery (1989-1991) and samples collected since 2005 by the MRFSS For-Hire Survey. Since 2005, the MRFSS For-Hire Survey discard samples have been used in concert with the MRFSS sub-legal landed lengths to directly characterize the length frequency of the recreational discard. As noted earlier, a 15% discard mortality rate is assumed. Estimates of recreational fishery discards at age (Figure 6) and mean weights at age are presented in Tables 15-16.

Total Fishery Catch

Estimates of the total fishery catch at age and mean weights at age for 1984-2004 (the time series is limited by the availability of sampled fishery ages) are presented in Tables 17-18.

An extended time series of the total catch of scup has been estimated to provide an historical perspective of the exploitation of scup in the years before fishery aging data were available (Table 19). These estimates include commercial and recreational landings and discards. The catches before 1981 are the least reliable due to uncertainty about a) the level of domestic commercial fishery discards, b) distant water fleet (DWF) catch, and c) assumptions to estimate the recreational catch (50% reduction from interpolations made in Mayo 1982 for 1960-1978; recreational discards assumed to be 2% of the adjusted recreational landings). For years in which no observer data were collected (prior to 1989), commercial discards were estimated using the mean of GMDL approach ratios for 1989-2001.

Research Vessel Survey Indices

NEFSC

The NEFSC spring and fall surveys provide long time series of fishery-independent indices for scup. The NEFSC spring and fall surveys are conducted annually during March-May and September-November, ranging from just south of Cape Hatteras, NC to Canadian waters. NEFSC spring and fall abundance and biomass indices for scup exhibit considerable inter-annual variability (Table 20). The 2002 spring SSB index (9.24 kg/tow) was about twice the second highest spring SSB index, which was observed in 1977 (4.35 kg/tow)(Figure 7). The spring numeric abundance indices are similar; in 2002, the estimated index of spring abundance is the highest observed in the series (154.86 fish/tow) and about twice the 1970 index (78.50 fish/tow). These dramatic increases were evident across all ages in the estimated 2002 spring numbers at age (Table 21; Figure 8). Fall survey estimates of numbers at age in 2001 did not reflect relatively large values from which corresponding 2002 spring numbers at age might be expected to derive (Table 22, Figure 9) , nor did they translate to exceptional indices of biomass or SSB in fall 2002 or spring 2003. Spring survey SSB and abundance indices decreased subsequent to 2002, but are still above the low values of the late 1990s. Fall survey abundance and biomass have been highly variable since 2002.

The NEFSC winter survey was started in 1992 primarily as a flatfish survey (used a different trawl net than the spring and fall surveys), was conducted during February, and ranged from Cape Hatteras, NC to the southwestern part of Georges Bank. The winter survey 2002 abundance and biomass indices were, like the spring survey, the largest of the time series (Table 23). Similar to the spring estimates, numbers at age estimated for the 2002 winter survey were also exceptionally large (Table 24, Figure 10). Winter survey abundance and biomass decreased subsequent to 2002, but were still above the low values of the late 1990s. The winter trawl series ended in 2007.

As noted in Sections 1-4, indices of scup SSB per tow were developed from the NEFSC spring offshore strata series for use as proxy biomass reference points. The 1998 SAW 27 panel (NEFSC 1998) selected a three-year moving average of the NEFSC spring SSB index as a representative measure of scup SSB, based on the characteristics of the survey age structure, the magnitude of the survey catch, and the trend in the extended series of commercial and total fishery catch estimated back to 1960 (Table 19, Figures 1-2). FMP Amendment 12 defined the biomass threshold reference point as the maximum (at the time) observed value of this three-year moving average: the 1978 value (mean of 1977-1979) of 2.77 SSB kg/tow (Table 20, Figure 2). FMP Amendment 14 defined the target biomass BRP as twice the threshold value of this three-year moving average, or 2 times 2.77 = 5.54 SSB kg/tow.

Massachusetts DMF

The Massachusetts Division of Marine Fisheries (MADMF) has conducted a semi-annual bottom trawl survey of Massachusetts territorial waters in May and September since 1978. Survey coverage extends from the New Hampshire to Rhode Island boundaries and seaward to three nautical miles including Cape Cod Bay and Nantucket Sound. The study area is stratified into geographic zones based on depth and area. Trawl stations are allocated in proportion to stratum area and are chosen randomly within each stratum. A 20 minute tow at 2.5 knots is made at each station with a 3/4-size North Atlantic two- seam otter trawl (11.9 m headrope, 15.5 m footrope) rigged with a 19.2 m chain sweep with 7.6 cm rubber discs. The net contains a 6.4 mm mesh codend liner to retain small fish. Approximately 95 stations are sampled during each survey. Standard bottom trawl survey techniques are used to process the catch of each species. Generally, the total weight (nearest 0.1 kg) and length frequency (nearest cm) are recorded for each species on standard trawl logs. Collections of age and growth structures, maturity observations, and pathology observations are taken. The MADMF spring survey catches are characterized mainly by scup of ages 1 and 2, while the fall survey often captures large numbers of age 0 fish. The spring biomass and abundance indices dropped sharply from a high in the early 1980s to relatively low levels through the remainder of the time series, with the exception of spikes in 1990, 2000, and 2002, the latter event in common with the NEFSC spring trawl survey (Table 25, Figure 11). The MADMF fall indices can include large numbers of age 0 fish, and on a numeric basis are more variable than the spring indices. The fall biomass index is less variable than the spring, however, and exhibits an increasing trend since the mid 1990s (Figure 12).

Rhode Island DFW

The Rhode Island Division of Fish and Wildlife (RIDFW) has conducted autumn and spring surveys since 1979 based on a stratified random sampling design. Three major fishing grounds are considered in the spatial stratification, including Narragansett Bay, Rhode Island Sound, and Block Island Sound. Stations are either fixed or randomly selected for each stratum. To maintain continuity in the number of stations sampled per stratum each season, an alternate list is generated for substitution in the event of an unexpected hang-up or questionable bottom type. At each station, a 3/4-scale High Rise bottom trawl is towed for 20 minutes at an average speed of 2.5 knots. The net average vertical opening is estimated at 10 feet. The otter trawl doors are 2 ft by 4 ft in dimension, set 7.5 fathoms ahead of the wings of the net. The RIDFW spring survey mainly catches scup of ages 1 and 2. The spring indices show relatively levels of scup abundance and biomass through 1999 followed by a steep increase during 2000-2002, in common with the NEFSC and MADMF indices. No scup were caught in the spring 2003 survey, but the index has since rebounded to pre-2000 levels (Table 26; Figure 11). The RIDFW fall survey is dominated by age 0 scup. Fall abundance indices show a general increase to its 1993 peak, followed by a steep decline until 1998, and a general increase since then, reaching a time series peak in 2007 (Figure 12).

Connecticut DEP

The Connecticut Department of Environmental Protection (CTDEP) trawl survey program was initiated in May 1984 and encompasses both New York and Connecticut waters of Long Island Sound. The stratified random design survey is conducted in the spring (April-June) and fall (September-October). Each survey consists of three cruises, with 40 stations sampled during each cruise, providing a sampling density of one station per 20 square nautical miles per cruise. Prior to 1990, the survey was conducted monthly from April to November. The CTDEP spring indices exhibit relatively low levels through most of the survey period, but have increased substantially since 1999 (Table 27, Figures 11 & 13). The CTDEP fall survey, which often catches large numbers of age-0 scup, indicates that recruitment was relatively stable during most of the survey period, but fall indices have also increased substantially since 1999 (Table 28, Figures 12 & 14). The age compositions of the CTDEP spring and fall surveys generally include a higher proportion of age 2 and older fish than the other state or NEFSC surveys (Figures 13-14).

New York DEC

The New York Department of Environmental Conservation (NYDEC) initiated a small mesh trawl survey in 1985 to collect fisheries-independent data on the age and size composition of scup in local waters. This survey is conducted in the Peconic Bays, the estuarine waters which lie between the north and south forks of eastern Long Island. Tows are 20 min in duration. The net used has a 16 ft headrope and a 19 ft footrope and is constructed of polypropylene netting with 1.5 in stretch mesh in the body and 1.25 in stretch mesh in the codend. No survey data are available for 2005. The NYDEC survey provides age 0, 1, and 2+ indices of scup abundance. The age 0 indices are generally low over the survey period, with peaks in 2000, 2002, 2003, 2006, and 2007 that may indicate recruitment of strong cohorts in those years (Table 29). In the early years of the survey there often has not been a strong correspondence between the age 0 indices and age 1 and 2+ indices in the following years (Figure 15).

New Jersey BMF

The New Jersey Bureau of Marine Fisheries (NJBMF) conducts a stratified random bottom trawl survey of New Jersey coastal waters from Ambrose Channel south to Cape Henlopen Channel. Latitudinal strata boundaries correspond to those in the NEFSC trawl survey; longitudinal boundaries correspond to the 30, 60, and 90 foot isobaths. Each survey includes two tows per stratum plus one additional tow in each of nine larger strata for a total of 39 tows. A three-in-one trawl with a 100 ft footrope, an 82 ft headrope, 3- 4.7 in mesh throughout most of the body and a 0.25 in mesh codend liner is used. From 1991 to present, the area has been surveyed in January, April, June, August, and October; from 1988-1990, February and December surveys were incorporated instead of the January survey. The NJBMF abundance and biomass indices exhibit variable patterns over the early part of the time series. The index reached a minimum in 1996, and has generally increased since then, reaching time series highs in numbers and biomass in 2007 (Table 29; Figure 11).

Virginia Institute of Marine Science (VIMS)

The Virginia Institute of Marine Science (VIMS) has conducted a juvenile scup survey in lower Chesapeake Bay during June-September since 1988. The VIMS age-0 scup survey shows a general decline in recruitment from relatively high levels with peaks in 1990 and 1993 to relatively low levels from 1994 to 2004, and the indication of stronger year classes in 2006 and 2007 (Table 29).

University of Rhode Island Graduate School of Oceanography (URIGSO)

University of Rhode Island Graduate School of Oceanography (URIGSO) has conducted a standardized, two-station trawl survey in Narragansett Bay and Rhode Island Sound since the 1950s, with consistent sampling since 1963. Irregular length-frequency samples for scup indicate that most of the survey catch is of fish from ages 0 to 2. The aggregate numbers-based index reached a peak in the late 1970s, was relatively low during the late 1990s, reached a second peak in 2002 in common with the NEFSC, MADMF, RIDFW spring biomass indices, and has since been variable at relatively high level (Table 30, Figure 11).

Chesapeake Bay Multispecies Monitoring and Assessment Program (ChesMMAP)

The Chesapeake Bay Multispecies Monitoring and Assessment Program (ChesMMAP) trawl survey is designed to support bay-specific stock assessment activities at both a single and multispecies scale. While no single gear or monitoring program can collect all of the data necessary for quantitative assessments, ChesMMAP was designed to fulfill data gaps by maximizing the biological and ecological data collected for several recreationally and commercially important species in the bay. Total abundance and biomass indices for scup mainly of age 0 and 1 are available since 2002, and indicate strong recruitment in 2005 and 2006 (Table 31).

Natural Mortality

Instantaneous natural mortality (M) for scup was assumed to be 0.20 (Crecco *et al.* 1981, Simpson *et al.* 1990). The largest/oldest scup sampled in NEFSC surveys (1973, 1978) were fish 38-41 cm (fork length) and 14 years old. The largest/oldest scup in NEFSC commercial fishery samples (1974) was 40 cm (fork length) and 14 years old.

Models of Fishing Mortality and Stock Size

Background Information

The 1998 SAW 27 Panel (NEFSC 1998) rejected an ADAPT VPA for scup as the basis for assessing stock status or as the basis for projections. The panel indicated that the amount of variance in the scup catch at age, particularly for the commercial discards, was unreasonably large. The Panel concluded that the precision of estimates of fishing mortality and stock size from the VPA was unacceptably low and would provide an unreliable basis for any estimates of stock size and fishing mortality rates (NEFSC 1998). The SAW 27 Panel also reviewed a surplus production model for scup developed in the ASPIC framework. The Panel noted that the inability to directly estimate historical commercial fishery discards (1968-1988) and recreational catch (1968-1978) cast uncertainty on the validity of the ASPIC absolute estimates of stock biomass, fishing mortality rates, and biological reference points. Since the ASPIC analysis suffered from many of the same input data inadequacies as the VPA, the SAW 27 Panel rejected the ASPIC analysis as a basis for stock status, projections, or reference points (NEFSC 1998).
State and NEFSC survey indices at age for scup are highly variable. The patterns in proportions at age in survey indices and survey catchability coefficients at age estimated in the VPA suggested that all ages of scup may not be equally available or susceptible to capture by survey trawl gear. As a result, the SAW 27 Panel noted that mortality estimates derived from survey catch at age indices are highly variable and may be positively biased, and are probably not a reliable basis for evaluating fishing mortality rates (NEFSC 1998). These conclusions about the lack of reliability of surplus production, VPA, or catch curve analyses for scup, due mainly to an inability to evaluate the uncertainty of results, have been supported by subsequent SAW Panel reviews of the scup assessment (NEFSC 2000, 2002).

In the absence of reliable analytical model results for scup, the 2000 SAW 31 Panel (NEFSC 2000) developed and the MAFMC Monitoring Committee has subsequently used a Relative Exploitation Index (REI) as a metric for the instantaneous fishing mortality rate (F). The scup REI is computed as the ratio of total fishery landings to the NEFSC spring trawl survey

SSB three year average index. Landings, rather than total catch, are used in the REI because of the relatively high uncertainty of commercial fishery discard estimates. The REI is therefore assumed to reflect the fishing mortality on age 2 and older scup because fishery landings and survey catch in the NEFSC spring SSB index are generally scup of ages 2 and older. The low REI values in the early 1980s were consistent with the Mayo (1982) assessment of scup (Figure 16; note that the REI is plotted on a log scale). There was a general increasing trend in the REI through the mid-1990s followed by a steady decline through 2001, with an increasing trend since 2001.

The 2000 SAW 31 Panel (NEFSC 2000) concluded that A ...catch curve analyses of survey indices indicate that F for ages 0-3 exceeds 1.0...for the 1994-1998 year classes.@ The 2002 SAW 35 Panel (NEFSC 2002) concluded, however, that AThough the relative exploitation rates have declined in recent years, the absolute value of F cannot be determined.@ In recent years, the MAFMC Monitoring Committee has used the REI as part of the assessment information used to recommend an annual Total Allowable Landings (TAL) for the stock. The MAFMC Monitoring Committee has assumed that F in 1999 was equal to 1.0 (NEFSC 2000), equating to an annual exploitation rate of 58%, which in turn equates to the 1999 REI = 62.4. An estimate of the current year exploitation rate has then been developed by assuming the same ratio between the current REI and exploitation rate, to provide advice on an appropriate level for the next year TAL.

The SAW 35 Panel (NEFSC 2002) reviewed an application of the NOAA Fisheries Toolbox model called AAn Index Method,@ or AIM, to scup fishery and survey catch data. That work used the extended total catch series noted earlier, and found that the NEFSC fall survey series provided a better model fit than the NEFSC spring series used as the basis for the biomass reference point and as input to the REI described earlier. The SAW 35 Panel (NEFSC 2002) noted that for scup, the AIM approach had A...considerable promise as a monitoring tool to evaluate stock trajectories and provide valuable information in interim years between analytical assessments@ and A...utility in presenting an integrated picture of stock dynamics for resources where only catch statistics and survey trends are available.@ While this approach was not adopted by the 2002 SAW 35 Panel to monitor the status of the stock, further research using the AIM model was recommended.

As noted earlier, the most recent update of the current stock assessment approach was completed in July 2008 to support the specification of fishery regulations for 2009. The update indicated that while the stock was overfished in 2007 (1.16 kg per tow, 21% of the biomass target of 5.54 kg per tow; Figure 16), the exploitation rate was at about the rebuilding target rate (9%; F = 0.10), suggesting that overfishing was not occurring in 2007. However, the stock rebuilding rate was slower than indicated by the FMP Amendment 14 projection, with the actual 2007 index (2006-2008 three-year average = 1.16 kg per tow) at only 56% of the forecast 2007 index (2.08 kg per tow).

An Index Method (AIM)

The AIM model (NFT 2008a) fits a relationship between time series of relative stock abundance, such as survey indices of abundance or biomass, and fishery catch data that might include landings and discards. Underlying the approach is a linear model of population growth, which characterizes the population response to varying levels of fishing mortality. If the underlying model is valid over the range of densities observed, AIM can be used to estimate the level of relative fishing mortality at which the population is likely to be stable (e.g., a proxy for

FMSY). The approach can be used to construct reference points based on relative abundance indices and catches, and to perform deterministic and stochastic projections to achieve a target stock size.

The basic calculations of the AIM model are two derived quantities, the Replacement Ratio (RR) and Relative F (RF). Replacement ratio is the ratio between the current year observed index and a smoothed value of the index over a given number of the current and previous years (typically 3 to 5), and is a measure of the trend in abundance or biomass of the population. Relative F is the ratio of the observed catch to a centered average index over a given number of years (typically 2 to 3). It should be noted that the application of any smoothing technique reflects a choice between signal and noise, with a greater degree of smoothing eliminating noise but possibly failing to detect a true change in signal (Rago 2001).

When fishing mortality rates exceed to capacity of a population to replace itself the population is expected to decline over time; likewise the population is expected to increase if fishing mortality rates are less than the capacity of a population to replace. In the AIM approach, the RR will have a stable point = 1 when the fishing mortality rate is in balance with recruitment and growth, resulting in a stable population. Robust regression techniques are used in AIM to estimate the RF ($RF_{threshold}$) corresponding to RR = 1. Values of RF in excess of $RF_{threshold}$ are therefore expected to lead to stock decline (i.e., fishing mortality exceeds FMSY), while RF values less than $RF_{threshold}$ would be expected to allow populations to increase. Randomization tests are used to test the null hypothesis that the input fishery catch and survey index time series represent a random ordering of observations with no underlying association, and that in turn the relationship between RR and RF is not spurious.

The AIM approach was tested with data for scup in the 2002 SAW 35 review (NEFSC 2002). An extended series of total catch beginning in 1963 and the NEFSC spring and fall biomass indices through 2001 were used as inputs. In the SAW 35 work, only the NEFSC fall series provided a statistically significant regression between the RR and RF, and results indicated that the RR first increased above 1.0 in 1996, and that the RF during 2000 was lowest of the time series. The SAW 35 work also indicted that re-examination of the reliance on the NEFSC spring survey series as the primary signal of stock abundance was warranted (NEFSC 2002).

The current AIM implementation for scup was tested over a range of degree of smoothing of both the RR and RF to explore the sensitivity of results to those inputs. Also, three different lengths of the extended catch time series (Table 19) were tested: beginning in 1963 (advent of the NEFSC trawl surveys), beginning in 1974 (to include the peak in NEFSC Surveys used as the basis for the current biomass reference point), and beginning in 1981 (to include the least number of assumptions for catch estimates). All of the available NEFSC and state agency survey series of stock biomass and abundance were initially tested for their utility in the AIM approach.

The best (i.e., a significant model at the p = 0.10 level) simple regression fits in AIM were provided by the NEFSC fall, URIGSO, NJBMF annual, and MADMF spring survey series (Figures 17-20). The MADMF and NJBMF series are too short to serve as the sole stock index for scup in the AIM model - neither series captures the historical peaks and trends in biomass. The 1974 and 1981 AIM run configurations suffer from the same shortcoming. The URIGSO, MADMF and NJBMF series also failed to satisfy the randomization test at the p = 0.10 level. These initial results indicated that only the NEFSC fall survey biomass index (Figures 17 and 19) provided acceptable fit statistics and other diagnostics within the AIM model framework.

In an attempt to include the recent information content of the multitude of state agency surveys as well as the historical perspective provided by the long-term NEFSC and URIGSO series, a model-based index including all of the index series in a GLM framework was developed. Alternative configurations included lognormal, Poisson, and negative binomial error distribution assumptions; Asurvey@ was used as the classification variable, with the Ayear@ classification variable coefficient acting as the index of abundance. The Working Group adopted the GLMALL index with Poisson error (Figure 21) for input to AIM based on the GLM model fit statistics and diagnostics. AIM results for the GLMALL index with Poisson error showed a significant regression model ($p < 0.10$) and feasible Relative F and Replacement Ratio results (Figure 22), but a failed randomization test.

These results suggest that the most appropriate AIM model would include only the NEFSC fall survey biomass index. However, the NEFSC spring and fall *Albatross IV* time series have ended, and even if reliably calibrated indices from the *Henry B. Bigelow* series can be developed (Figure 23), they will likely not be available for at least a few years. Thus, the Working Group concluded that the AIM results provided the impetus to explore a more complex statistical catch at age model (such as ASAP) that is better able to accommodate the numerous sources and relatively high uncertainty of both fishery and survey data for scup.

Age Structured Assessment Program (ASAP) Model

The fishery and research survey data for scup described earlier were used as input for the Age Structured Assessment Program (ASAP) statistical catch at age model in NFT version 2.0.17 (NFT 2008b). NEAMAP survey data were considered by the Data Poor Working Group but were not used to calibrate the scup population model. It was not clear that the NEAMAP data could serve as an abundance index yet given the very short survey time series and the high variance between seasons.

The ASAP model is able to estimate residuals (error) for the fishery catch components as well as for the survey indices used for calibration. The ASAP model also allows control in specifying the selection (partial recruitment) characteristics for both the fisheries and the surveys, in specifying the underlying stock-recruitment relationship, and in the relative emphasis of the different likelihood components that influence the model estimation results.

Initial Runs

The fishery catch data (aggregate catches in weight for 1963-2007; catches at age in number for 1984-2004) were input as four component fisheries (commercial landings, commercial discards, recreational landings, recreational discards; in aggregate weight and as number at age) and associated mean weights at age. Natural mortality (M) was set equal to 0.2, and maturity at age was set as in the SAW 27 assessment (NEFSC 1998) with proportions mature as follows: age 0 = 0.00, age 1 = 0.13, age 2 = 0.75, age 3 = 0.99, and age 4 and older = 1.00. In the initial ALL configuration, the following research survey abundance indices at age were used: NEFSC spring ages 1-4, NEFSC fall ages 0-4, NEFSC winter ages 1-4, CTDEP spring ages 1-6+, CTDEP fall ages 0-5+, NYDEC ages 0-1, and VIMS age 0. Aggregate biomass or abundance indices from the NEFSC winter, spring, and fall, MADMF spring and fall, RIDFW spring and fall, CTDEP spring and fall, NJBMF annual, and VIMS surveys were also used as input in initial runs. Fishery selectivity was estimated for two time periods: 1984-1996 and 1997-2007, with the break roughly coinciding with the advent of substantial regulatory changes in the fisheries (Amendment 8 in 1997 and Amendment 12 in 1998). Other model options (survey CVs, stock-recruit function CVs and lambdas, etc.) were configured to provide stable and feasible results. Alternative input data model configurations tested included a) only NEFSC surveys, b) only STATE surveys, and c) only NEFSC and URIGSO (NEC-URI) surveys.

The four initial model configurations (ALL, NEFSC, STATE, and NEC-URI) provided comparable time series trends in SSB and F through the late 1990s: high abundance and low F in the early 1960s, a decline and then rebuilding to a period of abundance in the late 1970s, and then a decline in abundance under high Fs in the mid-1980s to mid-1990s resulting in a period of low abundance in the late 1990s. The alternatives differed substantially in the development of the stock since 2000, and in the estimate of current abundance with respect to the previous peak in the late 1970s, mainly as a result of differing estimates of recruitment since the late 1990s (Figures 24-26). The STATE run provided the highest recent estimates of SSB, due to the scaling of recent large year classes (with the notable exception of 2006) about 50% higher than the ALL run and 100% higher than the NEFSC and NEC-URI runs. Comparison of the alternative estimates of SSB and F with ASAP internally calculated BRPs indicates that the stock in 2007 was about two to four times SSBMSY, with Fs at about 20-50% of FMSY (Figure 27).

Modifications to Survey Input Data

The initial runs indicated that the stock should be considered to be fully rebuilt with no overfishing. With a stock at that level of abundance, there is an expectation that both fishery and survey catches would reflect a robust age structure with significant numbers of older fish. There is evidence of expansion of the age structure of the fishery catch since about 2000 (Figures 3-6), likely reflecting the combined effects of a) increasing minimum retention sizes b) more restrictive trip limits in the fisheries, c) recent decreases in quotas/harvest limits and d) real increases in recruitment and subsequently SSB.

However, there is little evidence of substantial expansion of the age structure of the stock in the survey catches (Figures 8-10, 15), except for the CTDEP survey catches (Figures 13-14). Previous and current reviews of the scup research trawl survey data have noted that the catchability and/or availability of age 3 and older fish is likely reduced compared to age 0-2 fish. The NEFSC survey catches likely reflect this higher catchability of ages 0-2 relative to older fish (ages 3 and older), and so the aggregate biomass indices likely reflect mainly the abundance of ages 0-2, but not of ages 3 and older. Examination of the available length and age frequencies suggests the same properties likely apply to the MADMF, RIDFW, URIGSO, NYDEC, and ChesMMAP indices for scup. The CTDEP survey catches, however, are distributed across ages more in line with realistic total mortality rates, suggesting that the CTDEP survey older age indices (ages 3 and older) may be reflective of true abundance, with aggregate indices in turn more reflective of total stock biomass (Figures 13-14).

In an attempt to resolve the inconsistent signals provided by the fishery and survey catches, a number of modifications were made to the input survey data and to the manner in which the survey data are modeled in ASAP. For the NEFSC survey indices at age, input data were limited to the age 0-2 indices. The NEFSC long-term aggregate biomass indices were recompiled with a length cut-off at age 2 (winter = 22 cm; spring = 20 cm; fall = 23 cm; Figures 28-30), and selectivity (selex) within the ASAP model limited to ages 0/1 to 2. The consistency of rank order and trends between the original and modified NEFSC aggregate indices indicates that those series best index the abundance and biomass of ages 0/1 to 2.

For the MADMF, RIDFW, NJBMF, and URIGSO aggregate indices, selectivity within the ASAP model was also limited to ages 0/1 to 2. Alternative runs were made with different inputs and assumptions for the CTDEP indices, to test the inclusion of age 3 and older indices and aggregate indices, and correspondingly varying the selectivity of the aggregate indices. The newly modified runs are identified as:

Sep08_ALL: All indices, all ages, aggregate index selex for ages 0/1 to 7+
SV0to2: Use only age 0-2 indices, no aggregate indices
SV0to2_AGG0to2 Use only age 0-2 indices, aggregate indices selex for age 0/1 to 2
SV0to2_AGG0to2_CTALL: Use all CT indices, CT aggregate indices selex for ages 0/1 to 7+

The modified runs generally provided a different recent pattern of stock biomass in relation to the early 1960s and late 1970s peaks compared to the four initial runs, and also higher recent biomass in absolute terms. The four initial run estimates of SSB in 2007 ranged from 55,000 mt to 140,000 mt (Figure 24); the four modified run estimates ranged from 90,000 mt to 180,000 mt (Figure 31). The Sep08_ALL run, which includes some additional input data series (URIGSO, ChesMMAP and updated NYDEC) and some modifications to initial settings, provided results closest to the initial ALL run.
The two modified runs with older ages excluded from both the at-age and aggregate indices (SV0to2 and SV0to2_AGG0to2) estimated higher recent recruitment and thus lower recent F and higher recent SSB than the Sept08_ALL run (Figures 31-33). The run including all ages in the CTDEP indices (SV0to2_AGG0to2_CTALL) estimated extremely high recent recruitments (three year classes > 300 million age 0 fish) and correspondingly low F and high SSB. The SV0to2_AGG0to2_CTALL run had the poorest diagnostics of the four runs, in terms of a) large residuals for many of the survey indices, b) relatively poor fits to the estimated commercial and recreational fishery aggregate discards, and c) relatively poor fits to the estimated commercial and recreational fishery discards at age. For those reasons, the SV0to2_AGG0to2_CTALL configuration was not considered further.

The other three runs had comparable residual patterns and fits to the estimated catches. Four objective function components, a) fishery total catch, b) fishery age compositions, c) survey indices (age compositions plus aggregate indices), and d) recruitment deviations, account for 99% of the total objective function for all four modified runs. With the SV0to2_AGG0to2_CTALL excluded, the remaining three runs had comparable objective function distribution and fit diagnostics. Figure 34 shows that restricting the input survey data to only the age 0-2 indices (run SV0to2) shifts more of the influence on the model solution to the fishery catch (total and age composition) components, compared to the other runs that also include aggregate indices (whether restricted to ages 0-2 or allowed to include older ages). The SV0to2 run does not include the long-term aggregate indices that are included in the Sep08_ALL and SV0to2_AGG0to2 runs, fishery independent data that increases the precision of historical stock size estimates in those runs. However, run Sep08_ALL includes indices at age 3 and older that are less likely to be reflective of true abundance than indices for ages 0-2. Therefore, by elimination of configurations with diagnostic or data fit concerns, the SV0to2_AGG0to2 run was carried forward for further examination of the sensitivity of the model to changes in configuration.

The next step was to examine the retrospective performance of the SV0t2_AGG0to2 run to judge its= potential utility to reliably monitor the stock. Six retrospective peels (a seventh, terminal year 2001 retrospective peel did not converge) indicated that the SV0to2_AGG0to2 run was stable with little retrospective pattern evident in SSB, F, or R (Figure 35).

Sensitivity to Fishery Catch Lambdas (Weighting Factors) and Time Series Length

Next, model sensitivity to fishery catch lambdas (the weighting or emphasis factors on the four aggregate fishery catch components) was examined. The initial and modified runs described earlier were made with lambdas set at 0.10 (i.e., CV = 10%) for all four aggregate fishery catch components. Further sensitivity runs were made with lambda set at 0.10 for commercial landings and 0.20 for the commercial discards, recreational landings, and recreational discards (run CAT20); with 0.10 for commercial landings and 0.30 for the commercial discards, recreational landings, and recreational discards (run CAT30); with 0.10 for commercial landings and 0.60 for the commercial discards, recreational landings, and recreational discards (run CAT60); with 0.10 for commercial landings and lambda changing from 0.30 to 0.10 in 1981 for the commercial discards, recreational landings, and recreational discards (run CAT30to10); and with 0.10 for commercial landings and lambda changing from 0.60 to 0.30 in 1981 for the commercial discards, recreational landings, and recreational discards (run CAT60to30). The 1980/1981 time split coincides with the more reliable estimation of recreational catches.

The results of the SV0to2_AGG0to2 run configuration were sensitive to the catch lambda specifications. The 1980/1981 time split in the CAT30to10 and CAT60to30 runs did not have an important effect on the results. However, the change from lambdas of 0.10 to lambdas of 0.20 and higher did have an important effect on SSB results, as reflected by the Ashift@ from the initial SV0to2_AGG0to2 and CAT30to10 runs (all recent catch lambdas set at 0.10) to the runs with recent commercial discards, recreational landings, and recreational discards lambdas set at 0.20 or higher. Results for F and R were less strongly affected. Lambdas reflecting greater uncertainty of the magnitude of commercial discards and recreational catch resulted in lower recent estimates of SSB and a different relationship between current estimates and previous peaks in SSB in the 1960s and late 1970s (Figure 36-38). This result occurs because the influence of the survey indices in these run configurations is mainly restricted to ages 0-2, and so the magnitude and uncertainty of the input fishery catches has the strongest influence on estimates of recent SSB.

The input assumptions for the age range for which the survey indices can be considered reliable, and the estimate or assumption for the uncertainty of the input fishery catch, both have strong influence on the model results. Based on the work presented earlier, an assumption that most survey indices are likely to be reflective of true abundance only for ages 0 to 2 is appropriate - hence the subsequent work using run SV0to2_AGG0to2 as a basis. Further investigation of the empirical precision of the commercial fishery discards and recreational catches indicated that the precision of commercial fishery discards averaged (unweighted average of annual PSE) 39% for 1997-2007 (Table 4) and 32% for the entire NEFSC Observer Program sample period (1989-2007). The precision of recreational fishery landings (catch types A+B1 numbers) during 1981-2007 averaged 10%; the precision of recreational fishery discards (catch type B2 numbers) during 1981-2007 averaged 12%. A new run, BASE_Nov08, was configured to reflect this empirical information about the uncertainty of the fishery catch for scup, with commercial landings lambda assumed to be 0.10, commercial discards lambda set at 0.32, recreational landings lambda set at 0.10, and recreational discards lambda set at 0.12; for all years 1963-2007. The results of the BASE_Nov08 run were similar to the sensitivity runs with commercial discard and recreational catch lambdas of 0.20 and greater, indicating that the current magnitude of SSB is about the same as in the 1960s and higher than in the late 1970s, with very low current F and several very large year classes recruiting to the stock since 2000 (Figure 39-41).

A sensitivity exercise was conducted to test the influence of the length of the catch time series modeled. The BASE_Nov08 time series includes a time series of fishery catches extended back to 1963, using ratios to extend the commercial discards (1963-1988) and recreational landings and discards (1963-1980; Table 19). The BASE81_Nov08 run was configured to include only fishery and survey data from 1981-2007, the time period for which most of the fishery catches are reported or estimated from sampling, rather than extrapolated from ratios. The shorter time series provided 10-30% lower estimates of SSB during the early 1980s, and 10-20% higher estimated of SSB since 2003, when compared to the 1963-2007 BASE_Nov08 run (Figure 42). Patterns and levels of F and R were very similar, however (Figures 43-44). The BASE_Nov08 run SSB varied from about 103,000 mt in 1963 to a time-series low of 4,100 mt in 1995 to a time-series high of 107,100 mt in 2007; Fs varied from a high of 1.13 in 1993 to a low of 0.06 in 2007; recruitment varied from a low of 32 million age 0 fish in 1996 to a high 367 million in 2007. The BASE81_Nov08 run SSB varied from a low of 4,200 mt in 1995 to a high of 122,700 mt in 2007; Fs varied from a high of 1.14 in 1994 to a low of 0.06 in 2007; recruitment varied from a low of 35 million age 0 fish in 1996 to 308 million in 2007. Biological Reference Points calculated from the BASE_Nov08 and BASE81_Nov08 runs are presented in Figure 45. Given the similarity of the results, the November 2008 Working Group decided to use to the BASE_Nov08 runs with the full 1963-2007 time series as the basis for further model development.

Sensitivity to 2002 Survey and Commercial Discard Estimates

The next step in model development was to add preliminary fishery catch at age estimates for the four fishery fleets for 2004-2006, which provided model run configuration BASE_C2006. The November 2008 Working Group reviewed the diagnostics of the BASE_C2006 run in detail, and noted that some components of the calendar year 2002 survey data and the 2002 commercial fishery discard aggregate estimate provided large residuals (Figure 46-48). The unusually high values for many survey indices in 2002 has been noted previously, and is presumed to result mainly from increased availability of fish to the surveys, especially during the first half of 2002, rather than true increases in abundance (e.g., Figures 7-8, 11). The same type of availability event may have affected the 2002 commercial fishery discard sampling, resulting in higher than usual discard rates and increased estimated discards at age in 2002 (Figure 4). To explore the sensitivity of the ASAP model for scup to these data, two new runs were configured. The first, BASE_C2006_No02SV, dropped all the calendar year 2002 survey indices (at age and aggregate) from the model fit. The second, BASE_C2006_No02SV_NoCD02, also dropped the 2002 commercial fishery discard estimates at age and used the average of the 2001 and 2003 estimates as a substitute for the 2002 aggregate discard weight.

Figures 49-51 summarize the results of these BASE_C2006 runs. The BASE_C2006 run with fishery catch at age through 2006 provided results very similar to the BASE_Nov08 run with fishery catch at age through 2004, with SSB in 2007 estimated at just over 100,000 mt, F in 2007 estimated at about 0.05, and the large recent recruitments in 2000 and 2007 estimated at 300-400 million fish. Dropping the 2002 survey indices in the BASE_C2006_No02SV run increased the SSB in 2007 to about 125,000 mt, substantially reduced the 2002 recruitment estimate from about 296 million to 156 million fish, changed the pattern of recruitment so that the 1999 year class (212 million) was larger than the new estimate of the 2000 year class, and increased the estimated of recruitment in 2007 to about 376 million fish. Dropping the 2002 Commercial Discards at age and substituting for the high 2002 aggregate discard in weight in the BASE_C2006_No02SV_No02CD run had relatively little additional effect on results, other than eliminating the large residual for the 2002 estimate, and so the November 2008 Working Group decided to retain the original 2002 commercial fishery discard estimates in subsequent model runs.

The November 2008 Working Group extensively debated whether it was appropriate to exclude the 2002 survey data in a BASE case run for subsequent development. It was noted that the model Acompensated@ for the missing data, changing the rank order of recruitments over the last decade, and increasing the size of the 2007 year class. It was also noted that there may have been other abrupt, but substantial Apositive availability@ events that have occurred in the past (e.g., NEFSC spring survey in 1977, NEFSC fall survey in 1976, 1989, and 1999; Table 20, Figure 7), that were not being considered for exclusion from the analysis. Likewise, there may have been several abrupt, but substantial Anegative availability@ events that have occurred (e.g., NEFSC spring 2003, 2005, and 2007, NEFSC fall 2005), and no exclusion was being considered for those possible events. The November 2008 Working Group found it difficult to develop an objective justification for the exclusion of the 2002 survey data, and so they were retained in subsequent model runs.

Alternative Assumptions for Natural Mortality (M)

A range of alternative assumptions for the instantaneous natural mortality rate (M) was tested in a series of runs derived from the BASE_C2006 run. The values ranged from 0.10 to 0.40, in runs BASE_C2006_M10 to BASE_C2006_M40. A sensitivity profile indicated that the ASAP model for scup fit best (lowest total likelihood value) at M = 0.10 (Figure 52). This was considered a counter-intuitive result, as most members of the November 2008 Working Group expected a higher value of M (e.g., in the 0.3-0.4 range) to perform better, given the maximum observed age in survey and fishery samples of 14 years, and configuration of the model with an oldest age group of 7-plus. Those expectations were not born out by the results, however, and so the November 2008 Working Group retained the initial assumption of M = 0.2 for all ages in subsequent model runs.

Update with final 2004-2007 Catches: BASE_C2007 runs

Final fishery catch at age estimates for 2004-2007 became available in mid-November 2008, after the November 2008 Working Group meeting, and model runs including these data were called BASE_C2007 runs. In the BASE_C2007 and all previous runs, the same mid-year mean weights at age were used for the total catch, January 1 total stock biomass, and June 1 SSB mean weights at age. Once the fishery catches at age were finalized through 2007, mean weights for the January 1 and SSB biomass were re-calculated using the Rivard method (NFT 2008c), to provide run BASE_C2007_RIV. As a final model tuning step, the ratio of the estimated Effective Sample Sizes (ESS) to the input ESS was calculated for the four fishery fleets, and the ratio used to adjust the ESS for the final run, BASE_C2007_T1.

Figures 53-55 summarize comparative results for the runs configured during and since the November 2008 Working Group meeting. The addition of the preliminary 2004-2006 fishery catches at age to the BASE_Nov08 run to create the BASE_C2006 run had a very minor effect on the results. The addition of the final 2004-2007 catches at age to create the BASE_C2007 run had a slightly larger effect on recent trends, increasing the SSB in 2007 from 103,000 mt to about 113,000 mt, and increasing recruitment in 2000 (from 297 million to 302 million) while decreasing recruitment in 2007 (from 364 million to 305 million). Re-calculation of the mean weights at age in the BASE_C2007_RIV run affected only the SSB estimates by increasing the recent estimates by a few percent, with the SSB in 2007 increasing from 113,000 mt to 121,000 mt. The final tuning of the ESS created the final run BASE_C2007_T1, with a slight decrease in SSB and R in recent years compared to the previous run, and an estimate of SSB in 2007 of 119,000 mt, F of 0.054, and recruitment in 2007 of 308 million fish. The December 2008 Northeast Data Poor Stocks Peer Review Panel accepted the BASE_C2007_T1 ASAP run as the basis for subsequent calculation of biological reference points and status evaluation. Run BASE_C2007_T1 did not exhibit substantial retrospective patterns in SSB, F, or R (Figures 56-58).

Summary estimates, estimated January 1 stock size at age in numbers, and estimated fishing mortality (F) at age from the accepted BASE_C2007_T1 run for 1984-2007 (the years with input fishery catches at age) are provided in Tables 32-34. Spawning stock biomass (SSB) decreased from about 102,000 mt in 1963 to about 50,000 mt in 1969, then increased to about 75,000 mt during the late 1970s (Figure 53). SSB declined through the 1980s and early 1990s to only 4,000 mt in 1995. With greatly improved recruitment and low fishing mortality rates since 2000, SSB has steadily increased since to about 113,000 mt in 2007 (Table 32, Figure 53). There is an 80% chance that SSB in 2007 was between 111,204 and 130,120 mt (Figure 59). Fishing mortality varied between F = 0.100 and F = 0.274 during the 1960s and 1970s (Figure 54). Fishing mortality increased steadily during the 1980s and early 1990s, peaking at F = 1.120 in 1994. Fishing mortality decreased rapidly after 1994, falling to less than F = 0.100 since 2004, with F in 2007 = 0.054 (Table 32, Figure 54). There is an 80% chance that F in 2007 was between 0.048 and 0.060 (Figure 60). Recruitment at age 0 averaged 91.4 million fish during 1963-1983, the period during which recruitment estimates are influenced mainly by the internal ASAP stock-recruitment relationship (Figure 55). Since 1984, recruitment estimates are influenced mainly by the fishery and survey catches at age, and recruitment at age 0 averaged 119.6 million fish during 1984-2007, with the 2000 and 2007 year classes estimated to be the largest of the time series, at 311.2 and 307.9 million age 0 fish (Table 32, Figures 55 and 61).

Recommended Biological Reference Points and Status Determination

The December 2008 Northeast Data Poor Stocks Peer Review Panel accepted the BASE_C2007_T1 ASAP run as the basis for biological reference points and status determination for scup. Biological reference points were calculated using the non-parametric yield and SSB per recruit/long-term projection approach recently adopted for summer flounder (NEFSC 2008a) and New England groundfish stocks (NEFSC 2008b). In the yield and SSB per recruit calculations, the most recent five year averages were used for mean weights and fishery partial recruitment pattern (Table 35). For the projections, the cumulative distribution function of the 1984-2007 recruitments (corresponding to the period of input fishery catches at age) was re-sampled to provide future recruitment estimates (mean = 117.2 million age 0 fish).

The Peer Review Panel recommended $F_{40\%}$ as the proxy for F_{MSY}, and the corresponding $SSB_{F40\%}$ as the proxy for SSB_{MSY}. The F40% proxy for F_{MSY} = 0.177, the proxy estimate for SSB_{MSY} = 92,044 mt, and the proxy estimate for MSY = 16,161 mt (13,134 mt of landings, 3,027

mt of discards). The stock biomass threshold of ½ SSB_{MSY} = ½ $SSB_{40\%}$ = 46,022 mt = 101.461 million lbs.
The 2007 F estimate of 0.054 is 31% of F_{MSY} = 0.177, indicating no overfishing was occurring. The 2007 SSB estimate of 119,343 mt is 30% above SSB_{MSY} = 92,044 mt, indicating the stock was not overfished. Total catch (landings + discards) was 7,867 mt in 2007, about 49% of MSY (Table 36). Estimates of biomass and catch reference points corresponding to F_{MAX} and $F_{35\%}$ are also listed in Table 36 for comparison.

Uncertainty and Risk for Scientific and Statistical Committees (SSCs) to Consider

The accepted ASAP model of scup population dynamics and recommended BRPs provides a more stable tool for monitoring stock status and specifying annual fishery regulations than the current single index-based model. The ASAP model integrates a broad array of fishery and survey input data and should be less sensitive to inter-annual changes in any single data component than the current model. The accepted model results and recommended BRPs indicate that the stock was above the SSB_{MSY} proxy and being fished at below the F_{MSY} proxy in 2007. This status represents a significant change from the July 2008 biomass status update, which indicated that the stock was overfished in 2007 (NEFSC spring SSB three-year average index = 1.16 kg per tow, 21% of the biomass target of 5.54 kg per tow) and rebuilding more slowly than indicated by the Amendment 14 projection (see Section 3). The current REI proxy for F did indicate that F in 2007 was low (about 0.10) and therefore was not experiencing overfishing, in accord with the accepted ASAP model.

The 2007 stock abundance indicated by the accepted model is the result of historically low fishing mortality rates and historically high levels of recruitment since about 2000 (Figures 53-55). Age 0 fish accounted for about 40% of the stock size in 2007 due to the large size of the 2007 year class, but the relative percentages of the age 1 and older fish are within of few percent of what might be expected in the stock if it was fished at Fmax = 0.283 over the long-term (Figure 62). The age 7+ fish accounted for about 6% of the stock size in 2007. The model results indicate that stock has not been fished at low levels of F long enough to accumulate as high a percentage in the age 7+ group (16%) as would be expected if fished at F = 0.05 over the long-term (Figure 62). Since 2000, a high proportion of the SSB has accumulated at ages 3 and older (those expected to be fully mature). The percentage of SSB in 2007 at fully mature ages 3-6 (56%) is near what would be expected if the stock were fished at F = 0.050 over the long-term (46%), while the age 7+ fish accounted for about 35% of the SSB in 2007 (Figure 63).

A retrospective look at historical stock assessments for scup shows that the accepted ASAP model estimates of SSB and R are comparable to those previously estimated for the same time period in the 1995, 1997 and 1998 assessments using ADAPT VPA; estimates of F are somewhat higher in the VPA assessments (NEFSC 1995, 1997, 1998) (Figures 64-66). The 1995 SAW19 assessment was the last accepted peer-reviewed analytical assessment. The analytical components of the 1997 and 1998 assessments were not accepted as valid bases for assessing the stock. The historical analyses used input fishery and research survey data time series beginning in 1984.

The recommended MSY proxy for scup in terms of total catch is 16,161 mt (35.6 million lbs), with total landings of 13,134 mt (29.0 million lbs) and total discards of 3,027 mt (6.7 million lbs). The extended catch series estimated for scup (Table 19) indicates that this MSY proxy is a feasible estimate. Total fishery catch is estimated to have averaged about 34,000 mt

(75.0 million lbs) during 1960-1965, while reported commercial landings alone averaged about 19,000 mt (41.9 million lbs) in that period (Table 19 and Figure 1).

While the accepted long-term MSY estimate appears feasible given historical evidence from the fishery, managers may wish to take an adaptive approach to the specification of fishery quotas in the short-term. Total fishery landings over the last five years (2003-2007) have averaged 6,214 mt (13.7 million lbs). If the stock is fished at F40% = 0.177 over the long-term, the corresponding annual total MSY landings would be 13,134 mt (29.0 million lbs), more than double the recent five year average. The Peer Review Panel recommended that "…rapid increases in quota to meet the revised MSY would be unwarranted given uncertainties in recruitments. A more gradual increase in quotas is a preferred approach reflective of the uncertainty in the model estimates and stock status."

Research Recommendations

Short term analytical tasks

a) Evaluation of indicators of potential changes in stock status that could provide signs to management of potential reductions of stock productivity in the future would be helpful.

b) A management strategy evaluation of alternative approaches to setting quotas would be helpful.

Long term data and analytical needs

a) Current research trawl surveys are likely adequate to index the abundance of scup at ages 0 to2. However, the implementation of new standardized research surveys that focus on accurately indexing the abundance of older scup (ages 3 and older) would likely improve the accuracy of the stock assessment.

b) Continuation of at least the current levels of at-sea and port sampling of the commercial and recreational fisheries in which scup are landed and discarded is critical to adequately characterize the quantity, length and age composition of the fishery catches.

c) Quantification of the biases in the catch and discards, including non-compliance, would help confirm the weightings used in the model. Additional studies would be required to address this issue.

d) The commercial discard mortality rate was assumed to be 100% in this assessment. Experimental work to better characterize the discard mortality rate of scup captured by different commercial gear types should be conducted to more accurately quantify the magnitude of scup discard mortality.

Table 3. Summary NEFSC Domestic Observer program data for scup. Geometric mean discards to landings ratios (GMDL; retransformed, mean ln-transformed D/L per trip) are stratified by half-year period (HY1, HY2) and trip landings level (< 300 kg, => 300 kg). N is the number of observed trips with both scup landings and discard, which are used to calculate the per-trip discard to landings ratios. Corresponding dealer landings are from the NEFSC database.

Table 9. Summary of sampling for scup in the NEFSC Observer Program. OT =number of otter trawl trips sampled with scup discard lengths. HY1 = first half year; HY2 = second half year. GMDL reflects the estimate of discard based on applying geometric mean observed ratios of discards to landings by trip, stratified by landings level (< 300 kg per trip, = > 300 kg per trip) to reported dealer landings (from Table 4).

Year	OT	Lengths			GMDL Discard	Intensity
	trips	HY1	HY2	Total	(mt)	(mt/100 lengths)

Table 19. Extended time series of total fishery catch (mt). To estimate commercial discards for 1960-1988, the discards to landings ratio for 1989-1997 = 0.504 was applied to commercial landings. To estimate recreational catch for 1960-1980, 50% of the Mayo 1982 estimates were included.

Year	Comm. Land.	Comm. Disc.	DWF Land.	Rec Catch	Total Catch

The SAW19, SAW25, and SAW27 analyses used the ADAPT VPA model for data beginning in 1984, while the 2008 DPSWG assessment uses the ASAP accepted model for data beginning in 1963.

Black Sea Bass

by

Gary Shepherd
National Marine Fisheries Service
Northeast Fisheries Science Center
166 Water St., Woods Hole, MA 02543

Northeast Data Poor Stocks Working Group Meeting
Woods Hole, MA
December 8-12, 2008

Executive Summary

The northern stock of black sea bass (*Centropristis striata*) was evaluated using length-based population models. Under the existing fishery management plan (FMP), black sea bass has been regulated based on annual changes in the Northeast Fisheries Science Center (NEFSC) spring bottom trawl survey index. Fishing mortality resulting in maximum sustainable yield was considered equal to F_{MAX} equal to 0.33. Overfishing status was evaluated only with an approximation of F, based on a relative exploitation rate. A new approach was presented to the Data Poor Workshop review panel (December 2008) which involved estimates of fishing mortality and population size determined from changes in the size composition of the population (SCALE model). In addition, a length based yield per recruit model was developed to determine the associated biological reference points. An array of natural mortality estimates was considered, ranging from 0.2 to 0.9, and they were modeled as either a constant value or in the form of a logistic function where M varied with body length. The panel adopted results using a constant M=0.4 as the preferred model. The resulting $F_{40\%}$, as a proxy for F_{MSY}, was equal to 0.42 with an associated SSB equal to 12,537 mt and MSY of 3,903 mt. Assuming a catch of 2,685 mt, F_{2007} was estimated to be 0.48 and SSB equal to 11,478 mt. Therefore the conclusions are that overfishing is occurring, but the stock is not overfished (assuming a biomass threshold equal to ½ B_{MSY}). These new reference points and stock status determinations should be used with caution due to the uncertainty in the natural mortality estimate, the model input parameters, residuals patterns in model fit, and significant uncertainty associated with managing a protogynous species (i.e., individuals change sex from female to male).

Terms of Reference

1. Recommend biological reference points (BRPs) and measurable BRP and maximum sustainable yield (MSY) proxies.
2. Provide advice about scientific uncertainty and risk for Scientific and Statistical Committees (SSCs) to consider when they develop fishing level recommendations for these stocks.
3. Comment on what can be done to improve the information, proxies or assessments for each species.

Life History

Black sea bass (*Centropristis striata*) are distributed from the Gulf of Maine to the Gulf of Mexico, however, fish north of Cape Hatteras, NC are considered part of a single fishery management unit. Sea bass are generally considered structure oriented, preferring live-bottom and reef habitats. Within the stock area, distribution changes on a seasonal basis and the extent of the seasonal change varies by location. In the northern end of the range (New York to Massachusetts), sea bass move offshore crossing the continental shelf, then south along the edge of the shelf. By late winter, northern fish may travel as far south as Virginia, however most return to the northern inshore areas by May. Sea bass originating inshore along the Mid-Atlantic coast (New Jersey to Maryland) head offshore to the shelf edge during late autumn, travelling in a southeasterly direction. They return inshore in spring to the general area from which they originated. Black sea bass in the southern end of the stock (Virginia and North Carolina) move offshore in late autumn/early winter. Given the proximity of the shelf edge, they transit a relatively short distance, due east, to reach over-wintering areas.

Fisheries also change seasonally with changes in distribution. Inshore commercial fisheries are prosecuted primarily with fish pots (baited and unbaited) and handlines. Recreational fisheries generally occur during the period that sea bass are inshore. Once fish move offshore in the winter, they are caught in a trawl fishery targeting summer flounder, scup and *Loligo* squid (Shepherd and Terceiro, 1994). Handline and pot fisheries in the southern areas may still operate during this offshore period. Additionally a small sector of the NJ charter fleet target sea bass offshore during the winter.

Black sea bass are protogynous hermaphrodites and can be categorized as temperate reef fishes (Steimle et al. 1999, Drohan et al. 2007). Transition from female to male generally occurs between the ages of two and five (Lavenda 1949, Mercer 1978). Based on sex ratio at length from NMFS surveys, males constitute approximately 30% of the population by 20 cm, with increasing proportions of males with size (Figure 1). Following transition from female to male, sea bass can follow one of two behavioral pathways; either becoming a dominant male, characterized by a larger size and a bright blue nuccal hump during spawning season, or subordinate males which have few distinguishing features. The initiation of sexual transition appears to be based on visual rather than chemical cues (Dr. David Berlinsky, UNH, Personal communication). In studies of protogny among several coral reef fish species, transition of the largest female to male may occur quickly if the dominate male is removed from the reef, however, similar studies have not been published for black sea bass.

Spawning in the Middle Atlantic peaks during spring (May and June) when the fish reside in coastal waters (Drohan et al. 2007). The social structure of the spawning aggregations is poorly known although some observations suggest that large dominant males gather a harem of females and aggressively defend territory during spawning season (Nelson et al. 2003). The bright coloration of males during spawning season suggests that visual cues may be important in structuring of the social hierarchy.

Black sea bass attain a maximum size around 60 cm and 4 kg. Although age information is limited for the northern stock of black sea bass, growth curves are available from one published study as well as several unpublished studies. Lavenda (1949) suggests a maximum age for females of 8 and age 12 for males. However he noted the presence of large males (>45 cm) in deeper water that may have been older. Available growth curves are listed in Table 1. The Von Bertalanffy parameters were averaged across studies for input to models used in this analysis. (The growth parameters from Caruso, MADMF, appeared to be unique, possibly due to geographic growth differences and were not included in the model average). Although growth information was available for use in models, annual age length keys were not, therefore sea bass modeling efforts are length based rather than age based.

Maturity data is routinely collected on Northeast Fisheries Science Center survey cruises. Proportion mature for all years and sexes combined (n=10,318) was fitted to a logistic model (Figure 2). The model estimate for length at 50% maturity was 20.4 cm with 95% maturity attained by 28 cm.

Fisheries

In the Northwest Atlantic, black sea bass support commercial and recreational fisheries. Prior to WWII in 1939 and 1940, 46-48% of the landings were in New England, primarily in

Massachusetts. After 1940 the center of the fishery shifted south to New York, New Jersey and Virginia. Landings increased to a peak in 1952 at 9,883 mt with the bulk of the landings from otter trawls, then declined steadily reaching a low point in 1971 of 566 mt (Table 2). Historically, trawl fisheries for sea bass have focused on the over-wintering areas near the shelf edge. Inshore pot fisheries, which were primarily in New Jersey, showed a similar downward trend in landings between the peak in 1952 and the late 60s. The large increase in landings during the 1950's appears to be the result of increased landings from otter trawlers, particularly from New York, New Jersey and Virginia (Figure 3). During the same period, a large increase in fish pot effort, and subsequent landings, occurred in New Jersey (Figure 4). In recent years, fish pots and otter trawls account for the majority of commercial landings with increasing contributions from handline fisheries. Landing since 1974 have remained relatively steady around 1400 mt. (Table 2). Recreational landings, available from MFRSS data since 1982, average about 1,600 mt annually (Table 2). Estimates for recreational sea bass landings in1982 and 1986 (4,485 mt and 5,618 mt, respectively) are unusually high, as they are for other species for those years. Similarly, recreational landings for 1998 and 1999 are lower than expected. Although the estimates have been confirmed by MRFSS, they remain suspect.

The species affinity for bottom structure during its seasonal period of inshore residency increases the availability to hook and line or trap fisheries compared to the decreasing susceptibility to bottom trawl gear commonly used for scientific surveys. In autumn when water temperatures decline, black sea bass migrate offshore to areas along the edge of the continental shelf (Moser and Shepherd 2009). During this offshore period, sea bass are vulnerable to otter trawls as part of a multispecies fishery (Shepherd and Terceiro 1994).

Stock assessment history summary

Black sea bass stock assessments have been reviewed in the SARC/SAW process (SAWs 1, 9, 11, 20, 25, 27, 39 and 43) beginning with an index based assessment in 1991. In 1995 a VPA model was approved and the results generally showed fishing mortalities exceeding 1.0 (estimated using an M=0.2). The VPA was reviewed again in 1997 and at this time was considered too uncertain to determine stock status but indicative of general trends. In 1998, another review was conducted and both VPA and production models were rejected as either too uncertain or inappropriate for use with an hermaphroditic species. A suggestion was made to use an alternative method such as a tag/recapture approach. The NEFSC survey remained the main source of information regarding relative abundance and stock status. A tagging program was initiated in 2002 and the first year results were presented for peer review in 2004. The review panel concluded that a simple tag model using the proportion recovered in the first year at large, as well as an analysis of survey indices, produced acceptable results to determine exploitation rate and stock status. The release of tags continued through 2004 and results of tag models as well as indices were presented for SARC review in 2006. Their findings were that the tag model did not meet the necessary assumptions and the variability in the survey indices created uncertainty which prevented determination of stock status. The panel did not recommend any alternative reference points, however they did recommend continued work on length based analytical models.

Existing Biological Reference Points

Based on revision through Framework 7 to the Summer Flounder, Scup and Black Sea Bass (SFSCBSB) FMP, the status determination criteria is defined for each of the species managed under the FMP. The maximum fishing mortality threshold for each of the species under the FMP is defined as F_{MSY} (or a reasonable proxy thereof) as a function of productive capacity, and based upon the best scientific information consistent with National Standards 1 and 2. Specifically, F_{MSY} is the fishing mortality rate associated with MSY. The maximum fishing mortality threshold (F_{MSY}) or a reasonable proxy may be defined as a function of (but not limited to): total stock biomass, spawning stock biomass, total egg production, and may include males, females, both, or combinations and ratios thereof which provide the best measure of productive capacity for each of the species managed under the FMP. Exceeding the established fishing mortality threshold constitutes overfishing as defined by the Magnuson-Stevens Act.

The minimum stock size threshold for each of the species under the FMP is defined as ½ B_{MSY} (or a reasonable proxy thereof) as a function of productive capacity, and based upon the best scientific information consistent with National Standards 1 and 2. The minimum stock size threshold (½ B_{MSY}) or a reasonable proxy may be defined as a function of (but not limited to): total stock biomass, spawning stock biomass, total egg production, and may include males, females, both, or combinations and ratios thereof which provide the best measure of productive capacity for each of the species managed under the FMP. The minimum stock size threshold is the level of productive capacity associated with the relevant ½ MSY level. Should the measure of productive capacity for the stock or stock complex fall below this minimum threshold, the stock or stock complex is considered overfished. The target for rebuilding is specified as B_{MSY} (or reasonable proxy thereof) at the level of productive capacity associated with the relevant MSY level, under the same definition of productive capacity as specified for the minimum stock size threshold.

The best scientific information consistent with National Standards 1 and 2, has not recommended revising the definitions for biological reference points set forward under Amendment 12 to the SFSCBSB FMP. Therefore, these reference points and values are defined as follows in Amendment 12: Overfishing for black sea bass is defined to occur when the fishing mortality rate exceeds the threshold fishing mortality rate of F_{MSY}. Because F_{MSY} cannot be reliably estimated, F_{MAX} (0.33) is used as a proxy for F_{MSY}.

The current biomass reference points are a function of the NEFSC spring bottom trawl survey. The current definitions were adopted as a way to measure stock status in the absence of an analytical age-based stock assessment. Commercial landings of black sea bass reached a peak in 1952 at nearly 9900 mt. From that peak through 1965, the landings averaged nearly 4600 mt whereas from 1966 through 1980 commercial landings averaged 1200 mt. The rationale behind the existing reference point was that the substantial landings prior to 1966 likely represented potential yield at B_{MSY}. The landings in the late 1960s-80s were likely more representative of ½ B_{MSY}. NEFSC spring survey indices began in 1968 and it was concluded that the maximum survey indices coinciding with landings in the 1970s were around ½ B_{MSY} and would therefore represent a biological threshold. To limit year to year variation, the spring offshore survey indices were calculated as a 3 point moving average. The 1977-1979 three year moving average of the spring survey value of exploitable stock biomass (index of black sea bass $\geq$ 22 cm = 0.98 kg/tow), would serve as a biomass threshold. B_{MSY} cannot be reliably estimated for black sea bass.

Without an analytical stock assessment, no current fishing mortality estimates are available to compare to the F_{MAX} proxy of F_{MSY} (0.33). A relative index of exploitation is calculated as total landings /spring survey index of exploitable biomass (defined as sea bass $\geq$ 22 cm). Changes in the relative exploitation index are evaluated for development of management advice. The current definition suffers from the inability to accurately measure fishing mortality relative to F_{MSY}. In addition, reviewers at SARC 43 concluded that the use of the spring offshore survey was not an appropriate measure of relative abundance and was not a valid basis of a biomass reference point. From the SARC 43 reviewer's summary:

"The perception of the status of the stock relative to biomass thresholds is very sensitive to the method used to calculate the survey indices. Not only are the confidence intervals very large, meaning the current biomass is probably indistinguishable from the BRP, but calculating both current biomass and the BRP on a consistent scale (i.e always arithmetic or always logged) can lead to a divergent perceptions of current stock size relative to the BRP. The definition of the biomass threshold was not considered satisfactory. One reviewer questioned whether it was consistent with F_{MAX}. The other pointed out that establishing the biomass threshold as the period of low biomass from which the stock recovered is as plausible as setting the BRP to the early period of high biomass. Given the uncertainty over growth, mortality and selectivity, the estimation of F_{MAX} is uncertain and there is no credible estimate of current fishing mortality with which to compare it. Hence the evaluation of status relative to fishing mortality reference points is not possible."

New analyses

Development of updated biological reference points for black sea bass is hampered not only by a lack of annual age data but also by limited understanding of how black sea bass productivity responds to exploitation. Traditional fisheries models, generally developed for gonochoristic species, may not apply to a protogynous hermaphrodite (Hamilton et al. 2007). Simulation studies of populations exhibiting protogny suggest that conservation of large terminal males is critical for sustainability (Alzono et al. 2008, Brooks et al. 2008, Hamilton et al. 2007, Heppell et al. 2006, Huntsman and Schaaf 1994). The implication is that removal of the terminal male will not only hamper male fertilization success but will induce transitioning of the larger females into males. The consequence is not only removal of male biomass but removal of potential egg production in the larger females. Reduction of dominant males in a population may, in effect, have a similar effect as increasing natural mortality on females.

Tag Release/Recapture model

To evaluate mortality rates, a tag release/recapture study was conducted with 13,794 tagged black sea bass (12,310 legal-size) released between Massachusetts and Cape Hatteras, NC from 2002 to 2004. Of these legal-size releases, 1,683 were recaptured during 2002 to 2007. An instantaneous rates configuration of a Brownie band recovery model was used to estimate both fishing and natural mortality. A seasonal model of fishing mortality, adjusted for non-mixing, and a constant natural mortality best explained the tag recoveries (Shepherd and Moser 2008, *Appendix I*). Fishing mortality estimates ranged between 0.3 and 0.4 whereas the natural mortality estimate was equal to 1.08 (Table 3). The estimate of natural mortality includes the effects of all unaccounted tag losses which could be influenced by an over-estimate of reporting rate (resulting from violation of the assumption that the return rate of high reward tags equaled 100%) or tag attrition (resulting from decreasing legibility of the tags, expulsion of the tags, etc.). An alternative model assuming only 75% reporting of $100 tags and a 9% attrition of tags per season over the recovery period resulted in a decreased estimate of natural mortality of 0.66. Despite uncertainty in the tag model, the results imply that natural mortality of the black sea bass population exceeds 0.2 as used in previous assessments.

Tag recovery data also indicates that extensive seasonal movements occur and are not homogeneous throughout the stock (Moser and Shepherd 2009). During summer months fish throughout the stock remain stationary in coastal areas with very little mixing among adjacent areas. In autumn, offshore migration toward the edge of the continental shelf begins in the north and progresses southward. During the offshore overwintering period on the continental shelf out to the shelf edge, intermixing of fish from various inshore areas is more frequent. Recaptures following spring inshore migrations demonstrate a high degree of site-fidelity with occasional straying to adjacent areas.

Length-based Analytical model

Since annual age information was unavailable, a length based model (SCALE developed by Paul Nitschke, NEFSC) was explored as a method for evaluating sea bass population dynamics. The model details are described in *Appendix II.* SCALE data input included catch time series (mt), NEFSC spring and winter survey recruit and adult indices, growth information, survey length frequencies and catch length frequencies. The model covered the period 1968 to 2007 based on the times series of NEFSC spring offshore surveys.

Commercial length frequencies were compiled beginning with samples in 1984. Sampling was done randomly by market categories and expanded as the ratio of sample weight to total landings, by calendar quarter. Black sea bass were culled as small, medium, large, jumbo or unclassified. In the rare cases where fish were categorized as extra small and extra large, they were combined with small and large, respectively. Total annual length measurements ranged from 300 to 7768 fish with an average of 2956 per year (Table 4).

Commercial discards were estimated since 1989 using a standard approach developed for national standardized by-catch reporting. (Wigley et al., 2008). Observer samples for sea bass were limited to otter trawl trips since 1989. Discard estimates were developed from the ratio of discarded black sea bass in mt to total landings (mt) of all fish species in the comparable statistical area, by half-year periods. Discards from pot and handline fisheries were estimated using the annual ratio of reported discards to landings in vessel trip reports, expanded to total annual landings. Since a component of the pot fishery is prosecuted solely in state waters without a requirement to submit VTR logs, they are not included in the total. A 50% discard survival rate was applied across all commercial gears. Total discards averaged 111 mt annually and represented 17% of reported commercial landings (Table 2). Discards in 1993 and 2004 were well above average at 35% and 62% of landings, respectively.

Complete recreational landings were available from the Marine Recreational Fisheries Statistics Survey (MRFSS) since 1981. Landings for 1968 to 1980 were hindcast based on the relationship between inshore commercial pot and handline landings and recreational landings between 1981 and 1997 (Table 2). In 1998 management regulations were imposed which controlled landings based on quota. The two abnormally large recreational landings in 1982 and 1986 were excluded. The ratio between average recreational landings and pot/handline landings was 2.63. This ratio applied to the commercial pot landings produced the 1968 to 1980 recreational landings. Length frequencies of sea bass were based on dockside sampling by MRFSS staff.

Recreational discard mortalities beginning in 1981 were calculated from MRFSS B2 estimates using a 25% discard mortality rate (Table 2). Discard number was converted to weight assuming comparable mean weight as landings. Between 1981 and 1998 the ratio of discards to landings was relatively constant with an average of 50%. Since 1999, the proportion discarded has increased dramatically averaging 179% of landed sea bass by weight. With a 25% mortality applied, the weight of discards was approximately 50% of landed weight. Length frequencies for recreational discards were not available for the time series.

Fishery Independent Indices

The NEFSC spring bottom trawl survey conducted since 1968 provided indices of relative abundance in number and weight. The review panel in SARC 43 questioned the use of NEFSC bottom trawl survey indices as an index of relative abundance. During autumn, sea bass are generally inshore on structured bottom that is not conducive to sampling with an otter trawl. Consequently those survey results are not considered indicative of sea bass abundance. However, since the 1930's commercial trawl fisheries have had significant landings of sea bass caught offshore during the winter and early spring on the continental shelf. The spring offshore bottom trawl survey takes place in the same areas suggesting that the use of trawl gear for sampling sea bass at this time of year is no less limited by habitat than commercial trawlers. Comparison of survey length frequencies and length frequencies of commercial landings suggest the selectivity at length is comparable (Figure 5). Additionally, the winter survey time series of relative abundance from 1992 to 2007, which uses a trawl with a chain sweep rather than roller gear, was highly correlated to the spring abundance. Although the catch per tow in the spring survey was low, the correlation to the winter survey as well as the comparable length frequency to the commercial fishery suggests that the survey adequately samples sea bass. Finally, the index of abundance from the spring survey also closely resembles the time series of recreational catch per angler trip estimated from MRFSS dockside sampling (Figure 6).

Concern has been raised in the past that environmental conditions significantly influence catchability of black sea bass in the survey. The relationship between catch and environmental anomalies (water temperature and salinity) was evaluated for the survey time series. There was no apparent pattern in deviations of annual survey catches around the time series mean and anomalous temperature or salinity conditions (Figure 7). Local conditions may alter distributions but the influence on the spring index time series appears to be minimal.

The use of $\log_e$ transformation of the survey indices was also criticized by the SARC 43 review panel. A plot of the mean number per tow by strata against the associated variance shows that the variance increases non-linearly (Figure 8). To reduce the influence of over-dispersion on the estimation of the stratified mean, $\log_e$-transform indices (followed by re-transformation) were used in the model. NEFSC spring survey indices with and without transformation are presented in figures 9a and 9b.

The index of exploitable biomass (defined as fish $\geq$ 22 cm presented as the $\log_e$ re-transformed stratified mean weight per tow) beginning in 1968 increased to a peak value in 1976, followed by a decline to the series low in 1982 (Figure 10). A slight rise in abundance was evident in the late 1980s but was followed by a decade of fluctuations around low levels of abundance. Between 1999 and 2002 the index increased again, peaking with the series high in 2002 (1.07 kg per tow), followed by a steady decline through 2008 when the index dropped to 0.18 kg per tow. The 2008 value of 0.19 is below the long-term average of 0.27 fish per tow. The NEFSC winter survey, initiated in 1992, follows a similar pattern with a peak in the $\log_e$ re-transformed index value for 2003 (1.83 kg/tow) followed by declining indices to 0.40 kg/tow in 2007 (Figure 10).

Juvenile indices of black sea bass from the winter and spring surveys provide some insight into cohort strength. The juveniles appear as clearly defined modes at sizes $\leq$ 14 cm in the autumn surveys (Figure 11). There appears to be little growth during the winter, as the same distinct size mode appears in the winter and spring survey length frequencies. In the spring, fish $\leq$ 14 cm would be considered one year old. Indices were calculated as the sum of $\log_e$ re-transformed mean #/tow at length for sea bass less than or equal to 14 cm. The indices in both the winter and spring surveys suggest large 1999 and 2001 cohorts (peaks in the 2000 and 2002 surveys) (Figure 12). Both of these modes in the length frequency appear the following year as increases in a mode above 20 cm, which is consistent with known growth rates. The winter and spring surveys show an above average 2002 year class and the spring survey shows a strong 1998 cohort that was below average in the winter survey. The 2007 juvenile index in the winter survey was above average.

SCALE Model input

A critical issue in development of new biological reference points is the choice of natural mortality. In the case of black sea bass this becomes particularly difficult due to the unique life history. Methods have been proposed for estimating M based on longevity (Hoenig 1983, Hewitt and Hoenig 2005). Maximum age has been reported by Lavenda (1949) as 12, although he suggests sea bass may survive for up to 20 years, while the oldest fish in a study by Mercer (1978) was age 9. NMFS spring survey age data collected in the 1980s found a sea bass at age 10. More recently, a trawl caught sea bass of 61 cm and 4 kg was taken in the winter of 2007 off the mouth of the Chesapeake Bay and aged as 9 years using otoliths (Chris Batsavage, pers. comm.). Additionally, a study at VIMS repeating the work of Mercer identified a fish as age 12 (R. Pemberton, pers. comm.) while Caruso (1995) found the oldest fish to be age 7. Applying the Hoenig regression method for maximum age suggests that M could possibly be between 0.37 (age 12) and 0.55 (age 8) (Figure 13). The results of the tag model previously noted suggest a much higher natural mortality of 1.08 for the period 2003-2007. If M were really greater than 1.0 at all sizes, it would be equivalent to a maximum age of 4 in the Hoenig model. However, if the tagging model assumptions of 100% reporting of high reward tags were relaxed to equal 75% and tag attrition of 9% applied, the estimate of M decreases to 0.66. It is clear from multiple approaches that natural mortality of the population is greater than 0.2. As an alternative to a constant natural mortality across sizes, M was also modeled as a logistic function of size (Figure 14). This was an attempt to include both a high natural mortality and a subgroup with a longer potential life expectancy. The point of inflexion corresponded to the approximate age when transition occurs.

Included as input to the SCALE model were spring and winter offshore indices of adult and juvenile abundance. The spring series of stratified $\log_e$ re-transformed mean number per tow included 1968 to 2008 while the comparable indices from the winter survey were 1992 to 2007 (Figure 15). Mean lengths at age were predicted from a growth curve averaged from available studies and length-weight equation parameters were from fitted length-weight data collected on NMFS surveys. Total catch (mt) was commercial landings since 1968, recreational landings since 1981 estimated by MRFSS and 1968 to 1980 estimates derived from commercial inshore fishery landings, recreational discard losses since 1981 and commercial discard estimates since 1989. The model was not restricted to fitting the catch exactly by assuming error in the catch estimates. The model was fitted to survey length frequencies greater than 30 cm to counter the lack of discard length data in the fishery length frequencies. Selectivity periods were chosen based on regulatory changes in the fisheries. The three periods were 1968 to 1997, 1998 to 2000 and 2001 to 2007. The model was allowed to fit the initial fishing mortality in phase two.

Models were developed with a range of natural mortalities under an assumption of either a constant or logistic pattern. Within the logistic model assumption, a variety of logistic model parameters were used to generate a suite of M estimates. A total of 26 various M patterns were evaluated and the SCALE model results are presented in Table 5 and Figures 16-21.

In general, the SCALE model adequately described the length frequency data from the fisheries and the associated catch. The general pattern in the spring and winter survey indices were adequately predicted by the model, although the magnitude of some recruitment events was somewhat reduced. With constant M the model fit as defined by the objective function improved with increasing M until M exceeded 0.8. Similarly the value of the objective function declined with increasing M for the logistic M model. However, reduction in the objective function with increasing M may also be a result of faster removal of fish in the model which ultimately limits variation in model fit. Alternative models using higher M with different values at length are also possible. Within the output for each model run, SCALE produces values for selectivity at length, fishing mortality estimates, biomass and abundance estimates. Annual spawning biomass estimates were developed outside of the model software using population numbers at length multiplied by mean weight at length and proportion mature at length from NEFSC survey data.

New Biological Reference Points

The current overfishing definition for black sea bass is based on F_{MAX} as a proxy for F_{MSY}. The F_{MAX} value was calculated using an M=0.2 and a maximum age of 15 and predicts an F_{MAX}=0.33. The biomass reference point is a 3 year moving average of stratified mean weight per tow of exploitable biomass for 1977-1979. The proposed new reference point incorporates additional fishery and biological information in addition to the NEFSC spring and winter bottom trawl survey indices. Evaluation of natural mortality suggests that M is likely greater than 0.2.

A length based yield per recruit model from the NOAA Fisheries Toolbox was used to develop estimates of reference points. From each of the 26 SCALE models run, the associated M and fishery selectivity parameters were input to the YPR model. Per recruit values from each model run were expanded to population values using the average recruitment from the 1968-2007 time series as estimated by SCALE. Average von Bertalanffy growth parameters from among several studies were used to define growth (Figure 19) and an average selectivity curve from 2001-2007 (Figure 20) was incorporated into the yield per recruit model. Resulting yield per recruit and SSB per recruit at F40% were multiplied by average long-term recruitment (1968-2007) to produce total yield, spawning biomass (sexes combined). These values and F at $F_{40\%}$ were compared to the 2007 SCALE model results (Figures 21 and 22) to evaluate stock status.
Selection of the preferred model for black sea bass was based on a decision matrix using information from recent trends in NEFSC survey indices, comparison of MSY to long term yield and the ratio of 2007 F and total biomass to F and biomass at $F_{40\%}$. The reference point in the existing FMP for sea bass was predicated on the assumption that MSY occurred at some point midway through the decline in landings experienced in the 1950s and 1960s. However, since the decline leveled off in the late 1960s, catch has remained relatively stable around 3,100 mt (the period following implementation of quotas in 1998 was not included in this average). This implies that catches around 3,100 mt may be sustainable, although not necessarily maximum (landings greater than 10,000 mt in 1952 suggests an upper bound of potential landings). Recent trends in survey indices of the entire stock show a steady decline in abundance and biomass since 2003 and 2002, respectively. This declining trend despite restrictive quotas would suggest that

the stock is unlikely at or above any optimal biomass level. Therefore the suite of 26 model runs were judged using the proximity of predicted optimal yield relative to average yield since the 1960s which was assumed to be near MSY and the 2007 model estimates of fishing mortality and biomass relative to the associated biomass and F reference points. Among candidate models, only those with both 2007 F to $F_{40\%}$ ratios between 0.8 and 1.4, and predicted equilibrium yield between 3,900 and 4,200 mt were considered candidates as preferred models. Only three models fulfilled the selection criteria: constant M at 0.4 and two logistic models with starting F=0.6 (Table 6). Since there is currently no empirical evidence to suggest that natural mortality declines as a logistic function of size, the model using constant M=0.4 was chosen as the best model.

The preferred model option with a constant M=0.4 has an F at 40% of maximum spawning potential equal to 0.42 and $F_{0.1}$ of 0.37. F_{MAX} equals 0.975 and is poorly defined. The associated spawning stock biomass per recruit at $F_{40\%}$=0.45 and total biomass per recruit= 0.50 (Figure 23). Applying age 1 recruitment (averaged from 1968 to 2007) of 27,875,990 recruits to per recruit values, total biomass at F=0 is 32,816 mt and at $F_{40\%}$ is 13,977 mt. Spawning biomass (sexes combined) at $F_{40\%}$ equals 12,537 mt. The 2007 estimates of F from the SCALE model using the constant M for 0.4 is 0.48 with an estimated total biomass of 12,892 mt and a spawning stock biomass of 11,478 mt. Using $F_{40\%}$ as a proxy for F_{MSY}, the implication is that 2007 fishing mortality (0.48) exceeds F_{MSY} by 15% and 2007 spawning biomass (11,478 mt) is 8% below B_{MSY}. However, the biomass is above the threshold (1/2 B_{MSY}) and would not be considered overfished. The reference points for M = 0.4 are presented in Table 7.

As a check on the scale of the stock size estimates, yield associated with $F_{40\%}$ (a proxy for MSY) under average recruitment would be 3,903 mt. This compares with the estimated average catch since 1968 of 3,100 mt. In addition, the peak landings in the early 1950s of between 10,000 and 12,000 mt would be well above optimal yield and would expected to result in a declining abundance, as was observed.

Although predicted adult survey indices from model results using a constant M=0.4 followed the general trend of the observed values, residuals patterns show predicted indices greater than observed indices for 2004 to 2007 (Figure 24). This would suggest that the predicted abundance was greater than observed and consequently the model may overestimate predicted abundance. Additionally, the sensitivity of the yield per recruit at length and catch at length models has not been fully evaluated for sensitivity to input values.

Developing biological reference points for hermaphroditic species requires consideration of the unique life history characteristics. Simulation modeling studies have shown that protogyny has little effect on yield per recruit if growth rates between sexes are comparable (Shepherd and Idoine 1993). In contrast, the effect of transitioning can have a significant effect on the calculation of female spawning biomass. However, without information about spawning efficiency the optimal approach is to consider spawning biomass as combined male and female biomass (Brooks et al. 2008). In addition, if the efficiency of spawning is a function of the presence of a dominant male, then conservation of the large males may be critical (Alonzo,S.H. 2008, Heppell et al. 2006). However, the effect of removal of males on the sex ratio, and consequently transition rate from female to male, remains unknown for black sea bass.

Suggested improvements

In order to improve the stock assessment of black sea bass and corresponding biological reference points, additional fishery independent surveys for black sea bass may be necessary. An alternative survey gear for sea bass may be fish pots or hand lines. Since pots could cover a wider area, a stock wide fish trap survey should be developed to evaluate relative abundance. Additionally, experimental and field evaluation of spawning behavior is necessary to better understand the implication of exploitation on sea bass.

Age analysis of NEFSC survey samples is currently underway in cooperation with MA DMF and could potentially improve the assessment models. There is some evidence of regional differences in growth that should be further explored.

Tagging data suggests regional differences in migration pathways and possible sub-populations. Although the assessment model results suggest the overall stock is near F_{MSY} and B_{MSY}, local groups of sea bass could vary from this overall status. Consequently, increased catch in some areas may exacerbate already declining abundance. Consideration should be given to evaluating alternative management approaches that account for regional differences in recruitment patterns and abundance.

Acknowledgements

Michele Traver compiled historical commercial landing records for this report. Paul Nitschke modified the code for the SCALE model to accommodate natural mortality at length and the change was implemented into the graphical user interface by Mike Jones.

Black sea bass; Appendix 1

Abstract

Black sea bass in the Mid_Atlantic Bight, are exploited by recreational and commercial fisheries. To evaluate mortality rates, a tag release/recapture study was conducted with 13,794 tagged black sea bass (12,310 legal-size) released between Massachusetts and Cape Hatteras, NC from 2002 to 2004. Of these legal-size releases, 1,683 were recaptured during 2002 to 2007. An instantaneous rates configuration of a Brownie band recovery model was used to estimate both fishing and natural mortality. A seasonal model of fishing mortality, adjusted for non-mixing, and a constant natural mortality best explained the tag recoveries. Fishing mortality estimates were between 0.3 and 0.4 whereas the natural mortality estimate was greater than 1.0. The estimate of natural mortality includes the effects of all unaccounted tag losses, however the results suggest that natural mortality is likely greater than 0.2 which has been assumed based on a maximum age of 15. Higher overall rates of natural mortality could result from increased vulnerability at sexual transition in this hermaphroditic species.

Introduction

Stock assessments of marine fish populations have long been a key component in managing fishery resources. Information regarding past rates of exploitation, along with potential productivity, allow managers to determine how much future exploitation can be allowed. Traditionally, catch based population models have been the tool of choice in stock assessments but in recent years tag based models have been increasingly used either as independent estimates of exploitation (Latour et al. 2001; Lambert et al. 2006; Jiang et al. 2007) or in conjunction with catch data (Polacheck et al. 2006). If implemented within the framework of a properly designed experiment, tagging programs are capable of providing estimates of exploitation and population size as accurately as catch at age models (Pine et al. 2003).

In the Northwest Atlantic, black sea bass (*Centropristis striata*), support both commercial and recreational fisheries. Although black sea bass are distributed from the Gulf of Maine to the Gulf of Mexico, fish north of Cape Hatteras, NC are considered part of a single management unit. Commercial landings for this stock have remained relatively steady around 1400 mt since 1970, although landings in 1952 peaked at 9,900 mt (Shepherd 2007). Recreational landings, available since 1982, average about 1,600 mt annually. The species affinity for bottom structure during its seasonal period of inshore residency increases the availability to hook and line or trap fisheries while decreasing the susceptibility to bottom trawl gear commonly used for scientific surveys. In autumn when water temperatures decline, black sea bass migrate offshore to areas along the edge of the continental shelf. During this offshore period, sea bass are vulnerable to otter trawl gear as part of a multispecies fishery (Shepherd and Terceiro 1994).

Black sea bass are protogynous hermaphrodites and can be categorized as temperate reef fishes (Steimle et al. 1999). Transition from female to male generally occurs between the ages of two and five (Lavenda 1949; Mercer 1978). Males can follow one of two behavioral pathways, either becoming dominant males, characterized by a larger size and a bright blue nuccal hump during spawning season, or secondary males which have few distinguishing features. Spawning in the Middle Atlantic peaks during spring (May and June) when the fish reside in coastal waters. The social structure of the spawning aggregations is poorly known although some observations suggest that large dominant males gather a harem of females and aggressively defend territory during spawning season (Nelson et al. 2003). The cue which triggers the transition from females to secondary or dominant male is undocumented, although the bright coloration of males suggests that visual cues may be important in structuring the social hierarchy.

Development of an analytical stock assessment for black sea bass has been hampered by a lack of catch at age information, inadequate fishery independent abundance indices and the unique life history characteristics of this species (NEFSC 2007). A recommendation emanating from an assessment review was to develop a comprehensive coastwide tagging program as an alternative method of determining exploitation on the northern stock and as a way to examine migratory behavior (NEFSC 1998). A secondary goal of the tagging program was to create a cooperative approach to data collection involving both the commercial and recreational industries.

Methods

Tagging protocol

A basic assumption in mark-recapture programs is that the tagged animals will be dispersed equally among untagged animals (Brownie et al. 1985). This can be accomplished either with the tag and release of a single large group, allowing the animals to disperse, or by dispersing the sites of release throughout the tagging area (Ricker 1975). To ensure the greatest geographic dispersal of tagged sea bass throughout the range of the northern stock, we tagged and released fish among coastal states (MA, RI, NY, NJ, DE, MD and VA) relative to state landing quota allocations of the Mid-Atlantic Fishery Management Council (MAFMC). Within each state, tagging sites were distributed at regular spatial intervals.

Sample sizes for releases were determined following the methods of Polacheck and Hearn (2003). A target sample size was 2,500 tags per season based on estimation under a range of exploitation rates (15% to 45%) and assuming a reporting rate of 75%, which demonstrated that any further increase in sample size resulted in minimal reduction in the variance of the exploitation rate. Tagging was conducted annually from 2002 to 2004 within a 30 day period from mid-September to mid-October, as well as a 21day period in May 2003. Several autumn release events occurred within days of this time window, having been delayed by weather. High reward tags ($100) were interspersed among regular tag releases at an approximate rate of 1 per 25 regular tags.

Over the three year period, black sea bass were tagged and released aboard chartered commercial and recreational fishing vessels. Recreational gear was standard hook and line equipment while commercial vessels used fish traps or hook and line gear. Fishing was done in depths ranging from 6 to 46 m and, if necessary, captured fish were placed into a holding tank to await tagging or evaluate condition. The size of fish targeted for tagging were greater than the commercial legal length (28 cm); however, fish as small as 20 cm were tagged. Tag number, date, exact location, total length (to the half-centimeter) and relative condition were recorded for each fish tagged.

The tag type used was a Floy internal anchor tag (FM-84), which has exhibited long term retention in other species (Dunning et al. 1987; Waldman et al. 1991). The tags had a unique identification number, telephone contact number and “Reward” printed on each side and in opposite directions such that the tag number was present at both the base and end of the tag. Tags were either orange, whose reporting was rewarded with a cap, or red which resulted in the $100 reward. In later years of the study, entry into a $250 lottery was offered in lieu of a cap. Tags were inserted into the abdomen below the midpoint of the pectoral fin by removing 2-3 scales and making a 0.5 cm incision into the musculature. Tagged fish were either released immediately or, if necessary, placed into a holding tank for several minutes of observation. Sea bass caught at deeper sites often had extruded swim bladders which were deflated when the abdominal incision was made and tag inserted. Fish judged to be weak or swimming abnormally were not released with a tag.

Recaptured tags were reported by telephone, postal mail, or by an online tag reporting webpage. High reward tags were returned prior to payment. We collected information on the date of capture, fish length, gear type and fishery, port, and longitude and latitude of recapture (or at least some reference point within several miles), condition of the fish at the tag insertion point, and fisherman's contact information.

Tag effects

Tag retention rate and tag induced mortality were determined by holding tagged fish in tanks in three separate studies. The first study was conducted at the Northeast Fisheries Science Center (NEFSC) Woods Hole Aquarium. Fish collected by hook and line were tagged and then placed in a 3,500 L aquarium tank for nine months. A second experiment was conducted in the NEFSC J.J. Howard Laboratory in Sandy Hook, NJ. Fish collected from fish pots were held in 1,500 L for ten to twelve months. A third experiment was conducted by the Rhode Island Department of Environmental Management. Fish collected with fish pots were tagged and held in 1,500 L tanks for twenty-seven days. In each experiment, tag losses and mortality associated with tagging were recorded daily.

Tag Analysis

Black sea bass and their fisheries in the Mid-Atlantic occur during two seasons: May through early October, and late October through April. To account for these seasonal variations and the time of tag releases, the recapture information and subsequent analyses were divided into two periods. One period was May 1st to September 30th and the second period ran from October 1st to April 30th. Tag recapture information was compiled by release cohort and summarized in a recovery matrix as:

$$R = \begin{bmatrix} r_{12} & r_{22} & \cdots & r_{1J} \\ \text{—} & r_{22} & \cdots & r_{2J} \\ \vdots & \vdots & \ddots & \vdots \\ \text{—} & \text{—} & \text{—} & r_{IJ} \end{bmatrix}$$

where r_{IJ} is the number of tags recovered in period J that were released in period I.

An assumption of tag modeling is that the tagged fish are representative of the untagged population. The time series of tag recaptures from a release group can be treated as a catch cohort, and total mortality (F + M or Z) approximated as a catch curve by calculating the slope of the $\log_e$ of recaptures over time (Ricker 1975). The catch curve method was used to evaluate tag recapture consistency across seasons, after adjusting for reporting rate. The negative slopes of the regressions, estimated within Excel, were averaged across all release years for comparison to the full tag model.

Survival estimates from the mark-recapture data were modeled using a variation of the Brownie model parameterized as instantaneous rates (Hoenig et al. 1998a; Hoenig et al. 1998b). The instantaneous rates (IR) model allows for direct estimation of both fishing (F) and natural (M) mortality. Additionally, F in the first recapture interval can be modeled separately to account for incomplete mixing or partial selectivity to the fishery. The model of expected recoveries can be written as:

$$\mathrm{E}(R) = \begin{bmatrix} N_1\phi\lambda_1\mu_1(F_1^*,M) & N_1\phi\lambda_2\mu_2(F_2,M)e^{-(F_1^*+M)} & \cdots & N_1\phi\lambda_J\mu_J(F_J,M)e^{-(F_1^*+\sum_{k=2}^{J-1}F_k+(J-1)M)} \\ — & N_2\phi\lambda_2\mu_2(F_2^*,M) & \cdots & N_2\phi\lambda_J\mu_J(F_J,M)e^{-(F_2^*+\sum_{k=3}^{J-1}F_k+(J-2)M)} \\ \vdots & \vdots & \ddots & \vdots \\ — & — & — & N_I\phi\lambda_J\mu_J(F_J,M)e^{-(F_I^*+\sum_{k=I+1}^{J-1}F_k+(J-I)M)} \end{bmatrix}$$

where ϕ is the rate of tag loss at release, λ is the tag reporting rate, F_k is the instantaneous fishing mortality in period k, F* is F during the initial non-mixing period and M is instantaneous rate of natural mortality. In black sea bass fisheries where F and M occur simultaneously, then:

$$\mu_J(F_J,M) = \frac{F_J}{F_J+M}(1-\exp(-F_J-M))$$

and when $I=J$ then:

$$\mu_J^*(F_J^*,M) = \frac{F_J^*}{F_J^*+M}(1-\exp(-F_J^*-M))$$

Since the results are assumed to be a multinomial distribution, the optimal solution of model parameters was determined using maximum likelihood estimation. Comparisons between observed and predicted tag recovery frequencies were made with a chi-square goodness of fit test and evaluation of the best model was done using the quasi-likelihood Akaike's information criterion, $QAIC_c$, which accounts for over-dispersion in the data (Anderson et al.1994; Burnham and Anderson 2002). Profile likelihoods were developed for each parameter in the final model and used to calculate 95% confidence intervals (Gimenez et al. 2005). The model parameterization was developed using the solver function in Microsoft Excel.

Since tagging occurred in October or May, the resulting mortality estimates were not calendar year values. Annual fishing and natural mortalities were re-calculated using monthly values (seasonal mortality estimate / # months within the season) and these values re-configured to a calendar year rather than tagging year. Fishing mortality estimates in 2002 only included October to December and were not used in an annual mortality estimate. Results from the final three months of 2007 were assumed equal to the mean of the same period in 2006.

Reporting rate

Although it is possible to estimate reporting rate λ within the model (Jiang et al 2007), we used an empirical estimate based on high reward tag returns:

$$\lambda_{J} = \left[\frac{(\sum_{J=1} \text{regular tags returned} / \sum_{J=1} \text{regular tags released})}{(\sum_{J=1} \text{high reward tags returned} / \sum_{J=1} \text{high reward tags released})} \right]$$

The ratio was calculated only for the twelve months at large for each release cohort since the recapture ratio of regular tags to high reward tags in the second year is not independent of the reporting rate in the first year. A constant reporting rate was applied to the recaptures after spring 2005. The monetary award that was thought to ensure that return rates approach 100% was $100 (Murphy and Taylor 1991; Pollock et al. 2001; Taylor et al. 2006). The sensitivity of the model results to the assumption of high reward tag reporting rate was evaluated for rates from 25% to 100%.

Tag induced mortality estimates do not account for mortality associated with the capture and release process during tagging. Hooking mortality in black sea bass has been estimated at 5% (Bugley and Shepherd 1991). To account for potential mortality of tagged fish due to hook and line capture, the tag loss rate was inflated by five percent.

Growth

Growth rate of individuals was calculated as the change in length between release and recapture divided by the number of days at large. Since recapture lengths are provided by the public, these lengths were expected to have a greater measurement error than the release measurements taken by trained personnel. The overall average growth per day was estimated for the entire time series of returns, and for the time series following elimination of data from consecutive days at large. Average growth was calculated from the point where the average growth in the time series remained relatively stable.

Results

Between 2002 and 2004, a total of 13,794 black sea bass of all sizes were tagged and released with either regular or high reward tags. Among those released,12,310 fish were greater than or equal to 26 cm and were tagged with regular reward tags (Table 1, Figure 1). These were considered vulnerable to both recreational and commercial size fisheries within one season following release. From October 2002 to September 2007, 1,683 regular tagged sea bass were recaptured and reported (Figure 2), for an overall recapture rate of 13.7%. Tagged fish were recovered throughout the range from recreational fishermen (57.2%), commercial fishermen (39.2%), research trips (1.0%) and unknown sources (2.6%). The average size at release was 32.2 cm ($\pm$ one std. dev of 4.76) whereas the average size at recapture was 35.8 cm ($\pm$ one std. dev of 5.83). The size distributions of released fish were comparable to the size distributions of sea bass harvested by the recreational and commercial fisheries (Figure 3). Average time-at-large was 257 days and the total distance traveled between tagging and recapture locations averaged 27.0 km or 0.35 km day^{-1}.

Tag retention and tag induced mortality in black sea bass were evaluated in three separate experiments. Sixty-eight (68) fish, ranging in size from 26 to 41 cm, were held in aquaria up to twelve months. No mortalities were observed immediately following tag insertion and over the course of the three experiments, only seven tags were shed (Dr. Mary Fabrizio, NEFSC[2]; Brian Murphy, RIDEM, personal communication). Five of the seven tags were shed within the first several weeks. Tag loss in black sea bass tagged with internal anchor tags was estimated at 10%. In addition, to account for potential hook induced mortalities associated with the initial capture methods, total tag loss and mortality was set at 15%.

Growth of tagged fish was estimated as the difference in size between release and recapture, and the time at large. During the initial days at large, the growth of tagged fish would be expected to be negligible and therefore the difference between length at release and recapture during this period would be due to measurement error. Within the first ten days, the differences in recorded lengths between released and recaptured fish ranged from 0 to 7 cm, averaging 1.1 cm, with the largest discrepancy from legal size fish (≥ 29.5 cm). With increasing time at large, measurement error decreased relative to accumulated growth (Figure 4). Consequently, growth rate declined over the first 90 days but stabilized thereafter. After the initial 90 days, growth averaged 0.012 cm day^{-1} for fish ≥26 cm. Assuming constant growth, fish tagged at 26 cm would be expected to attain legal size of 28 cm within 167 days following release.

Estimation of survival in Brownie-type models requires knowledge of the reporting rate of the tags. Included in the tag releases were 662 high reward tagged fish distributed across release periods. Based on the ratio of regular tags to high reward tag recoveries (N=151), seasonal estimates of tag reporting rate ranged from 53% to 80% (Table 2). The rates for the fall-winter period (76%. 80% and 57%) were generally higher than spring-summer (53%, 59% and 62%). Reporting rates in the years without empirical data were held constant at 60%, the average of the last two periods of empirical data. An assumption in reporting rate estimation was 100% reporting of the high reward tags. In the reporting process not all fishermen were willing to provide complete information necessary for payment. Consequently, true reporting rate was unknown but probably slightly less than 100%. The influence of reduced reporting of high reward tags would be an over-estimation of actual reporting rates (Pollock et al. 2001).

An additional model assumption is constant selectivity once the fish reach the size of full recruitment to the fisheries. This assumption was tested using recovery rates by two cm size categories for all data combined (Figure 5). The selectivity for fish greater than 29 cm was tested for a departure from a slope of zero. Results show no significant difference from 0 (Pr = 0.2) indicating a constant selectivity with size.

A simple estimate of total mortality (fishing plus natural mortality) was calculated as the rate of reduction in tag recoveries over time (Figure 6). The rate of decline in recoveries was consistent among release cohorts and total mortality estimates ranged from 1.33 to 1.54. The overall average total mortality using the catch curve method was 1.41. This approach requires a priori information regarding natural mortality to derive fishing mortality. Alternative tagging models, such as the instantaneous rates model, allow partitioning of the sources of mortality and direct estimation of F.

The instantaneous rates non-mixing model can be configured in a variety of ways. Recaptures of fish ≥ 29.5 cm were evaluated using seven models which included: (1) a fully parameterized model with time specific F, F* and M; (2) constant F and M with time specific F*; (3) constant F, F* and M; (4) time specific estimates of F* by period, time specific F for periods 1 through 6 with constant F across periods 7 to 10 and constant M; (5) constant estimates per period across years for all parameters; (6) constant annual estimates (no seasonal effect); and (7) period F* and F estimates with constant M. The constant F for periods 7 to 10 was chosen to

---

[2] Present address Virginia Institute of Marine Science, Gloucester Pt. VA

account for small sample sizes in the upper right corner of the matrix. Results of the chi-square test indicated that predicted values were not statistically different than those expected, with Pr>0.05 for models 1, 4 and 7. Based on the QAIC value, model 1 provided the best combination of parsimony and fit (Table 3). However, the parameter estimates were not robust to the starting values in the solution algorithm as the F estimates in the final 3 periods converged to different solutions depending on initial values. The reduced model, model 4, provided a more robust solution and was selected as the most appropriate model configuration. A comparison of observed and expected tag recaptures (Figure 7) indicated that recaptures can be adequately predicted using this model. The residuals show a pattern of consistent under-estimation of tag recaptures from the spring 2003 release (Figure 8), although the magnitude of the residuals is very small. The residuals from the three fall releases show no trend.

Comparison of mixing and non-mixing estimates of fishing mortality suggest that black sea bass were more vulnerable to exploitation during the initial release period. In each of the three release cohorts where both a non-mixed and mixed F could be estimated, the non-mixing F was higher (Table 4). The difference was particularly obvious in the spring 2004 release where the non-mixing F for the initial period (F^*_3) was 0.18 whereas subsequent F_3 estimates were 0.10. Fall releases (F_2 and F_4) differed between mixing and non-mixing estimates by 15 and 20%, respectively.

Average seasonal mortality estimates were derived from the model partial Fs. During the October to December/January to April period, fishing mortality averaged 0.16 per month, compared to the partial F from May through September period when fishing mortality averaged 0.22. The annualized fishing mortality standardized to calendar year, increased from 0.32 in 2003 to 0.41 in 2005 but then declined in 2007 to 0.37 (Table 5). Natural mortality, estimated as constant across years and seasons, was 1.08 (Table 4).
The tagging results indicate that fishing mortality has been relatively stable since 2002. Profile likelihoods and the associated 95% confidence intervals for the suite of seasonal F, F* and M estimates are presented in Figures 9 and 10. The distinctiveness of the minimum likelihood decreases for the parameters furthest from the initial release period resulting in a greater uncertainty in the estimates at the end of the recovery time series.

The tag recaptures in the model are influenced by both tag retention and reporting rates. The reporting rate adjustments assume that all high reward tags recaptured are recovered. However, in situations where fish are being quickly discarded, tagged fish may not be recovered and may die soon after discarding. To examine the sensitivity of the natural mortality estimate to under-reporting, we incrementally decreased high reward reporting rates. Overall reporting rate decreased linearly with decreased high reward reporting and the estimate of natural mortality decrease was curvilinear (Figure 11). When the high reward reporting was equal to 28.2%, the model estimate of natural mortality was 0.2.

Discussion

Recent developments in mark-recapture models have advanced their use for evaluating the exploitation of marine fishes. In particular, the parameterization of the Brownie bird banding models into instantaneous rates makes tagging model results similar to traditional catch at age stock assessment models. The lack of an analytical stock assessment was the impetus for developing a tag recapture program for black sea bass. Consequently, the results from the tagging models may help in determining status of black sea bass in the Mid-Atlantic. The most recent estimate of the fishing mortality that produces the maximum yield per recruit (i.e. F_{max})

was calculated to be F=0.33 (NEFSC 2007). The tagging results imply that fishing mortality exceeds this level, although the distribution of the 95% confidence interval shows that there is some probability that F is actually below F_{max}.

Seasonal patterns in fishing mortality reflect differences in the black sea bass fisheries. During the inshore period, sea bass are exposed to a coastwide recreational fishery and a directed pot fishery, whereas the offshore fishery is generally a non-directed trawl fishery targeting species such as summer flounder or *Loligo* squid (Shepherd and Terceiro 1994). The locations of optimal inshore black sea bass habitat, such as artificial reefs, are generally well known to fishermen and are routinely targeted. Among several tag release locations on artificial reefs, the recovery rate was as high as 25 to 35%. Movement of black sea bass is highly seasonal and did not occur until several weeks after tagging. Consequently, the exploitation of tagged fish was greater before they mixed during migration but the non-mixing model was able to adjust for this pre-migration period.

The parameterization of the Brownie model into instantaneous rates allowed potential estimation of natural mortality. Fishing mortality is determined from tag recoveries while the estimation of natural mortality is based on unaccounted tags (Hoenig et al. 1998b). Consequently, the parameter M is true natural mortality but is influenced by biases resulting from tag attrition over time, overestimated reporting rates, changes in selectivity with size, permanent emigration from the study area, increased predation on tagged fish, etc. and any other process which could result in unaccounted for tag losses. Any of these processes could result in an over-estimation of natural mortality in the model.

In fisheries stock assessments, natural mortality is often based on the lifespan of the species (Hewitt and Hoenig 2005) and assuming a life expectancy of 15 years for black sea bass (Musick and Mercer 1977), M has been set at 0.2 in recent stock assessments (NEFSC 2007). The tag based estimate of 1.08 is significantly higher and contradictory to M predicted from maximum age. A biased estimate of M in the tagging model could be the result of model misspecification or biased tag data. However, model misspecification does not appear to be a problem as reflected in the residuals and profile likelihoods. Among tag return biases necessary to overestimate M, it would be difficult to create a scenario resulting in an M equal to 0.2. Initial tag loss (type 1), modeled as 15%, differs from long term attrition of tags (type 2) (Beverton and Holt 1957). Tag attrition can be parameterized similar to M but to reduce M to 0.2 based on misspecification of retention, tag attrition would have to approach 0.88. There is no direct evidence to suggest a loss of this magnitude. Holding studies demonstrated that tags could be retained for at least one year. An immunological response to tags resulting in encapsulation and expulsion has been documented in some species (Vogelbein and Overstreet 1987) but while this may have been possible in sea bass, there would have to be comparable chronic tag loss rates among all release cohorts. Reduction in tag legibility could also create tag attrition problems in the returns (Henderson-Arzapalo et al. 1999). However, there were few reports among fishermen returning tags that legibility was an issue.

Over estimation of reporting rates resulting from violation of the 100% reporting assumption of high reward tags could bias natural mortality estimates. A reporting rate of 30% on high reward tags would have been needed to produce an M of 0.2. This would be highly unlikely and would also imply an unrealistically high exploitation rate. Another possible bias could result from release of tagged fish independent of local abundance followed by non-mixing, but an area based model produced comparable results for M and the use of a non-mixing model should account for initial distribution problems. A potential bias resulting from a dome-shaped selectivity pattern was also discounted after examining the recovery rate by size.

Since tag recovery biases alone do not adequately explain the high natural mortality estimated in the tag models, the possibility exists that M on black sea bass is actually greater than expected. Sea bass are structure oriented, protogynous hermaphrodites with a transition from female to male generally between ages 3 to 5, which was approximately the size of fish tagged and released. During spawning, large dominant males undergo physiological changes and begin aggressively defending territory. The importance of secondary male *C. striata* to spawning success is not documented but in congeneric species the importance of secondary males has ranged from irrelevant to critical contributors to the gene pool (Petersen 1991). If these male *C. striata* only provide a pool of potential dominant males, there would be little evolutionary advantage for the population to maintain a large number of secondary males to compete with smaller females and the large males. The consequence could be a higher natural mortality from such things as senescence, increased aggression by dominant males or higher predation rates if the secondary males are forced into marginal habitats. If life expectancy of tagged fish was only three or four years beyond the age at release, the natural mortality of these fish could be significantly greater than 0.2. This does not imply that a high M was constant across all ages, but rather increases in the post transitional ages.

The tagging program for black sea bass in the Middle Atlantic was designed to simultaneously distribute tagged fish throughout the stock, test for tag induced mortality and tag loss, estimate annual reporting rates, and document recapture information. The release-recapture matrix was examined with an analytical tagging model that incorporated temporal variations in exploitation, and by association, spatial changes in exploitation. The results imply that this stock of black sea bass may be experiencing exploitation above the level currently considered optimal. The tagging results also suggest that our understanding of natural mortality developed from gonochoristic species may not be appropriate for this protogynous hermaphrodite. Biases in parameter estimation due to tag loss, etc. may explain in part the high value for natural mortality, but the magnitude of the value suggests that natural mortality is greater than would be predicted from maximum observed age.

Acknowledgments

We gratefully acknowledge the help of the numerous volunteers and vessel operators who participated in this study and made it possible. State and federal fishery agencies between Massachusetts and Virginia all provided expert help in the tagging program. This study was funded through a grant from the MARFIN program and the Northeast Fisheries Science Center.

SCALE Model

Introduction

Incomplete or lack of age-specific catch and survey indices often limits the application of a full age-structured assessment (e.g. Virtual Population Analysis and many forward projecting age-structured models). Stock assessments will often rely on the simpler size/age aggregated models (e.g. surplus production models) when age-specific information is lacking. However the simpler size/age aggregated models may not utilize all of the available information for a stock assessment. Knowledge of a species growth and lifespan, along with total catch data, size composition of the removals, recruitment indices and indices on numbers and size composition of the large fish in a survey can provide insights on population status using a simple model framework.

The Statistical Catch At LEngth (SCALE) model, is a forward projecting age-structured model tuned with total catch (mt), catch at length or proportional catch at length, recruitment at a specified age (usually estimated from first length mode in the survey), survey indices of abundance of the larger/older fish (usually adult fish) and the survey length frequency distributions. The SCALE model was developed in the AD model builder framework. The model parameter estimates are fishing mortality and recruitment in each year, fishing mortality to produce the initial population (Fstart), logistic selectivity parameters for each year or blocks of years and Qs for each survey index.

The SCALE model was developed as an age-structured model that does NOT rely on age-specific information on a yearly basis. The model is designed to fit length information, abundance indices, and recruitment at age which can be estimated by using survey length slicing. However the model does require an accurate representation of the average overall growth of the population which is input to the model as mean lengths at age. Growth can be modeled as sex-specific growth and natural mortality or growth and natural mortality can be model with the sexes combined. The SCALE model will allow for missing data.

Model Configuration

The SCALE model assumes growth follows the mean input length at age with predetermined input error in length at age. Therefore a growth model or estimates of the average mean lengths at age is essential for reliable results. The model assumes static growth and therefore population mean length/weight at age are assumed constant over time.
The SCALE model estimates logistic parameters for a flattop selectivity curve at length in each time block specified by the user for the calculation of population and catch age-length matrices or the user can input fixed logistic selectivity parameters. Presently the SCALE model can not account for the dome shaped selectivity pattern.

The SCALE model computes an initial age-length population matrix in year one of the model as follows. First the estimated populations numbers at age starting with age-1 recruitment get normally distributed at one cm length intervals using the mean length at age with the assumed standard deviation. Next the initial population numbers at age are calculated from the previous age at length abundance using the survival equation. An estimated fishing mortality (Fstart) is also used to produce the initial population. This F can be thought of as the average fishing mortality that occurred before the first year in the model. Now the process repeats itself with the total of the estimated abundance at age getting redistributed according to the mean length at age and standard deviation in the next age (age+1).

This two step process is used to incorporate the effects of length specific selectivities and fishing mortality. The initial population length and age distribution is constructed by assuming population equilibrium with an initial value of F, called F_{start}. Length specific mortality is estimated as a two step process in which the population is first decremented for the length specific effects of mortality as follows:

$$N^{*}_{a,len,y_1} = N_{a-1,len,y_1} e^{-\left(PR_{len}F_{start}+M\right)}$$

In the second step, the total population of survivors is then redistributed over the lengths at age *a* by assuming that the proportions of numbers at length at age *a* follow a normal distribution with a mean length derived from the input growth curve (mean lengths at age).

$$N_{a,len,y_1} = \pi_{len,a} \sum_{len=0}^{L_\infty} N^{*}_{a,len,y_1}$$

where

$$\pi_{len,a} = \Phi\left(len+1 \mid \mu_a, \sigma_a^2\right) - \Phi\left(len \mid \mu_a, \sigma_a^2\right)$$

where

$$\mu_a = L_\infty\left(1 - e^{-K(a-t_0)}\right)$$

Mean lengths at age can be calculated from a von Bertalanffy model from a prior study as shown in the equation above or mean lengths at age can be calculated directly from an age-length key. Variation in length at age a = σ_s^2 can often be approximated empirically from the growth study used for the estimation of mean lengths at age. If large differences in growth exist between the sexes then growth can be input as sex-specific growth with sex-specific natural mortality. However catch and survey data are still fitted with sexes combined.

This SCALE model formulation does not explicitly track the dynamics of length groups across age because the consequences of differential survival at length at age a do not alter the mean length of fish at age a+1. However, it does more realistically account for the variations in age-specific partial recruitment patterns by incorporating the expected distribution of lengths at age.

In the next step the population numbers at age and length for years after the calculation of the initial population use the previous age and year for the estimate of abundance. Here the calculations are done on a cohort basis. Like in the previous initial population survival equation the partial recruitment is estimated on a length vector.

$$N^*_{a,len,y} = N_{a-1,len,y-1} e^{-\left(PR_{len} F_{y-1} + M\right)}$$

second stage

$$N_{a,len,y} = \pi_{len,a} \sum_{len=0}^{L_\infty} N^*_{a,len,y}$$

Constant M is assumed along with an estimated length-weight relationship to convert estimated catch in numbers to catch in weight. The standard Baranov=s catch equation is used to remove the catch from the population in estimating fishing mortality.

$$C_{y,a,len} = \frac{N_{y,a,len}\, F_y\, PR_{len}\left(1 - e^{-\left(F_y PR_{len} + M\right)}\right)}{(F_y \;\; PR_{len}) + M}$$

Catch is converted to yield by assuming a time invariant average weight at length.

$$Y_{y,a,len} = C_{y,a,len} W_{len}$$

The SCALE model results in the calculation of population and catch age-length matrices for the starting population and then for each year thereafter. The model is programmed to estimate recruitment in year 1 and estimate variation in recruitment relative to recruitment in year 1 for each year thereafter. Estimated recruitment in year one can be thought of as the estimated average long term recruitment in the population since it produces the initial population. The residual sum of squares of the variation in recruitment $\sum(\text{Vrec})^2$ is than used as a component of the total objective function. The weight on the recruitment variation component of the objective function (Vrec) can be used to penalize the model for estimating large changes in recruitment relative to estimated recruitment in year one.

The model requires an age-1 recruitment index for tuning or the user can assume relatively constant recruitment over time by using a high weight on Vrec. Usually there is little overlap in ages at length for fish that are one and/or two years of age in a survey of abundance. The first mode in a survey can generally index age-1 recruitment using length slicing. In addition numbers and the length frequency of the larger fish (adult fish) in a survey where overlap in ages at a particular length occurs can be used for tuning population abundance. The model tunes to the catch and survey length frequency data using a multinomial distribution. The user specifies the minimum size (cm) for the model to fit. Different minimum sizes can be fit for the catch and survey data length frequencies.

The number of parameters estimated is equal to the number of years in estimating F and recruitment plus one for the F to produce the initial population (Fstart), logistic selectivity parameters for each year or blocks of years, and for each survey Q. The total likelihood function to be minimized is made up of likelihood components comprised of fits to the catch, catch length frequencies, the recruitment variation penalty, each recruitment index, each adult index, and adult survey length frequencies:

$$\mathrm{L}_{\mathrm{catch}} = \sum_{years}\left(l\,\mathrm{n}(Y_{\mathrm{obs,y}} + 1) - \ln\left(\sum_{a}\sum_{len} \mathrm{Y}_{\mathrm{pred,len,a,y}} + 1 \right)\right)^2$$

$$L_{catch\_lf} = -N_{eff} \sum_{y}\left(\sum_{inlen}^{L_\infty}\left((C_{y,len}+1)\ln\left(1+\sum_{a} C_{pred,y,a,len}\right) - \ln(C_{y,len}+1)\right)\right)$$

$$\mathrm{L}_{\mathrm{vrec}} = \sum_{y=2}^{Nyears} (Vrec_y)^2 = \sum_{y=2}^{Nyears} (R_1 - R_y)^2$$

$$\sum L_{rec} = \sum_{i=1}^{Nrec}\left[\sum_{y}^{Nyears}\left(\ln\left(I_{rec_i,inage_i,y}\right) - \ln\left(\sum_{len}^{L_\infty} N_{y,inage_i,len} * q_{rec\,i} \right)\right)^2 \right]$$

$$\sum L_{adult} = \sum_{i=1}^{Nadult}\left[\sum_{y}^{Nyears}\left(\ln\left(I_{adult_i,inlen+_i,y}\right) - \left(\sum_{a}\sum_{inlen_i}^{L_\infty} \ln\left(N_{pred,y,a,len} * q_{adult\,i}\right)\right)\right)^2 \right]$$

$$\sum L_{lf} = \sum_{i=1}^{Nlf}\left[-N_{eff}\sum_{y}\left(\sum_{inlen_i}^{L_\infty}\left((I_{lf_i,y,len}+1)\ln\left(1+\sum_{a} N_{pred,y,a,len}\right) - \ln(I_{lf_i,y,len}+1)\right)\right)\right]$$

In equation L_{catch_lf} calculations of the sum of length is made from the user input specified catch length to the maximum length for fitting the catch. Input user specified fits are indicated with the prefix "in" in the equations. LF indicates fits to length frequencies. In equation L_{rec} the input specified recruitment age and in L_{adult} and L_{lf} the input survey specified lengths up to the maximum length is used in the calculation.

$$Obj\ \ fcn = \sum_{i=1}^{N} \lambda_i L_i$$

Lambdas represent the weights to be set by the user for each likelihood component in the total objective function.

1 Atlantic surfclam Assessment

1.1 Foreword

The Northeast Regional Stock Assessment Workshop (SAW) process has three parts: preparation of stock assessments by the SAW Working Groups and/or by ASMFC Technical Committees/Assessment Committees; peer review of the assessments by a panel of outside experts who judge the adequacy of the assessment as a basis for providing scientific advice to managers; and a presentation of the results and reports to the Region's fishery management bodies.

Starting with SAW 39 (June 2004), the process was revised in two fundamental ways. First, the Stock Assessment Review Committee (SARC) became a smaller panel with panelists provided by the Independent System for Peer Review (Center of Independent Experts, (CIE). Second, the SARC provides little management advice. Instead, Council and Commission teams (e.g., Plan Development Teams, Monitoring and Technical Committees, Science and Statistical Committee) formulate management advice after an assessment has been accepted by the SARC. Starting with SAW 45 (June 2007) the SARC chairs were from external agencies, but not from the CIE. Starting with SAW 48 (June 2009), SARC chairs are from the Fishery Management Council's Science and Statistical Committee (SSC), and not from the CIE. Also at this time, some assessment Terms of Reference were revised to provide additional science support to the SSCs, as the SSC's are required to make annual ABC recommendations to the fishery management councils.

Reports that are produced following SAW/SARC meetings include: An *Assessment Summary Report* - a summary of the assessment results in a format useful to managers; an *Assessment Report* - a detailed account of the assessments for each stock; and the SARC panelist reports - a summary of the reviewer's opinions and recommendations as well as individual reports from each panelist. Both the SAW/SARC assessment reports and the CIE review reports are available online at http://www.nefsc.noaa.gov/saw/reports.html.

The 61st SARC was convened in Woods Hole at the Northeast Fisheries Science Center (NEFSC), July 19-21, 2016 to review a benchmark stock assessment of Atlantic surfclam (*Spissula solidissima*). CIE reviews for SARC61 were based on detailed reports produced by NEFSC Assessment Working Groups. This introduction contains a brief summary of the SARC comments, a list of SARC panelists, the meeting agenda, and a list of attendees (Tables 1 - 3). Maps of the Atlantic coast of the USA and Canada are also provided (Figures 1 - 5).

Outcome of Stock Assessment Review Meeting:

Text in this section is based on SARC-61 Review Panel reports (available at http://www.nefsc.noaa.gov/saw/ under the heading "SAW 61 Panelist Reports").

The Atlantic surfclam stock assessment was accepted by the SARC-61 panel. In 2015 overfishing was not occurring and the stock was not overfished. Population projections suggest that the population is unlikely to become overfished and that overfishing is unlikely to occur by 2025. Nine of the ten assessment Terms of Reference were met. The assessment was based on the Stock Synthesis III model (SS3). Commercial LPUE values show mostly declining trends, appearing to contradict increasing survey trends. Stock depletion may be real at a local level, but the limited coverage of the fishery suggests that the LPUE trends are not indicative of the stock as a whole.

The Panel endorsed the redefinition of the Biological Reference Points (BRP) based on relative stock status. The new BRPs can be used to provide catch limit advice. The Panel noted that the fishing mortality threshold calculation uses an estimate of FMSY. This value was derived from a simulation study, the details of which were not discussed by the Panel at the review meeting. The assessment did not determine whether the surfclam resource should be considered as one unit stock throughout the species' range in US federal waters or if regional stocks should be recognized. However, not meeting this ToR did not impact the overall acceptability of the assessment.

Due to the importance of the clam survey in this assessment, the Panel recommends caution in making any changes to the gear and survey vessel.

1.2 Executive summary

This assessment is for Atlantic surfclam in the US EEZ (federal waters, 3-200 nm from shore) individual transferable quota (ITQ) fishery (Appendix 7). The assessment divides the US stock into a northern (Georges Bank or GBK) and a southern area (south of GBK to Cape Hatteras) for modeling purposes (Figures 6 and 7). However, the resource is managed as a single stock so estimates for the north and south are combined for status determination.

TOR 1. Estimate catch from all sources including landings and discards. Map the spatial and temporal distribution of landings, discards, fishing effort, and gross revenue, as appropriate. Characterize the uncertainty in these sources of data.

Commercial landings and fishing effort data are reported by processors based on cage tags, in logbooks by ten-minute square (TNMS) and considered reliable. Catch includes a 12% allowance for incidental mortality. Atlantic surfclam discards were near zero except during 1982-1993 when minimum size regulations were used (Table 3).

Landings, fishing effort and landings per unit effort (LPUE, bu per hour fished) shifted north after 2000 as fishery productivity in the south declined (Figures 13-18). During 2006-2015, total landings declined from about 27 to 18 (mean 21) thousand mt (Tables 4-5 and Figures 8-9). Fishing effort after 2006 varied without trend or declined in the south but is still relatively high. Effort increased dramatically in in the north (Table 6 and Figure 10). Processors prefer large Atlantic surfclam but the sizes of landed Atlantic surfclam have declined in the south (Figures 22-27).

TOR 2. Present the survey data being used in the assessment (e.g., indices of relative or absolute abundance, recruitment, state surveys, age-length data, etc.). Use logbook data to investigate regional changes in LPUE, catch and effort. Characterize the uncertainty and any bias in these sources of data. Evaluate the spatial coverage, precision, and accuracy of the new clam survey.

The NEFSC clam survey used the *RV Delaware II* and a small 5 ft dredge (RD) prior to 2012 and a commercial fishing vessel and modified commercial dredge (MCD) since. The entire resource was surveyed with the RD in 2011 (Tables 10-11). The MCD was used in 2012 and 2015 in the south but only on GBK in 2013. Data from the two periods are not comparable although capture efficiency and size selectivity estimates can be used to calculate relatively consistent swept-area stock size for 1997-2015. Based on two swept-area estimates, biomass declined in the south after 2011 (Figure 39). It is not possible to evaluate recent trends off GBK.

Landings per unit effort declined steadily for the stock as a whole and in the south to near record lows in 2015 but is high on GBK (Table 8 and Figure 12). Survey data and other information indicate that the biological condition of the Atlantic surfclam resource as a whole and in the south is better than fishery conditions would suggest. Landings, effort and LPUE do not reliably measure trends in overall Atlantic surfclam stock size because the fishery operates in relatively few TNMS such that most of the stock and habitat are not accessed by the fishery (Figures 19-21).

TOR 3. Determine the extent and relative quality of benthic habitat for Atlantic surfclam in the Georges Bank ecosystem to refine estimates of stock size based on swept area calculations.

The proportion of untrawlable ground that is potentially poor clam habitat was recalculated to be 14% which is slightly higher than the 12% figure used in this assessment. New information will be available soon for refining these imprecise estimates (Appendix 13).

TOR 4. Quantify changes in the depth distribution of Atlantic surfclam over time. Review changes over time in Atlantic surfclam biological parameters such as length, width, and growth.

The distribution of Atlantic surfclam in the south is shifting towards deeper water due to warming as suitable nearshore habitat areas have decreased and offshore habitats increased (Figures 72-77). Survey data indicate that overlap between Atlantic surfclam and ocean quahogs which inhabit relatively deep water habitat has increased (Figures 78-79). Maximum shell length had declined in the south while the von Bertalanffy growth parameter K increased (Figures 86-87).

TOR 5. Estimate annual fishing mortality, recruitment and stock biomass (both total and spawning stock) for the time series (integrating results from TOR 3, as appropriate) and estimate their uncertainty. Include a historical retrospective analysis to allow a comparison with previous assessment results and previous projections.

The primary assessment was a statistical catch at age model implemented in SS3. Each of two areas were assessed separately and the results were combined to provide management advice for the stock (Part 1.7). The scale of absolute abundance was uncertain, which is a problem typical of low fishing mortality fisheries. The trend in biomass was relatively well determined. The southern area, where recent recruitment has been strong is near its unfished biomass (B_0). The northern area, where recent recruitment has been poor is at a lower level, but still above $\frac{1}{4}B_0$. Fishing mortality is low for both areas.

TOR 6. State the existing stock status definitions for "overfished" and "overfishing". Then update or redefine biological reference points (BRPs; point estimates or proxies for B_{MSY}, $B_{THRESHOLD}$, F_{MSY} and MSY) and provide estimates of their uncertainty. If analytic model-based estimates are unavailable, consider recommending alternative measurable proxies for BRPs. Comment on the scientific adequacy of existing BRPs and the "new" (i.e., updated, redefined, or alternative) BRPs, particularly as they relate to stock assumptions.

The current and recommended stock status definitions are listed in Table 4 (Part 1.8). The current stock status definitions were revised based on a management strategy evaluation (Part 8) and assessment model improvements, because the overfishing definition depended on the estimate of absolute abundance in the assessment, which is uncertain. The recommended stock status definitions are trend-based as trend is relatively well estimated in this assessment.

TOR 7. Evaluate stock status with respect to the existing model (from previous peer reviewed accepted assessment) and with respect to any new model or models developed for this peer review.

1. *When working with the existing model, update it with new data and evaluate stock status (overfished and overfishing) with respect to the existing BRP estimates.*
2. *Then use the newly proposed model and evaluate stock status with respect to "new" BRPs and their estimates (from TOR-5).*

The Atlantic surfclam population is not overfished and overfishing is not occurring under either the current or recommended reference point definitions and using either the previous or newly developed models (Part 1.9; Tables 27 - 29).

TOR 8. Develop approaches and apply them to conduct stock projections.

1. *Provide numerical annual projections (five years) and the statistical distribution (e.g., probability density function) of the OFL (overfishing level) (see Appendix 15). Consider cases using nominal as well as potential levels of uncertainty in the model. Each projection should estimate and report annual probabilities of exceeding threshold BRPs for F, and probabilities of falling below threshold BRPs for biomass. Use a sensitivity analysis approach in which a range of assumptions about the most important uncertainties in the assessment are considered (e.g., terminal year abundance, variability in recruitment).*
2. *Comment on which projections seem most realistic. Consider the major uncertainties in the assessment as well as sensitivity of the projections to various assumptions.*
3. *Describe this stock's vulnerability (see 15) to becoming overfished, and how this could affect the choice of ABC.*

Projections indicate that the population is unlikely to be overfished and that overfishing is unlikely to occur by 2025 using a wide range of possible biomass scales and assumed catches (Part 1.10; Tables 30 - 31).

TOR 9. Evaluate the validity of the current stock definition. Determine whether current stock definitions may mask fishery related reductions in sustainable catch on regional spatial scales. Make a recommendation about whether there is a need to modify the current stock definition.

The invertebrate subcommittee did not reach consensus on stock definitions. All members of the workgroup agree that stock definitions are unlikely to affect management, yield, or biological risk in the near term as long as fishing mortality rates remain low and overall abundance and biomass are relatively high in both the northern and southern areas. If fishing mortality increases substantially, or a portion of the stock declines substantially, then the current stock definition has the potential to mask conditions in the affected area and lead to reduced yield and biomass. The single stock assumption also complicates and adds uncertainty to stock status determinations based on current and recommended reference points (Part 1.11).

TOR 10. Review, evaluate and report on the status of the SARC and Working Group research recommendations listed in most recent SARC reviewed assessment and review panel reports. Identify new research recommendations.

Research recommendations were reviewed and evaluated and new ones were developed (Part 1.12).

Terms of Reference

A. Atlantic surfclams

1. Estimate catch from all sources including landings and discards. Map the spatial and temporal distribution of landings, discards, fishing effort, and gross revenue, as appropriate. Characterize the uncertainty in these sources of data.

2. Present the survey data being used in the assessment (e.g., indices of relative or absolute abundance, recruitment, state surveys, age-length data, etc.). Use logbook data to investigate regional changes in LPUE, catch and effort. Characterize the uncertainty and any bias in these sources of data. Evaluate the spatial coverage, precision, and accuracy of the new clam survey.

3. Determine the extent and relative quality of benthic habitat for surfclams in the Georges Bank ecosystem to refine estimates of stock size based on swept area calculations.

4. Quantify changes in the depth distribution of surfclams over time. Review changes over time in surfclam biological parameters such as length, width, and growth.

5. Estimate annual fishing mortality, recruitment and stock biomass (both total and spawning stock) for the time series (integrating results from TOR 3, as appropriate) and estimate their uncertainty. Include a historical retrospective analysis to allow a comparison with previous assessment results and previous projections.

6. State the existing stock status definitions for "overfished" and "overfishing". Then update or redefine biological reference points (BRPs; point estimates or proxies for B_{MSY}, $B_{THRESHOLD}$, F_{MSY} and MSY) and provide estimates of their uncertainty. If analytic model-based estimates are unavailable, consider recommending alternative measurable proxies for BRPs. Comment on the scientific adequacy of existing BRPs and the "new" (i.e., updated, redefined, or alternative) BRPs, particularly as they relate to stock assumptions.

7. Evaluate stock status with respect to the existing model (from previous peer reviewed accepted assessment) and with respect to any new model or models developed for this peer review.
   (a) When working with the existing model, update it with new data and evaluate stock status (overfished and overfishing) with respect to the existing BRP estimates.
   (b) Then use the newly proposed model and evaluate stock status with respect to "new" BRPs and their estimates (from TOR-5).

8. Develop approaches and apply them to conduct stock projections.
   (a) Provide numerical annual projections (five years) and the statistical distribution (e.g., probability density function) of the OFL (overfishing level) (see Appendix to the SAW TORs). Consider cases using nominal as well as potential levels of uncertainty in the model. Each projection should estimate and report annual probabilities of exceeding threshold BRPs for F, and probabilities of falling below threshold BRPs for biomass. Use a sensitivity analysis approach in which a range of assumptions about the most important uncertainties in the assessment are considered (e.g., terminal year abundance, variability in recruitment).

(b) Comment on which projections seem most realistic. Consider the major uncertainties in the assessment as well as sensitivity of the projections to various assumptions.

(c) Describe this stock's vulnerability (see 15) to becoming overfished, and how this could affect the choice of ABC.

9. Evaluate the validity of the current stock definition. Determine whether current stock definitions may mask fishery related reductions in sustainable catch on regional spatial scales. Make a recommendation about whether there is a need to modify the current stock definition.

10. Review, evaluate and report on the status of the SARC and Working Group research recommendations listed in most recent SARC reviewed assessment and review panel reports. Identify new research recommendations.

1.3 TOR 1: Commercial

In this assessment for Atlantic surfclam the northern area was federal waters (3-200 nm from shore) on Georges Bank and the southern area was federal waters from south and west of Georges Bank to Cape Hatteras (Figures 6 and 7). Commercial landings were provided in meat weights for ease of comparison to survey data and in analyses, but were originally reported in units of industry cages. Landings per unit of fishing effort (LPUE) data were reported in this assessment as landings in bushels per hour fished, based on mandatory clam logbook reports. The spatial resolution of the clam logbook reports was usually one ten-minute square.

Unit	Equivalent
1 cage	32 bushels
1 bushel	1.88 ft^3
1 bushel	17 lbs. meats
1 bushel	7.71 kg meats

As in previous stock assessments (Northeast Fisheries Science Center 2013), "catch" was defined as the sum of landings, plus 12% of landings, plus discards. Based on prior calculations (Northeast Fisheries Science Center 2003), Atlantic surfclam catch in previous assessments was assumed to be 12% larger than landings to account for incidental mortality of clams in the path of the dredge. The 12% figure was considered an upper bound or overestimate because the area fished (e.g. 155 km^2 during 2004) is small relative to area covered by the stock (Walace and Hoff 2005). Furthermore, the ITQ (see below) clam fishery operates with little or no regulation induced inefficiency due to area closures, trip limits, size limits, etc. so that fishing effort and incidental mortality are reduced. The support for this estimate was reevaluated in this assessment based on data also used by Northeast Fisheries Science Center (2003), and more realistic algebraic relationships proposed by Dr. Deborah Hart (NEFSC, Woods Hole, MA) for sea scallops in Northeast Fisheries Science Center (2014).

The ratio of Atlantic surfclam in the path of a commercial dredge that are caught relative to those killed but not caught is $R = \frac{e}{c(1-e)}$ where e is capture efficiency and c is the fraction that die but are not caught. Indirect mortality due to contact with a clam dredge is in the range of 5-20% with an extreme upper bound of 50% (Table C10, (Northeast Fisheries Science Center 2003)). If F_L is fishing mortality for landed Atlantic surfclam and F_I is the incidental mortality rate then $F_I = \frac{F_L}{R} = \frac{F_L c(1-e)}{e}$ and $\frac{F_I}{F_L} = \frac{c(1-e)}{e}$. The ratio $\frac{F_I}{F_L}$ is the same as the ratio of numbers landed to numbers killed but not caught. If landed and incidental clams have the same size composition, then the ratio of landed weight to incidental weight is also $\frac{F_I}{F_L}$. The average efficiency of a commercial clam dredge for Atlantic surfclam is about 0.73 (Table A10 in NEFSC 2003). The range of estimates $c = 0.05$, 0.2 and 0.5 indicate that incidental losses are 2%, 7% and 18% of landings which together average about 13%. The Subcommittee concluded that the 12% incidental mortality estimate was reasonable for Atlantic surfclam.

Recreational catch is near zero, although small numbers of Atlantic surfclam are taken recreationally in shallow inshore waters for use as bait. Atlantic surfclam are not targeted recreationally for human consumption.

Discard data

Discards were zero from 2008-2015 since the last assessment. Some discards occurred during 1979-1993; as the result of a minimum size (shell length) requirement for landing that was in place over that period (Table 3). No new information about discards was available for this assessment.

Age and size at recruitment to the fishery

Age at recruitment to the Atlantic surfclam fishery depends on growth rates, which vary both spatially and temporally (see 1.4). The age at recruitment depends on the area being modeled (north vs. south), and the time period in question, as growth may change over time. Size at recruitment depends on the fishery selectivity estimated in the model. This issue is discussed in detail in section (1.7).

Landings, fishing effort and prices

Landings and fishing effort data for 1982-2015 were from mandatory logbook reports (similar but more detailed than standard Vessel Trip Reports used in most other fisheries) with information on the location, duration, and landings of each trip. Data for earlier years were from Northeast Fisheries Science Center (2003) and Mid-Atlantic Fishery Management Council (2006).

Landings data from Atlantic surfclam logbooks are considered accurate in comparison to other fisheries because of the Individual Transferable Quota (ITQ) and cage tag systems. However, effort data are not reliable for 1981–1990 due to regulations that restricted the duration of fishing to 6 hours. Effort data are considered reliable for years before 1985 and after 1990.

Atlantic surfclam landings were mostly from the US Exclusive Economic Zone (EEZ) during 1965 to 2011 (Table 4 and Figure 8). EEZ landings peaked during 1973–1974 at about 33 thousand mt, and fell dramatically during the late 1970s and early 1980s before stabilizing beginning in about 1985. The ITQ system was implemented in 1990. EEZ landings were relatively stable and varied between 18 and 25 thousand mt during 1985 to 2015. Landings have not reached the quota of 26,218 mt since it was set in 2004 because of limited markets. The quotas are set at levels much lower than might be permitted under the FMP. Approximate state landings are shown in Table 4, and more accurate state landings are available in Appendices (7). Both New Jersey and New York have seen a sharp decline in Atlantic surfclam biomass within their state territorial waters over the past 15 years, and an accompanying drop in landings (7).

The bulk of EEZ landings were from the DMV region (Figure 7) during 1979-1980. After 1980, the bulk of landings were from the NJ region (Table 5 and Figure 9). Landings from LI were modest but began increasing in 2001. Landings from SNE were modest but increased starting in 2004. The high proportion of landings on GBK reflects the high catch rates there (see below).

Total fishing effort increased after 1990 and has been relatively high, but stable since 2007, particularly in the DMV and NJ regions (Table 6 and Figure 10). The bulk of the fishing effort was in areas where the majority of landings come from.

Real ex-vessel prices for the inshore and EEZ fisheries have been stable, since the mid-1990s (Table 7 and Figure 11). Nominal revenues for Atlantic surfclam during 2013 were about $33 million.

Landings per unit effort (LPUE)

Nominal landings per unit effort (LPUE) based on logbook data was computed as total landings divided by total fishing effort for all vessels and all trips (Table 8 and Figure 12). Standardized LPUE was not estimated for this assessment because the data are not used analytically and because Northeast Fisheries Science Center (2007) showed that nominal and standardized trends were almost identical, when standardized trends were estimated in separate general linear models for each region with vessel and year effects.

Nominal LPUE has been declining steadily in SVA, DMV and NJ, which have recently been at or near record lows. LPUE in GBK and SNE have generally been high.

LPUE is not an ideal measure of fishable biomass trends for sessile and patchy stocks like Atlantic surfclam because fishermen target high density beds and change their operations to maintain relatively high catch rates as stock biomass declines (Hilborn et al. 1992).

Spatial patterns in fishery data

Mean landings, fishing effort, and LPUE were calculated by ten-minute square (TNMS) from 1979-2015 in 5 year blocks (Figures 13 – 18). Only TNMS where more than ten bu of Atlantic surfclam were caught over the time period were included in maps. TNMS with reported landings less than 10 bu were probably in error, or from just a few exploratory tows. Inclusion of TNMS, with less than 10 bu distorted the graphical presentations because the area fished appeared unrealistically large.

Figures 13 – 18 show the spatial patterns of the Atlantic surfclam fishery over most of its history. In most blocks, the greatest concentration of fishing effort and landings occurred in the same thirty or so TNMS in the NJ region, with intermittent fishing activity in other regions and recent emphasis on SNE and GBK.

TNMS with the highest LPUE levels over time have been mostly in the NJ and DMV regions with irregular contributions from GBK and the Nantucket Shoals region of SNE.

Important TNMS

TNMS important to the fishery were identified by choosing the 10 TNMS from with the highest mean landings during each 5 year time block. For example, a TNMS important during 1991-1995 could be selected regardless of its importance during earlier or later time periods. The list contains a subset of the total TNMS, because of overlap between the time periods and because the same TNMS tend to remain important. These plots are complicated by the "rule of three", which states that fine scale fishing location data cannot be shown for areas fished by three or fewer vessels due to confidentiality concerns. Trends in landings, effort, and LPUE were plotted (Figures 19 – 21) for each TNMS to show changes in conditions over time within individual TNMS.

With the exception of GBK, there are very few important ten-minute squares in which the LPUE has trended upwards in recent years, if they are still being fished. Most are currently at or below about 100 bushels per hour.

Fishery length composition

Since 1982, port samplers have routinely collected shell length measurements from approximately 30 random landed Atlantic surfclam from selected fishing trips each year (Table 9).

Port sample length frequency data from the four regions show modest variation in size of landed Atlantic surfclam over time with declines in modal size in DMV and NJ since 2008 (Figures 22 – 28). Care should be taken in interpreting these due to small sample sizes in some cases (especially LI, SNE and GBK), but in general the data indicate that most landed Atlantic surfclam have been larger than 120mm SL. Commercial size distributions are discussed in detail in section (1.7).

Fishery management

The Atlantic surfclam is managed by the Mid-Atlantic Fishery Management Council (Council). The Council is one of eight regional fishery management councils created when the United States (U.S.) Congress passed Public Law 94-265, the Magnuson Fishery Conservation And Management Act of 1976 (also known as Magnuson-Stevens Act or MSA). The law created a system of regional fisheries management designed to allow for regional, participatory governance. The Council develops fishery management plans and recommend management measures to the Secretary of Commerce through the National Marine Fisheries Service (NMFS) for its fisheries in the Exclusive Economic Zone of the U.S. (EEZ; 3-200 miles off the east coast). There are also fisheries for Atlantic surfclam in New Jersey, New York, and Massachusetts within state waters (within 3 miles of shore); the state authorities are responsible for managing these fisheries, although fishing and survey data for state fisheries were presented in this document (see 7).

Atlantic surfclam is managed with another species (Ocean quahog, *Arctica islandica*) under a single fishery management plan, that was first developed by the Council in 1977. The Atlantic surfclam fishery was initially managed through limited-entry restrictions, quarterly quotas, and fishing time restrictions. By the mid-1980s, effort limitation combined with overcapacity in the fishery meant that capacity utilization was very low, with vessels operating only 6 hours every other week in 1990. An individual transferrable quota (ITQ) system was established in 1990 which initially allocated shares to vessel owners based on a formula including historical catch and vessel size. Economic efficiency improved and management monitoring decreased as a result of initial ITQ implementation, but it also led to consolidation and displacement of labor (particularly non-vessel owning captains and crew). ITQ shares can be traded or leased to any non-foreign person or entity, with no pre-conditions of vessel ownership. Market consolidation and existing vertical integration have increased over time. From 1990 to 2005, the Atlantic surfclam fleet size decreased by about 70%.

Under the current management system, managers set an annual catch limit for Atlantic surfclam and allocate landings to the ITQ shares. The Council's annual catch limit recommendations for the upcoming fishing year(s) cannot exceed the acceptable biological catch (ABC) recommendation of its Scientific and Statistical Committee (SSC). The SSC serves as the Councils primary scientific/technical advisory body, and provides ongoing scientific advice for fishery management decisions, including recommendations for ABC, preventing overfishing, maximum sustainable yield, and achieving rebuilding targets.

In order to participate in the Atlantic surfclam fishery, fishermen must have a permit to commercially harvest and sell Atlantic surfclam (using valid ITQ shares), and there are mandatory reporting and vessel-monitoring requirements, as well as clam cage-tagging requirements. There is a minimum size for Atlantic surfclam, which can be suspended by managers if it is demonstrated the harvest of small Atlantic surfclam is below a certain threshold. Fishing areas can be closed due to environmental degradation or due to the toxins that cause paralytic shellfish poisoning (PSP). PSP is a public health concern for Atlantic surfclam. It is caused by saxitoxins, produced by the alga *Alexandrium fundyense* (red tide), that accumulate in shellfish, and has resulted in fishery closures in the Georges Bank Area of the EEZ. NMFS recently (2013) reopened portions of the closed areas to harvest of Atlantic surfclam for those vessels using a protocol for onboard screening and dockside testing to verify that clams harvested from these areas are safe. Areas can also be closed to Atlantic surfclam fishing if the abundance of small clams in an area meets certain threshold criteria. This small Atlantic surfclam closure provision was applied during the 1980's with three area closures (off Atlantic City, NJ, Ocean City, MD, and Chincoteague, VA), with the last of the three areas reopening in 1991.

1.4 TOR 2: Survey

NEFSC clam surveys

Survey data used in this assessment were from 2 different sampling platforms. The first was the NEFSC clam surveys conducted during 1982–2011 by the *RV Delaware II* during summer (June–July), using a standard NEFSC survey hydraulic dredge with a submersible pump. The survey dredge had a 152 cm (60 in) blade and 5.08 cm (2 in) mesh liner to retain small individuals of the two target species (Atlantic surfclam and ocean quahogs). The survey dredge differed from commercial dredges because it was smaller (5 ft instead of 8-12.5 ft blade), had the small mesh liner, and because the pump was mounted on the dredge instead of the deck of the vessel. The survey dredge was useful for Atlantic surfclam as small as 50 mm SL (size selectivity described below). Changes in ship construction, winch design, winch speed and pump voltage that may have affected survey dredge efficiency were summarized in Table A7 of Northeast Fisheries Science Center (2003). The second survey platform was the *ESS Pursuit*, a commercial vessel that was contracted to conduct the NEFSC clam survey since 2012, when the *RV Delaware II* was retired. The *ESS Pursuit* used a modified commercial dredge described in detail in Hennen et al. (2016). Surveys conducted from the *ESS Pursuit* have taken place in August each year since 2012.

Surveys prior to 1982 were not used in this assessment because they were carried out during different seasons, used other sampling equipment or, in the case of 1981, have not been integrated into the clam survey database (Table A7 in (Northeast Fisheries Science Center 2003)).

NEFSC clam surveys were organized around NEFSC shellfish strata and stock assessment regions (Figure 7). Most Atlantic surfclam landings originate from areas covered by the survey. The survey did not cover GBK during 2005 and provided marginal coverage there in 1982, 1983, and 1984. Individual strata in other areas were sometimes missed. Strata and regions not sampled during a particular survey were "filled" for assessment purposes by borrowing data from the same stratum in the previous and/or next survey if these data were available (Table 10). Survey data were never borrowed from surveys before the previous, or beyond the next survey. A model–based imputation was investigated for the last assessment (Northeast Fisheries Science Center 2013), but the imputation tended to over–emphasize unsampled years and areas. Alternative approaches to imputing missing strata were not further pursued in this assessment.

Surveys followed a stratified random sampling design, allocating a pre-determined number of tows to each stratum. A standard tow was nominally 0.125 nm (232 m) in length (i.e. 5 minutes long at a speed of 1.5 knots) although sensor data used on surveys since 1997 show that tow distance increases with depth, varies between surveys and was typically longer than 0.125 nm (Weinberg et al. 2002). These problems were eliminated in 2012 when the survey was switched to the *ESS Pursuit*. For trend analysis, when using data from before 2012, changes in tow distance with depth were ignored and survey catches were adjusted to a standard tow distance of 1.5 nm based on ship's speed and start and stop times recorded on the bridge. Stations used to measure trends in Atlantic surfclam abundance were either random or "nearly" random. The few, nearly random tows were added in some previous surveys in a quasi–random fashion to ensure that important areas were sampled. Other non-random stations were occupied for a variety of purposes (e.g. selectivity experiments) but not used to estimate trends in abundance. Locations and catches of all stations in the survey have been mapped (Figures 29–34).

Occasionally, randomly selected stations were found to be too rocky or rough to tow, particularly on GBK. The proportion of random stations that could not be fished was an estimate of the proportion of habitat in an area that was not suitable habitat for Atlantic surfclam (1.5). These estimates were used in the calculation of Atlantic surfclam swept-area biomass (see below).

Following most survey tows, all Atlantic surfclam in the survey dredge are counted and shell length is measured to the nearest mm. Large catches were subsampled. Mean meat weight (kg) per tow was computed with shell length-meat weight (SLMW) equations (updated in this assessment) based on fresh meat weight samples obtained during the 1997–2015 surveys (see below).

Survey tow distance and gear performance based on sensor data

Beginning with the 1997 survey, sensors were used to monitor depth (ambient pressure), differential pressure (the difference in pressure between the interior of the pump manifold and the ambient environment at fishing depth), x-tilt (port- starboard angle, or roll), y-tilt (fore-aft angle, or pitch) and ambient temperature during survey fishing operations. At the same time, sensors on board the ship monitor GPS position, vessel bearing and vessel speed. Most of the sensor data are averaged and recorded at 1 second intervals. These metrics of tow performance can be used to accurately gauge the true distance fished by the dredge.

Determination of time fishing

The determination of time fishing, the “fishing seconds” for each tow (after 1997), was based on a measurement of the pitch of the dredge during each second of the tow. Pitch data were smoothed using a 7 second moving average and then compared to a “critical angle” to determine when the dredge was fishing effectively. When the dredge was above the critical angle it was assumed to be pitched too steeply for the blade to penetrate the sediment. When the dredge was pitched below the critical angle, it was assumed to be near enough to horizontal that the blade should penetrate and thus be actively fishing.

It is important to find a critical angle for tow distance that is neither too small, nor too large. When the dredge is bouncing over rough terrain it is unlikely to be fishing effectively and those seconds should be excluded. There is however, a certain amount of pitch that is within fishing tolerance and a certain amount of noise in the data. If the critical angle is too small, many seconds when the dredge was actually fishing would be excluded, which would tend to bias estimates of tow distance down. Further discussion of the determination of critical angle as well as summaries of dredge performance by year are in appendices (16–18).

NEFSC clam survey trends and composition data

NEFSC clam survey data for Atlantic surfclam, including the number and weight caught per tow were tabulated by year, region and for the entire stock (Table 11). Mean numbers per tow were used in the plots of trends because trends in mean kg per tow were similar. Approximate asymmetric

95% confidence intervals were based on the CV for stratified means and assume that the means were log normally distributed.

Survey trends for small Atlantic surfclam (Figure 35) provide some evidence for recruitment trends over time. Recruitment appears to be increasing in DMV, NJ, LI, and SNE since the last assessment. Survey trends for fishable (120+mm) Atlantic surfclam (Figures 36) show evidence of decreasing abundance in the SVA, and possibly LI regions, but there are increasing trends in abundance in DMV, NJ and SNE. We cannot make inference on trends in abundance or recruitment on GBK because there is only one data point available from the new survey. Based on survey data for the entire southern area, recruitment and fishable abundance have been increasing since the last assessment in 2011 (Figures 37 – 39).

Survey age–length keys and stratified mean length composition data were used to estimate the age composition of Atlantic surfclam in NEFSC clam survey catches and the stock as a whole by year and region. Age composition was estimated for the years between 1982 and 2015 when surveys occurred. Ages ranged from 1-37 (Figures 40 – 46). Specific year classes and trends in length and age composition are discussed in the context of the assessment model (see 1.6).

Shell length composition data (Figures 47 – 52) can be helpful in visually identifying shifts in population demography. For example, there is evidence of recent recruitment in the southern area regions.

Dredge efficiency

Changes to the NEFSC survey involved changes to the survey gear. In particular, shifting the survey dredge from the research dredge (RD) used on the *RV Delaware II* to the modified commercial dredge (MCD) used on the *ESS Pursuit* was an important modification in that it necessitated a re-evaluation of capture efficiency. Fortunately the MCD was the same dredge that was used in previous depletion experiments (Northeast Fisheries Science Center 2013) so estimates of capture efficiency already exist. These are discussed in detail in Appendix 4 and Northeast Fisheries Science Center (2013).

Estimates of survey dredge efficiency were used to generate prior distributions for capture efficiency for each survey in the assessment model (see 1.7). A comparison of the prior distribution for the RD to the prior distribution for the MCD shows that the MCD has higher and more precisely estimated efficiency (Figure 53).

Size selectivity

Selectivity data were collected on the *ESS Pursuit* during selectivity experiments in 2008 – 2015. Data from the experiments were used to estimate size-selectivity for the MCD. The MCD was configured for survey operations, rather than commercial fishing operations. Thus, the size selectivity estimates for the commercial dredge used by the *ESS Pursuit* during cooperative survey work are not directly applicable to commercial catch data. Selectivity experiments are described in Hennen et al. (2016).

The data available for each selectivity study site included shell length data from: one MCD tow, and one F/V selectivity tow using either a commercial dredge lined with wire mesh or a specially designed selectivity dredge (SD). Gear testing work done in 2014 showed that the SD and the lined commercial dredge should be interchangeable in selectivity studies (Hennen et al. (2016)).

Shell length data from selectivity experiments conducted since the last assessment were tabulated using 1 mm shell length size groups (Tables 12 – 13). Survey size selectivity was estimated using data from 47 total sites.

Selectivity was modelled as a generalized additive mixed model (GAMM), where the shell length bin was a factor, predicting the binomial proportion of the survey catch over the total catch (SD + MCD). The fully saturated model was

$$P_L = e^{(\alpha + s(L) + s[YrSta, L] + offset)} \quad (1)$$

Where P_L is the binomial proportion (logit link) estimated for shell length L with intercept α and vector of model terms evaluated over L. The $s()$ terms indicate a spline over variables, in this case shell length (L) and a random effect (indicated with braces) due to station and year. The final term is an offset (Pinheiro and Bates (2006)) based on the tow distance at each station. Tow distance is a potential source of bias because clams can be unevenly distributed on the sea floor. The nominal time fished for the lined dredge is 45 s compared to 5 min. for a nominal survey tow, while the SD was towed for 2 min.

Using the GAMM methodology allowed greater flexibility in the model, when compared to assuming any particular shape. The basis dimension (k) in a spline determines the amount of "wiggle" allowed in the spline. Wood (2009)[2] suggests an objective method for choosing a basis dimension in splines. This method allows the data to determine the shape required to adequately fit them rather than the modeller.

The inclusion of random effects based on station is important because there is a great deal of variation in selectivity between stations. Variation across stations is essentially a nuisance parameter in our assessment because we are interested in the general selectivity over all possible stations, rather than the differences between them (Figure 54). Because we believe that clams taken from a particular place and time would tend to experience similar selectivity when compared to clams taken from a different place and time, it is appropriate to model selectivity using random effects.

Approximate confidence intervals were estimated using

$$CI_L = elogit^{(\rho_L \pm 1.96\sigma_L)} \quad (2)$$

Where CI_L is the approximate confidence interval for selectivity at length L, ρ_L is the corresponding logit scale model estimate, σ_L is the standard error and elogit is the inverse of the logit function.

Selectivity estimates (Tables 14 – 15; Figure 55) were used to generate swept area and survey index plots (Figures 35 – 39) and are useful for comparison to assessment model results.

[2]See R package mgcv documentation

Shell length, meat weight relationships

The shell length-meat weight (SLMW) relationships are important because they are used to convert numbers of Atlantic surfclam in survey catches to meat weight equivalents. The survey meat weight equivalents are inputs in the stock assessment models used to estimate stock biomass, which is reported in units of meat weight. Meat weights for Atlantic surfclam include all of the soft tissues within the shell. All meat weights greater than 0.5 kg were assumed to be data entry error, and were removed from the analysis.

Generalized linear mixed models (GLMM; Venables and Dichmont (2004)) were used to predict clam meat weight, using equations of the form:

$$MW = e^{(\alpha+\beta_0 ln(L)+\beta_1 c_1+\beta_2 c_2+\cdots+\beta_n c_n)} \tag{3}$$

where MW was meat weight, L was shell length, $c_1, \cdots, c_n$ were covariate predictors (*e.g.*, region or depth), and α and β_i were the estimated parameters. Examination of the variance of the weights as a function of shell length indicated that weight increased approximately linearly with shell height, implying that the Poisson family was reasonable for the distributions of meat weights (McCullagh and Nelder 1989). The GLMM in all analyses used the quasi-Poisson family with a log link. Quasi-Poisson is a Poisson distribution with a variance inflation parameter that relaxes the Poisson requirement that the mean must equal the variance. Because shell length to meat weight relationships for Atlantic surfclam at the same station are likely to be more similar than those at other stations, we considered the sampling station as a grouping factor ("random effect") in the analysis.

We fit models with fixed effects for year and region (Table 16). The best model by AIC and BIC was a model with fixed effects for shell length, depth, and region and random effects for shell length slope and the intercept, using both the year and the station as the grouping variables.

Regional differences in meat weight are meaningful, particularly for the largest animals (Figure 56), though some of the differences between regions can be explained by the different depths found there (Figure 57).

Age and growth

Atlantic surfclam were measured at sea and the shells were retained for ageing in the laboratory. Shells for ageing were collected based on a length stratified sampling plan. A recent study confirmed that rings on shells collected during the summer clam survey are annuli that can be used to estimate age (Northeast Fisheries Science Center 2010). Age and length samples are available for most regions, but not from every survey (Table 17).

Plots of age vs. shell length by year and region (Figures 58 – 64) indicate that growth patterns have been relatively constant in most regions over time with DMV and NJ, where growth has slowed and maximum size has decreased over the last two decades.

Von Bertalanffy parameters for growth in shell length were estimated for each region and each survey year for which sufficient data existed (Table 18). The Von Bertalanffy growth curve used in the calculations was:

$$L_a = L_\infty(1 - e^{(-k(a-t_0))}) \tag{4}$$

Where L_a was length (mm) at age a, and L_∞, k and t_0 are Von Bertalanffy parameters.

Atlantic surfclam are thought to mature very early. Data are limited but Atlantic surfclam off New Jersey may reach maturity as early as 3 months after settlement and at lengths of less than 5 mm (Chintala and Grassle 1995; Chintala 1997).

Survey trends and LPUE for important ten-minute squares

We analyzed commercial LPUE and survey data for 1982 - 2011 for important ten-minute squares (TNMS see section 1.3) in the southern New Jersey and Delmarva regions where fishing is traditionally concentrated to better understand potential fishing effects on key southern fishing grounds. Modes in size composition data from the commercial catch declined steadily in these areas over the last decade (Figures 22 – 28) but the declines are not clear in survey size composition data through 2011 when survey gear changed (Figures 47 – 52), probably due to size selective removals of large clams on fishing grounds. Survey and LPUE data suggest that abundance trends in areas where fishing occurs were similar to trends for the New Jersey and Delmarva regions as a whole. Thus, fishing seems to have had modest effects on abundance in TNMS where fishing was highest.

TNMS were much smaller than survey strata and not all squares were sampled during each year. We therefore analyzed the data "as is" (ignoring the unsampled squares) and after filling the holes with imputed survey "data" from a GAM model. The GAM model (mgcv library in the R programming language) was $gam(N_{tow} \sim s(Y, tnms) + tnms)$. In this model, N_{tow} is the number of Atlantic surfclam caught in the tow, Y is the survey year (continuous) and $tnms$ is the ten-minute square (a categorical factor). About 5% of survey tows had zero catch so we fit the model using the default log link function assuming errors from a Tweedie distribution, which is a combination of a logistic distribution (for zero observations) and a Gamma distribution (for positive catches). Given these specifications, the model handles zero and non-zero catches directly while estimating a different intercept (average catch rate) and different interannual trends for each TNMS. In effect, there was a separate model for each TNMS.

The imputed data from the fitted GAM model ($R^2 = 0.48$, deviance explained=75%, N=299) amount to interpolations between years with observed data and extrapolations for missing years at the beginning and end of the time series (Figure 65). Extrapolation is possible in the mgcv GAM software as long as the years involved are within the range of years in the dataset as a whole, even though the models for different TNMS are nearly independent. The surveys were usually triennial so that interpolations and extrapolations were over relatively long periods of time (1-11 years). Extrapolation is not valid from a statistical point of view and should (along with interpolations over many years) be viewed with caution but the analysis was exploratory and results did not depend strongly on using imputed data (see below).

Interannual time series for the New Jersey and Delmarva regions were calculated by averaging all values (observed and/or predicted values) for each region and year. TNMS were the same size so the annual averages amounted to stratified random mean numbers per survey tow. Results with and without imputed data were similar (Figure 66). All results indicate that abundance declined rapidly during 1995-2005 (on fishing grounds) to current relatively low levels (Figure 67).

LPUE and survey data for important TNMS show that LPUE remained high as abundance declined off New Jersey (correlation coefficient $\rho = 0.2$, Figure 67). Survey trends in important TNMS and for New Jersey as a whole were strongly correlated ($\rho = 0.79$). In contrast to New Jersey, trends in survey and LPUE in important TNMS off Delmarva had a linear relationship and were strongly correlated ($\rho = 0.59$). Survey trends in important TNMS and for Delmarva as a whole were also strongly correlated ($\rho = 0.52$).

Evaluation of new survey

Spatial coverage

The assessment working group reviewed information showing fishing activity and survey catches in an area south of Nantucket that is not routinely surveyed, they also evaluated several approaches for identifying Atlantic surfclam habitat based on data from multiple surveys, multi-beam acoustic data, published studies, environmental measurements and habitat suitability models (Appendix 13). Such data would be useful for expanding the survey to cover new grounds, restratification and in improving the NEFSC clam survey design. The approaches presented appeared potentially useful and should be further developed for consideration by a future working group tasked specifically with evaluating survey design. NEFSC Survey Branch personnel and program managers would need to be heavily involved in the discussions.

Changes in the spatial distribution of biomass

We calculated relative swept-area survey biomass of Atlantic surfclam (all sizes) by region and area during 2012-2015. No adjustments were made for capture efficiency, size selectivity or changes when the new survey began in 2012 to keep the analysis simple and because these parameters may be the same for all regions in the same year and should tend to “cancel out”. The proportion of biomass in year y and region r was calculated $p_{y,r} = \frac{p_{y,r}}{\sum_s p_{y,s} A_s}$ where A_s is the area (nm^2) of one of the regions. The northern and southern areas were sampled in different years after 2011, so data from the survey in the northern area during 2013 was used in these calculations for both 2012 and 2015.

Results show the increase in the proportion of total biomass in GBK and declines off DMV during 1982-2011 measured using the old survey dredge (Figure 68). These patterns were attributed to rising water temperatures in the last assessment. Unexpectedly, proportions of total biomass on GBK dropped during 2012-2015 while fractions in NJ and DMV increased based on survey data from the new dredge. Biomass indices increased after 2011 in all regions because the new dredge is more efficient and sweeps more ground. However, increases during 2012-2015 in the south were larger than increases in the north. It is possible that these patterns reflect changes in spatial distribution but they may also be due to reduced capture efficiency in the new survey using the MCD in the relatively rough and rocky GBK region. The latter possibility could be investigated by conducting depletion studies on GBK to estimate capture efficiency directly.

Precision

The MCD survey was expected to be more precise than the original survey because the new dredge is more efficient (see 4), tow distance is more consistent (see below) and because the area swept by a tow in the new survey is larger (RD mean about 580 m^2 with CV=25% and MCD mean=1764 m^2 with CV=11%). However, there was no clear reduction in CVs for survey abundance indices (stratified mean catch per tow) with the MCD (Table 11 and Figures 35–38). Lower numbers of tows beginning in 2012 reduced the precision of abundance indices for the southern area. There is no evidence that the variance among individual tows in the same stratum was reduced after 2012 (Table 10 and Figure 35–38). However, swept-area stock size estimates were probably more precise (Figure 38) when using the MCD despite little or no improvement in abundance indices because capture efficiency estimates for the MCD are more precise than estimates for the RD (Figure 53; Table 10) and 4).

Borrowing should be less common in the future because NEFSC expects to survey the northern and southern areas completely during sequential years rather than in parts (see 2 for a discussion of the borrowing required for this assessment). This plan and the goal of reducing the frequency of unsampled strata are important because of the difficulties in borrowing lengths and ages from other years now that length and age data are used in the assessment model. Borrowing from adjacent surveys is a type of imputation, but further work on imputation techniques is warranted. NEFSC (2007) used negative binomial GAM models to impute catches for strata with no data that could not be filled by borrowing but with modest effect on results. Model based approaches might have larger effect if all strata with missing data were imputed.

The total number of stations in the NEFSC clam survey is limited by the time devoted to the survey with deductions for transit time, bad weather, etc. The proportion of the total number of random survey stations in each stratum for each region (northern or southern) in the new survey was based on stratum area and on the mean catch and variance in catch for Atlantic surfclam plus ocean quahogs in previous surveys (Cochran 1977). This standard approach minimizes the variance of the total stratified mean catch per tow but does not minimize the variance for either individual species.

It might be possible to improve overall precision of the clam survey by changing the relative amounts of time used to sample the northern and the southern areas in subsequent years without changing the total time or cost for the survey as a whole.

The precision of stratified random mean estimates like clam survey abundance estimates depends on the number of tows and variance in catches within each stratum (Table 10). The reduction in the number of tows in the southern area after 2011 increased the standard deviation and CVs of the stratified means.

Tow distance with the RD varied strongly with depth and among years when tow procedures changed unintentionally (Figure 69). Tow distances since 2012 have been less variable in general and relatively constant across depth and years. These changes should improve precision of survey data for recent years.

Analysis of precision was complicated by limited number or zero samples in some strata and years, a high proportion of tows with no catch (about 60%), different temporal trends among strata, and the tendency for variance to increase with the mean catch per tow. We dealt with these problems by considering variance in the proportion of positive tows and variance in log catch for positive tows separately, and by calculating the variance of randomized quantile residuals from models with likelihoods that were calculated using the compound Tweedie distribution which accommodates both zeroes and positive values. These analyses used data from random tows with sensor data collected since 1997, from strata that were sampled consistently (in all surveys) in each region (Table 19). In particular, we used survey data from northern strata 55, 57, 59, 61, 70-71 and 73-74 sampled during 1997, 1999, 2002, 2008, 2011 (RD), and 2014 (MCD) and data for southern strata 9, 10, 13, 17, 18, 21-22, 25-26, 29-30, 33-34 and 84-93 sampled during 1997, 1999, 2002, 2005, 2008, 2011 (RD), 2012 and 2015 (MCD) in the south.

To begin, we calculated the mean and standard deviations for a dummy variable that identified positive tows (=1 if Atlantic surfclam were caught and 0 otherwise) and for log of Atlantic surfclam catch in positive tows (Figure 70). There were no obvious changes in the proportion of positive tows in the new survey or in the variance of the dummy variable or log positive catch. Higher proportions and lower variance in the dummy variable for positive tows might be expected using a dredge that affords higher precision although positive tows are likely at even low Atlantic surfclam densities using either survey dredge (10).

Next, we fit a series of GLM and GAM models to catches (tows with and without catch combined) and used AIC to determine the "best" (by AIC) model (Table 20). The best model (gamB) explained 45% of the total deviance, 23% of the total variance and the residuals were close to normally distributed. The distributions and standard deviation of residuals from the best model do not indicate increases in precision of individual tows beginning in 2012 (Figure 71).

1.5 TOR 3: Habitat

This TOR was driven by concern that relatively high densities of clams measured by survey tows in easy to sample areas on Georges Bank might be applied to rocky low density habitats that are difficult to sample so that model and swept-area biomass estimates are biased high. In stock assessment calculations, stock biomass $B = \frac{bA}{ae} = bQ$ where b is mean catch per tow, A is the area surveyed (the parameter of concern), a is area swept and e is capture efficiency. In recent assessments, the area surveyed on Georges Bank (A) was reduced by 12% assuming that the proportion of untowable stations represents grounds that were poor habitat with no Atlantic surfclam. For this assessment, the working group reviewed survey procedures and recalculated the proportion of untowable ground.

A list of random survey stations is prepared prior to the first leg of each clam survey and the captain determines towability when the ship reaches each random station. In the past, during the 1999, 2002, and 2005 surveys (Georges Bank was not surveyed in 2005), untowable stations were noted in station logs using a special "SHG=151" code. In the more recent survey during 2013-2014, text in comment fields and other SHG codes can be used to determine if a station was untowable, if the dredge was filled with rocks and no Atlantic surfclam, or the dredge was damaged by rocks. Based on "151" codes, 12/83=14% of random stations on GBK were not trawlable. In later years, 13/74=18% of random stations were not trawlable. The combined average (14%) is somewhat higher than the 12% figure used in this assessment. New habitat databases and models under development will soon be available for refining estimates of poor Atlantic surfclam habitat for GBK (Appendix 13). In addition, procedures for dealing with untrawlable stations in the survey may need to be modified so that this information is collected routinely and is clear in the survey database.

1.6 TOR 4: Depth and changes in biological parameters

As ocean temperatures increase, the distribution and biology of Atlantic surfclam are potentially changing with potential effects on fishery productivity. For example, increasing water temperature may result in changes to the biological parameters that describe growth (Munroe et al. 2016). Increasing water temperature may also be driving a shift in Atlantic surfclam distribution, to deeper water in the southern area (Weinberg et al. 2002). It is reasonable to assume that any responses to temperature would be strongest in the southern-most regions (SVA, DMV and NJ), where ocean temperatures are warmest and probably nearest the warm water tolerance for Atlantic surfclam.

Depth and temperature

Survey stations are distributed randomly relative to depth within a stratum and the same strata tend to be sampled over time within a region (Table 10). Therefore, if the depth distribution of Atlantic surfclam were trending over time, the depth at which most of the animals were caught within a region might be expected to increase. Plots of the depth at which the median cumulative catch within each region occurs over time show this relationship in two regions, DMV and NJ (Figures 72 – 77).

Warming coastal waters might change the spatial overlap between Atlantic surfclam in relatively shallow water and ocean quahogs that are found in adjacent deeper water. Overlap is important because the fishery operates most efficiently where only one species is caught. The depth at which 95% of the cumulative catch of Atlantic surfclam was taken during 1982-2011 clam surveys was used as the offshore habitat boundary for Atlantic surfclam and the depth at which 5% of the cumulative quahog catch was used as the inshore boundary for ocean quahogs (Figure 78). In the 1980s and with the exception of the LI region, the two habitat boundaries were similar indicating that the habitat was partitioned across depth as expected. There was no evidence that the inshore boundary of ocean quahog habitat changed in later years but there was clear evidence that the offshore boundary of Atlantic surfclam habitat shifted to deeper water in the southern NJ and DMV regions and, surprisingly, in the northern most GBK region. By the mid- to late 1990s, the overlap in Atlantic surfclam and ocean quahog habitat was pronounced in the south. The shift on GBK may have been due to increases in Atlantic surfclam abundance (Figure 36). In contrast, abundance generally decreased after 1982 in the south and the change in habitat boundaries was more likely. Results for LI were anomalous given that the offshore boundary for Atlantic surfclam was consistently deeper than the inshore boundary for ocean quahogs, probably due to high density beds of ocean quahogs in cold shallow water (Figure 78) and the increased presence of clay as substrate, which tends to contain more ocean quahog than Atlantic surfclam.

The sampling properties of presence-absence data from NEFSC survey tows were characterized analytically (Appendix 11). Results show that survey tows are almost certain to detect clams at relatively low densities (roughly 0.013 per m^2, corresponding to about 15 encounters per tow in the RD). Thus, presence absence data are useful for detecting clams at relatively low densities but not for tracking trends in abundance when density is higher. Based on these results, presence-absence data were used in this assessment to quantify extent but neither quality of habitat nor density of clams.

Presence-absence GAM models showed that the probability of co-occurrence (both species in the same tow) decreased almost linearly during 1982-2011 in the SNE region while increasing almost linearly in the LI and NJ regions (Figure 79 and Appendix 10). Trends were not statistically significant in the DMV and GBK regions where strong changes in abundance may complicate interpretation.

The amount of habitat for Atlantic surfclam was quantified by dividing the area surveyed consistently in each region into relatively small areas based on latitude and longitude as well as two other coordinate systems (Appendix 12). Presence-absence GAM models with time and position as predictor variables were selected from a set of candidates based on AIC. Habitat was quantified by summing the predicted probability of a positive tow from the best model over all of the small areas in each region and year. Results suggest that habitat area declined in the south in the DMV area due to losses in shallow water, increased along the central Mid-Atlantic Bight (NJ and LI areas) due to increases in deep water and varied without trend in the north (SNE and GBK areas). Temperature data were not available but these changes were likely due to water temperatures increasing above the preferred range for Atlantic surfclam in nearshore coastal areas off DMV (Weinberg 2005) and above the lower bound of the preferred range in deep waters off NJ and LI.

Temperature was recorded as part of the survey station data (beginning in 2002), and may be a useful indicator of habitat preference for Atlantic surfclam. Plots of the temperature and depth recorded at each survey station over time, against the total number of Atlantic surfclam caught are provided here (Figures 80 – 85). The results indicate that temperature and depth preferences vary by region, but appear to be relatively consistent over (recent) time. This may be indicative of local adaptation, or there may be other local factors, potentially correlated with temperature and depth, that influence habitat preference in each region.

Changes in biological parameters

If increasing ocean temperature negatively affects the fitness of Atlantic surfclam, one might expect to see decreases in the biological parameters that describe growth, particularly in the southernmost regions where water temperatures are highest. Analysis indicates that DMV and NJ have experienced declines in average maximum length (L_∞) through time (Figure 86). NJ and SNE have shown decreases in the rate at which an animal approaches its theoretical maximum size (K; Figure 87).

1.7 TOR 5: Model

The Atlantic surfclam assessment model was implemented in SS3[3] (Methot and Wetzel 2013). Separate SS3 models were developed for Atlantic surfclam in the southern and northern areas. Divergent population dynamics (*i.e.*, different biomass and mortality trends, changes in proportion of total biomass in the two areas over time, very limited fishing in the north, and differences in occurrence of strong year classes) made it too difficult to estimate "average" population dynamics for the areas combined. Also, data would be lost if the areas were combined because surveys were not available for the entire combined assessment region in some years. In this assessment, biomass, fishing mortality, recruitment, and other quantities for the combined regions were estimated by combining elements for the southern and northern areas.

Configuration

Fishery and survey selectivity were functions of size rather than age in SS3 models. Conditional age at length data, rather than traditional age composition data, were used in fitting models. The conditional age vector with indices t, a, L for example, gives the proportion or number of observed ages (a) from samples of length L in year t of the NEFSC clam survey. The major advantage of the conditional approach is that more information about growth (including variance in size at age) and year-class strength is preserved. Size composition data are not used twice (once as size composition data and once in calculation of traditional catch at age). Finally, the sampling distribution of conditional age data is probably easier and more accurately characterized as a multinomial, conditional on the number of ages (at t and L) actually sampled.

The same types of data (Figures 88 and 89) were available for both areas, although more precise and numerous data were available for the southern area. The additional data for the south made it possible to estimate additional catchability, recruitment and selectivity parameters, as well as biomass and mortality over a longer time period (Tables 21 – 22). It was necessary to borrow some of these parameter estimates from the south in modelling Atlantic surfclam in the north because data were so limited and catches were nearly zero over much of the time series.

Dome shaped survey selectivity curves with parameters fixed at field study estimates were used in SS3 models for the MCD survey in the south and north and the RD survey in the south (Figure 90). Field estimates were used because they were relatively precise, based on a great deal of data, and were obtained from designed experiments carried out in association with the stratified random survey using actual survey sampling gear (Figure 55; Northeast Fisheries Science Center (2013)). Allowing the model for the north to estimate the ascending limb of the RD survey selectivity curve was helpful in reducing diagnostic problems.

The number of trips sampled by port agents was used as initial effective sample sizes for fishery length data in each year. The number of survey tows that caught Atlantic surfclam was used as initial effective sample size for survey size composition data in each year. The number of fish aged in each size group and year was used as the initial effective sample size for survey conditional catch at age data. Initial log scale standard deviations for survey abundance trend data were derived

[3] Stock Synthesis Model version SS-V3.24Y compiled for 64-bit linux.

from the CV for mean numbers per tow in each year (and assumed that errors were lognormal). These initial specifications for length and age data were "tuned" (adjusted up or down) based on preliminary model fits by multiplying the values for each type of data by a constant based on the recommendations of (Francis 2011). The initial standard deviations for survey trend data were tuned, if necessary, based on preliminary model fits by adding a constant to the standard deviation for each observation in the time series (Francis 2011).

Priors for survey dredge capture efficiency

The prior distributions for survey dredge capture efficiencies were important because the models are not otherwise strongly informed regarding scale. The last Atlantic surfclam assessment (Northeast Fisheries Science Center 2013) details the work that was done to estimate a prior for the distribution of capture efficiency for the research dredge (RD) last used in 2011. Appendix 4 details the work done to estimate a prior for the distribution of the modified commercial dredge (MCD) used since 2011.

Issues

South

The Atlantic surfclam assessment for the south is unable to estimate scale (absolute stock size) although trends in biomass were estimated more reliably. This is typical of a low F fishery. In general, there are several different scenarios involving combinations of selectivity, biological parameters and biomass scale that might explain the observed population dynamics when fishing mortality cannot account for it. Therefore the model is easily shifted from one scale to another based on small changes in the data or model.

Some of the issues with the assessment model for the south stem from the fact that there are only two years of data in the MCD survey. Because of this limitation, the prior distribution on the MCD survey catchability was very influential (see section 1.7).

The base model has some poorly determined parameters (Table 23). Most of these are recruitment deviations, which are generally difficult to estimate when the survey and commercial gear do not sample the youngest animals well. Both the survey and commercial gear have selectivity curves such that they are unlikely to capture very many animals less than about 3 years old. Therefore, poorly determined recruitment deviations are not unexpected. The model has particular trouble estimating the Q parameter associated with the catchability of the MCD survey. This is probably because the survey contributes only two data points to the model. This parameter is therefore strongly influenced by its prior distribution. Sensitivities in which the prior distribution was turned off were run and are discussed in section 1.7. The other poorly determined parameter is the one that describes the width of the plateau of the selectivity curve for the fishery (see Figure 90). This parameter was difficult to determine because the commercial length comps show conflicting tendencies over time. In the early years of the fishery the length composition was heavily weighted towards longer clams, and in later years the composition was broader and shows a higher proportion of smaller clams. This pattern was difficult to fit with one selectivity curve. Sensitivity runs designed to estimate this parameter better using time varying selectivity are described in section 1.7.

Other potential issues are the use of assumed parameter values for M, steepness and growth. The growth values estimated in the model were near the experimentally derived values presented in part 1.4 and the M value used was based on observed longevity. There was no experimental basis for the assumed steepness ($h = 0.95$) used in the assessment model as there were no observations of recruitment at low stock size available. The h used was high and resulted in no apparent relationship between spawning biomass and recruitment. Sensitivities testing each of these assumptions are described in section 1.7.

North

The Atlantic surfclam assessment model for the north is also uncertain relative to scale. As in the south, the model does not have enough information to estimate scale with precision because the population is lightly fished and there is little contrast in the survey indices. The model from the north also suffers from a shorter time series for catch, survey, age composition, and length composition data.

The estimated biomass trend in the early part of the time series does not fit the survey index well. The early part of the time series is uncertain relative to trend because the survey index increased rapidly in the absence of any prior fishery removals that would have accounted for the population being in a depleted state (where the increase would represent recovery). There is no support for a low biomass in the early part of the time series in the composition data either. With no mechanism to explain the increase from 1984 to 1995 (or more precisely the low biomass in 1984), the model does not believe the survey. Sensitivities to explore the affect of forcing the model to fit the survey index better are discussed in section 1.7.

The base model has some poorly determined parameters (Table 24). Most of these are recruitment deviations, which are generally difficult to estimate when the survey and commercial gear do not sample the youngest animals well. Model precision can be improved by increasing the weighting on the MCD survey. This approach was not taken because the MCD survey consists of only one data point and because increased model precision is not desirable when the information provided to the assessment is uncertain. In the case of the northern area, the model has little meaningful information and should not reflect an unrealistically precise estimate of biomass. Sensitivity runs in which the MCD index was heavily weighted and also removed from the calculation of the likelihood surface are described in section 1.7.

Fit and estimates from basecase models

South

The biological parameters used in the assessment model were based on experimentally derived values (Figures 91 – 93). Fishery selectivity was estimated and retained the domed shape seen in the last assessment (Figure 90). The fit to the surveys was acceptable and the residuals did not show trends or high variance (Figures 94 – 96). The fit to the composition data was generally tight, with the possible exception of the MCD survey which showed conflicting length composition over only two years and was difficult to fit well with one selectivity pattern (Figures 97 – 109). Data weighting decisions are shown in Figure 110. Model time series results are shown and in Figure 111 and parameter estimates are shown in Table 22.

North

The biological parameters used in the assessment model were based on experimentally derived values (Figures 112 – 114). Fishery selectivity was partially estimated and shared the domed shape seen in the model for the south (Figure 115). The fit to the surveys was reasonable given the constraints of the data and the residuals did not have high variance (Figures 116 – 117). The fit to the composition data was generally tight, with the possible exception of the MCD survey which had only a single year of data (Figures 118 – 128). Selectivity for the MCD survey was assumed because allowing the model to fit a single year of data would have resulted in overfitting. Data weighting decisions are shown in Figure 129. Model time series results are shown and in Figure 130 and parameter estimates are shown in Table 22.

Likelihood profile analysis

South

Likelihood profile analysis of the model for the southern area consisted of fixing the unfished recruitment parameter (R_0) at successive values that bracketed the R_0 solution (from the base case model) and estimating all of the other parameters in the model.

Likelihood profile results for the south indicate that goodness of fit for the priors on survey catchability were best near the basecase model run (Table 25 and Figure 131). Survey age data support higher R_0 (higher biomass) and length composition data lower R_0 (lower biomass). However, the differences in total likelihood were small (Table 25). The one area of data conflict that appears to make a substantial difference in total likelihood is between the parameter prior distributions (on survey catchability), which prefers the solution, and the age composition data, which prefer a lower values of R_0.

North

There is model tension between the RD survey index and its composition data (Table 26 and Figure 132) in the model for the north. The composition data support a higher R_0 (higher biomass), while the survey data support a smaller R_0 (lower biomass). The biomass scale at the solution is set by prior distributions on survey catchability, which affect the MCD survey and RDscale index (RDscale did not contribute to the likelihood in the north because the Q were not estimated and RDscale was not fit for trend. See Table 21).

Sensitivities

Experimental model runs testing the effects of model manipulations (for example with either extra parameters or fewer sources of data) were informative.

South

Natural mortality was fixed at $M = 0.15$, based on the observed longevity of Atlantic surfclam in the base model, and an experimental run was conducted to estimate it. M was estimable and decreased with age (Figure 133). Estimating M produced a slightly better fit to the commercial length composition data, but a slightly worse fit to the survey length composition data compared to the base run. The fits to other data were unchanged. There was virtually no change in either the trend or scale of biomass and the base model was preferred due to parsimony.

The growth parameter K was fixed at values derived in the last assessment (Northeast Fisheries Science Center 2013) in the base model run. An experimental run attempted to estimate it. The Von Bertalanffy K parameter and the coefficients of variation around the growth curve were estimable. The estimated K was slightly less than the K assumed in the base model, while the estimated parameters describing uncertainty around the growth curve were nearly identical to the values used in the base model. Estimating growth had virtually no effect on the model fit and the base model was preferred due to parsimony.

There is experimental evidence that growth has changed over time in at least part of the southern stock area (Figure 86). In one sensitivity run growth was allowed to vary over time. The closest SS3 equivalent to the Von Bertalanffy L_∞ parameter was estimated for two time blocks (<2000 and >1999). This run had a negligible effect on the biomass estimates in the model (Figure 134). An additional run in which the Von Bertalanffy K parameters were fit in each of the time blocks produced only slight changes as well. This run improved the fit to the length composition very slightly at a minor cost to the fit of the conditional age at length composition data. There was virtually no change in either the trend or scale of biomass and the base model was preferred due to parsimony.

Although commercial selectivity was estimated, it may have changed over time. The evidence for this is in the apparent lack of fit to commercial length composition data that occurs in the early years of the time series (Figure 97) and the fact that the the model has trouble estimating the parameter describing the width of the plateau of the commercial selectivity curve (Table 23). The gear used by the commercial fishery has not changed substantially over time so any changes in fishery selectivity were probably due to changes in behavior. That is, the fishery probably targeted the beds with the largest and oldest clams first, and then later moved to beds of smaller clams when those were fished down. Sensitivity runs where commercial length composition was allowed to vary in time blocks (<1986 and >1985) produced better fits to the commercial length composition data. The overall fit to the commercial length composition data was already fairly good, however, and there was virtually no change in either the trend or scale of biomass and the base model was preferred due to parsimony.

The base model somewhat underfits the RD survey (Figure 96). This base case solution is fairly stable. In order to force the model into a fit tight enough to reduce the standard deviation of the standardized residuals of the fit the RD survey, the lambda (likelihood weighting component) of the RD survey had to be increased by a factor of 10. Forcing the model to better fit the RD survey trend changed the overall biomass trend somewhat (Figure 135). It also caused a degradation in the fit to the composition data, and the conditional age at length composition data in particular. Biomass scale was unchanged and given the large weight being put on the survey data, the base model was preferred.

There is tension between the survey data and the composition data (Figure 131). The weights associated with each of these data sources determines the shape and scale of the model to some extent. A sensitivity run in which the variance associated with the composition data (both length, and age at length composition data) was increased relative to the base model, so that the harmonic mean of the effective sample size matched the mean of the input sample size (implicitly decreasing the information content of the RD survey). This was compared to the base model and the previous sensitivity run (Figure 135) in which the weight of the RD survey was increased (implicitly decreasing the information content of the composition data). The trade off between the composition data and the RD survey indices are clear in the comparison in that weighting the composition data more heavily tends to smooth out the biomass trajectory, while weighting the RD survey tends to introduce additional topography to the trend. All three runs show similar scales, while the base model is a compromise between the two in trend.

Profile analysis showed that the prior distribution associated with the MCD survey was influential in the base model solution. A sensitivity run in which the prior was not used confirmed this. The scale of estimated biomass shifted considerably, though the trend was very similar to the base run (Figure 136). The fits to the composition data were not affected by the removal of the prior distribution on catchability. When the prior distribution for the RD survey was removed, the effect on the model was almost undetectable, further indicating that the prior on the MCD survey is influential. When both prior distributions were removed, the model estimated a lower biomass (R_0 near the lower end of the range covered in the likelihood profile analysis), but the trend and fit to composition data were similar to the base model.

The MCD survey has only two data points in the base model, which is a small sample size to use for estimating trend. When the MCD survey index contribution to the likelihood was removed (multiplied by $\lambda = 0$), the scale of the estimated biomass shifted and trend was not strongly affected (Figure 137). This implies that the MCD survey and its prior are important for setting scale in the assessment model, but that they do not have a strong influence on the trend, even over the period that the MCD survey covers (>2011).

The steepness of the stock recruit relationship is assumed ($h = 0.95$) in the base model. There are no observations of the stock at low biomass in the time series (typical of a low F fishery) and so there is little information available with which to estimate steepness. A sensitivity run estimated steepness at 0.33 ($cv = 0.54$; Figure 138), but it is difficult to credit this estimate given the lack of information available to the model. The lower steepness value had little affect on the scale, trend or fit of the model, but would have an affect on biological reference points, if they were derived from the stock-recruit relationship. This aspect will be discussed further in 1.8.

The split survey in 2012 and 2013 caused some difficulty in compiling the data for the assessment model. In particular, the inclusion of 2013 data with the 2012 ages (Table 17) introduced additional observation error in the conditional age at length composition data. The error in the length composition data was expected to matter less because Atlantic surfclam grow relatively slowly, are fished lightly and the length composition from one year to the next should not change very much. A sensitivity run in which the conditional age at length information from 2013 was left out of the model was indistinguishable from the base run (Figure 139).

A comparison of the biomass time series estimated in several sensitivity runs demonstrated that the model varied in scale (Figure 140), but was relatively stable in trend (Figure 141). Allowing flexibility in the model by estimating more parameters, including time varying growth and natural mortality, produced runs that started and ended at similar biomass levels and had confidence intervals with a high degree of overlap. The run that used no prior information for estimating the catchability of the surveys had a different scale than the other runs, but showed a similar trend. In general, the model for the southern area was stable over many different configurations.

North

The assessment model for the north does not fit the survey well in the early part of the time series. One possible explanation for this is that the population was in a period of low recruitment and is currently in a period of high recruitment. A sensitivity run in which the parameter R_0 was estimated for each of two time periods (before 1995 and after) did estimate a lower R_0 for the early part of the time series, but did not substantively improve the fit to the survey index (Figure 142).

It was not possible to estimate recruitment variation (around the stock recruitment curve) in the model for the north in any of the runs tested. It is possible that the assumed value for recruitment variation was too low to provide the model enough flexibility to fit the early part of the RD survey well. A sensitivity run in which the recruitment variation was increased by 100% did not improve the fit to the survey (Figure 143).

Forcing the model to fit the RD survey better, by increasing its likelihood weight by a factor of ($\lambda = 10$), caused a degradation in the fit to the composition data (Figures 144 – 145). It was necessary to increase the weight on the survey by an order of magnitude before the model was able to fit the early RD index well (Figure 146).

The model was sensitive to the inclusion and relative weighting of the MCD survey. The MCD survey contributed only one year to the model. The MCD composition data were not particularly well fit by the model using an assumed selectivity, but it was not reasonable to allow the model to estimate selectivity given the single data point. When the variance associated with the MCD survey index was reduced (increasing its relative information content), the model produced a far more certain biomass estimate for the whole time series (Figure 147). While this result improved model diagnostics, it relied heavily on the information provided by a single data point and is therefore unstable. This is easily demonstrated by removing the MCD index from the likelihood calculation (making its contribution 0), which resulted in a model with a different biomass scale. The change in scale indicates that the entire model depends heavily on the catchability parameter for the MCD survey. The dependence on the prior for the MCD index in setting scale was clear from sensitivity runs in which the MCD index was included but the prior on catchability for it was not (Figure 148).

The inclusion of the 2014 conditional age at length composition with the 2013 data introduced additional observation error to the model. Removing the age data from 2014 would be expected to cause a bigger change in the model for the north, than the corresponding removal of 2013 data from the model for the south, because a higher proportion of the total data for the north came from the staggered year (Table 17). A sensitivity run in which the conditional age at length information from 2014 was left out of the model was similar to the base run (Figure 149), and the base run was preferred in order to make use of more of the available data and because the differences were minor relative to the uncertainty in the model.

A comparison of the biomass time series estimated in several sensitivity runs demonstrated that the model was relatively stable in trend (Figure 150), except when the trend was forced to fit the early part of the survey time series in the run called "WeightRD". Allowing flexibility in the model by including time varying recruitment, or increasing the variance around recruitment produced runs that started and ended at similar biomass levels and had confidence intervals with a high degree of overlap. Removing either the trend or the prior on catchability for the MCD survey tended to reduce the scale of the estimated biomass, though trends were still similar (Figure 151).

Internal retrospective

South

There is a shift in scale when the MCD survey drops out of the assessment (retrospective peels that do not include years after 2011; Figure 152). The Atlantic surfclam model for the southern area however, does not have a retrospective pattern in trend, which can be seen in a plot of the relative biomass from each retrospective run (Figure 153). Relative biomass was determined by dividing the biomass in each year and run by 25% of the virgin biomass estimated in that run.

North

The shift in scale in the model for the northern area is larger than in the southern area, and the trend is less stable over 10 peels of retrospective analysis (Figure 154 - 155).

Whole stock results

A simulation testing the relative merits of different approaches to combining F from multiple areas when absolute abundance was poorly determined, demonstrated that the abundance weighted average F was negatively biased when the correlation between abundance and F was close to -1 (See 9). The simulation also showed that the geometric mean of the F from each of two areas was close to the true combined F at all correlation levels. However, the geometric mean was strongly negatively biased when F is very low and in fact undefined when $F = 0$, which is true for a substantial proportion of the Northern area time series. The abundance weighted mean was therefore the preferred method of calculating combined F for the stock and determining the stock status relative to 2015.

Whole stock fishing mortality was $F_W = \frac{(C_S+C_N)}{(\widehat{N_S}+\widehat{N_N})}$ where C_S and C_N were the catch in numbers from each area and $\widehat{N_S}$ and $\widehat{N_N}$ were average fully selected abundances

$$\widehat{N_a} = \sum_L s_L \frac{N_L(1 - e^{Z_L})}{Z_L}$$

where the total mortality rate (Z) was based only on fully selected lengths and s_L was commercial fishery size selectivity. Whole stock results are discussed in part 1.9.

The F in projections was far enough from zero to allow the use of the geometric mean as a method for combining F from different areas. Therefore, the whole stock fishing mortality in projections was $F_W = e^{log(F_S)+log(F_N)}$. Whole stock projection results are discussed in 1.10. Fortunately, this choice had little effect on the whole stock results because F was so low. If F increases in the future it may be prudent to revisit the method for combining F from different areas in order to minimize the potential bias caused by correlation between F and abundance (9).

Whole stock spawning biomass estimates for clams was $SSB_W = e^{log(\frac{SSB_S}{SSB_{Threshold,S}})+log(\frac{SSB_N}{SSB_{Threshold,N}})}$, where $SSB_{Threshold,A} = \frac{SSB_{0,A}}{4}$ and A was area (either N or S). The variance around $\frac{SSB_A}{SSB_{Threshold,A}}$ was

$$\sigma^2_{SSB_A} = \left(\frac{\widehat{SSB}_A}{\widehat{SSB_{Threshold}}}\right)^2 \left(\frac{\sigma^2_{SSB_A}}{\widehat{SSB}_A{}^2} + \frac{\sigma^2_{Threshold,A}}{\widehat{SSB_{Threshold,A}}{}^2} - \left(\frac{2 * cov[SSB_A, SSB_{Threshold}]}{(\widehat{SSB}_A * \widehat{SSB_{Threshold}})}\right)\right)$$

Historical retrospective

The estimated whole stock biomass in this assessment is higher in scale than previous assessments (Figure 156). The scale shift over time reflects the difficulty in determining scale in the Atlantic surfclam assessment, progress as priors for catchability were developed, and is typical of a low F fishery.

1.8 TOR 6: Reference points

Current reference points

According to the harvest control rule in the FMP for Atlantic surfclam, overfishing occurred whenever the annual fishing mortality rate on the whole stock was larger than the overfishing limit (OFL), which was defined as a proxy for F_{MSY} ($F_{Threshold} = M = 0.15\, y^{-1}$). B_{Target} was defined as a proxy for B_{MSY} ($B_{Target} = \frac{1}{2} B_{1999}$ where B_{1999} was near the highest estimated biomass in previous assessments). The stock was overfished if total biomass fell below $B_{Threshold}$, which was $\frac{1}{2} B_{MSY}$ ($B_{Threshold} = \frac{1}{2} B_{MSY} = \frac{1}{4} B_{1999}$).

Current and recommended biological reference points (BRP) for Atlantic surfclam are proxies because spawner-recruit relationships required to determine F_{MSY} and B_{MSY} directly have not been estimated (low stock size has never been observed). Both current and recommended biomass reference points are based on trends/status ratios such as $\frac{B_{2015}}{B_{Threshold}}$ rather than absolute biomass estimates because the overall level of Atlantic surfclam biomass is uncertain. The current fishing mortality reference point is a fishing mortality rate but the recommended reference point is based on relative catch, again because of the uncertainty in biomass.

Reference points may be selected based on fishery performance and/or policy (risk aversion). Recommendations in this assessment are based on fishery performance criteria leaving MAFMC to consider policy to consider risk involved in setting catch targets, with the advice of its Scientific and Statistical Committee.

The $B_{MSY} = \frac{1}{2} B_{1999\, proxy}$ currently used for Atlantic surfclam has no theoretical justification beyond the notion that the biomass in 1999 was high at that time and might approximate carrying capacity. The major advantage was that both B_{1999} and biomass in the terminal year (e.g. B_{2015}) were estimated in the same model so that uncertainty in the overall scale of population size cancelled out in ratios used to determine stock status such as $\frac{B_{2015}}{\frac{1}{2} B_{1999}}$. In effect, the current approach is based on estimated trends in biomass but not on the absolute size of the estimates themselves. This property is important because sensitivity and historical retrospective analyses in this assessment show that estimated stock size trends are more robust for Atlantic surfclam than estimates of scale (Figures 147 - 156).

F_{MSY} and proxies depend on spawner-recruit, and yield/spawning biomass per-recruit relationships. Proxies for F_{MSY} are often set at some fraction of M ($F_{MSY} = cM$, $c < 1$ such that M is an upper bound for F_{MSY}) or at the fishing mortality rate corresponding to some fraction of maximum average reproductive output per recruit ($F_{SPR\%}$, Zhou et al. 2012). Existing $F_{SPR\%}$ proxies are not applicable to Atlantic surfclam because the analyses on which they are based generally assume that individuals mature and recruit to the fishery at about the same time. In addition, F_{MSY} cannot be computed directly because we have never observed a low stock size and thus have no way to characterize the stock recruit relationship. The current $F_{MSY\, proxy}$, $F = M = F_{Threshold}$ relies on biomass scale, and status determination relative to fishing mortality was therefore subject to the uncertainty associated with scale in the assessment.

Simulation analyses can be used to identify robust reference points that work well across a range of potential spawner-recruit curves and life-history patterns. This assessment includes management strategy evaluation (MSE) simulations which were tailored to Atlantic surfclam and the uncertainties about their life history and dynamics (8). The MSE analysis included two scenarios of particular interest. The primary scenario reflects current practice in managing two spatial areas (Northern and Southern) with different biological properties and independent recruitment patterns as a single unit. The secondary scenario uses separate harvest control rules for each unit and provides a means for assessing the potential costs and benefits of managing the two regions as a unit or separately.

MSE

MSE simulations were used to evaluate how MAFMC control rule parameters (a simplified version) affect average biomass relative to virgin biomass $\frac{SSB}{B_0}$[4], average relative yield measured as $\frac{Y}{B_0}$, interannual variation in yield cv(Y) and the proportion of years with no fishing ($t_{F=0}$). Simulations included a relatively wide and realistic range of random inputs for recruitment parameters, natural mortality, Beverton-Holt and Ricker spawner-recruit patterns, and other important, but uncertain parameters (8).

MSE results for combined region management and assuming both Beverton-Holt and Ricker recruitment patterns showed that $F_{Threshold}$ (F_{MSY} proxy) in the simulations, B_{Target} (B_{MSY} proxy) and $B_{Threshold}$ were all important for Atlantic surfclam in the MAFMC control rule (Figures 234 - 235). However, a wide range of different combinations of these parameters performed well based on MSE results. To simplify analysis we base recommendations on results for $F_{Threshold} < M = 0.15$ (an upper bound for F_{MSY}) and MAFMC control rule values of B_{MSY}=B_{Target}=$\frac{1}{2}B_0$, $B_{Threshold}$=$\frac{1}{4}B_0$.

For simulations at B_{Target}=$\frac{1}{2}B_0$, and considering combined area management, and with two spawner-recruit patterns, $F_{Threshold}$ values near 0.12 maximized yield while maintaining relatively high average spawning biomass with low interannual variation in yield and infrequent years with no fishing (Tables 41 - 44 and Figures 236 - 237).

Recommendations

$F_{MSY\,proxy} = 0.12$ is preferred over $F_{MSY proxy} = 0.15$ because higher levels of biomass, lower levels of variation in catch and less frequent years with no fishing would be expected according to the MSE (Appendix 8). $F_{MSY\,proxy} = 0.12$ is lower than the upper bound estimate $M = 0.15$, as should be expected. It is slightly larger than the range of $F_{MSY} = cM$ proxies for finfish with $0.63 < c < 0.74$ and $0.09 < F_{MSY} < 0.11$ (Zhou et al. (2012)). $F_{Threshold} = 0.12$, $B_{Threshold} = \frac{1}{4}B_0$ and $B_{Target} = \frac{1}{2}B_0$ provided high levels of catch and stock biomass at relatively low levels of variation in catch and years with no fishing. There is no reason to change the biomass reference points $B_{Target} = \frac{1}{2}B_0$ or $B_{Threshold} = \frac{1}{2}B_{Target}$ because they performed well in MSE simulations. These results were robust to assumptions about the underlying spawner recruit curve (Figures 236 - 237).

Based on the MSE analysis, mean stock biomass would increase by about one-third at $F_{Threshold} = 0.12$, with no change in mean yield if Atlantic surfclam in both areas were managed separately

[4]Because Atlantic surfclam mature before age 1, there is no practical difference between B_0 and SSB_0 and the terms may be used interchangeably

although variance in catch and the number of years with no catch would increase (Figure 235). The simulations assume that all available yield is taken. Changes in average biomass, average yield, variance in catch, and years with no fishing would be smaller in the current fishery where catches are low relative to the levels calculated using the MAFMC control rule.

The recommendation $F_{Threshold} = 0.12$ is superior to $F_{Threshold} = 0.15$ on theoretical grounds but it shares an important implementation problem given that estimated fishing mortality rates are uncertain due to uncertainty in the scale of the biomass estimates. Thus, it would be very difficult to reliably compare an estimated fishing mortality rate to $F_{Threshold}$ and determine if overfishing is occurring. The assessment working group concluded it would be better to employ an $F_{Threshold}$ reference point based on trends using the average fishing mortality rate between 1982 and 2015 (the period for which we have survey data) in the southern area.

$$E_{y=1982}^{2015}[F_y] = F^*$$

The catch during that time period did not appear to result in overfishing. There is no evidence of overfishing in the current age/size compositions and current biomass estimates are near B_0 (see 1.7 and 14). The highest average fishing mortality between 1982 and 2015 for the southern area in sensitivity analyses was $F^*_{Max} = 0.03$. There is a high probability that $\frac{F_{MSY}}{F^*} > 4$ because

$$\frac{F_{MSY}}{F^*_{Max}} = \frac{0.12}{0.03} = 4$$

and F^*_{Max} was taken from the sensitivity run with the lowest biomass and thus highest F of any model run for the southern area. In addition, catch curve total mortality $(F + M)$ estimates for the southern area during this time period averaged 0.14, compared to the assumed M of 0.15. Empirical exploitation rates < 0.05, provding further evidence that F was low (14). Thus any F^* calculated from another model run would likely be lower than F^*_{Max}.

The recommended fishing mortality reference point is

$$F_{OFL} = F_{Threshold} = F^* \frac{F_{MSY}}{F^*_{Max}}$$

rather than a specific rate such as 0.12. It is important that F^* be calculated using the period between 1982 and 2015 in this, and in future assessments, as that was a period during which overfishing was very unlikely. Allowing the years that compose the reference point to shift over time would allow the reference point to normalize to current behavior. That is, the reference point would decrease during a regime of less fishing pressure and increase during a regime of more fishing pressure, which is not a desirable characteristic for a reference point.

There are three primary advantages to this recommendation. First, the status ratio used to identify overfishing

$$\frac{F_y}{F_{Threshold}} = \frac{F_y}{F^* \frac{F_{MSY}}{F^*_{Max}}}$$

provides information about relative exploitation rates that is not available in the ratio $\frac{F_y}{0.12}$ given the high degree of certainty in estimated trends and high degree of uncertainty in the scale of biomass estimates. Second, the recommended reference point is robust because it will adjust to changes in the scale of Atlantic surfclam biomass estimates, which can be expected in future assessments, at least over the short term. Finally, the scaling factor $\frac{F_{MSY}}{F^*_{Max}}$ can be re-examined and/or replaced as biomass estimates improve.

Table 4: Biological reference points used in the last assessment and the revised values used in the current assessment.

Reference point	Previous assessment	Revised
$F_{MSY} = F_{Theshold}$	$M = 0.15$	$F^* \frac{F_{MSY}}{F^*_{Max}}$
K	B_{1999}	B_0
$B_{MSY} = B_{Target}$	$\frac{B_{1999}}{2}$	$\frac{B_0}{2}$
$\frac{B_{MSY}}{2} = B_{Threshold}$	$\frac{B_{1999}}{4}$	$\frac{B_0}{4}$

1.9 TOR 7: Stock status

The assessment model was configured some what differently from the base model in the last assessment (Northeast Fisheries Science Center 2013), with the most important change being the addition of the new survey MCD survey. No new data from the RD survey has been collected since the previous assessment. It was not possible to add the new survey data to the previous assessment model because it was not configured to accept data from a different survey. Therefore, the previous assessment model cannot be directly compared to the model used in the current assessment, though a reasonable effort has been made to do so in (6). It is, however, possible to compare the current assessment estimates of biomass and fishing mortality to the current and recommended biological reference points.

Current reference points

Comparing the terminal biomass (B_{2015}) and fishing mortality estimates (F_{2015}) to the current reference points (Table 4) shows a low probability of either overfishing or overfished status for the Atlantic surfclam stock in the US EEZ (Table 27; Figure 157). The current $F_{threshold}$ was a point estimate with no associated uncertainty. Therefore the probability of overfishing was equal to the probability of overlap between the distribution of F_{2015} and the point estimate of $F_{threshold}$.

Recommended reference points

There is a near zero probability that the Atlantic surfclam stock in the US EEZ is experiencing overfishing ($F_{2015} < F_{Threshold}$; Table 28; Figure 158–159), and there is a low probability that the Atlantic surfclam stock in the US EEZ is overfished ($B_{2015} < B_{Threshold}$; Table 29; Figure 158 and 160). According to the recommended reference point definitions, the Atlantic surfclam stock is not overfished and overfishing is not occurring.

1.10 TOR 8: Projections

Basecase models were used to project biomass of Atlantic surfclam, catch (mt), and fully recruited fishing mortality in both areas, and in the combined stock during 2016-2025 (Tables 30 - 31 and Figure 161). Three harvest policies were assumed: 1) $F = F_{Threshold} = F_{OFL}$ (F at the OFL), 2) status quo catch (20333 mt) and 3) the maximum allowed catch under the current FMP or "quota level" catch (29364 mt) in the combined areas. Results indicate that biomass will remain higher than the biomass threshold and projected fishing mortality levels will be lower than the fishing mortality threshold for the entire resource.

Projection calculations were carried out in SS3 for the two areas using basecase models. Results for the whole stock were derived by combining projections for the northern and southern areas. Thus, the distribution of catches, relative growth rates, etc., were the same as in the terminal years of the base case models. Catches were landings multiplied by 1.12 to account for assumed 12% incidental mortality. Catches during 2016 were assumed the same as during 2015. For lack of better information, catches in the northern area during 2016-2025 were assumed to be the same in the status quo catch and quota level catch scenarios. This assumption is likely reasonable for the first few years because of processor infrastructure and fleet range limitations.

Projections for each year assumed time series average recruitment with uncertainty in starting stock size equal to the uncertainty in the final (non-forecast) model year (Figure 162). Projected total catch for the combined area was obtained by adding catches estimates for the southern and northern areas. Fishing mortality for the combined area (whole stock) was computed as the geometric mean (see Appendix 9) of the F from each area (calculated separately for each catch scenario). Overfishing status determination in each year (y) for the combined area was computed as $\frac{F_y}{F_{Threshold}} = \frac{F_y}{F^* \frac{F_{MSY}}{F^*_{Max}}}$ (see 1.8), where F^* was the mean F for the whole stock between 1982 and 2015 (Table 31). Whole stock spawning stock biomass was the sum of the spawning stock biomass from each area. These were considered unreliable due to scale uncertainty and are only included to document the calculation of projected catch at the OFL. Whole stock status ratios were the geometric mean of the status ratios from each area. Overfished status ratios were computed as $\frac{SSB_y}{SSB_{Threshold}} = \frac{SSB_y}{0.25SSB_0}$.

It is unlikely that the stock will be overfished within the next five years. The maximum probability of overfished status coincides with the minimum biomass estimate over the five year time horizon. The distributions of SSB_y and $SSB_{Threshold}$ were assumed log normal with means equal to their respective point estimates and variances equal to their delta method variances. One million draws from possible threshold values were drawn from correlated distributions with means and variances as described above, where the correlation between them was equal to the correlation between SSB_y and $SSB_{Threshold}$ estimated in the model. Each pair of draws was compared. Overfished status occurred when the threshold draw was greater than the biomass draw. Probabilities were equal to the number of overfished occurrences divided by the number of comparisons made (Shertzer et al. 2008). The probability of the whole stock being overfished was low for all projection scenarios considered (Figure 163).

The most likely fishing scenario is probably status quo catch, because the fishery is market limited and has been catching less than the quota since 2004 (Table 4). The quota scenario with higher catches was therefore a reasonable upper bound on likely fishing pressure over the next ten years. Using the quota scenario, the maximum probability of being overfished in any one year in next five

(P^*) was low (Figure 163) and the cumulative probability of being overfished at any time during the next ten years $(1 - \prod_y \{1 - p_y^*\})$ (Table 32), where p_y^* is the P^* value for each year was also low (see Shertzer et al. (2008)).

Projected fishing mortality levels are lower than the fishing mortality threshold for the entire resource under all scenarios except $F = F_{OFL}$ for each of the stock areas (Figure 164; Table 31). The cumulative probability of experiencing overfishing using the status quo catch or quota scenarios in any of the projection years was also low (Table 32).

In order to test the sensitivity of the projections to uncertainty in biomass scale, as well as model specification, quota scenario projections were conducted using the sensitivity runs with the lowest and highest biomass scale from 1.7 ("NoQPriors" and "EstimateM" for the southern area; see Figure 140). For the northern area the sensitivity runs with the lowest scale were the runs that excluded the MCD survey and the scale was too low to be creditable. Projection sensitivities for the northern area were run with the two models with the highest and lowest creditable scales ("HighRecrVariance" and "WeightRD"; see Figure 150). Projecting forward using the status quo catch scenario with these sensitivity runs showed that probabilities of overfishing and overfished status for the southern, northern and whole stock areas were similar in projection over a wide range of initial biomass scales (Table 33). The projection sensitivity results indicate that the status of the stock over the projected time horizon is robust to uncertainty in biomass scale, when recruitment remains near time series average values.

Probability distributions of the catch at the OFL were generated by repeated draws from a lognormal distribution of catch in each year, with a mean equal to the point estimate of the catch and a cv equal to the model estimated cv for each catch value (Figures 165 - 167; Table 34).

1.11 TOR 9: Stock definitions

Atlantic surfclam are assumed in the fishery management plan to be one unit stock throughout their range in US waters. The stock assessment workgroup discussed stock definitions of Atlantic surfclam at length during the last assessment (SAW 56) without reaching consensus. After reviewing all of the information presented, the SARC 56 review panel, "could not and did not choose to draw any conclusions as to whether a one- or two-stock definition was appropriate (SARC 56, 2013)." Ideas and arguments about Atlantic surfclam stock structure were summarized in two tables for SAW 56 which are also presented in this report (Figures 168 and 169).

The validity of the current stock definition was discussed by the working group briefly again in this assessment without reaching consensus. Opinions on this issue are strongly divided between industry-supported academic scientists and other members. As a result, the working group was unable to develop consensus recommendations as to whether there is a need to modify the current stock definition. Most of the stock definition discussion to date has focused on whether Georges Bank should be treated as a separate stock, both because it tends to be reproductively isolated due to persistent oceanographic conditions, and because it is unique based on the biological and fishery factors listed in Figure 168.

Below, the workgroup chair has summarized opinions of the assessment workgroup for purposes of addressing this TOR. Working group members agree that Atlantic surfclam consists of two or more meta-populations with different population dynamics, degrees of connectivity, fishery, exploitation, recruitment, post-settlement survival, growth rates, and shell height-meat weight patterns. However, some working group members view these differences as clinal and suggest that stock distinctions could be drawn in other places or not at all. They suggest that flexibility and lack of potential constraints on fishing activity are the most important benefits from the one stock approach. The multi-stock approach could lead to management constraints on the fishery that might not be necessary.

Other workgroup members noted that reference points like F_{MSY} and B_{MSY} are not well defined for heterogeneous stocks with independent population dynamics. Proxy reference points might not protect either population unit or maximize yield when used by the Council's SSC to set catch and landings limits intended to prevent Atlantic surfclam from being overfished, or overfishing from occurring. Stock conditions may suffer overall because problems in one area will be masked by conditions in the other. As shown in MSE analyses for Atlantic surfclam in this assessment (see 8) and in other studies, yield is reduced at F_{MSY} because productive areas in good condition may be fished too lightly while unproductive areas in poor condition may be fished too hard. These disadvantages are pronounced and likely to be important if fishing mortality rates approach or exceed F_{MSY}.

All members of the workgroup agree that stock definitions are unlikely to affect management, yield, or biological risk in the near term as long as fishing mortality rates remain low and overall abundance and biomass are relatively high.

The single stock assumption complicates and adds uncertainty to stock status determinations based on current and recommended reference points because biomass trend estimates for the whole stock are sensitive to independent errors in estimating scale for each area. Stock status conclusions in this assessment were robust to this problem because stock size was relatively high in both areas such that overfished status and overfishing were unlikely in either.

1.12 TOR 10: Research recommendations

The following are research recommendations from the previous assessment, in no particular order:

1. Determine the best spatial and temporal distribution to use for Atlantic surfclam assessment models.

   There have been no changes in stock definition, but the consensus of the assessment working group is that two areas modeled independently (northern area and southern area) with the results combined is the best configuration for stock assessment.

2. Biomass reference points need to be reconsidered.

   The SS3 model used for the assessment estimates B_0 for both southern and northern areas upon which biomass reference points can be based. See discussion of reference points in 1.8.

3. Has Atlantic surfclam biomass shifted offshore into deeper water over time?

   Sections 11 and 12 address this question analytically.

4. Look into a better way to implement regime change into the SS3 model. Look into patterns which may match other species and climate indices.

   Model sensitivity runs for the southern area were done with two possible growth stanzas. The model did estimate decreased growth in the second stanza, but the differences in outcome were negligible. See 1.7 for details.

5. Look at habitat on Georges Bank

   Section 13 lists methods explored in order to better determine the Atlantic surfclam habitat in the northern area that can be sampled effectively with a hydraulic clam dredge. These approaches will become available when stratification of the survey is reconsidered in the coming year. The working group agreed that the current approach was adequate for now.

New research recommendations, in no priority order:

1. Include Nantucket Shoals in the surveyed area for Atlantic surfclam.
2. Re-stratify northern area to make the survey more efficient and effective.
3. Examine coefficients used to convert commercial catches in bushels to meat weights.

Table 7: Real and nominal exvessel prices and revenues for surfclam based on dealer data. Average price was computed as total revenues divided by total landed meat weight during each year, rather than as annual averages of prices for individual trips, to reduce effects of small deliveries at relatively high prices. The consumer price index (CPI) used to convert nominal dollars to 2009 equivalent dollars is for unprocessed and packaged fish, which includes shellfish and finfish (Eric Thunberg, NEFSC, pers. comm.).

Year	CPI	Nominal_Prices	Real_Prices	Nominal_Revenue	Real_Revenue

Table 10: Number of successful random tows in NEFSC clam surveys used for survey trends and efficiency corrected swept area biomass. 'Holes' (unsampled survey strata in some years) were filled by borrowing from adjacent surveys were possible (borrowed totals are negative numbers in gray shaded boxes). Holes that could not be filled have zeros in black boxes. Survey strata are grouped by region. In 2012 and later the NEFSC survey was conducted from a commercial platform using different gear, and tows were not borrowed across gear types. Starting in 2012, not all regions were sampled in each survey year. Instead the survey was conducted in either the northern or southern area. Areas intentionally not sampled are left blank in those years. 2014 was not intended to be a survey year, but some strata were sampled in order to fill holes left over from 2013. SNE was surveyed in 2013 (except stratum 96, which was surveyed in 2014), but the survey results were borowed to 2012 and not used in 2013. Survey strata not used for surfclams are not shown.

Table 11: Trends in abundance and biomass for surfclam > 50 mm shell length during 1982-2015 based on NEFSC clam survey data. Survey values are the clams caught in the survey dredge. Stock values are the survey values adjusted to account for the selectivity of the survey dredge. Fishable values are the stock values adjusted to account for the selectivity of a commercial dredge. Figures include original plus borrowed tows. The column "N strata" includes strata sampled by tows borrowed from the previous and subsequent surveys if needed.

	Survey				**Stock**				**Fishable**						
Year	$\frac{N}{tow}$	CV	$\frac{kg}{tow}$	CV	$\frac{N}{tow}$	CV	$\frac{kg}{tow}$	CV	$\frac{N}{tow}$	CV	$\frac{kg}{tow}$	CV	N tows	Pos. tows	N strata

Table 12: Shell length composition data used to estimate dredge selectivity for surfclams between 2012 and 2015. Number of surfclams caught (no.) and positive stations (pos.) for the modified commercial dredge used for the NEFSC survey and a lined dredge presumed to catch all animals available. Some of the stations were targeting ocean quahog and few surfclams were captured at these sites.

SL group	Lined no.	Survey no.	Lined pos.	Survey pos.

Table 13: Numbers of surfclams in survey dredge selectivity experiments by length bin and station between 2012 and 2015. For example, 3:8 in the row corresponding to shell length (SL) bin 40−50 indicates that 3 surfclams between 40 and 50 mm were caught in the survey dredge and 8 surfclams were caught in the selectivity dredge at that station. Stations with very few total surfclams caught were ocean quahog stations, but are included for completeness.

Table 14: Results from generalized additive model fits to selectivity data for the MCD survey. The response variable is number of surfclams caught in the survey dredge (a modified commercial dredge) compared to the number of surfclams caught in a lined dredge. The predictors are length bin (L), and a year−station (YrSta) effect. Some models included an offset based on the tow distance at each station. The s indicates a spline function and RE indicates random effects. The best model by AIC included random effects for each year−station combination in both intercept and length.

Model	AIC	BIC
s(L)+s(YrSta,RE)+s(YrSta,L,RE)	3223	3633
s(L)+s(YrSta,RE)	3594	3831
s(L)	6838	6879

Table 15: The MCD survey dredge (post 2011) selectivity coefficients estimated using the best (by AIC) selectivity model, by size bin.

Table 16: Results from model fits to predict meat weight. Predictors are ln(shell length) (L), ln(depth) (D), density (ρ), and region (R). Random effects are enclosed in parentheses and are limited to station (St), year (both affecting the estimate of the intercept), and length (affecting the estimate of the length coefficient). Regional coefficients are shown. SVA is assumed to have coefficient equal to 0.

Table 19: Numbers of successful random survey tows with sensor data used to evaluate the precision of the MCD survey. Tows are shown in the year they were made (with no borrowing).

Year	South	North
1997	266	57
1999	216	30
2002	251	28
2005	208	
2008	241	12
2011	221	84
2012	131	
2013	35	64
2014	1	19
2015	164	

Table 20: Models relating the proportion of positive tows in the survey to year and stratum used to evaluate the precision of the MCD survey, where C_t is catch in tow t, yr is year as a factor, and str is the stratum.

Model	Formula	Family	Link	df	AIC
glmA	$C_t = yr$	Tweedie(p=1.7)	log	9	14,060
glmB	$C_t = str$	Tweedie(p=1.7))	log	31	13,923
gamA	$C_t = s(yr, by = str)$	Tweedie(p=1.7)	log	67	14,160
gamB	$C_t = s(yr, by = str) + str$	Tweedie(p=1.7)	log	118	13,495

Table 21: Structure of SS3 models used for surfclams in the southern and northern areas.

Model aspect	South	North	Note
M	0.15	0.15	Constant for all ages and years
Age bins	0–30	0–30	
Length bins	1–20 cm	1–20 cm	
Time	1965–2015	1984–2015	
Seasons/morphs/subareas	0	0	
Commercial fleets	1	1	
Fishery selectivity	Double normal	Double normal	
Surveys (trend)	2	2	RD (trend) RD-SWAN (scale) MCD (scale and trend)
Survey selectivity RD	Double normal	Double normal	Based on field estimates
Survey selectivity MCD	Double normal	Double normal	Based on field estimates
Survey catchability (RD-SWAN)	Estimated	Estimated	Uses informative prior distribution
Survey catchability (MCD)	Estimated	Estimated	Uses informative prior distribution
Recruitment Model	Beverton-Holt	Beverton-Holt	Fixed steepness, estimated R_0 and variance (south)
Recruit dev years	1965–2015	1969–2015	
Bias Adjustment parameters	1955,1976,2008,2015,0.79	1961,1974,2006,2015,0.87	
F method	Hybrid	Hybrid	6 iterations (exact F)

Table 22: Parameters estimated internally and externally in SS3 base models for Atlantic surfclam in the southern and northern areas. Parameters listed as fixed or estimated apply to both areas. Parameters listed as estimated in one area are fixed in the other. Numbers of parameters are summarized in the last rows.

Parameter	South	North	Note
M	0.15	0.15	Fixed
Length at age 4	9.613	9.184	Estimated
Length at age 30	16.255	14.912	Estimated
Von Bertalanffy K	0.224	0.253	Fixed
CV of size at ages 5 y	0.172	0.17	Estimated in South
CV of size at age 30 y	0.088	0.077	Estimated in South
Shell length to meat weight multiplier	9e-05	0.00011	Fixed
Shell length to meat weight exponent	2.733	2.733	Fixed
Spawner recruit R_0	16.018	14.251	Estimated
Spawner recruit steepness	0.95	0.95	Fixed
Spawner recruit sd	0.861	1	Estimated
Catchability RD	0.103	0.098	Estimated (with prior)
Catchability MCD	0.738	0.661	Estimated (with prior)
Fishery selectivity peak	15.107	15.075	Estimated
Fishery selectivity top	-8.65802	-2.12929	Estimated in South
Fishery selectivity asc. width	1.638	2.199	Estimated
Fishery selectivity dec. width	1.375	0.553	Estimated in South
Fishery selectivity init	-999	-999	Fixed
Fishery selectivity final	-999	-999	Fixed
Survey (RD) selectivity Peak	8.819	9.534	Estimated in North
Survey (RD) selectivity top	-0.64891	-0.64891	Fixed
Survey (RD) selectivity asc. width	2.239	1.909	Estimated in North
Survey (RD) selectivity dec. width	2.356	2.356	Fixed
Survey (RD) selectivity init	-999	-999	Fixed
Survey (RD) selectivity final	-0.81743	-0.81743	Fixed
Survey (MCD) selectivity Peak	11	11	Fixed

Table 25: Likelihood profile over unfished recruitment parameter (R0). The values in the table are the differences, in likelihood units, between each profile run and the minimum likelihood for that row (likelihood component). Conflicts within the data are apparent when the minimum likelihood values (gray cells) occur in different columns for each row. That is, different likelihood components within the model were minimized at different values of R0. Because R0 is important for setting the scale of estimated biomass in the model (Relative B; last row), data conflicts around R0 tend to increase uncertainty in scale. The coloumn corresponding to the minimum total likelihood is shown in italics.

Table 27: Whole stock biomass (mt) and fishing mortality status estimates with cv and approximate 95% confidence intervals, using the current reference points from the previous assessment. The table shows the overlap between the distributions of the threshold and the terminal B (P[overlap]) and the probability of overfished status (P[overfishing]), which accounts for the correlation between the threshold and the terminal B. The current F reference point was a point estimate with no uncertainty and therefore the probability of overfishing was equal to the overlap.

	Estimate	CV	LCI	UCI	P[overlap]	P[overfishing]
SSB_{2015}	46355730	0.635	14822331	144974076	0.434	0.000

Table 32: Cumulative probability of being in overfished status in any of the years from 2016-2025 under a variety of catch scenarios for Atlantic surfclam in the southern, northern and combined areas. Overfishing determination for the northern area was not possible due to a lack of the exploitation history required to generate an area specific fishing mortality threshold.

Catch scenario	$P[Overfished]$	$P[Overfishing]$
Southern area		
Status Quo	0.007	0.000
Quota	0.007	0.008
F=FOFL	0.009	0.529
Northern area		
Status Quo	0.107	
Quota	0.116	
F=FOFL	0.111	
Whole stock		
Status Quo	0.091	0.095
Quota	0.093	0.240
F=FOFL	0.098	0.498

Table 33: Projected stock status ($\frac{SSB}{SSB_{Threshold}}$ and $\frac{F}{F_{Threshold}}$) during 2016-2025 for Atlantic surfclam in the southern, northern and combined areas from projections based on the highest and lowest (in biomass scale) of credible sensitivity runs for each area. Overfishing determination for the northern area was not possible due to a lack of the exploitation history required to generate an area specific fishing mortality threshold.The results indicate that projected stock status is reasonably robust to biomass scale uncertainty.

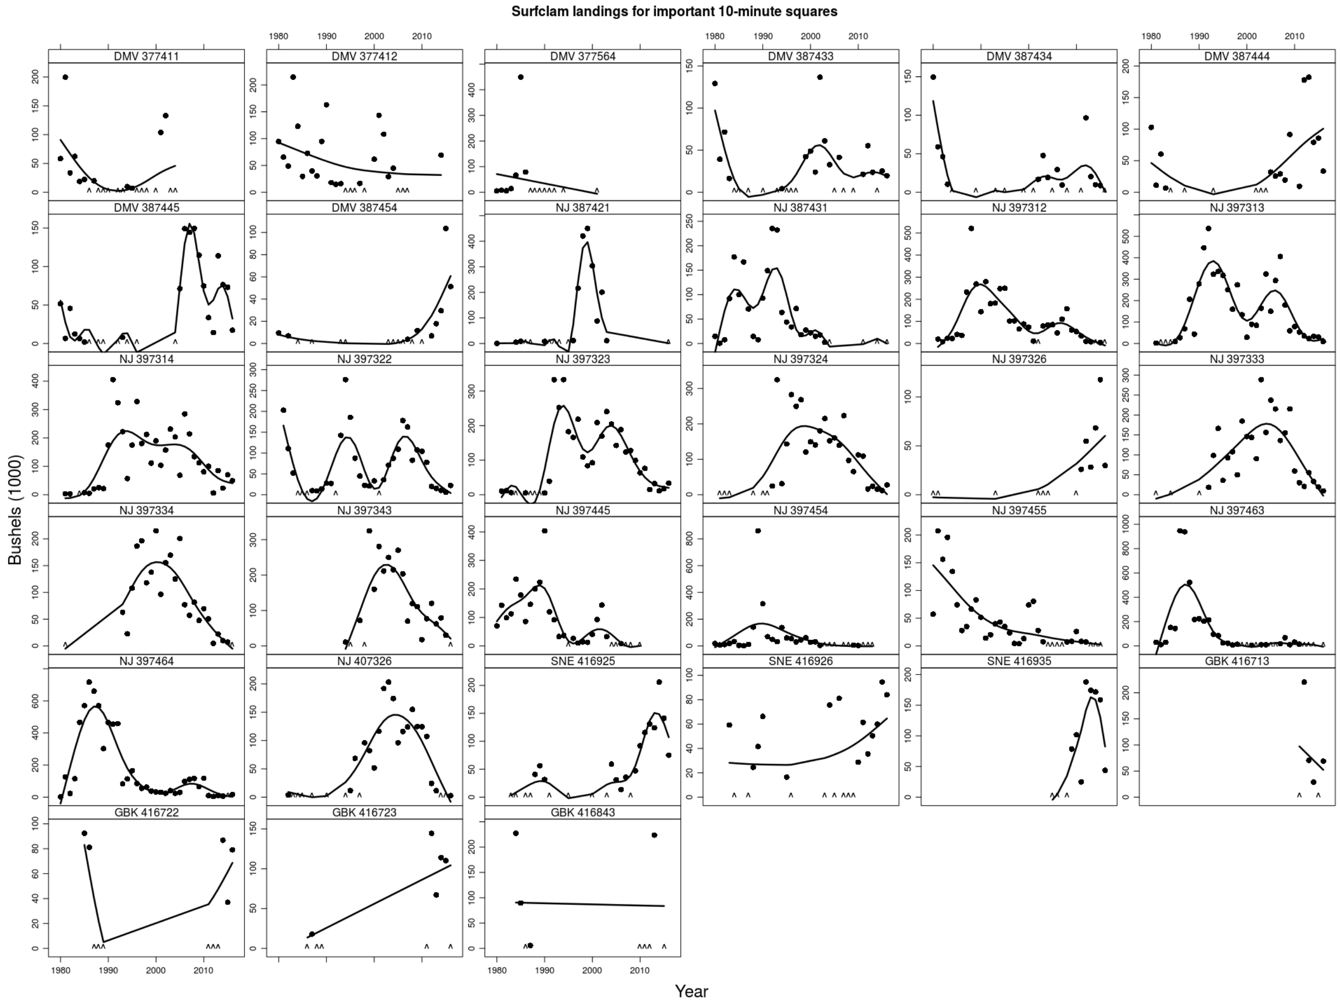

Figure 19: Annual surfclam landings in "important" ten minute squares (TNMS) during 1980-2015 based on logbook data. Important means that a square ranked in the top 10 TNMS for total landings during any five-year period (1980-1984, 1985-1989, ..., 2000-2004, 2005-2009, 2010-2015). To protect the privacy of individual firms, data are not plotted if the number of vessels is less than 3. Instead, a "$\wedge$" is shown on the x-axis to indicate where data are missing. The solid dark line is a spline intended to show trends. The spline was fit too all available data, including data not plotted.

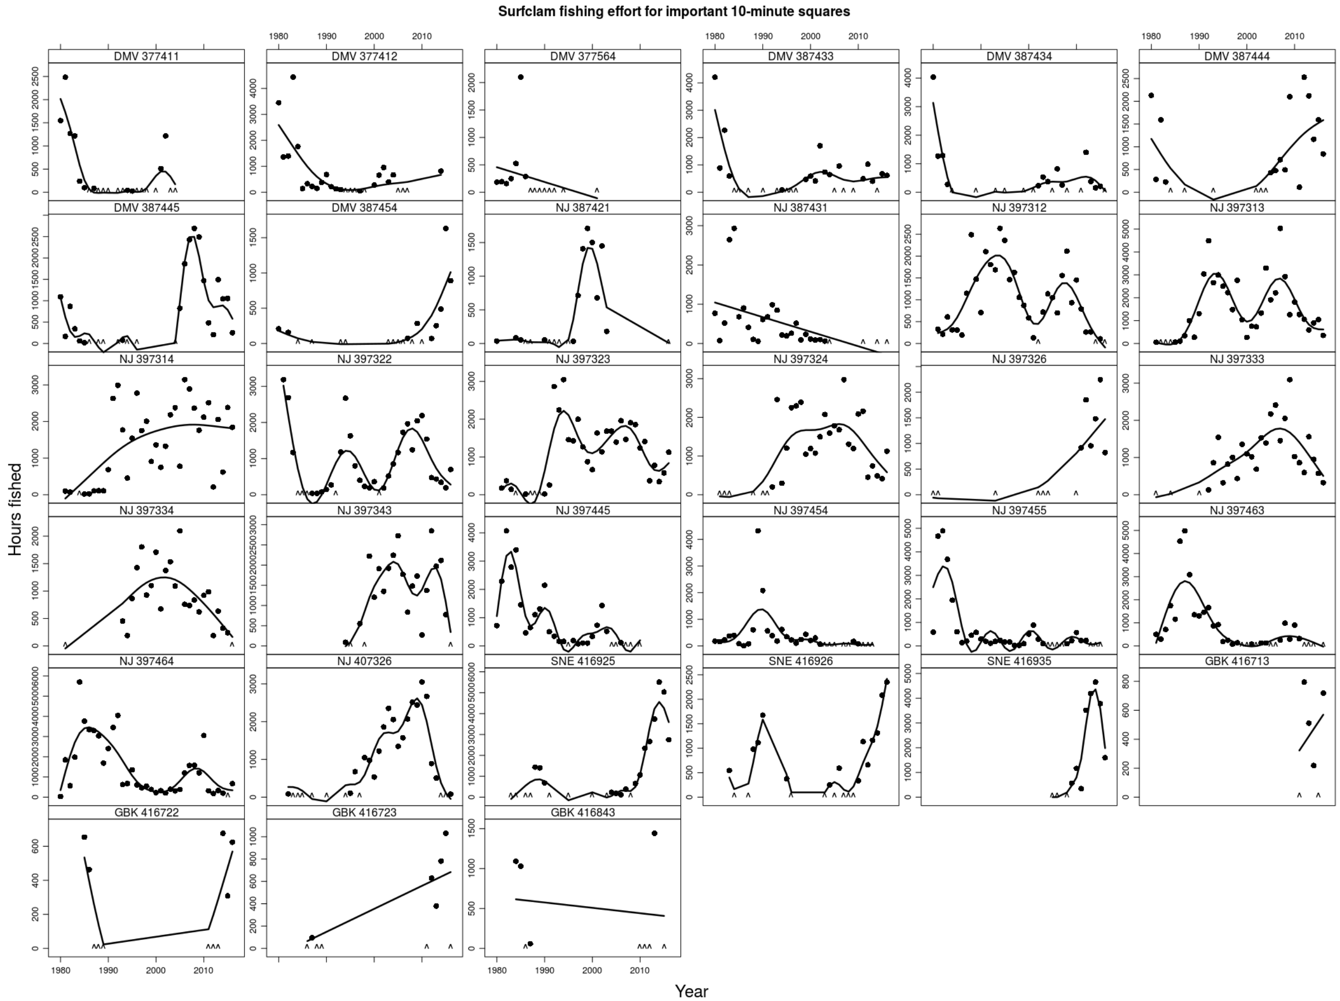

Figure 20: Annual surfclam effort (hours y^{-1}) in "important" ten minute squares (TNMS) during 1980-2015 based on logbook data. Important means that a square ranked in the top 10 TNMS for total landings during any five-year period (1980-1984, 1985-1989, ..., 2000-2004, 2005-2009, 2010-2015). To protect the privacy of individual firms, data are not plotted if the number of vessels is less than 3. Instead, a "$\wedge$" is shown on the x-axis to indicate where data are missing. The solid dark line is a spline intended to show trends. The spline was fit too all available data, including data not plotted.

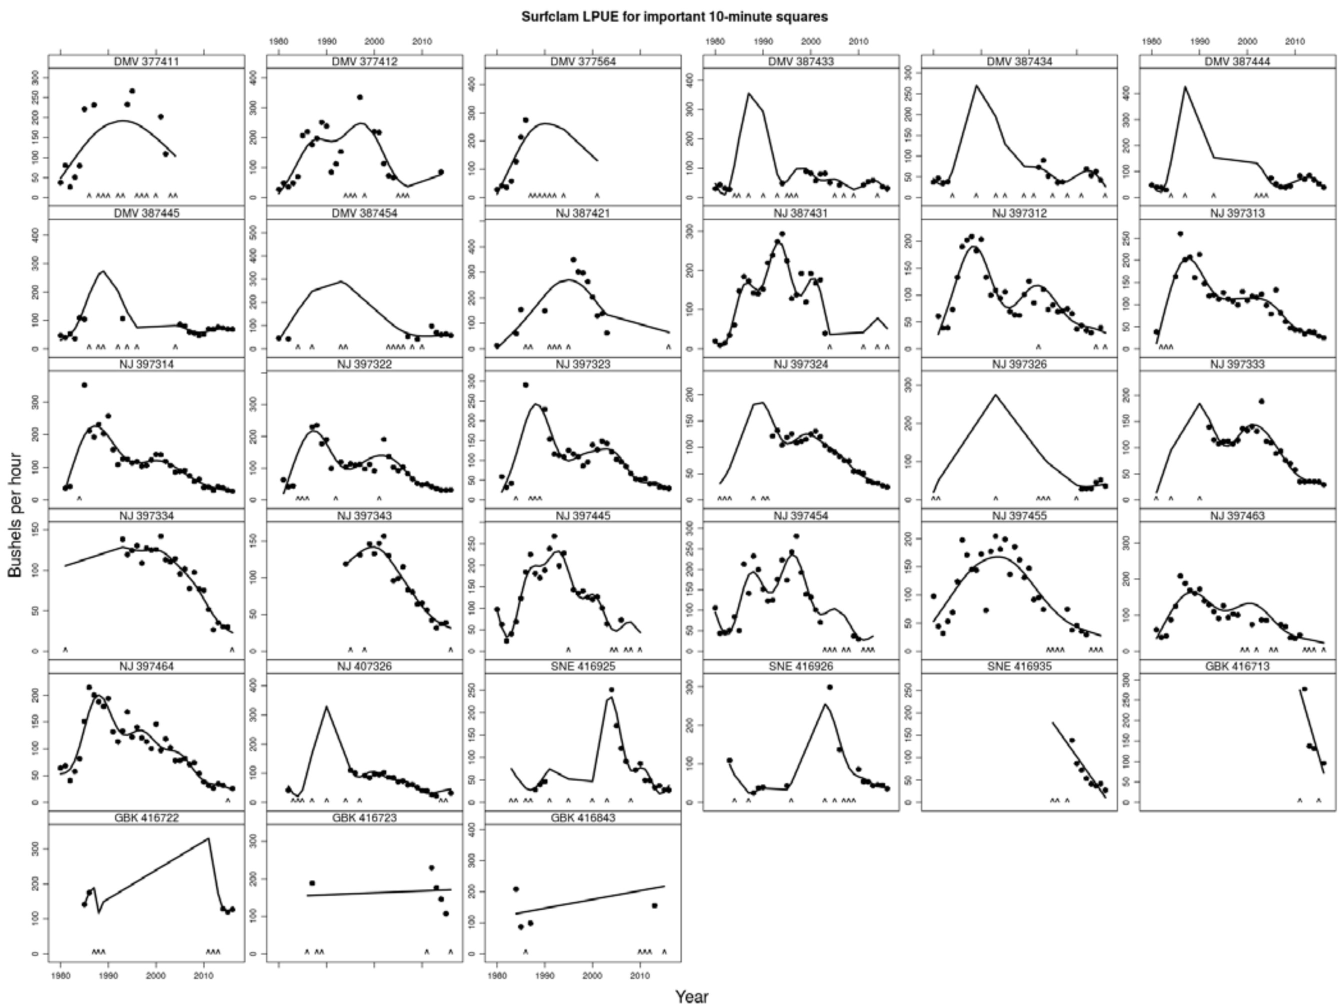

Figure 21: Annual surfclam LPUE (bu h^{-1}) in "important" ten minute squares (TNMS) during 1980-2015 based on logbook data. Important means that a square ranked in the top 10 TNMS for total landings during any five-year period (1980-1984, 1985-1989, ..., 2000-2004, 2005-2009, 2010-2015). Figure 50: Length composition of Atlantic surfclam in NEFSC surveys in LI, including the number of Atlantic surfclam measured in each year (n). The size selectivity of the survey changed after 2011 when the survey was switched to a commercial platform. Composition data from before 2011 are not directly comparable to data since 2012.

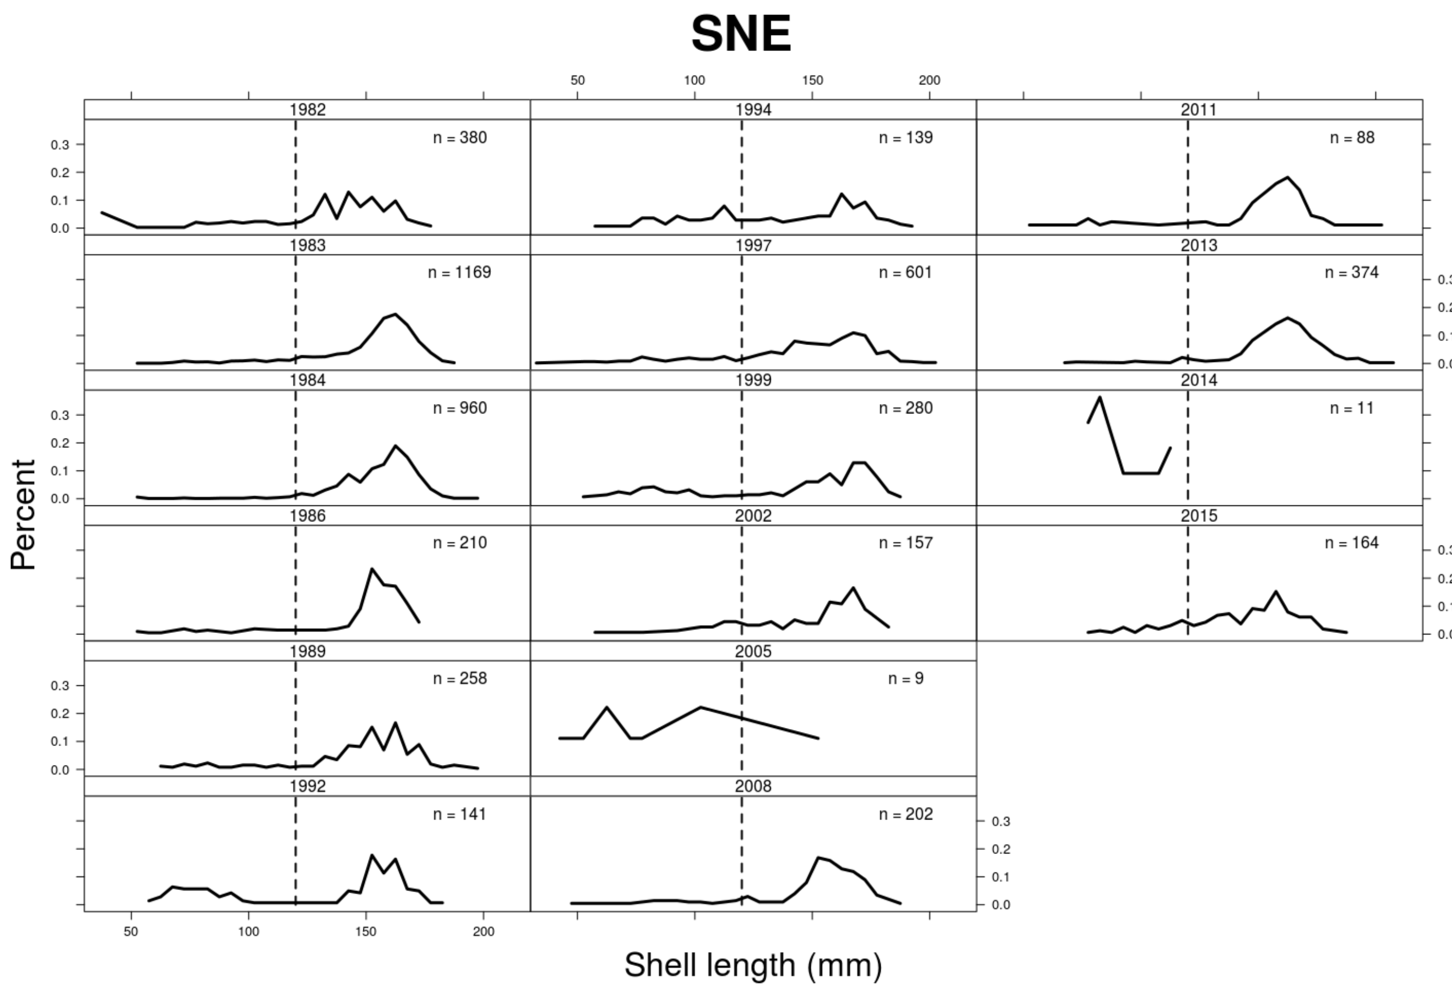

Figure 51: Length composition of Atlantic surfclam in NEFSC surveys in SNE, including the number of Atlantic surfclam measured in each year (n). The size selectivity of the survey changed after 2011 when the survey was switched to a commercial platform. Composition data from before 2011 are not directly comparable to data since 2012.

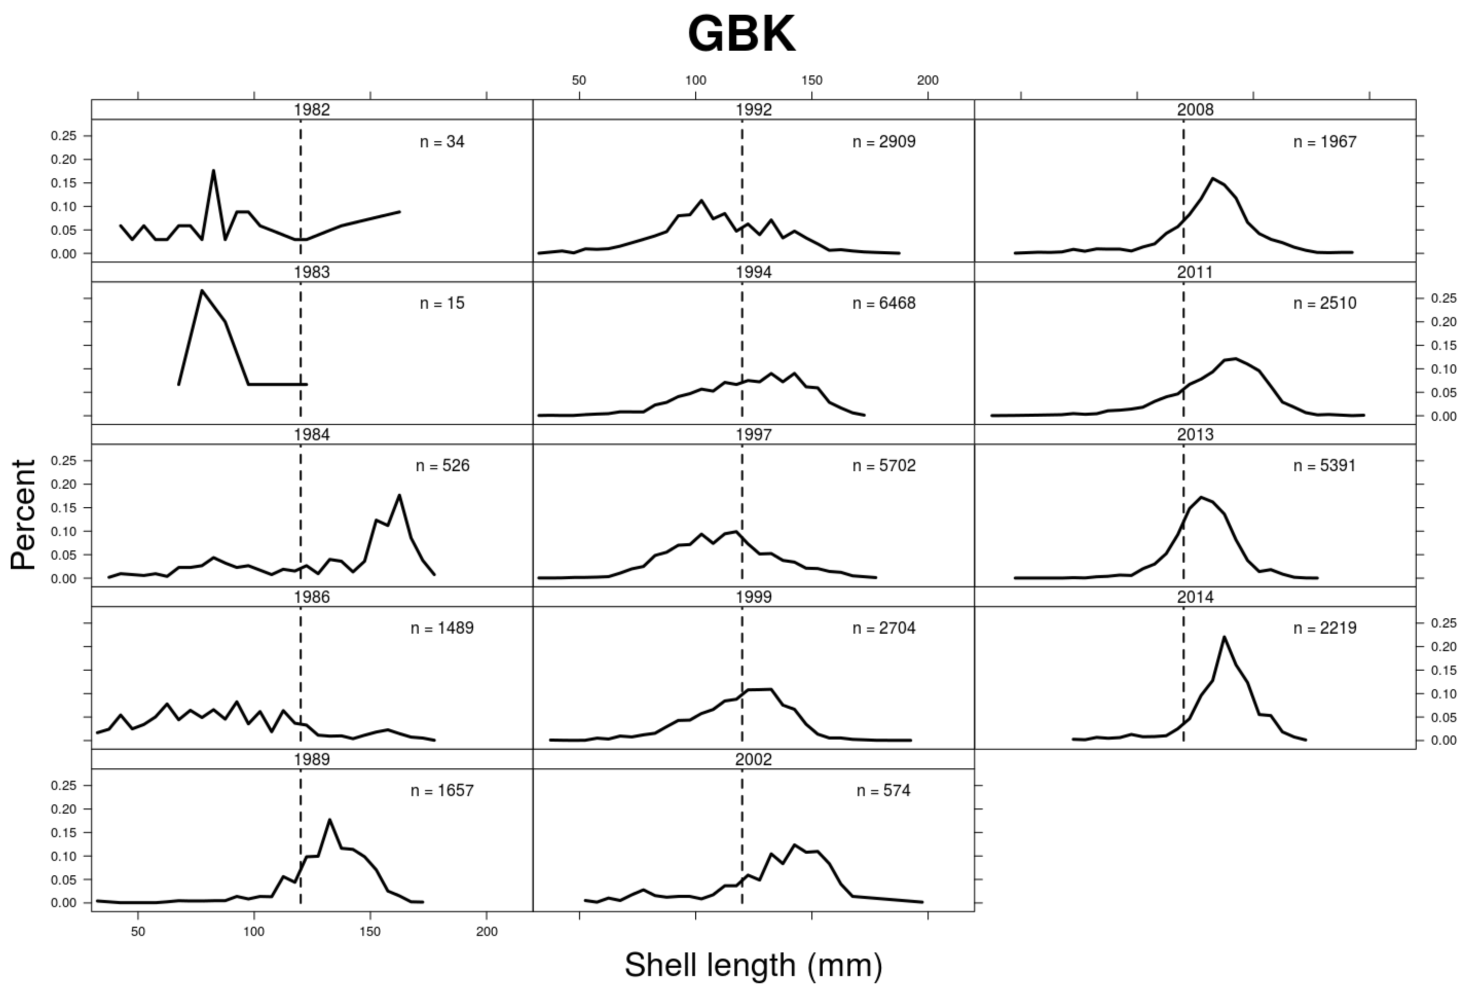

Figure 52: Length composition of Atlantic surfclam in NEFSC surveys in GBK, including the number of Atlantic surfclam measured in each year (n). The size selectivity of the survey changed after 2011 when the survey was switched to a commercial platform. Composition data from before 2011 are not directly comparable to data since 2012.

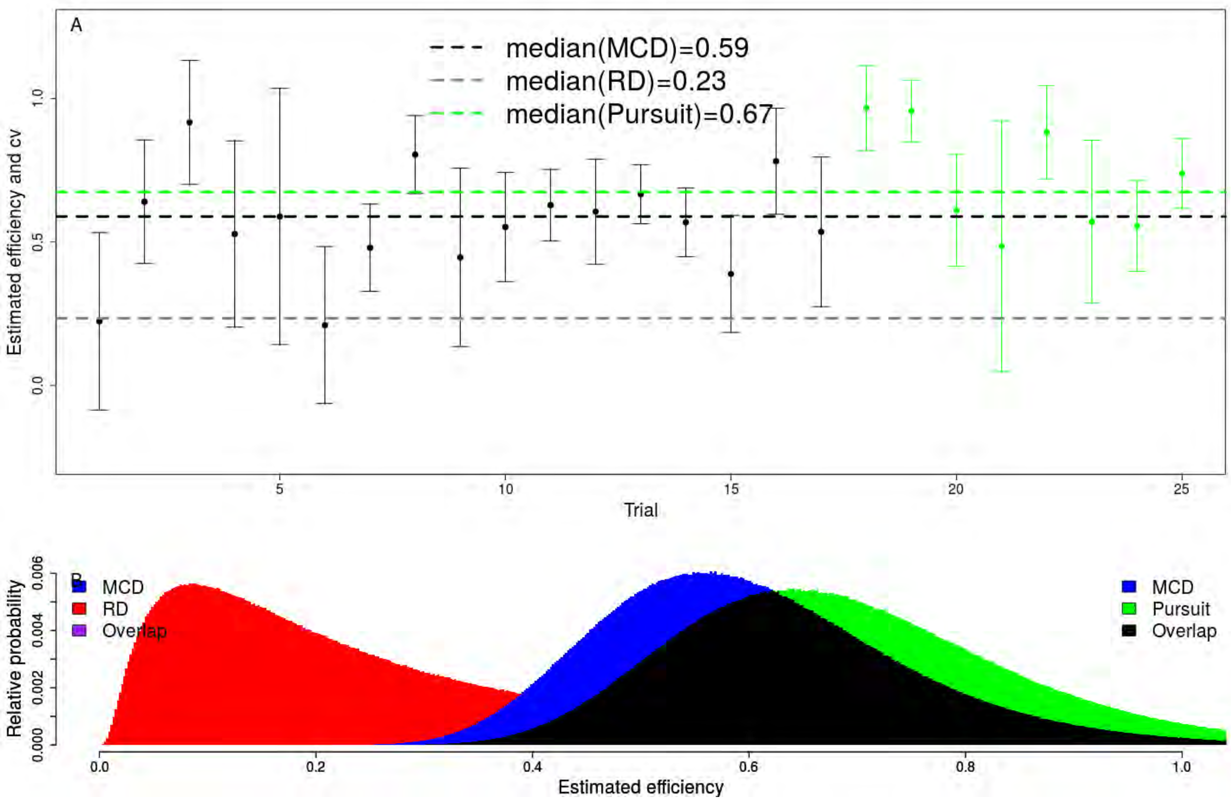

Figure 53: Panel A) Individual modified commercial dredge (MCD) capture efficiency estimates with coefficients of variation compared to median values for the MCD and the survey dredge used from the research vessel (RD) as well as the specific dredge used on the current survey (Pursuit). Panel B) A comparison of median values values incoprorating the pooled cv for each dredge where each is shown as a truncated lognormal distribution. The MCD and Pursuit dredge had higher and more precisely estimated capture efficiency than the RD.

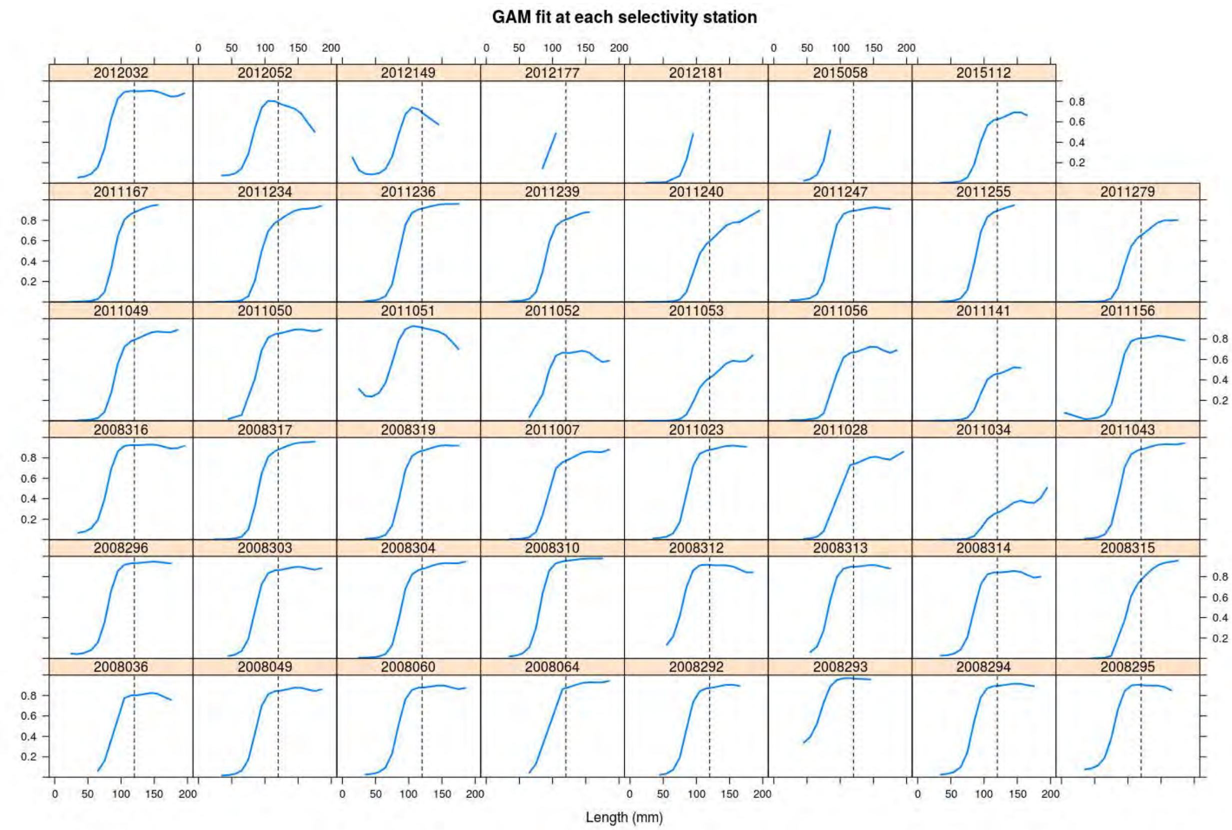

Figure 54: GAM fits to the selectivity data for Atlantic surfclam from field experiments (MCD compared to lined dredge) by year and station. The plots generally indicate flat topped selectivity curves.

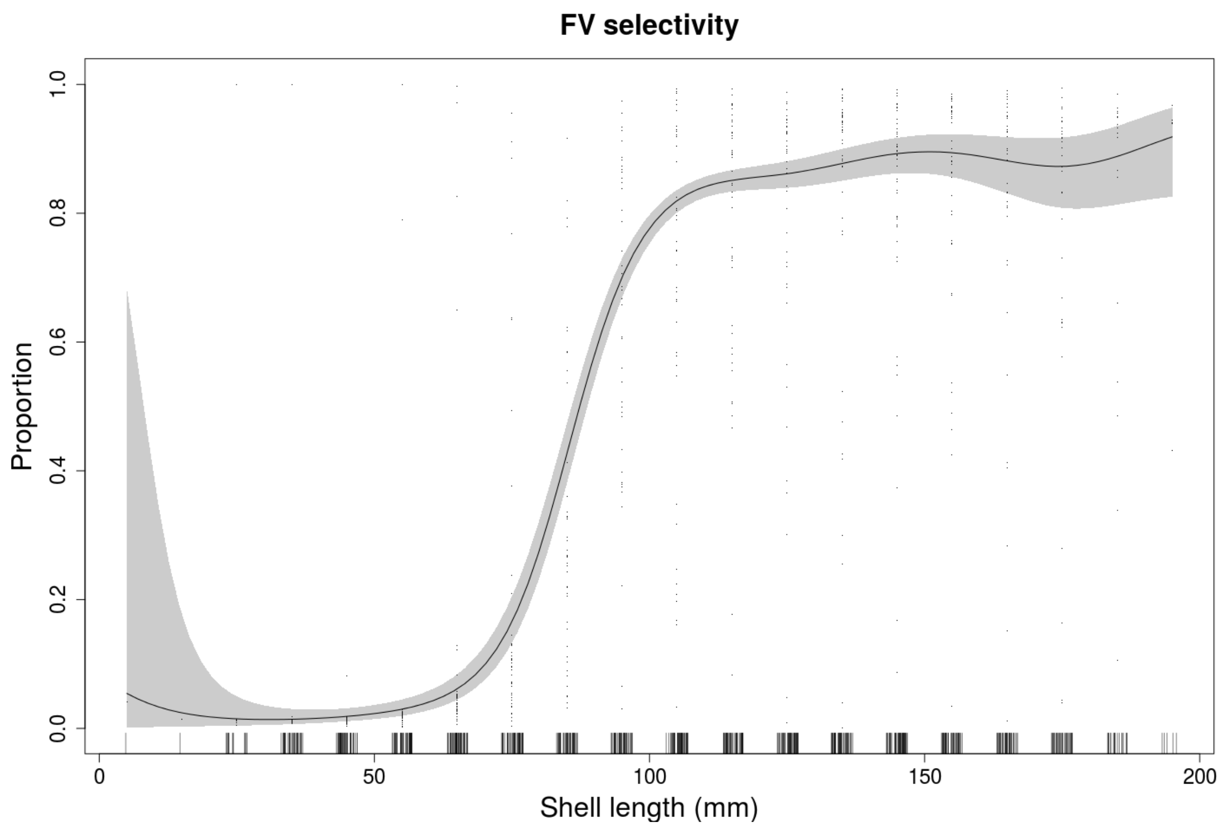

Figure 55: The GAM fit to all the selectivity data for Atlantic surfclam in the MCD in all years. The best (by AIC) model included random effects in both the intercept and spline over length. The data density is shown in the rug plot along the horizontal axis and relative confidence is represented by the shaded region.

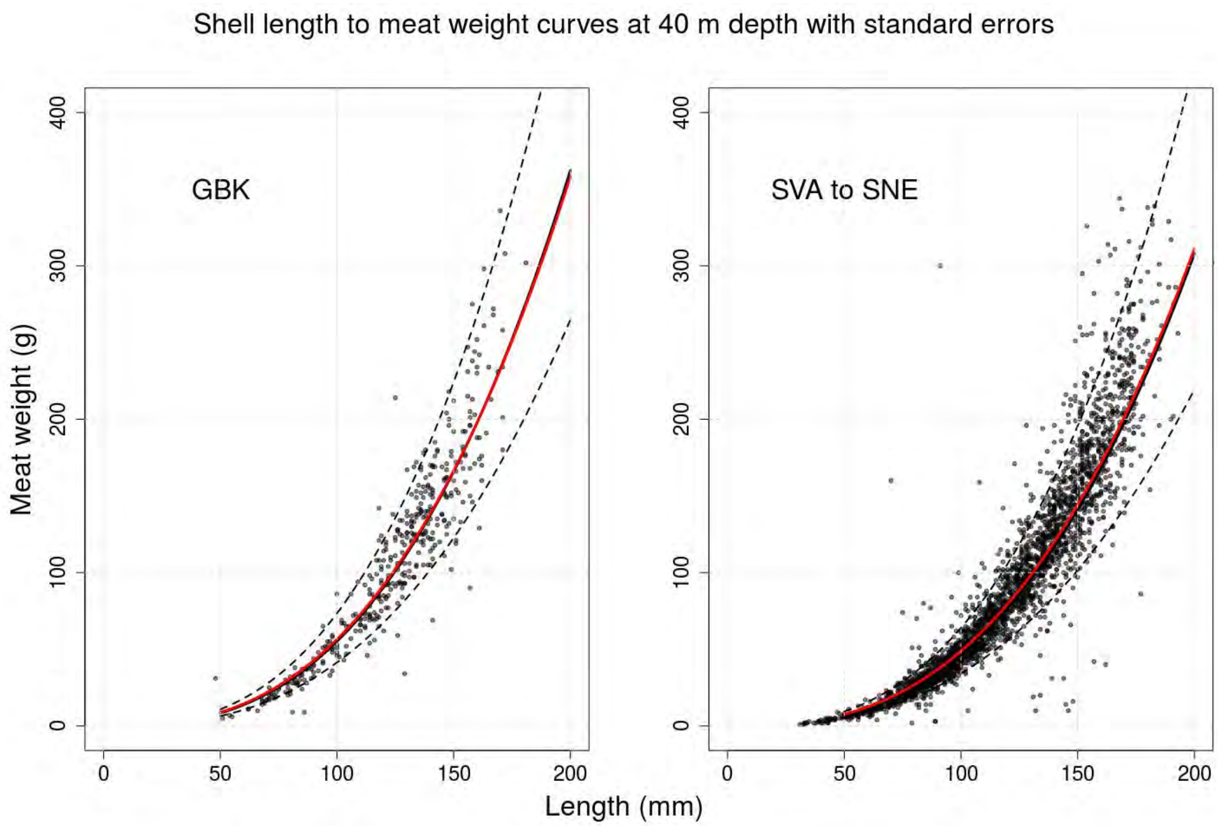

Figure 56: Broad scale area differences in allometric relationships for Atlantic surfclam based on survey data. The same depth (40 m) was used to generate the curves for each area. The 95% confidence regions are represented by the dotted line.

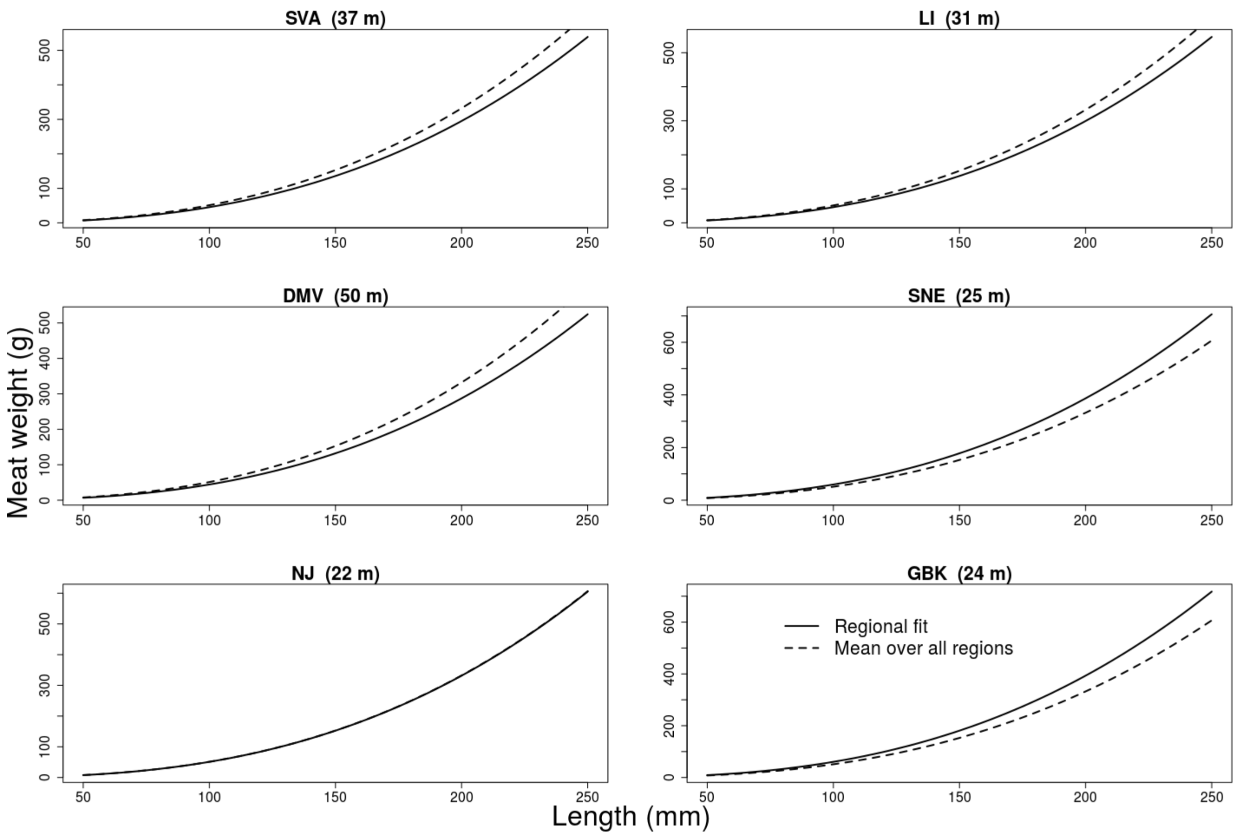

Figure 57: Regional differences in allometric relationships for Atlantic surfclam based on survey data. The median depth in each region was used to generate the curves. The global mean is represented by the dotted line.

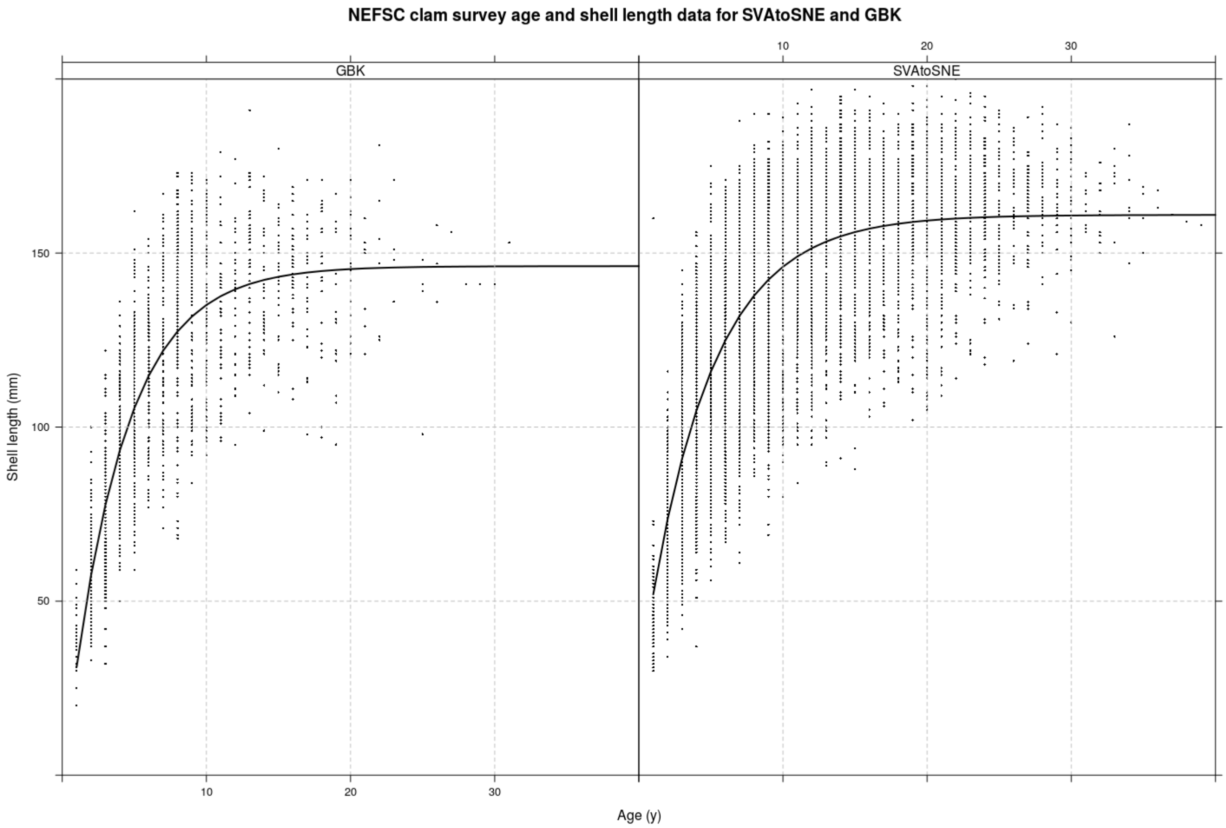

Figure 58: Age vs. length for Atlantic surfclam based on survey data with fitted Von Bertalanffy growth curve in different areas.

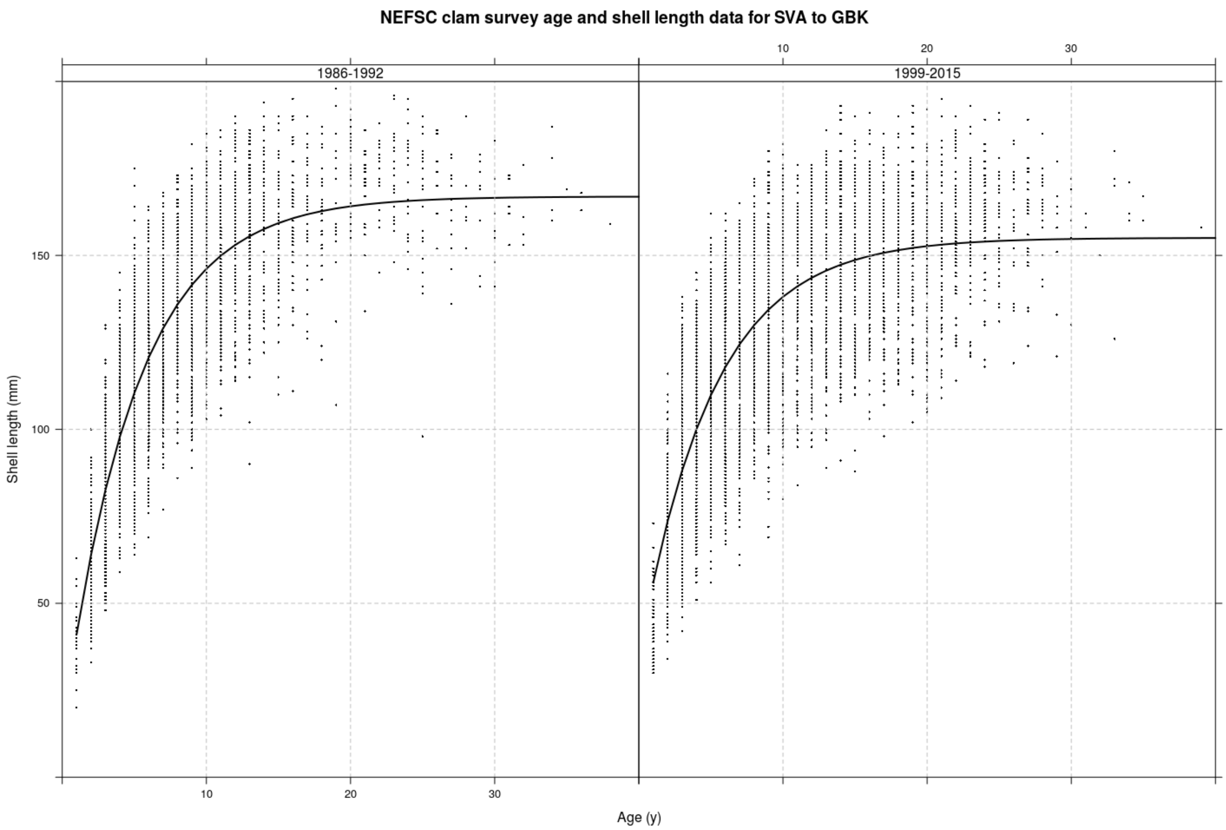

Figure 59: Age vs. length for Atlantic surfclam based on survey data with fitted Von Bertalanffy growth curve in different eras for the whole stock.

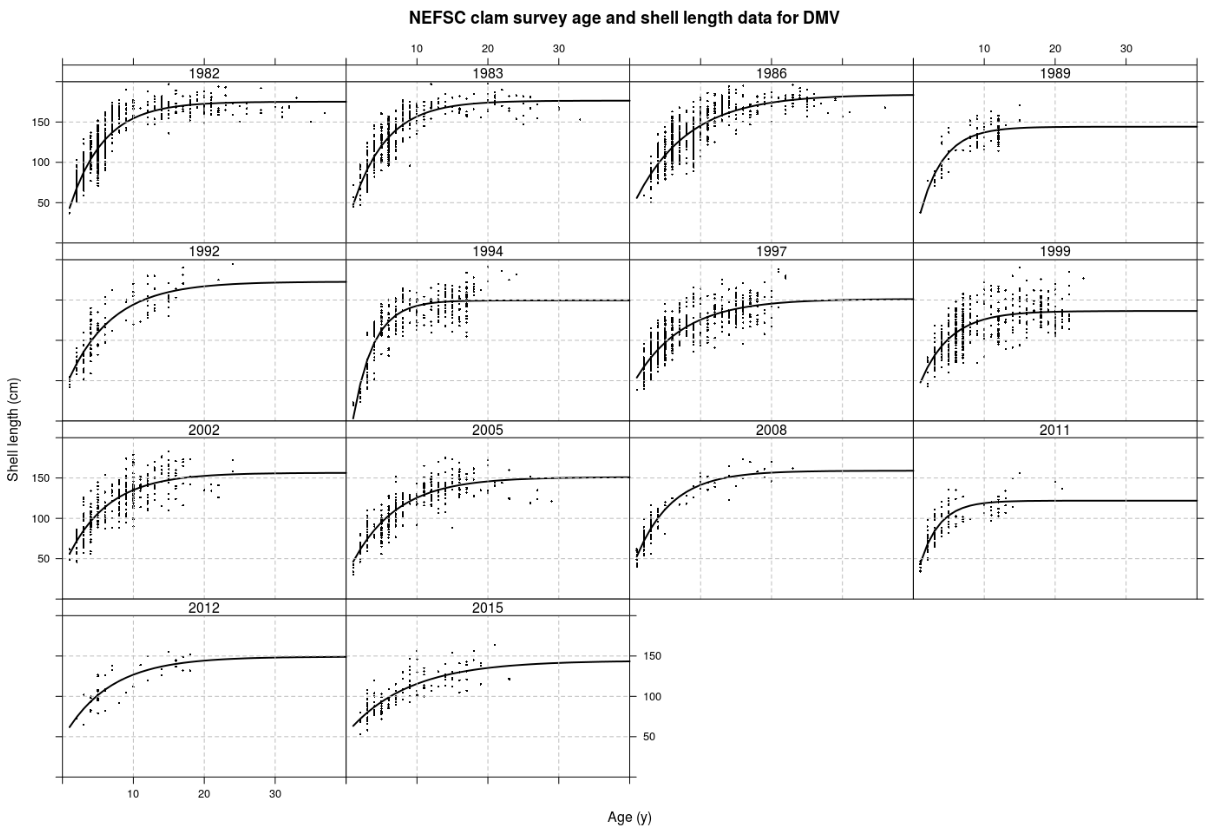

Figure 60: Age vs. length for Atlantic surfclam based on survey data with fitted Von Bertalanffy growth curve for the DMV region in each survey year.

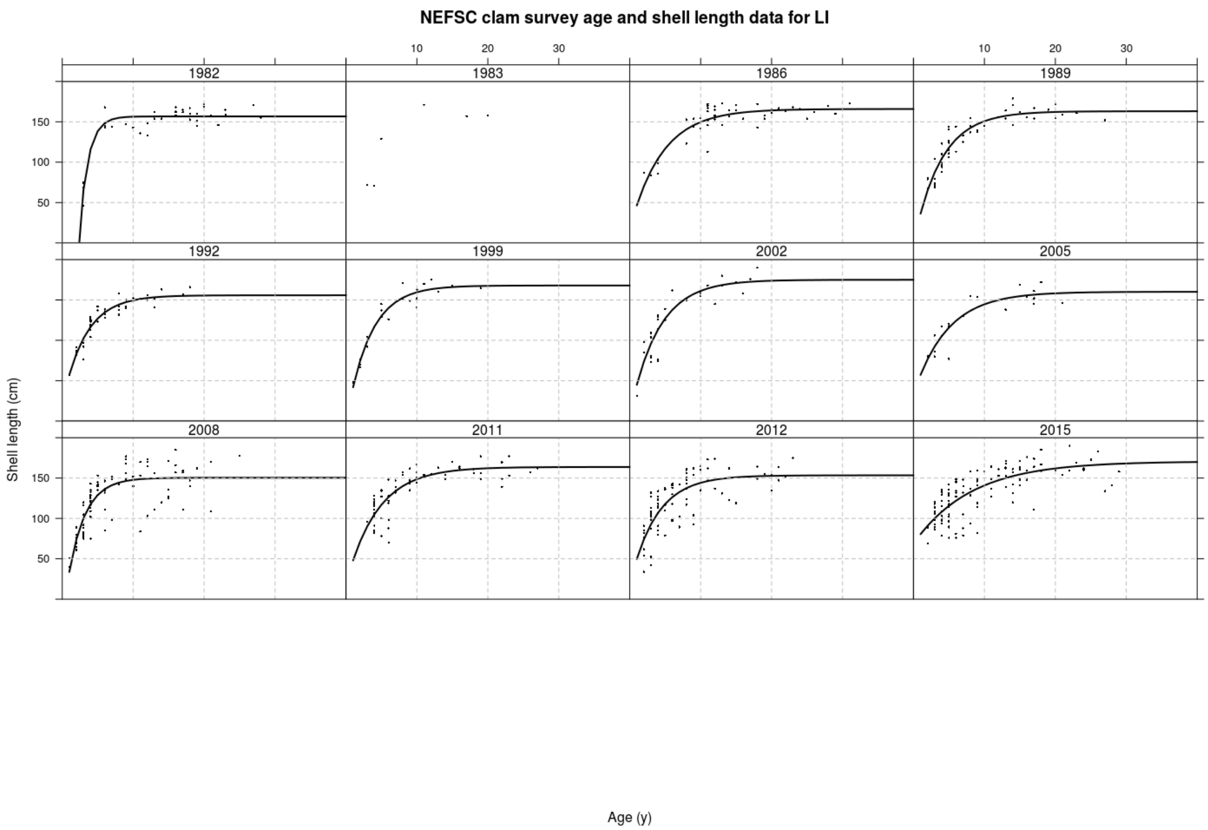

Figure 62: Age vs. length for Atlantic surfclam based on survey data with fitted Von Bertalanffy growth curve for the LI region in each survey year.

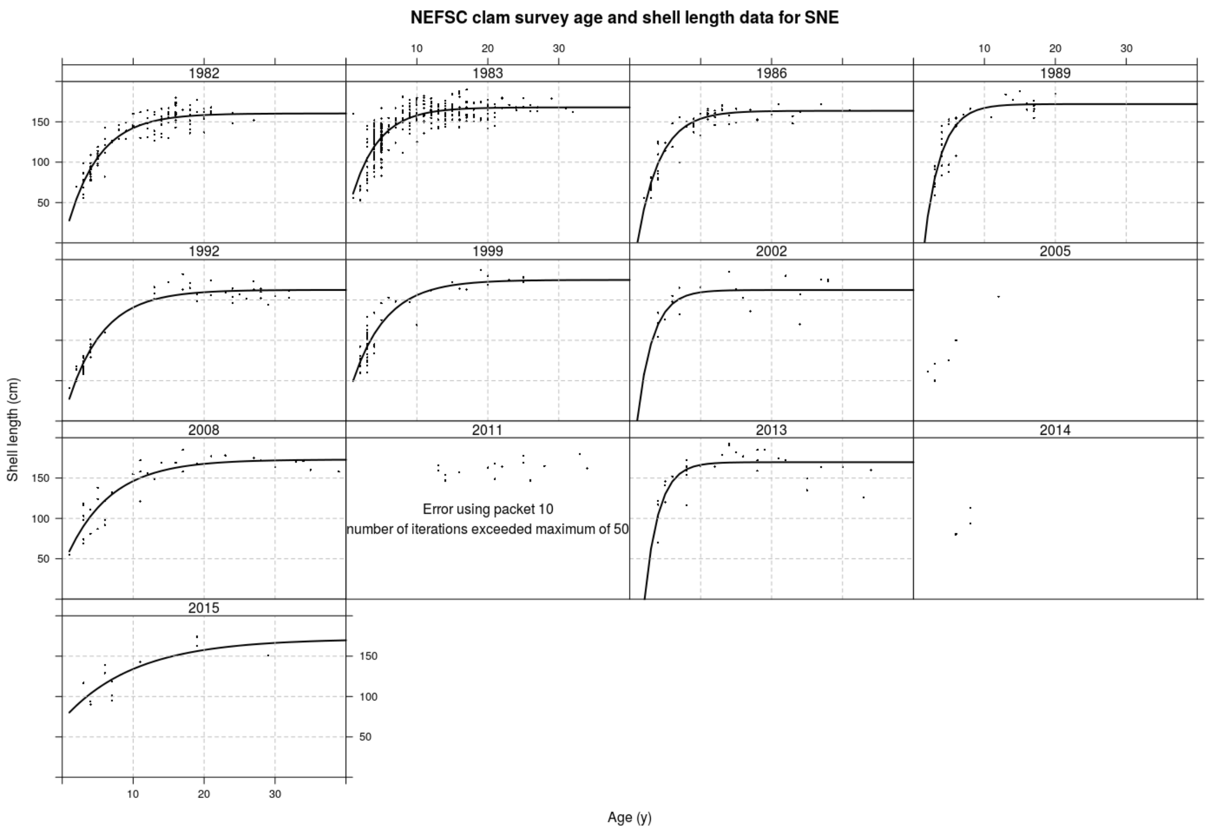

Figure 63: Age vs. length for Atlantic surfclam based on survey data with fitted Von Bertalanffy growth curve for the SNE region in each survey year.

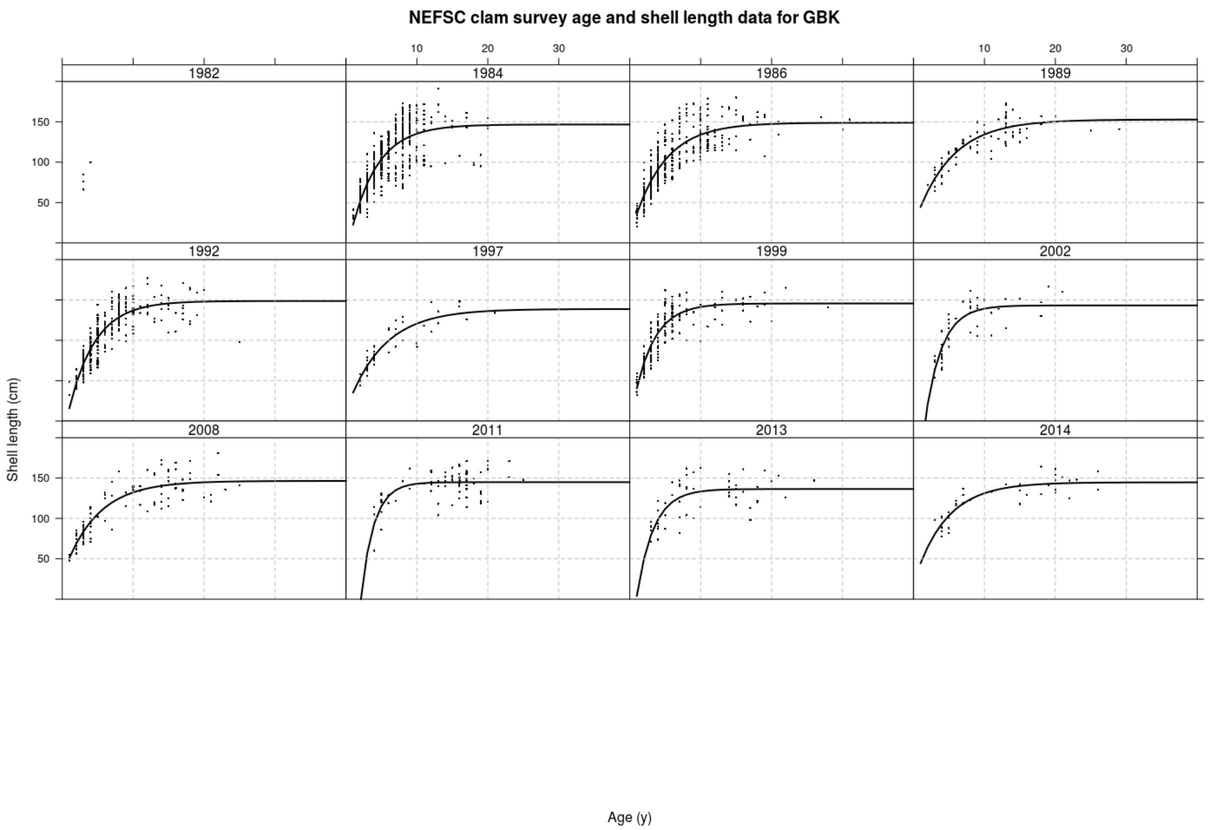

Figure 64: Age vs. length for Atlantic surfclam based on survey data with fitted Von Bertalanffy growth curve for the GBK region in each survey year.

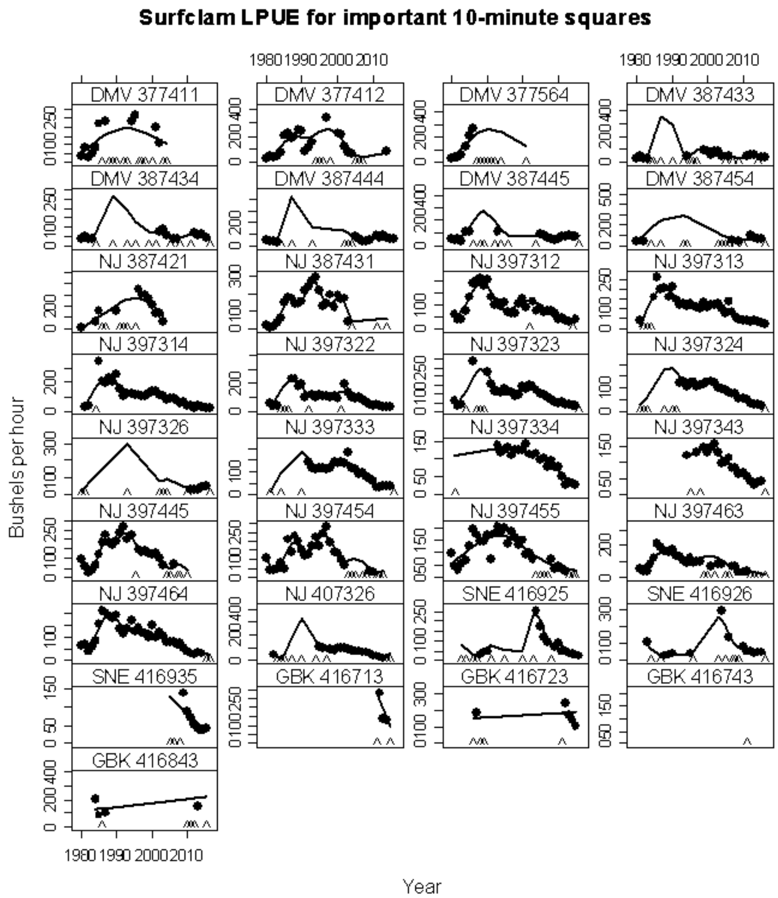

Figure 65: Observed and predicted survey catch rates in ten-minute squares that are important to the fishery.

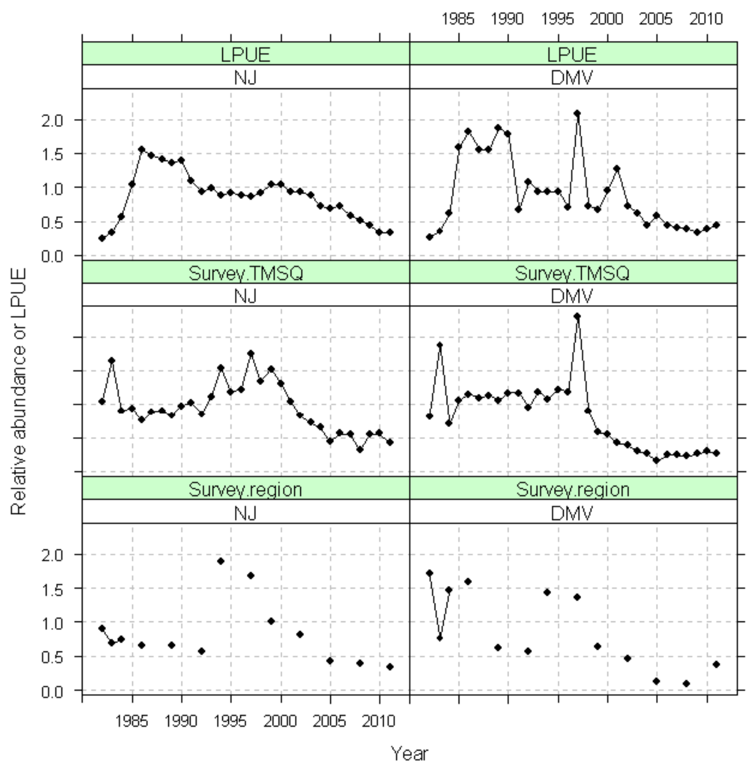

Figure 66: LPUE and survey abundance trends for Atlantic surfclam during 1982-2011 in the New Jersey (left) and Delmarva (right) regions (rescaled for convenience in plotting). LPUE and "Survey.TMSQ" are commercial catch rate and survey trends for important ten-minute squares. "Survey.region" is the survey trend for the entire region (all ten-minute squares).

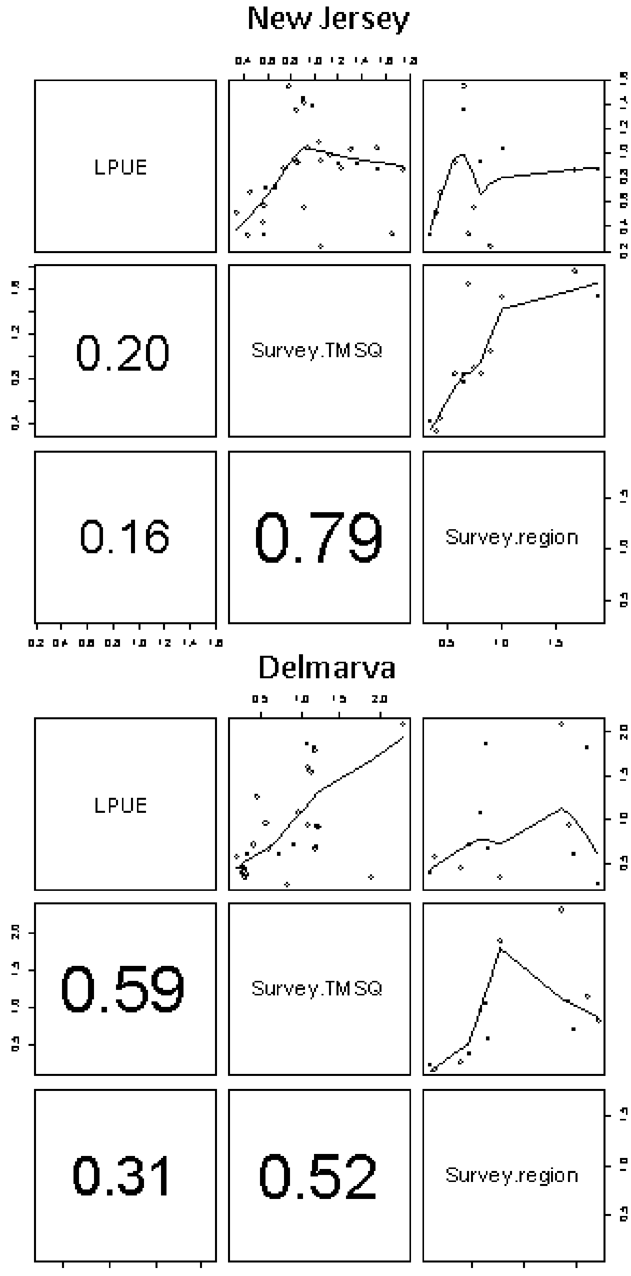

Figure 67: Relationships between LPUE and survey abundance trends for Atlantic surfclam during 1982-2011 in the New Jersey (top) and Delmarva (bottom) areas (rescaled for convenience in plotting). LPUE is commercial catch rates in important TNMS. Survey.TNMS is the survey trend in important TNMS. "Survey.region" is the survey trend for the entire region (all ten-minute squares). Scatter plots with smooth lines to show trends are above the diagonal in each panel and correlation statistics are below the diagonal.

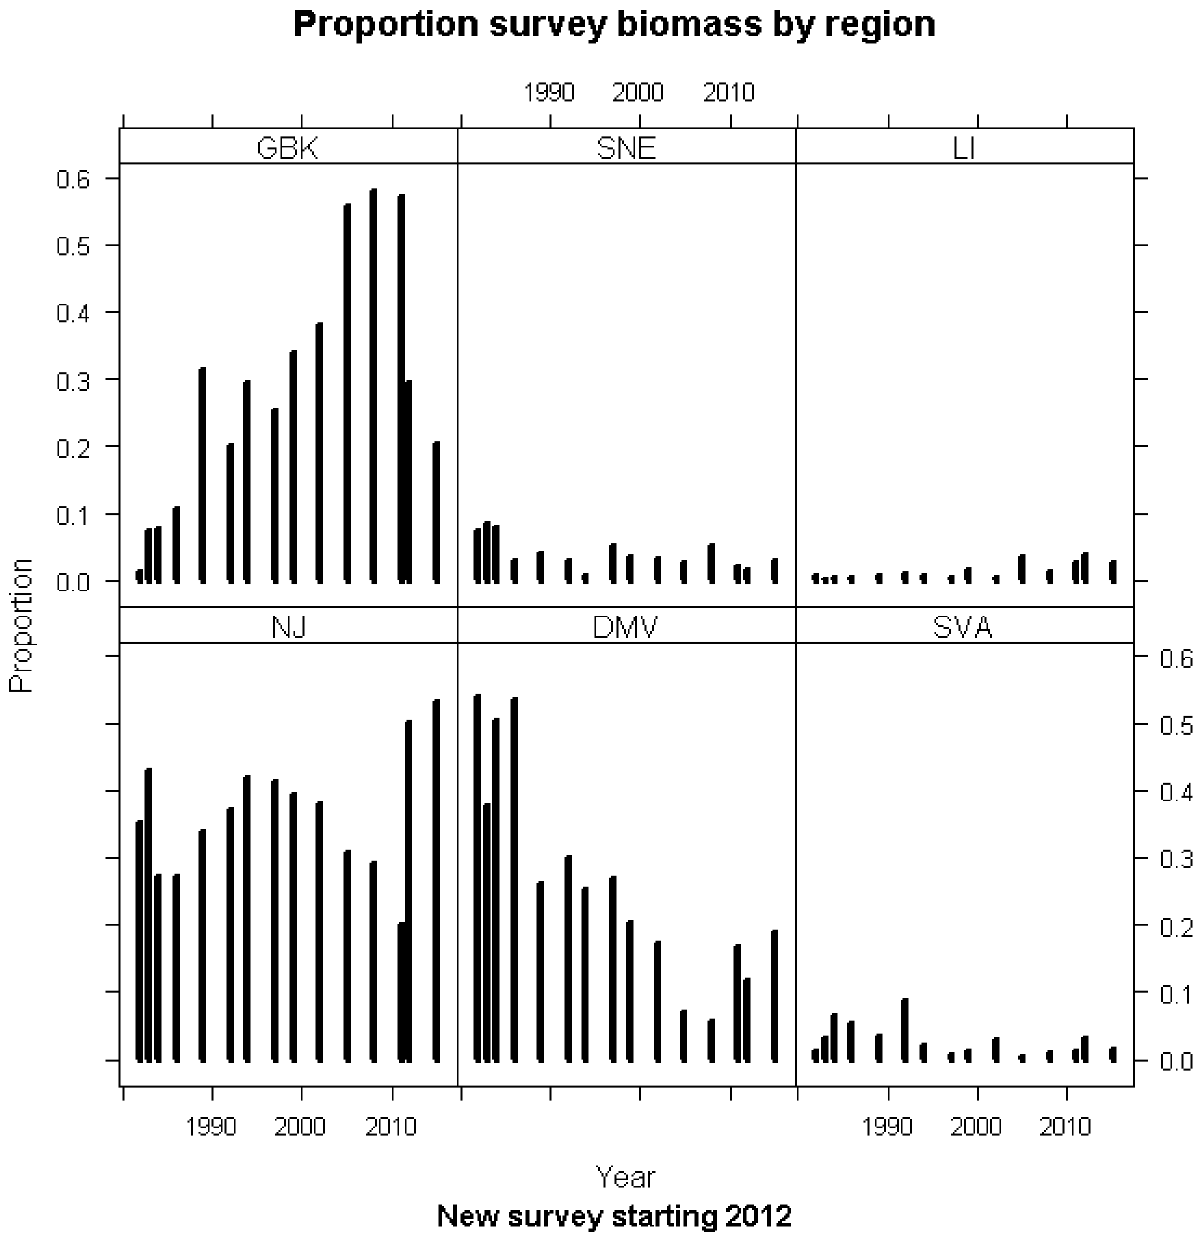

Figure 68: Proportions of relative survey biomass for surfclams by region during 1982-2015. For example, the proportion of total biomass on GBK during 2015 is about 20% and the sum of values plotted for 2015 in all regions is 100%. Estimates for 1982-2011 may not be comparable to estimates for 2012-2015 because a new survey using a different vessel, gear, etc. started in 2012.

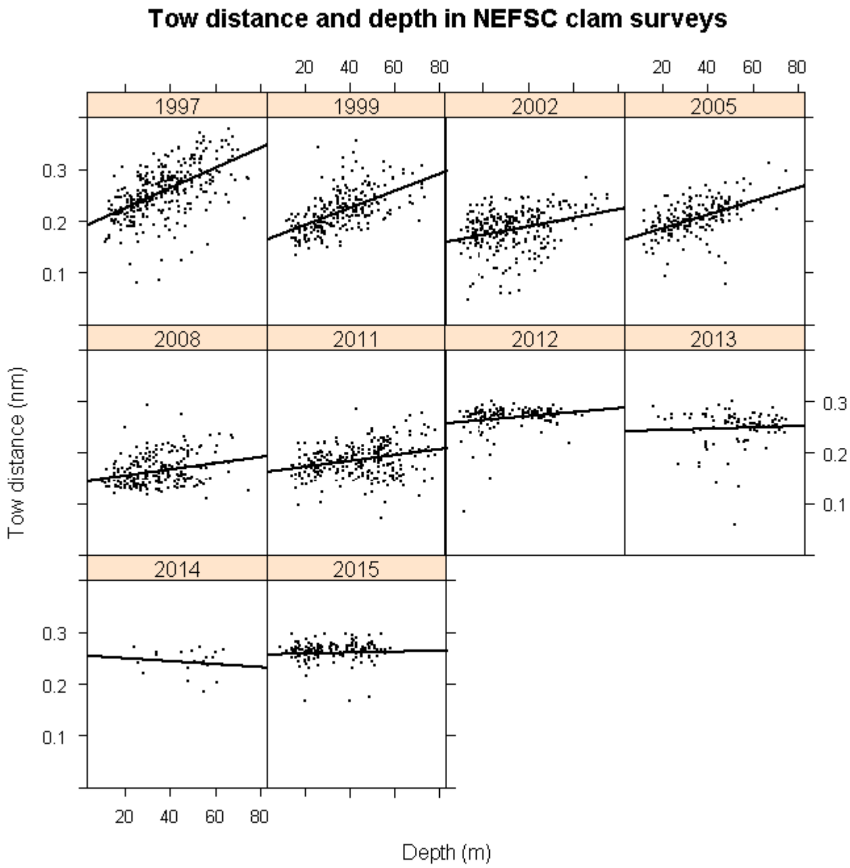

Figure 69: Relationships between tow depth and tow distance from inclinometer measurements in NEFSC clam surveys during 2007-2011 (RD) and 2012-2015 (MCD).

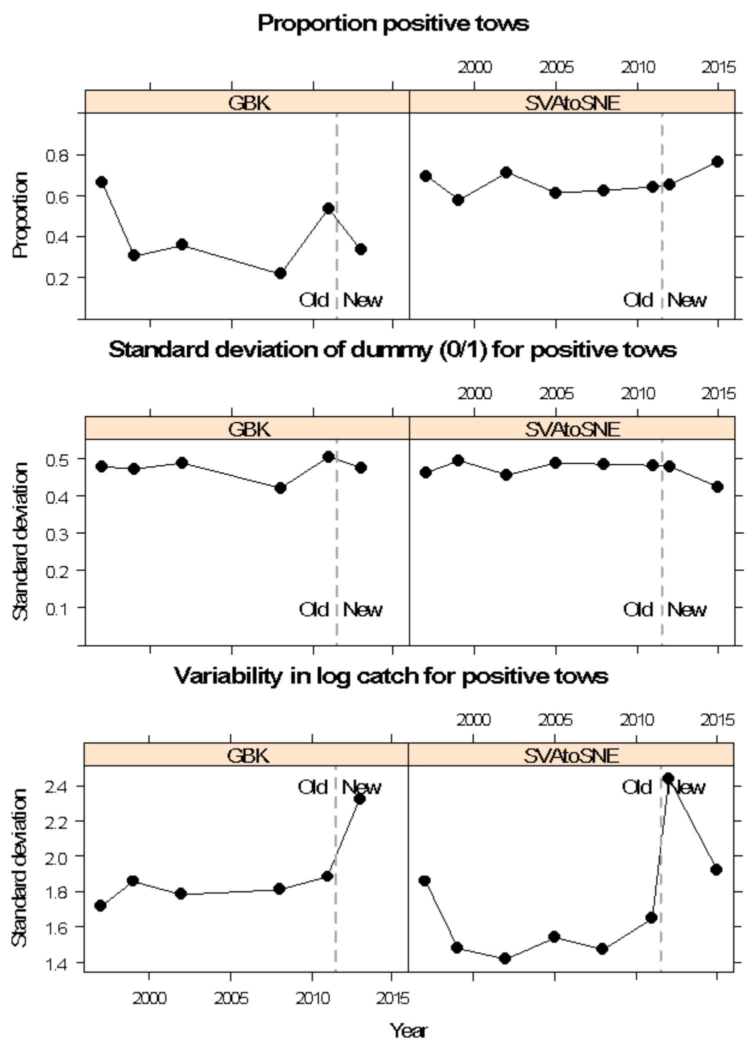

Figure 70: Trends in proportion positive tows (top), the standard deviation of a dummy variable that identifies positive tows (=0 if Atlantic surfclam catch was zero and 1 otherwise), and the standard deviation of log transformed catches (positive tows only) for Atlantic surfclam in NEFSC clam surveys during 1997-2015.

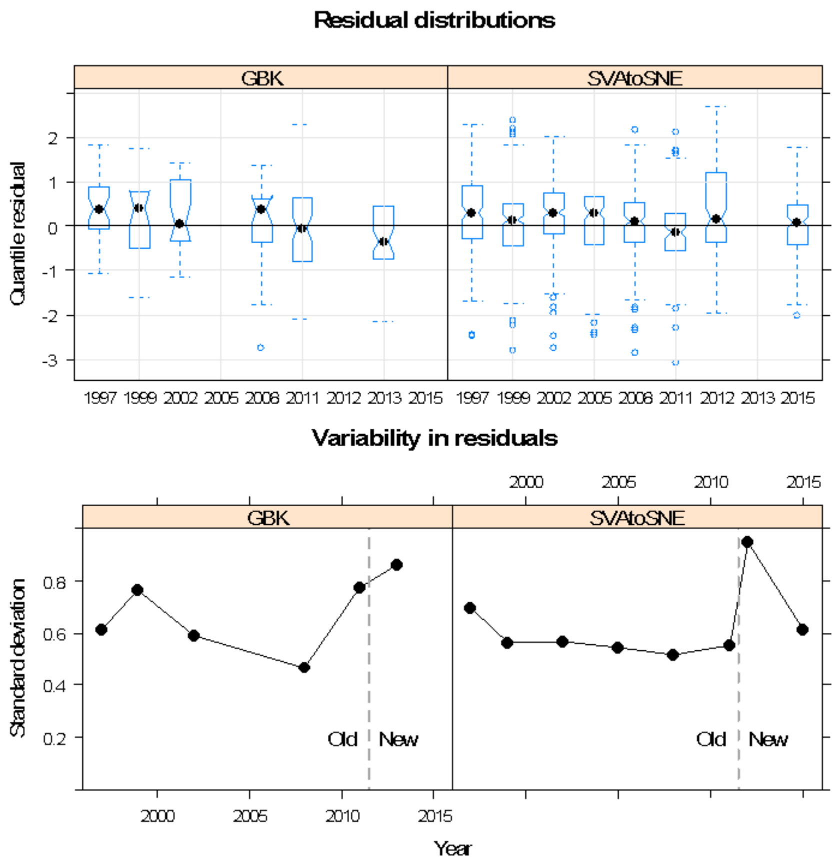

Figure 71: Top, distributions of randomized quantile residuals from the best GAM model (Tweedie family) fit to consistently sampled NEFSC clam survey strata. Bottom: standard deviations for residual distributions in top panel.

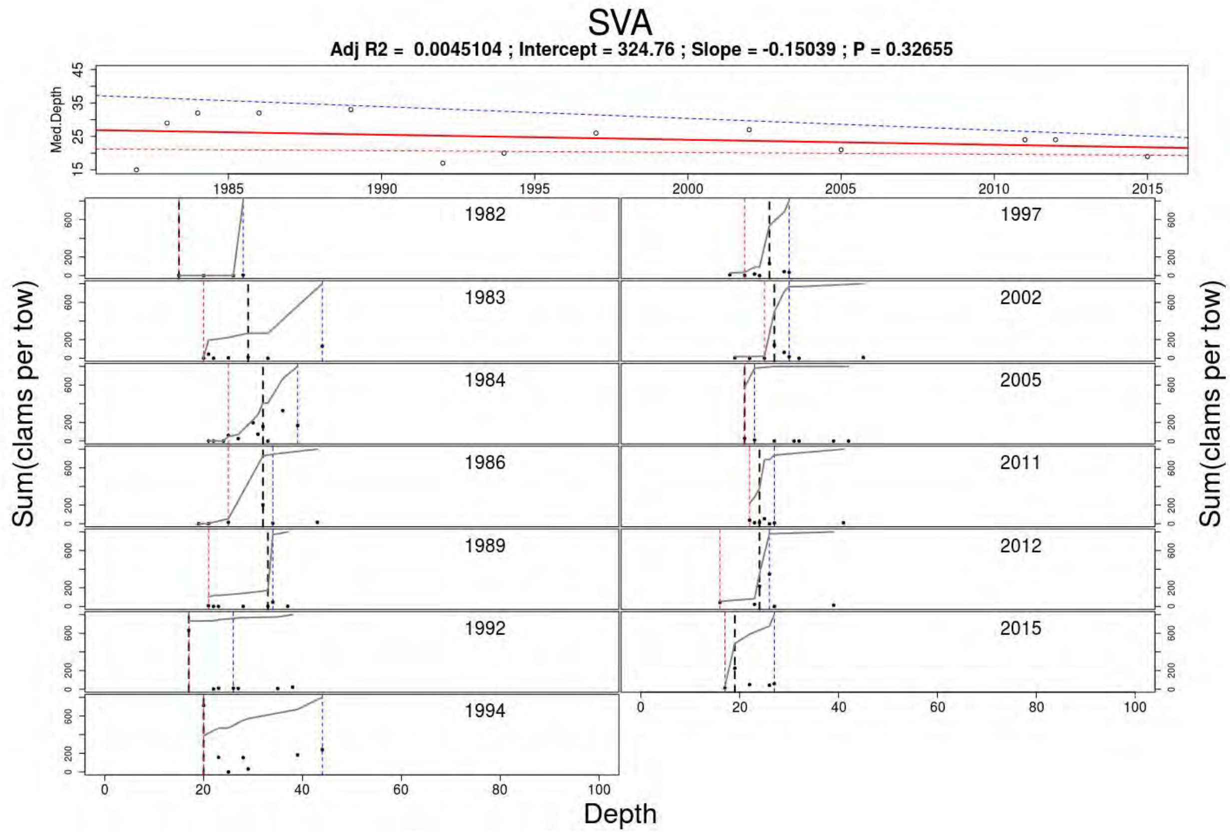

Figure 72: Total surfclams caught at depth by year in SVA. The points are clams caught aggregated by depth and the gray line is the cummulative sum of clams caught at depth. The dashed vertical line is the depth at which half of the cummulative total clams caught in that survey were taken. If the dashed vertical line is further to the right it indicates that more clams were caught in deeper water in that year. The top panel is a simple linear regression of median depth (the dashed vertical lines in each annual plot) over time. A positive slope indicates that a higher proportion of the total clams in a region were caught in deeper water in recent years. Inshore (shallow) strata were not well sampled in recent years and were excluded from this analysis

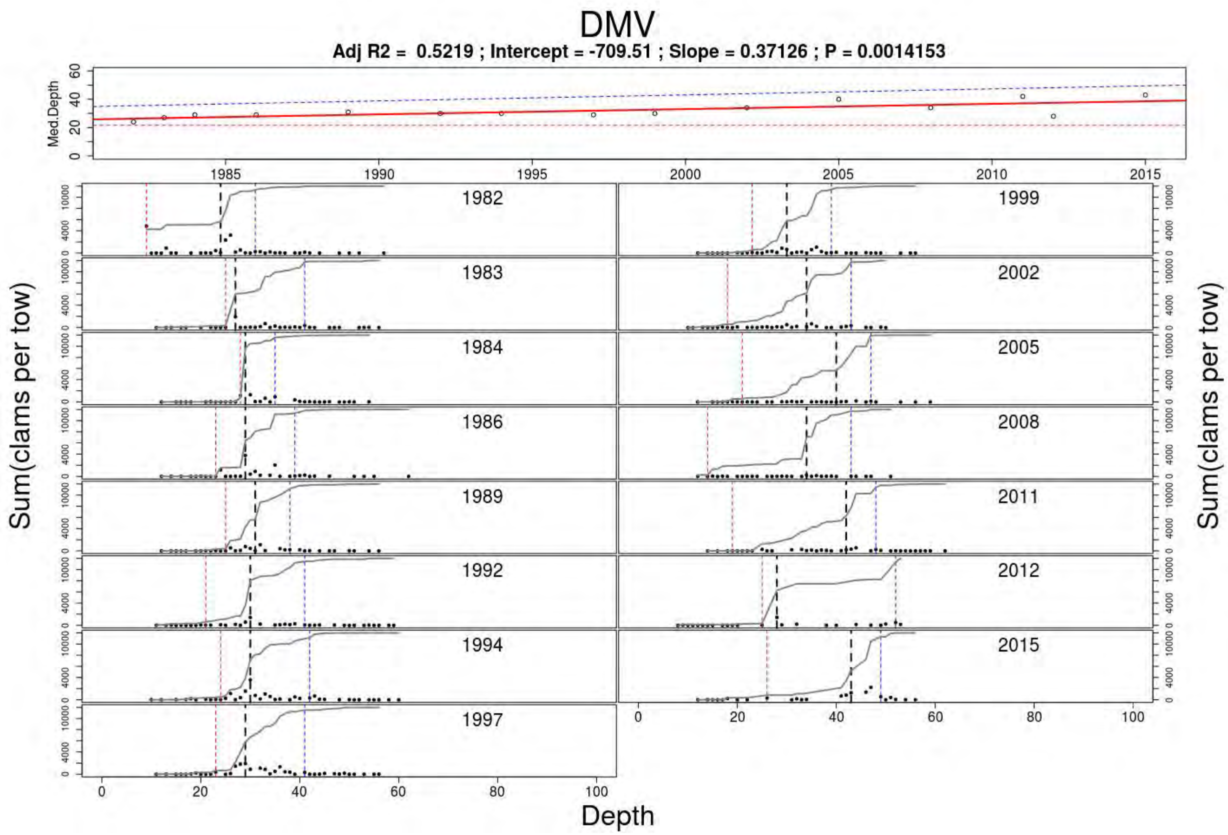

Figure 73: Total surfclams caught at depth by year in DMV. The points are clams caught aggregated by depth and the gray line is the cummulative sum of clams caught at depth. The dashed vertical line is the depth at which half of the cummulative total clams caught in that survey were taken. If the dashed vertical line is further to the right it indicates that more clams were caught in deeper water in that year. The top panel is a simple linear regression of median depth (the dashed vertical lines in each annual plot) over time. A positive slope indicates that a higher proportion of the total clams in a region were caught in deeper water in recent years. Inshore (shallow) strata were not well sampled in recent years and were excluded from this analysis

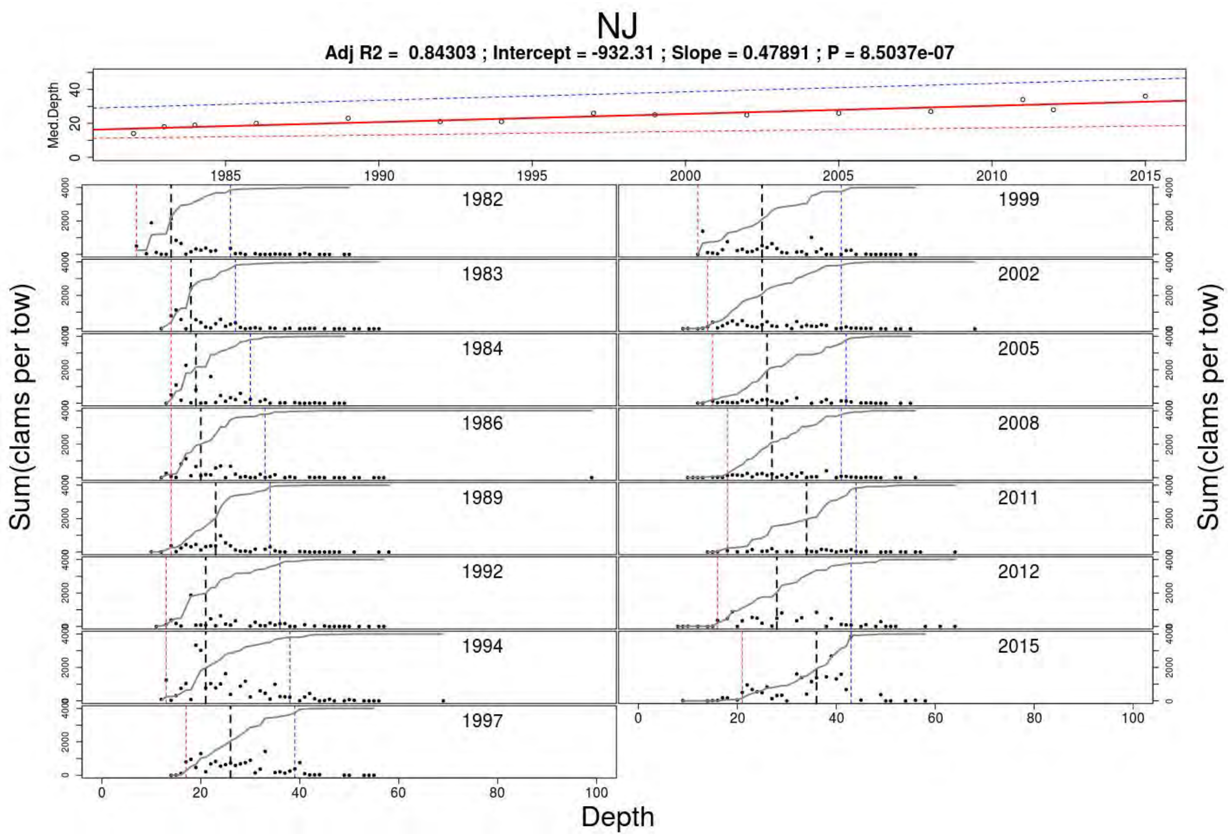

Figure 74: Total surfclams caught at depth by year in NJ. The points are clams caught aggregated by depth and the gray line is the cummulative sum of clams caught at depth. The dashed vertical line is the depth at which half of the cummulative total clams caught in that survey were taken. If the dashed vertical line is further to the right it indicates that more clams were caught in deeper water in that year. The top panel is a simple linear regression of median depth (the dashed vertical lines in each annual plot) over time. A positive slope indicates that a higher proportion of the total clams in a region were caught in deeper water in recent years.

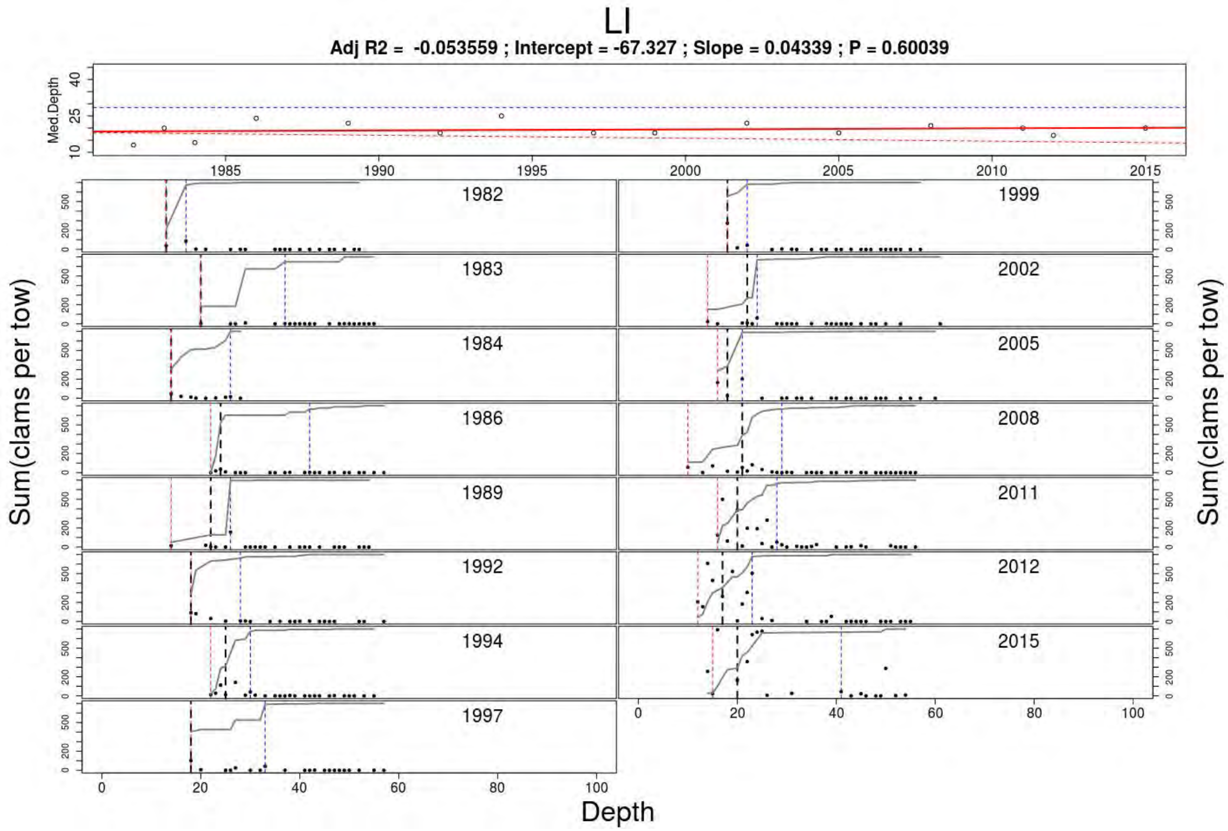

Figure 75: Total surfclams caught at depth by year in LI. The points are clams caught aggregated by depth and the gray line is the cummulative sum of clams caught at depth. The dashed vertical line is the depth at which half of the cummulative total clams caught in that survey were taken. If the dashed vertical line is further to the right it indicates that more clams were caught in deeper water in that year. The top panel is a simple linear regression of median depth (the dashed vertical lines in each annual plot) over time. A positive slope indicates that a higher proportion of the total clams in a region were caught in deeper water in recent years.

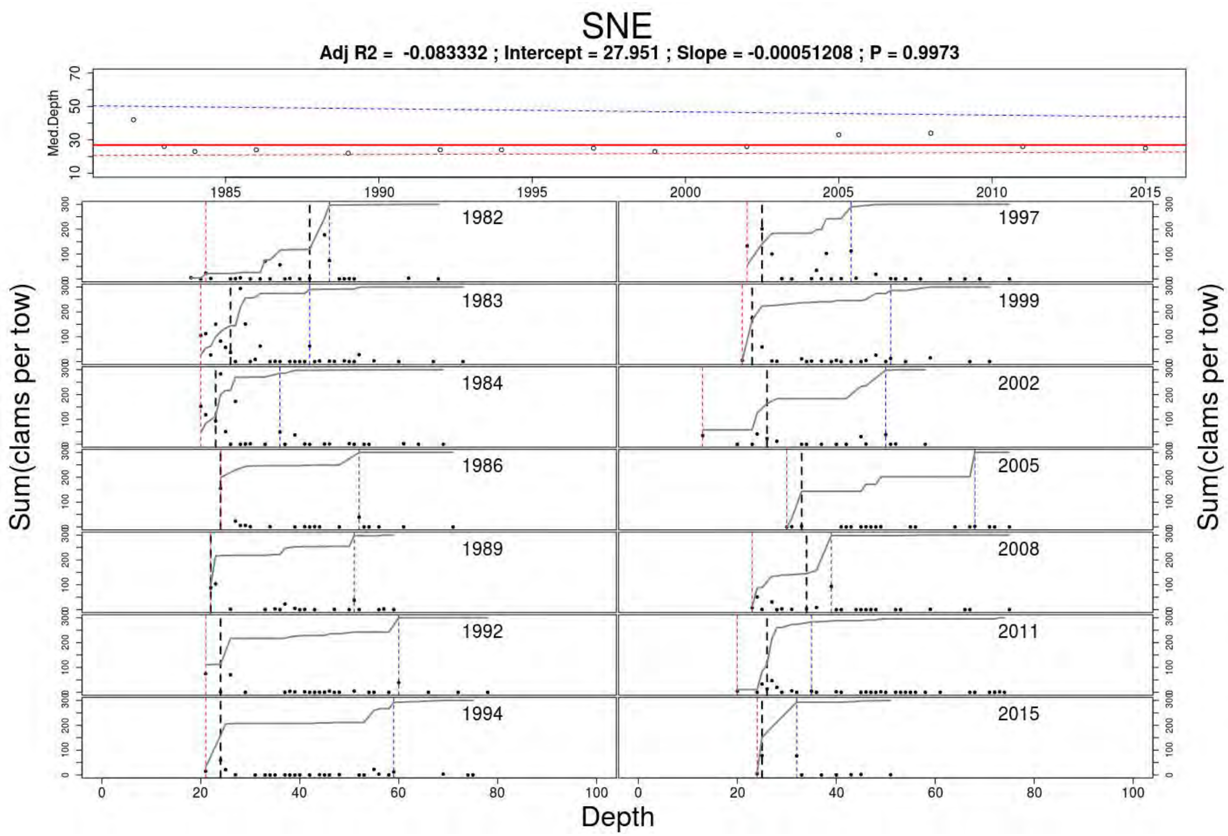

Figure 76: Total surfclams caught at depth by year in SNE. The points are clams caught aggregated by depth and the gray line is the cummulative sum of clams caught at depth. The dashed vertical line is the depth at which half of the cummulative total clams caught in that survey were taken. If the dashed vertical line is further to the right it indicates that more clams were caught in deeper water in that year. The top panel is a simple linear regression of median depth (the dashed vertical lines in each annual plot) over time. A positive slope indicates that a higher proportion of the total clams in a region were caught in deeper water in recent years.

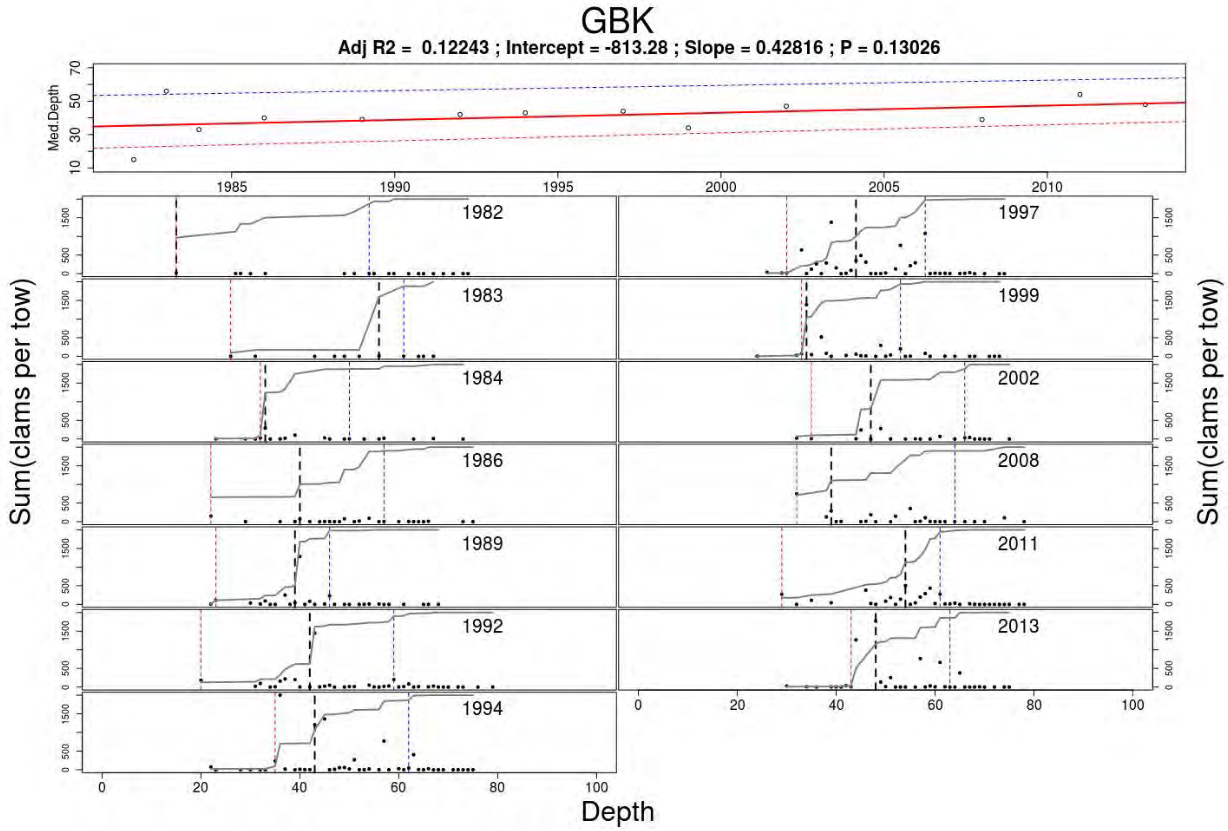

Figure 77: Total surfclams caught at depth by year in GBK. The points are clams caught aggregated by depth and the gray line is the cummulative sum of clams caught at depth. The dashed vertical line is the depth at which half of the cummulative total clams caught in that survey were taken. If the dashed vertical line is further to the right it indicates that more clams were caught in deeper water in that year. The top panel is a simple linear regression of median depth (the dashed vertical lines in each annual plot) over time. A positive slope indicates that a higher proportion of the total clams in a region were caught in deeper water in recent years.

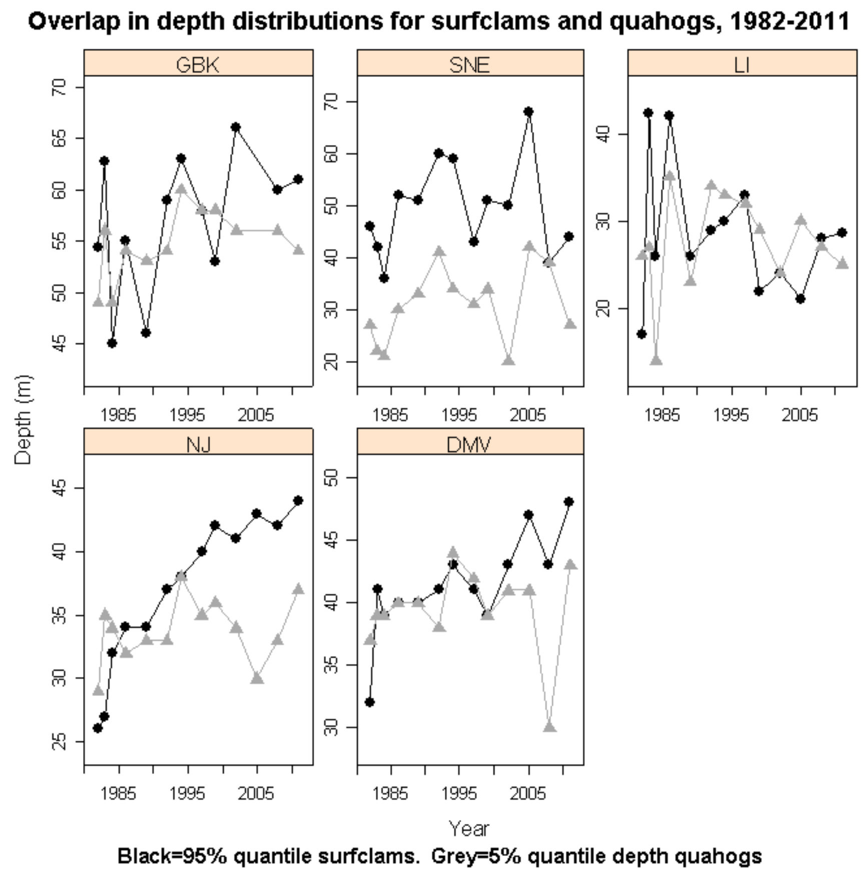

Figure 78: Trends in the offshore habitat boundary for Atlantic surfclam and the inshore habitat boundary for ocean quahog over time. The offshore boundary in each region is the 95% percentile for cumulative catch with depth in NEFSC clam surveys. The inshore habitat boundary for ocean quahogs is the 5% percentile for cumulative catch.

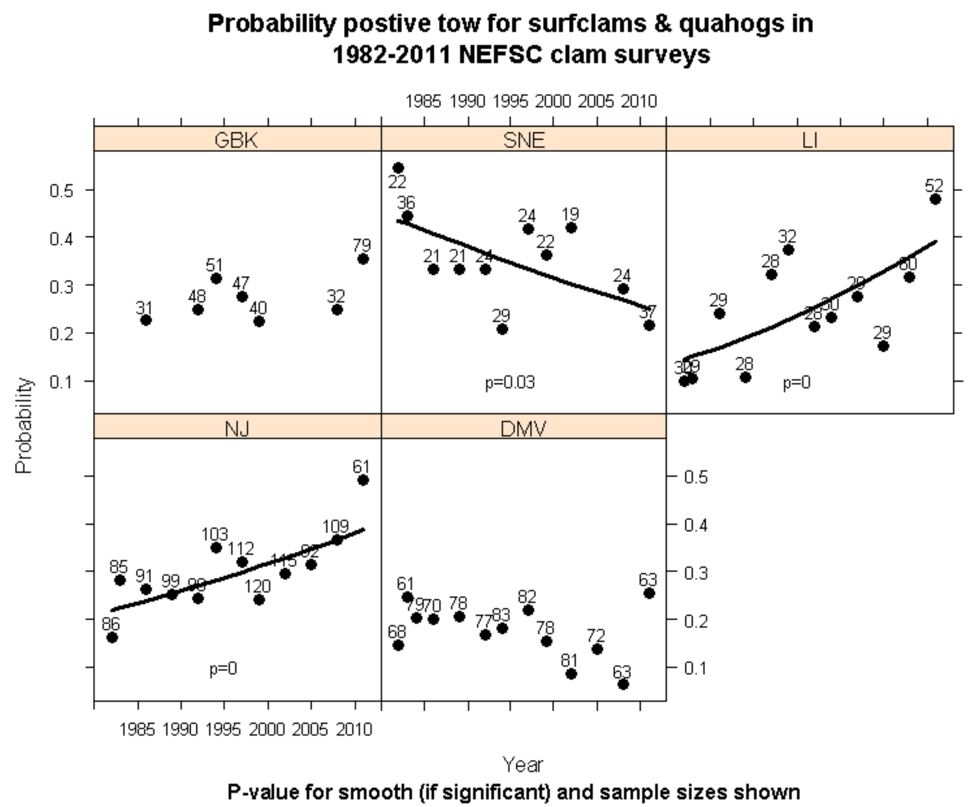

Figure 79: Probability that both Atlantic surfclam and ocean quahogs were taken in the same tow during 1982-2011 clam surveys in consistently sampled strata. Logistic regression lines and p-values are shown if the trend was statistically significant ($p < 0.1$).

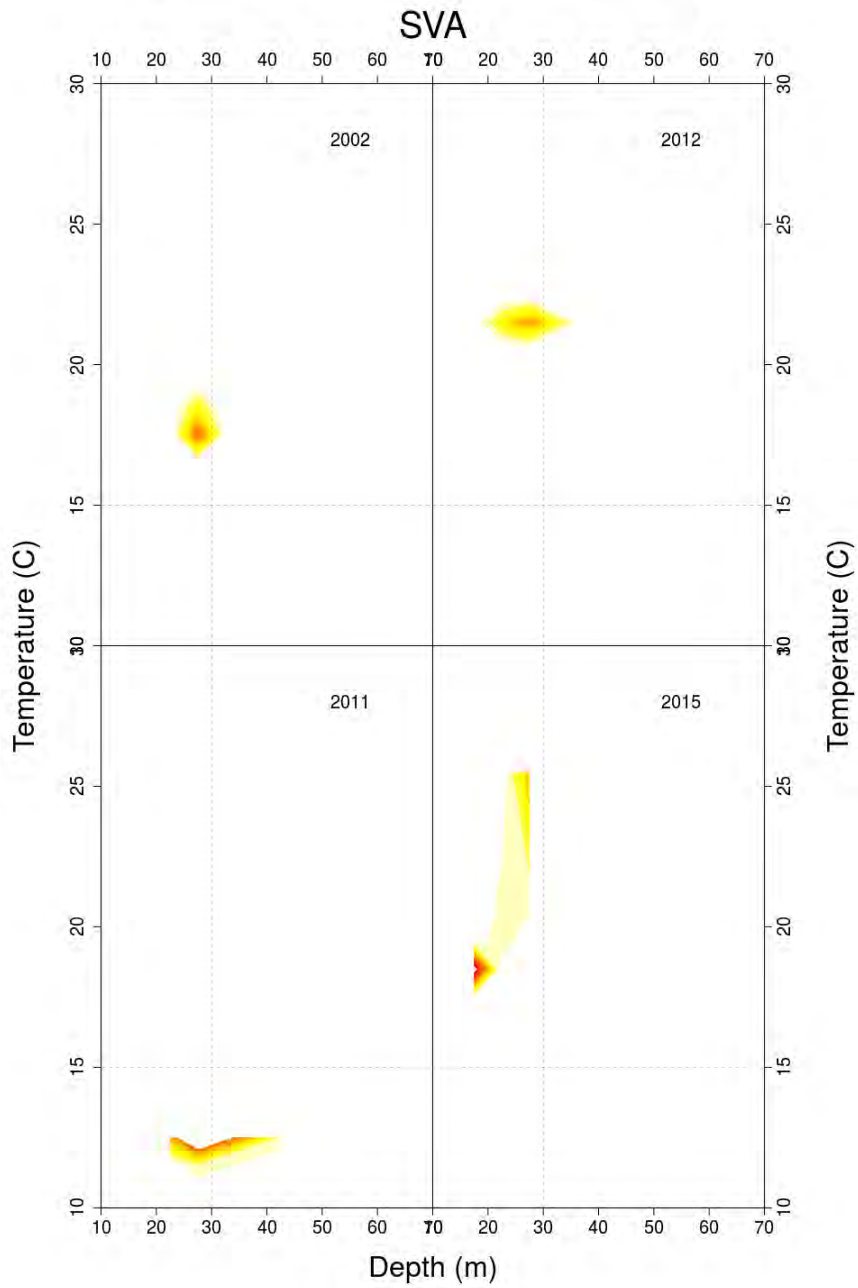

Figure 80: Total surfclams caught in the NEFSC clam survey at depth and temperature by year in SVA. Warmer colors in the contour represent larger catches. Catches are relative within each year and colors are not compareable across years. The dashed lines are drawn at 15° C and 30 m depth are for reference only.

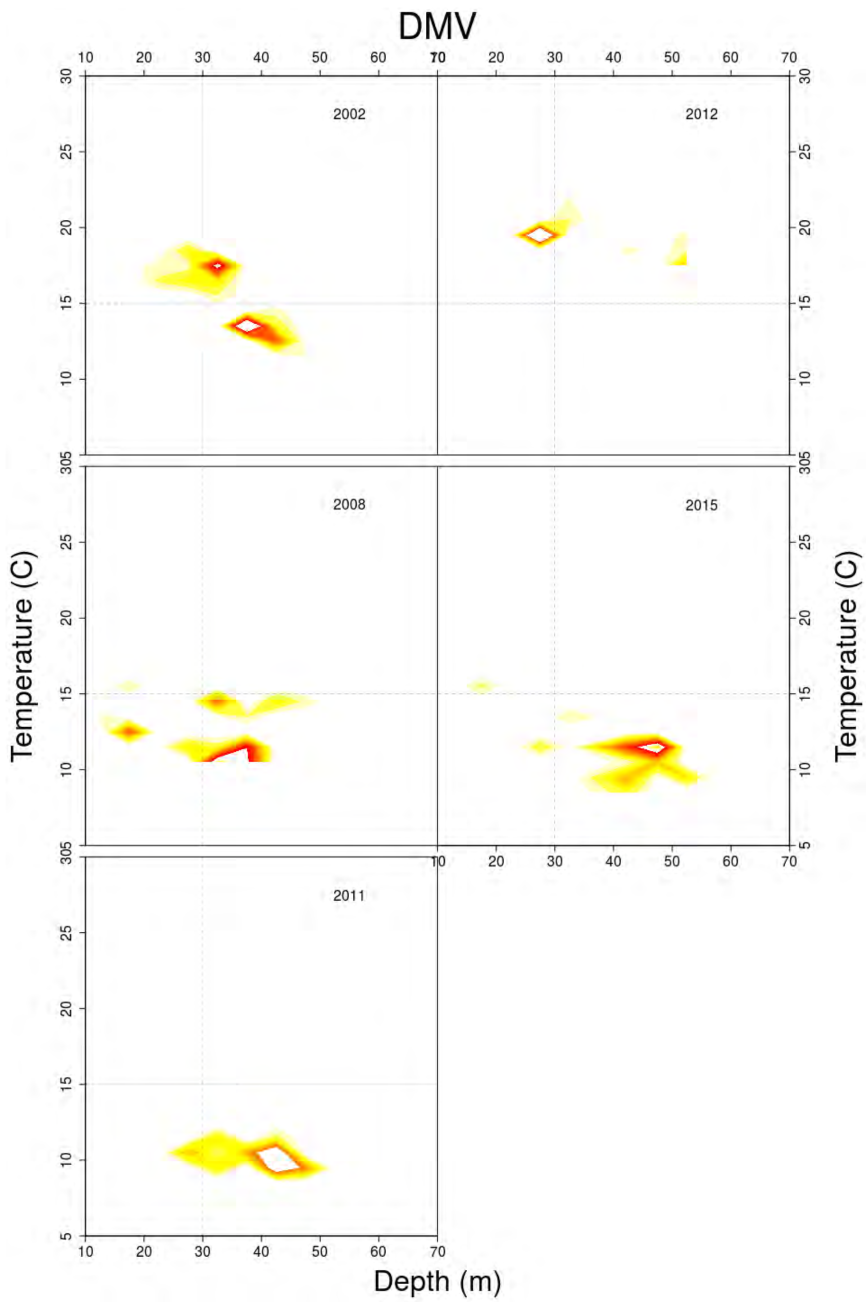

Figure 81: Total surfclams caught in the NEFSC clam survey at depth and temperature by year in DMV. Warmer colors in the contour represent larger catches. Catches are relative within each year and colors are not compareable across years. The dashed lines are drawn at $15°$ C and 30 m depth are for reference only.

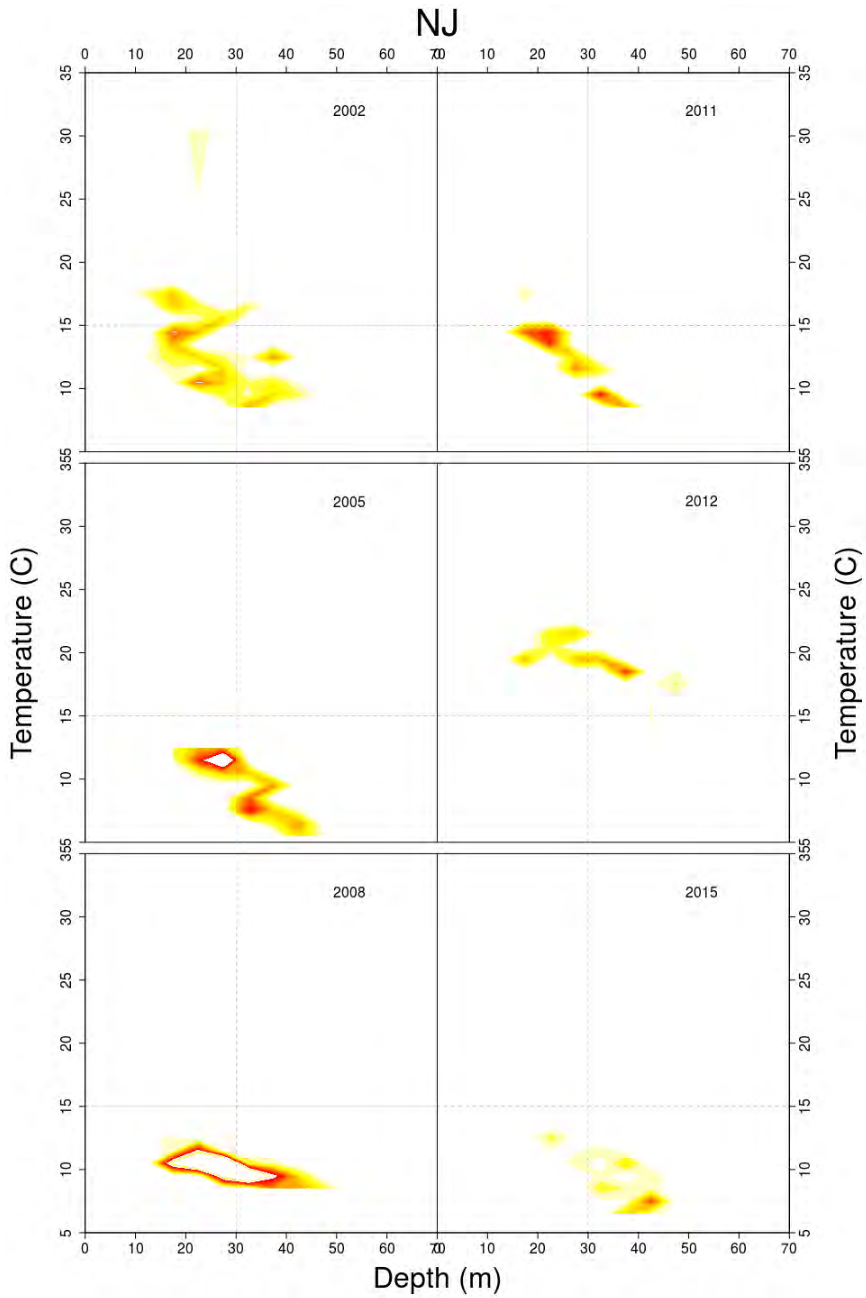

Figure 82: Total surfclams caught in the NEFSC clam survey at depth and temperature by year in NJ. Warmer colors in the contour represent larger catches. Catches are relative within each year and colors are not compareable across years. The dashed lines are drawn at 15° C and 30 m depth are for reference only.

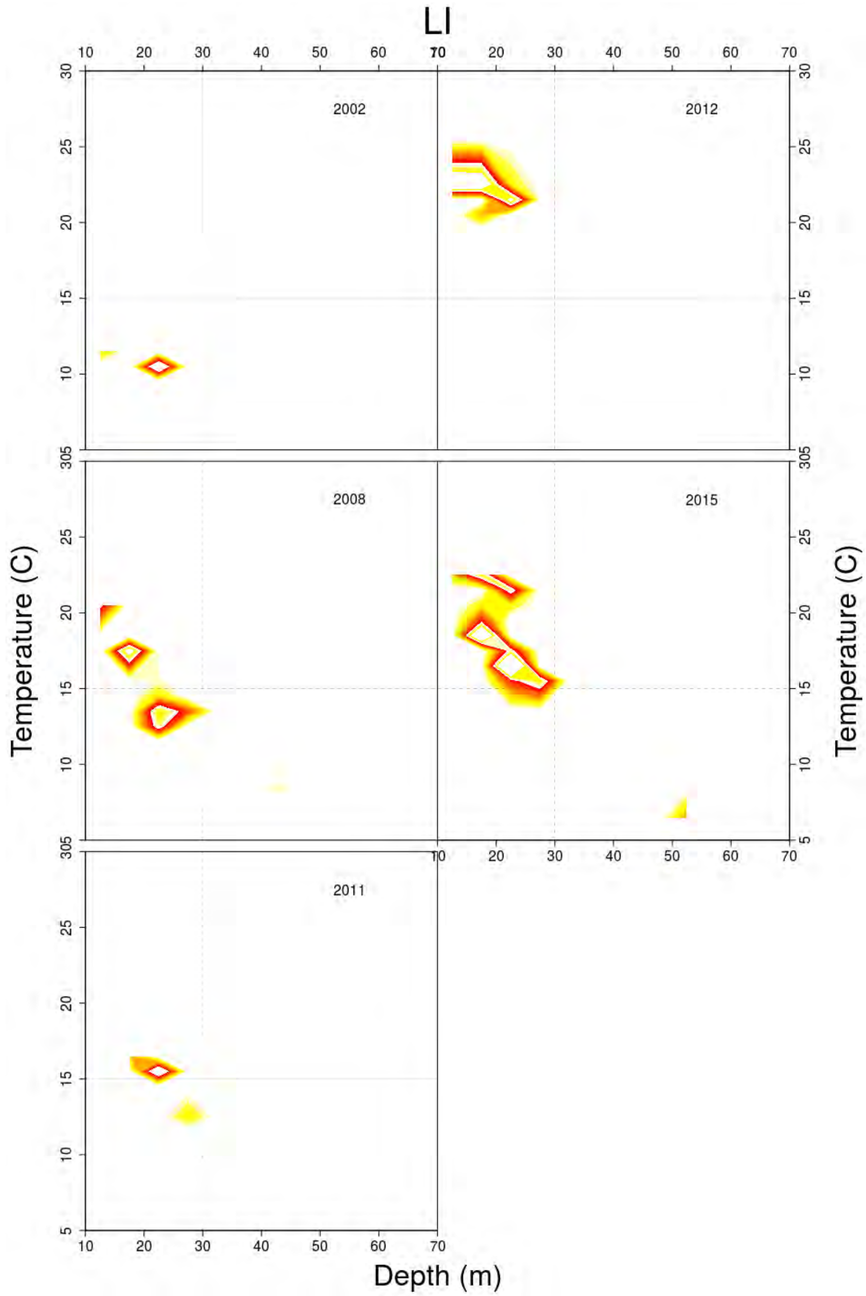

Figure 83: Total surfclams caught in the NEFSC clam survey at depth and temperature by year in LI. Warmer colors in the contour represent larger catches. Catches are relative within each year and colors are not compareable across years. The dashed lines are drawn at $15°$ C and 30 m depth are for reference only.

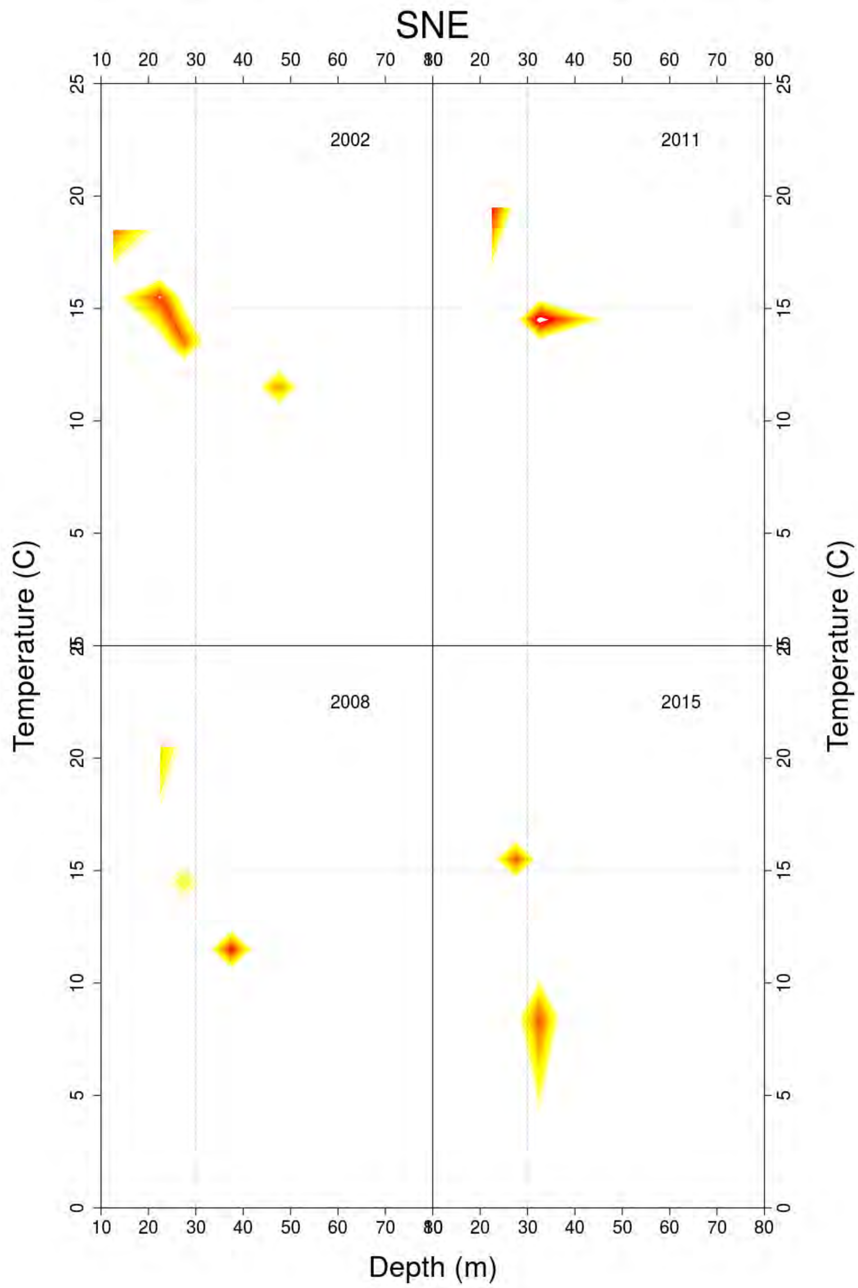

Figure 84: Total surfclams caught in the NEFSC clam survey at depth and temperature by year in SNE. Warmer colors in the contour represent larger catches. Catches are relative within each year and colors are not compareable across years. The dashed lines are drawn at 15° C and 30 m depth are for reference only.

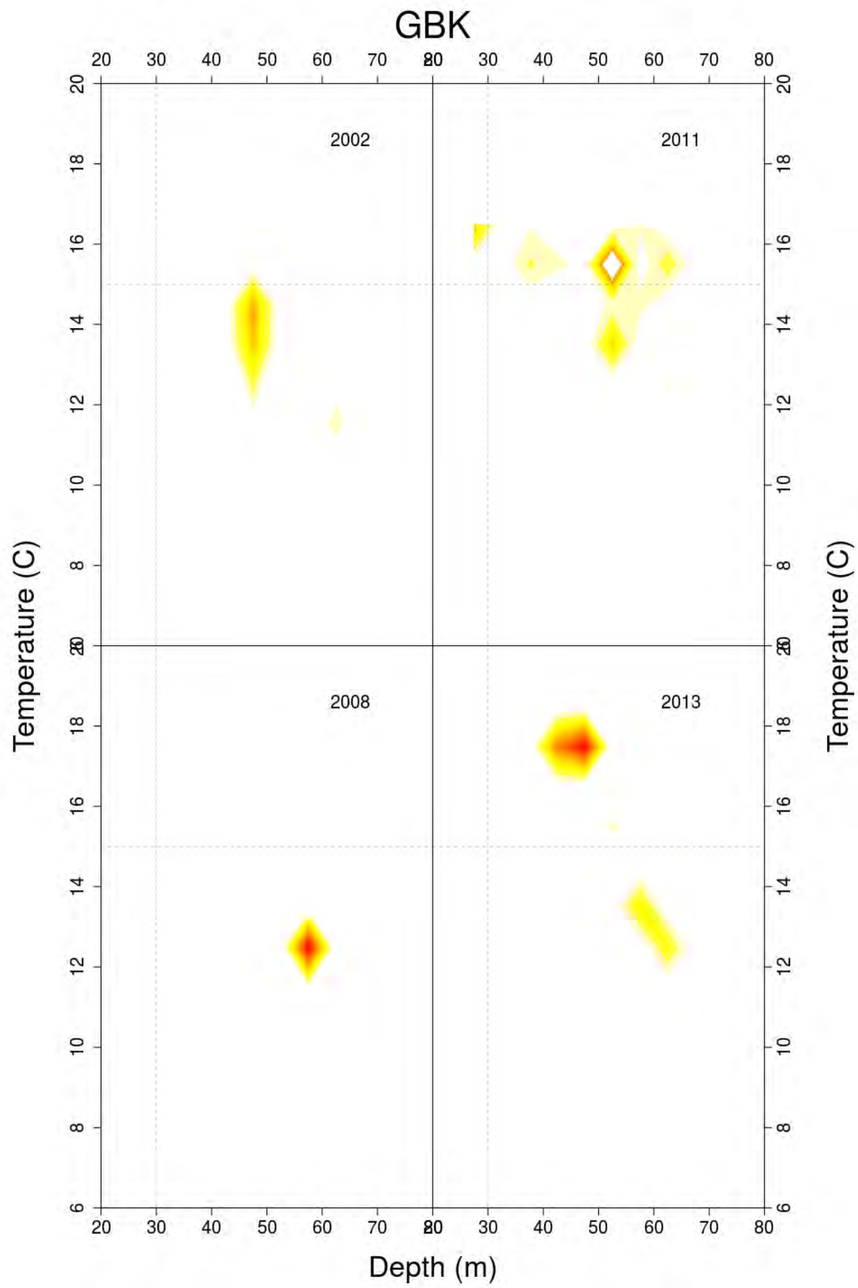

Figure 85: Total surfclams caught in the NEFSC clam survey at depth and temperature by year in GBK. Warmer colors in the contour represent larger catches. Catches are relative within each year and colors are not compareable across years. The dashed lines are drawn at 15° C and 30 m depth are for reference only.

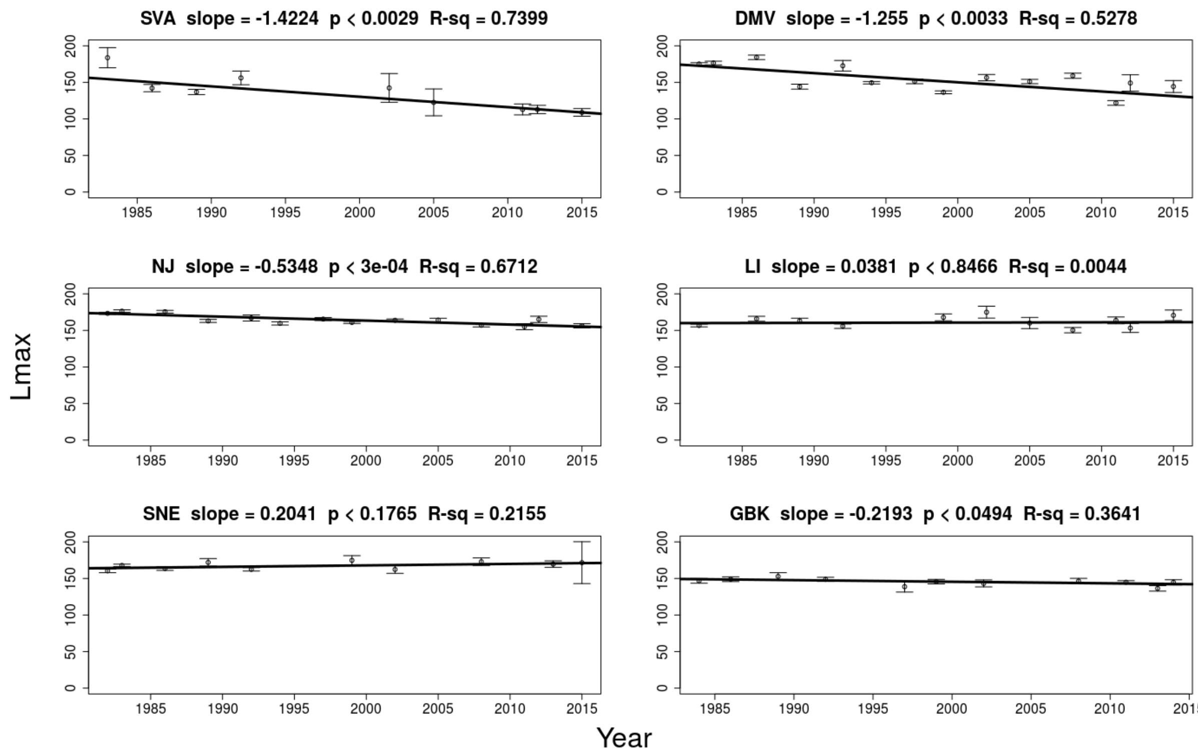

Figure 86: Estimated values of the parameter L_∞ for Atlantic surfclam in NEFSC clam surveys, over time in each region. The L_∞ values for each region were fit with an inverse variance weighted regression, and the slope, p-value and R^2 that result are shown above each plot.

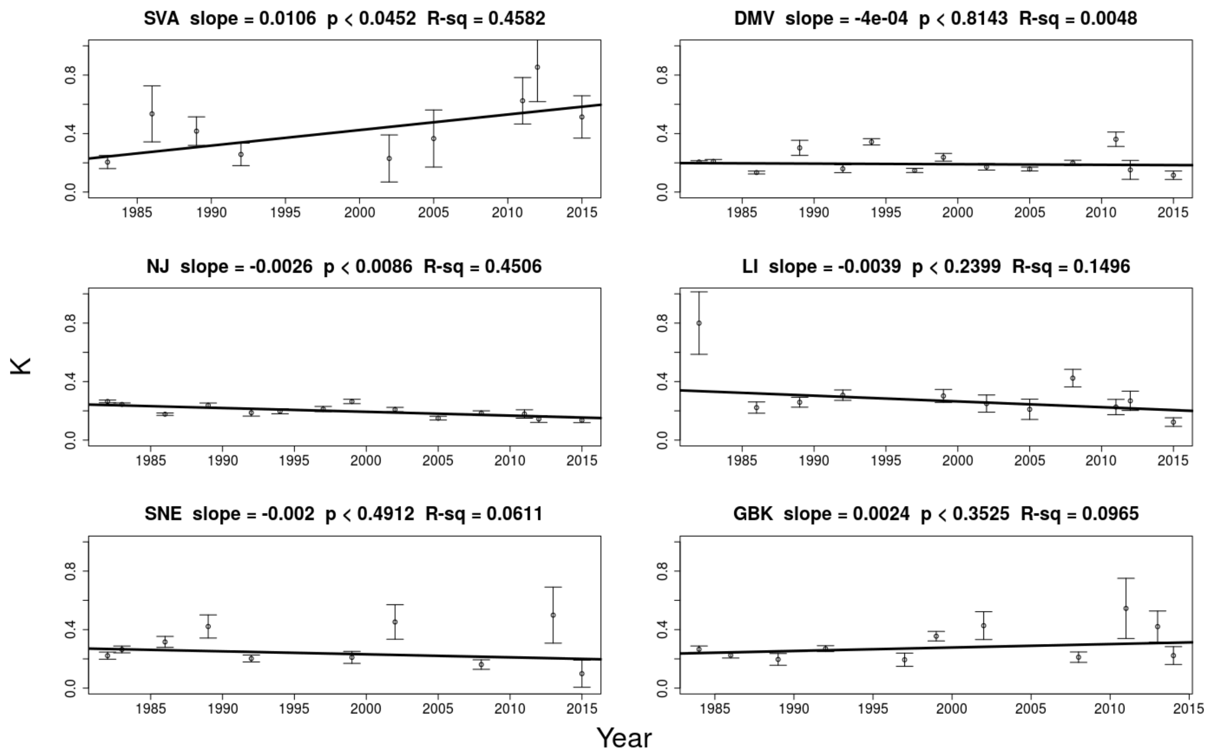

Figure 87: Estimated values of the parameter K for Atlantic surfclam in NEFSC clam surveys, over time in each region. The K values for each region were fit with an inverse variance weighted regression, and the slope, p-value and R^2 that result are shown above each plot.

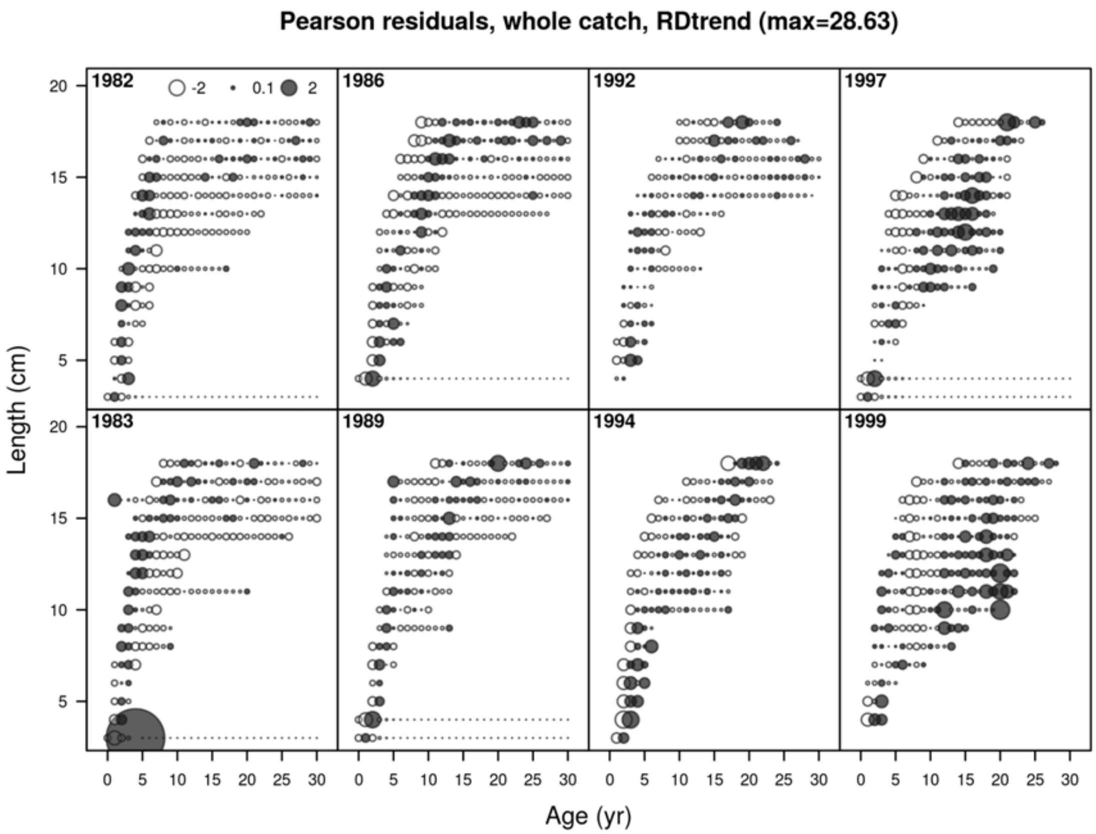

Figure 106: Pearson residuals from the fit to NEFSC survey (RD) conditional age at length composition data used in the assessment model for Atlantic surfclam in the southern area. Closed bubbles are positive residuals (observed > expected) and open bubbles are negative residuals (observed < expected).

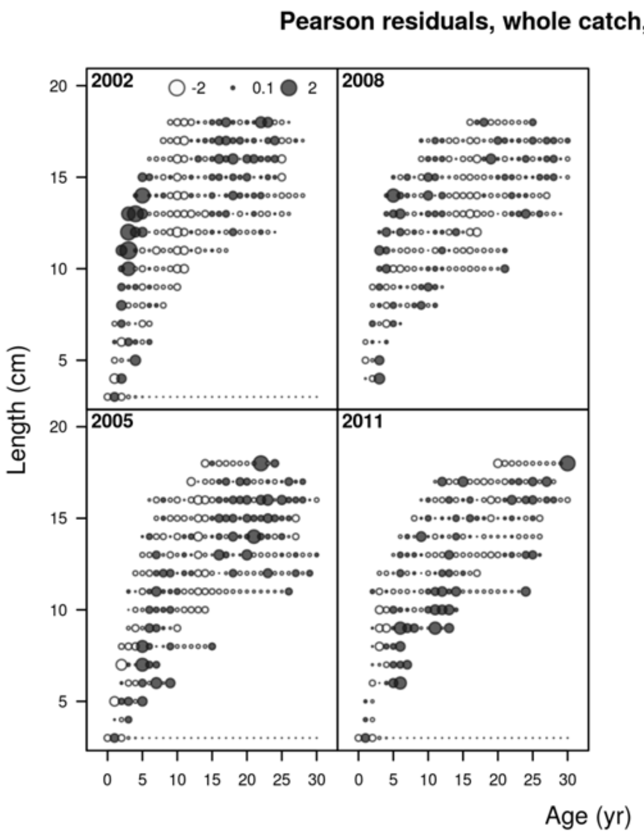

Figure 106 cont.

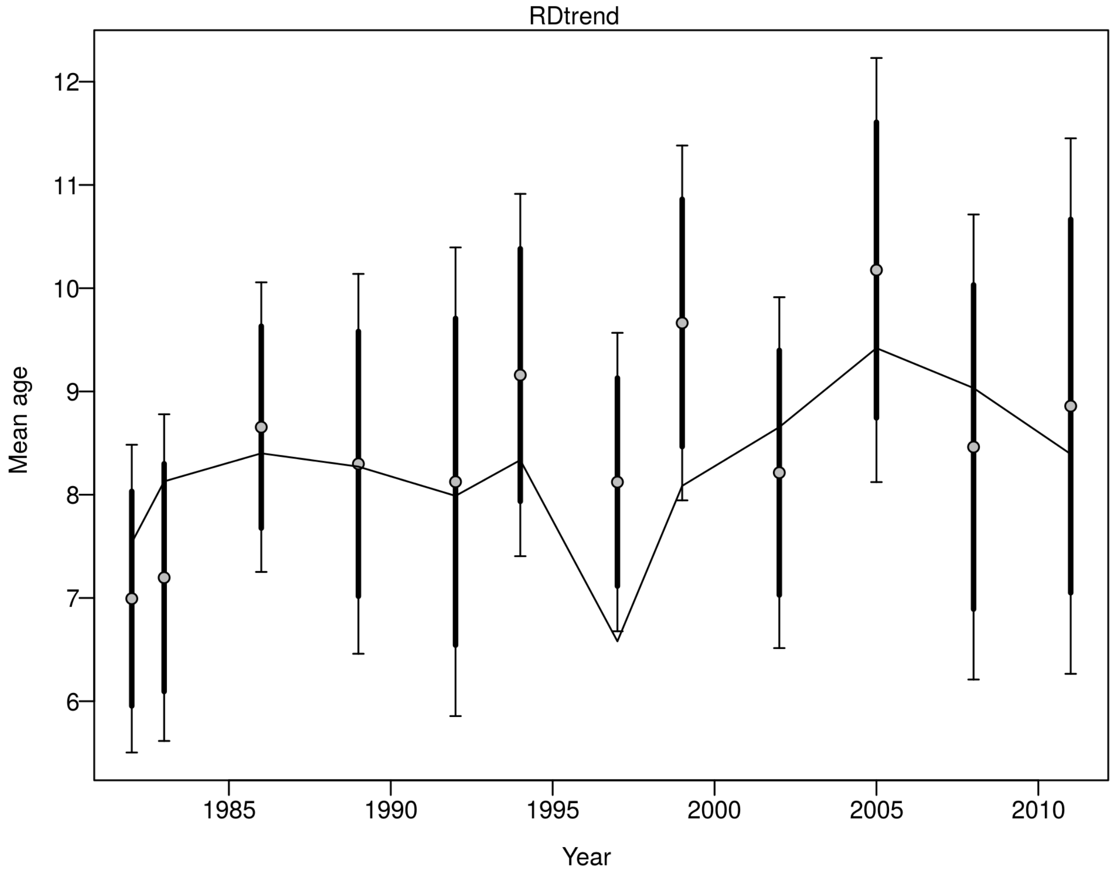

Figure 107: Observed mean age vs. the mean age predicted by the model based on fits to NEFSC survey (RD) age at length conditional composition data used in the assessment model for Atlantic surfclam in the southern area. The thicker vertical lines show the standard deviation of the observed data and the thinner lines show the standard deviation after accounting for the data weighting adjustments used in the model.

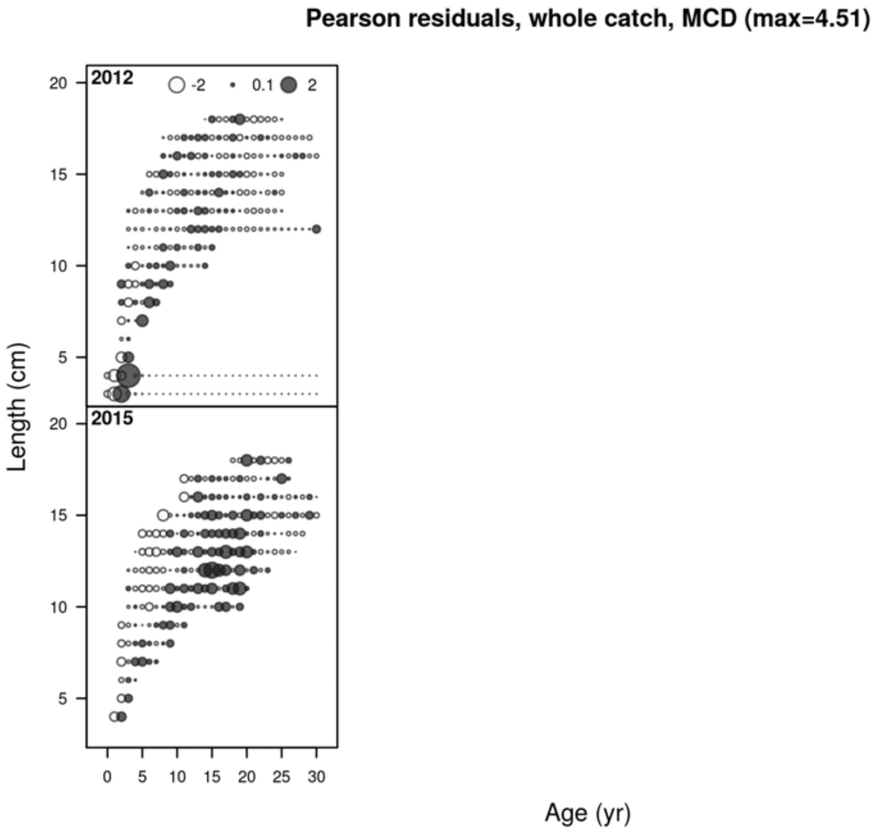

Figure 108: Pearson residuals from the fit to NEFSC survey (MCD) conditional age at length composition data used in the assessment model for Atlantic surfclam in the southern area. Closed bubbles are positive residuals (observed > expected) and open bubbles are negative residuals (observed < expected).

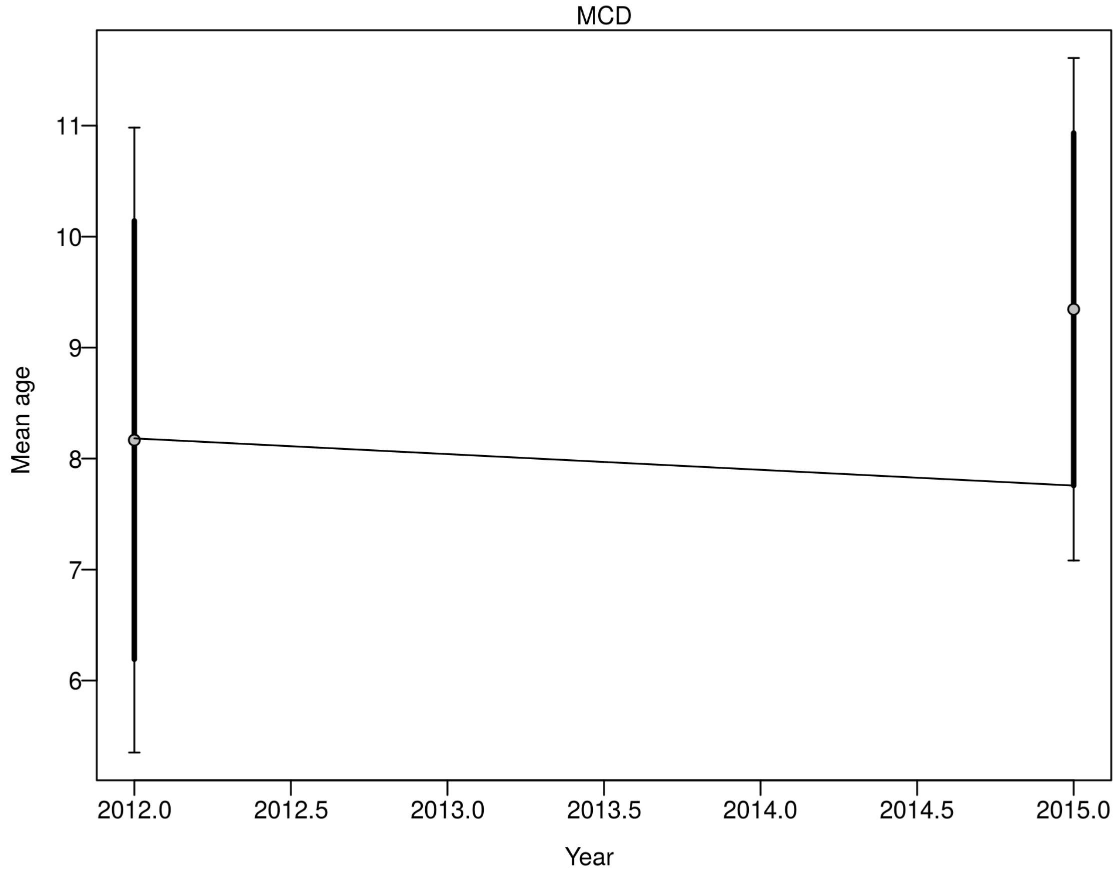

Figure 109: Observed mean age vs. the mean age predicted by the model based on fits to NEFSC survey (MCD) age at length conditional composition data used in the assessment model for Atlantic surfclam in the southern area. The thicker vertical lines show the standard deviation of the observed data and the thinner lines show the standard deviation after accounting for the data weighting adjustments used in the model.

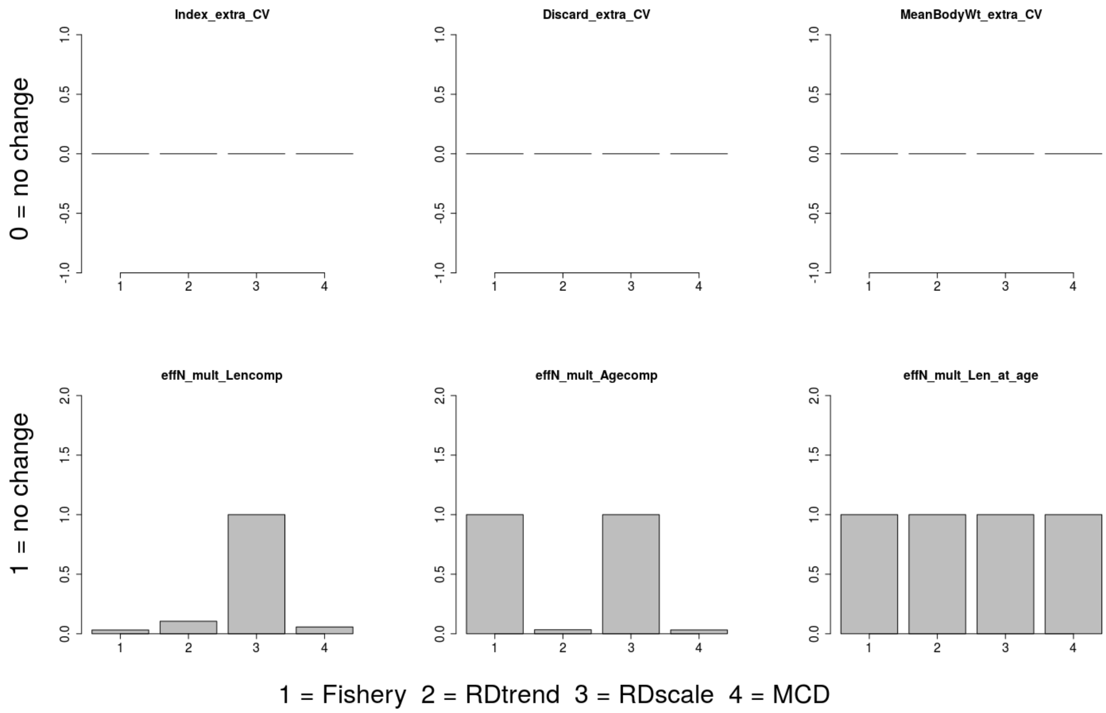

Figure 110: Adjustments made to variance components of model parameters used in the assessment model for Atlantic surfclam in the southern area. The bar plots reflect data weighting decisions. In the top row deviations from 0 are the amount added to the standard deviation around input parameters. In the bottom row, the value shown in the bar plot is multiplied by the input effective sample size associated with each composition component. Thus, for example a value of less than 1 represents a reduction in the relative weight of a component.

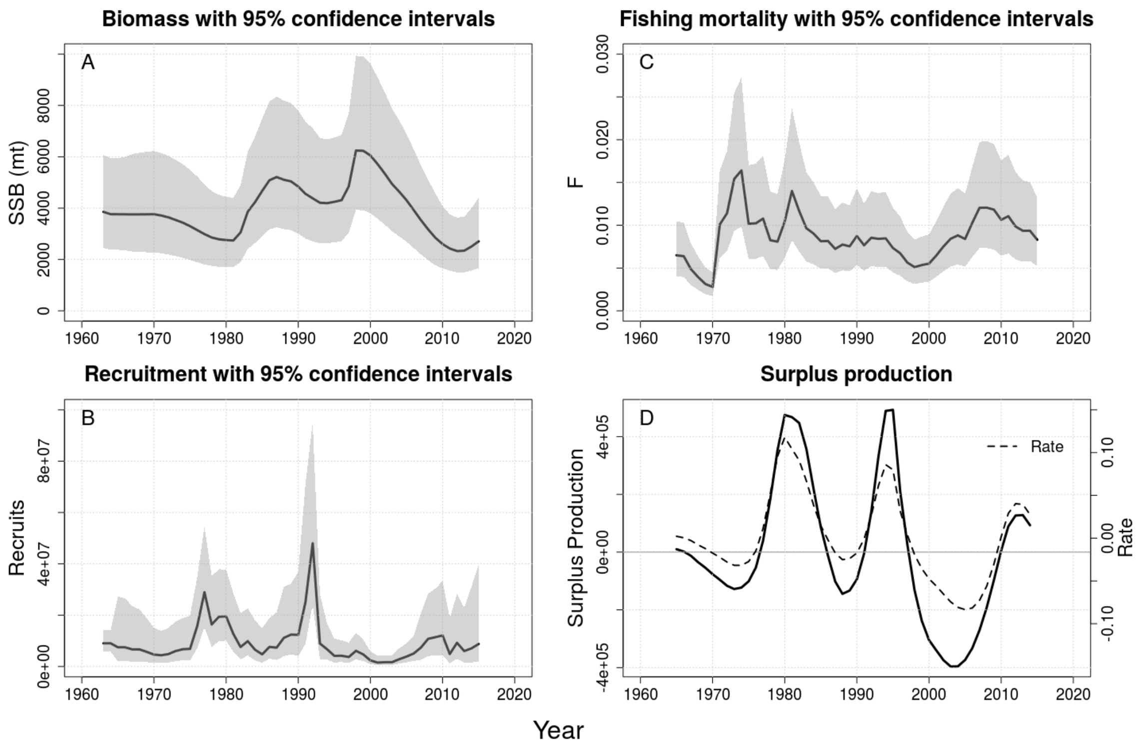

Figure 111: Estimated SSB and approximate 95% asymmetric confidence interval (A), estimated recruitment and approximate 95% asymmetric confidence interval (B), estimated fully selected fishing mortality and approximate 95% asymmetric confidence interval (C), and surplus production with surplus production rate (D), for the southern area.

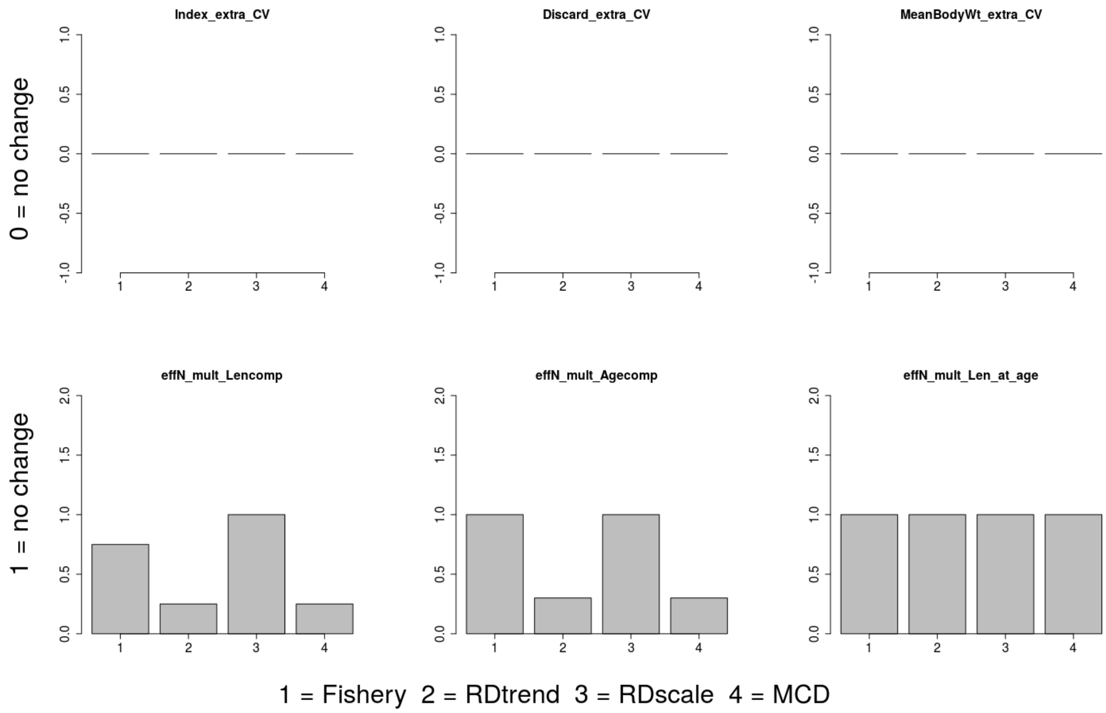

Figure 129: Adjustments made to variance components of model parameters used in the assessment model for Atlantic surfclam in the northern area. The bar plots reflect data weighting decisions. In the top row deviations from 0 are the amount added to the standard deviation around input parameters. In the bottom row, the value shown in the bar plot is multiplied by the input effective sample size associated with each composition component. Thus, for example a value of less than 1 represents a reduction in the relative weight of a component.

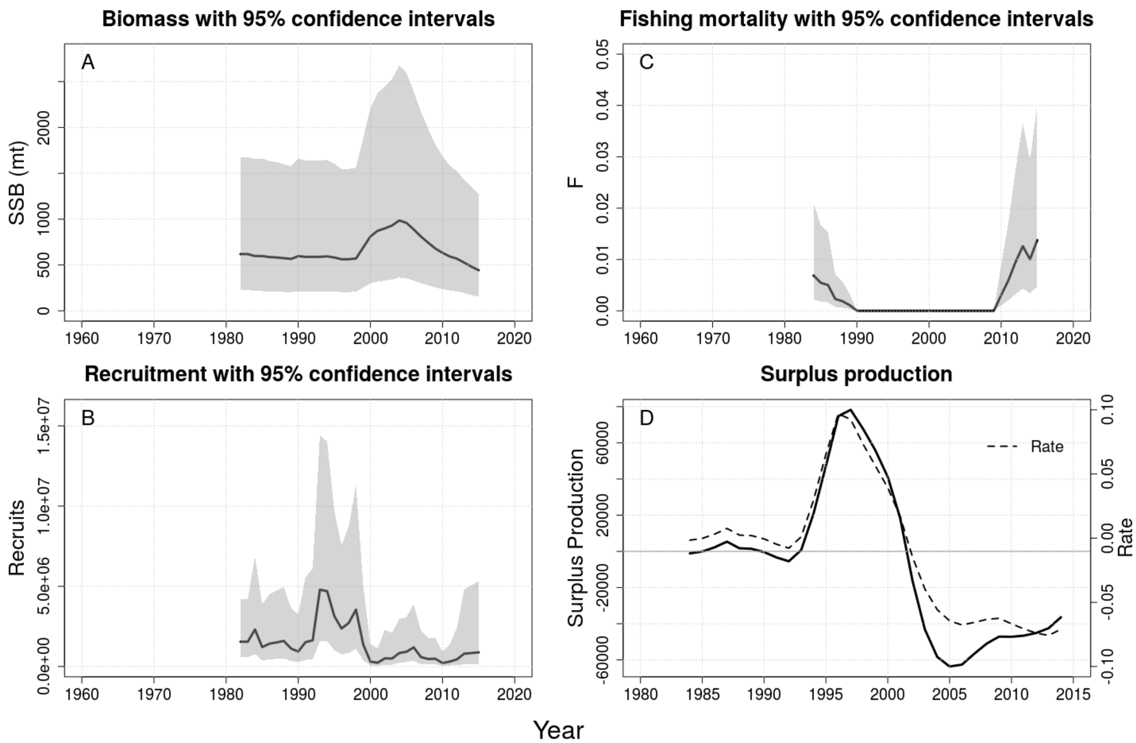

Figure 130: Estimated summary biomass and approximate 95% asymmetric confidence interval (A), estimated recruitment and approximate 95% asymmetric confidence interval (B), estimated fully selected fishing mortality and approximate 95% asymmetric confidence interval (C), and surplus production with surplus production rate (D), for Atlantic surfclam in the northern area.

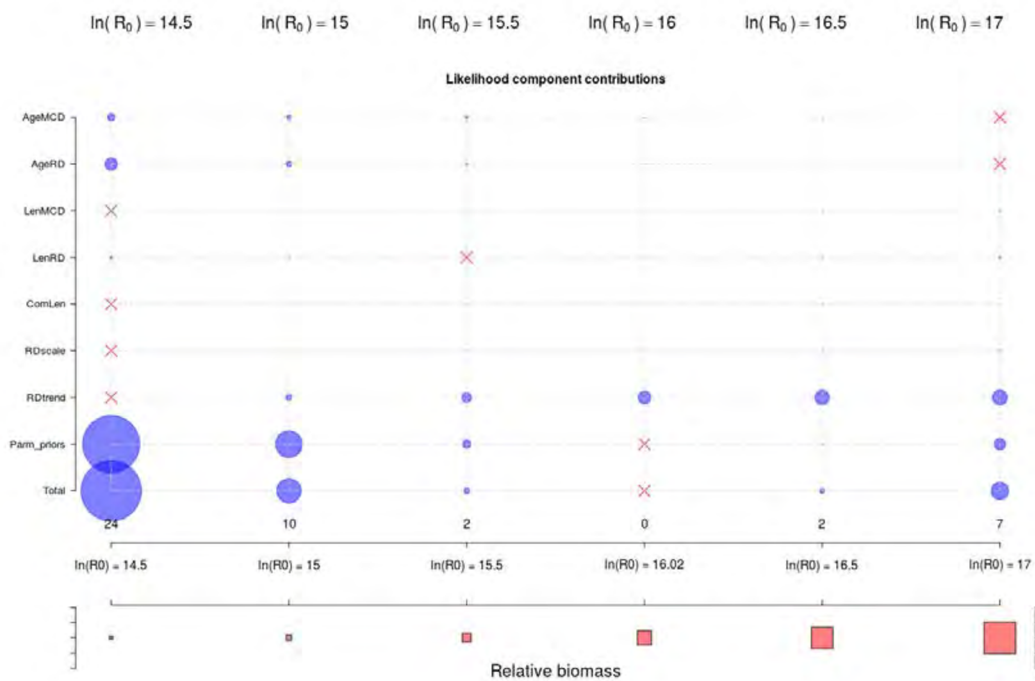

Figure 131: Likelihood profile over the virgin recruitment parameter (R0). A total of 5 model runs are depicted here. In each case, the R0 parameter was fixed at a different value. The columns of the large plot show how the component and total likelihoods change as the R0 parameter is varied. Each column of the large bubble plot represents one model run and the non-zero likelihood components in each run are shown in rows. For each row, the minimum likelihood component value was subtracted from each individual value, such that the minimum value in each row is represented by a red x. Bubbles are proportional to the values of each likelihood component in each run. The base value for R0 is the value at the model solution (middle column). The difference (in likelihood units) between each column and the minimum total likelihood is shown just above the x axis. Conflicts within the data are apparent when the minimum likelihood values (red x's) occur in different columns for each row. The red boxes show the relative difference in estimated terminal year biomass between runs.

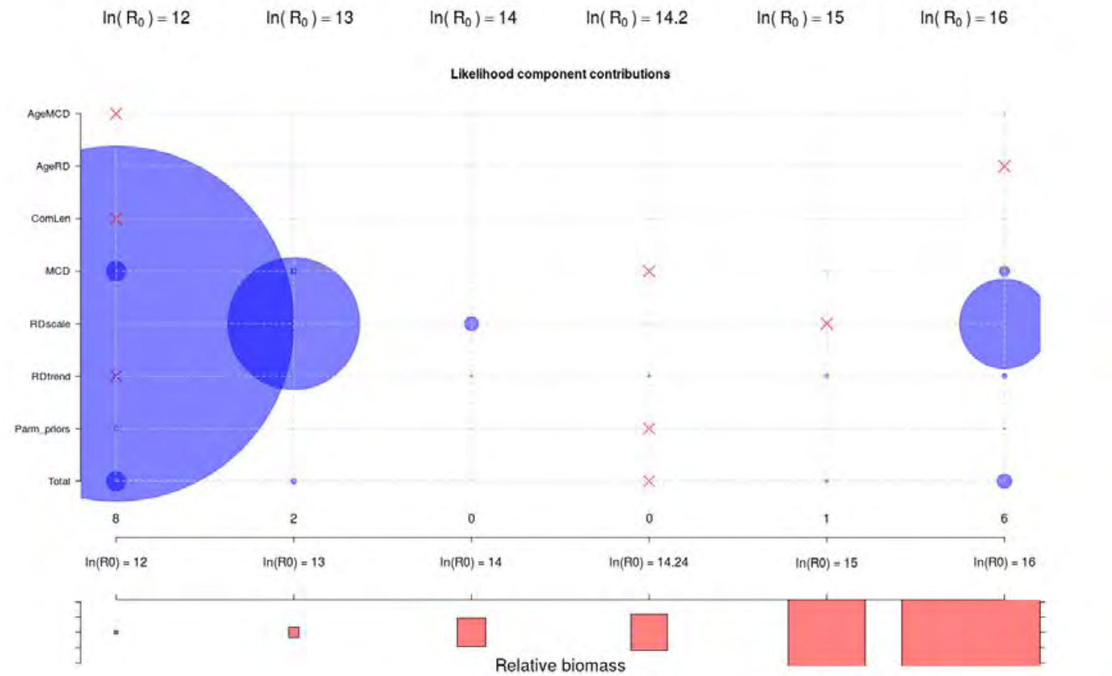

Figure 132: Likelihood profile over the virgin recruitment parameter (R0). A total of 5 model runs are depicted here. In each case, the R0 parameter was fixed at a different value. The columns of the large plot show how the component and total likelihoods change as the R0 parameter is varied. Each column of the large bubble plot represents one model run and the non-zero likelihood components in each run are shown in rows. For each row, the minimum likelihood component value was subtracted from each individual value, such that the minimum value in each row is represented by a red x. Bubbles are proportional to the values of each likelihood component in each run. The base value for R0 is the value at the model solution (middle column). The difference (in likelihood units) between each column and the minimum total likelihood is shown just above the x axis. Conflicts within the data are apparent when the minimum likelihood values (red x's) occur in different columns for each row. The red boxes show the relative difference in estimated terminal year biomass between runs.

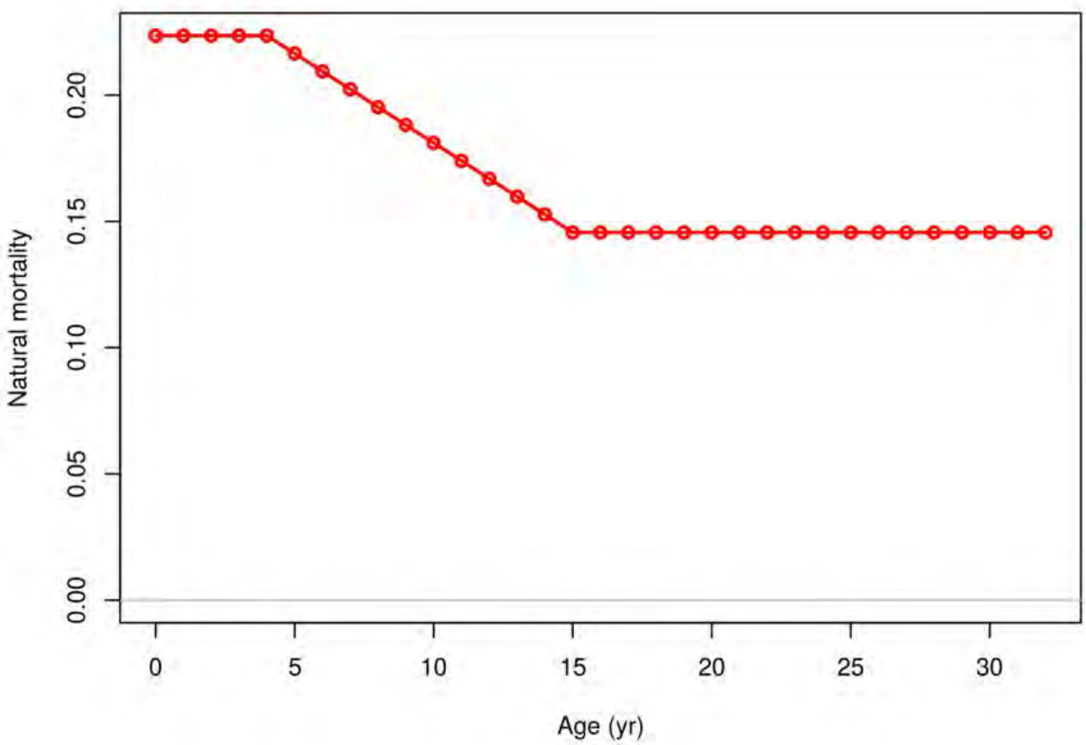

Figure 133: Natural mortality at age estimated in a model sensitivity run for Atlantic surfclam in the southern area.

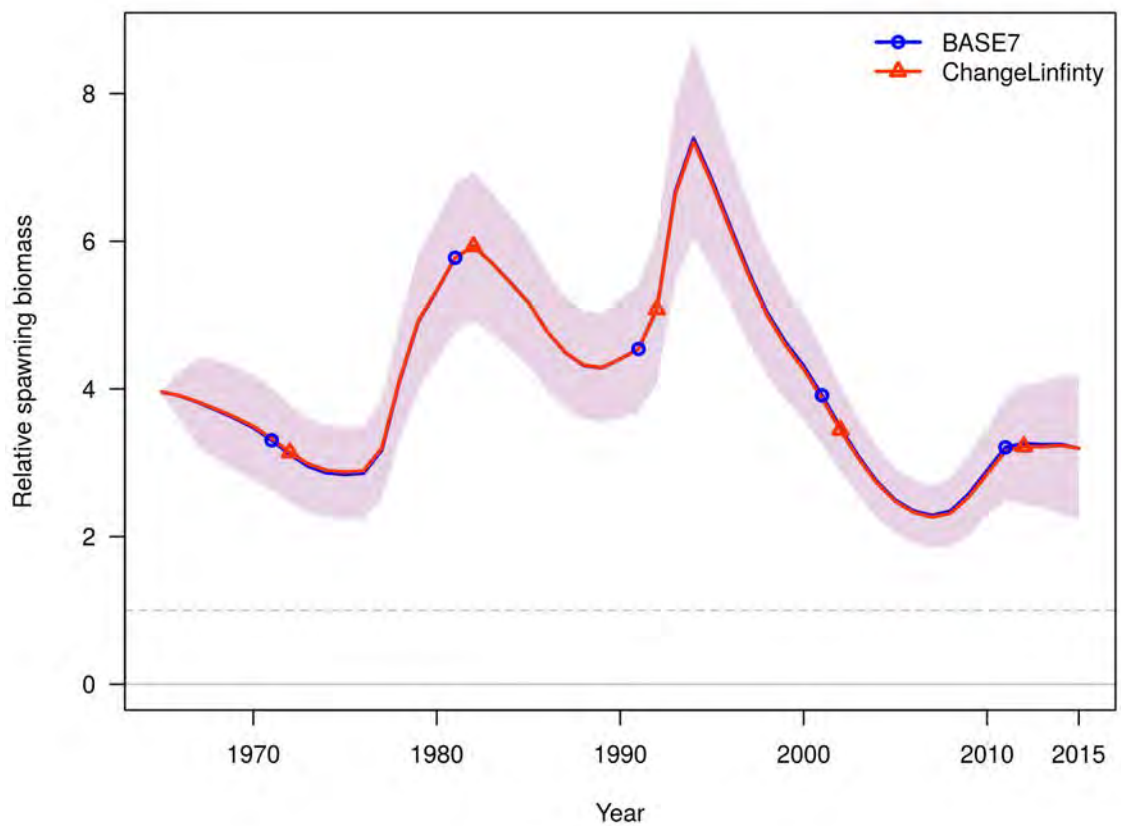

Figure 134: A comparison of the biomass trends of the base model (BASE7) for Atlantic surfclam in the southern area and a sensitivity run in which the length at A_{max} was estimated for each of two time blocks (<2000 and >1999). There was very little difference between the two runs. The trends depict the ratio of the biomass in each year to B_0 and include a dashed line at $\frac{B}{B_0} = 0.25$.

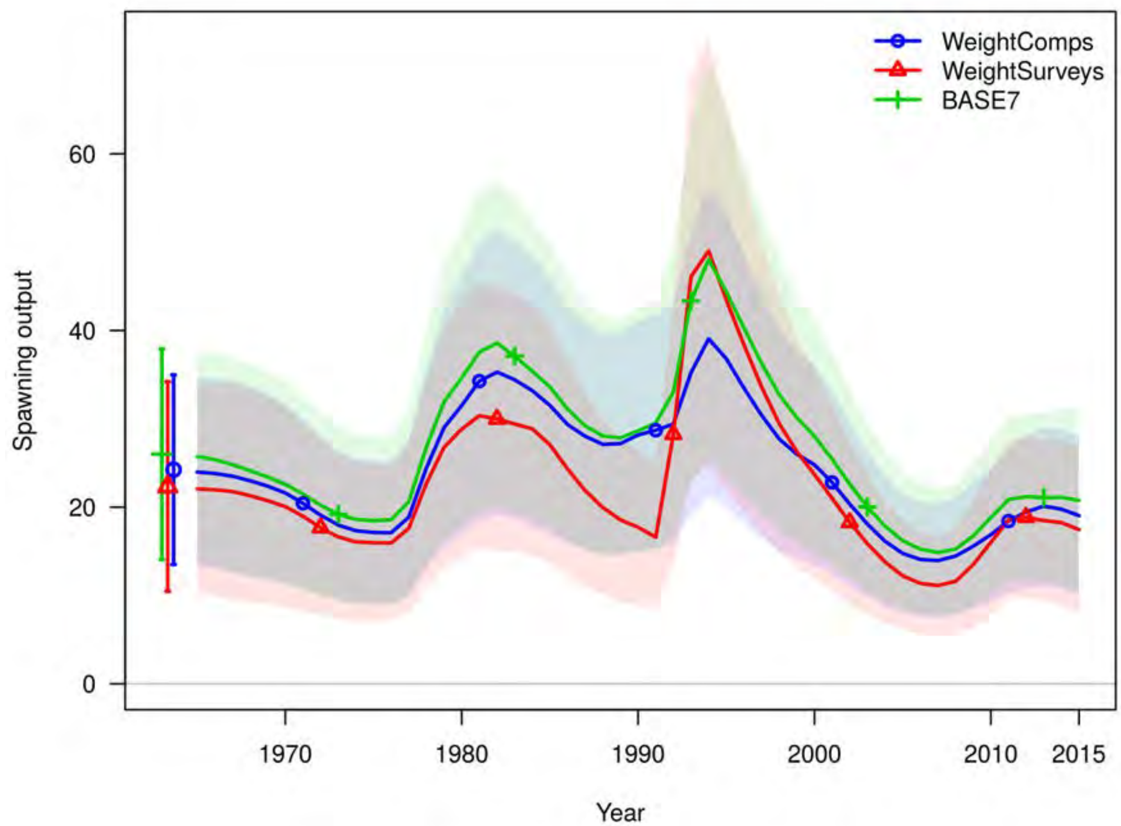

Figure 135: A comparison of the estimated biomass scales between the base run for Atlantic surfclam in the southern area (BASE7) and sensitivity runs in which the likelihood component associated with the fit the RD survey was increased by an order of magnitude (WeightSurveys), and where the variance associated with the composition data (both length and age at length) was adjusted so that the harmonic mean of the effective sample size matched the mean of the input sample size.

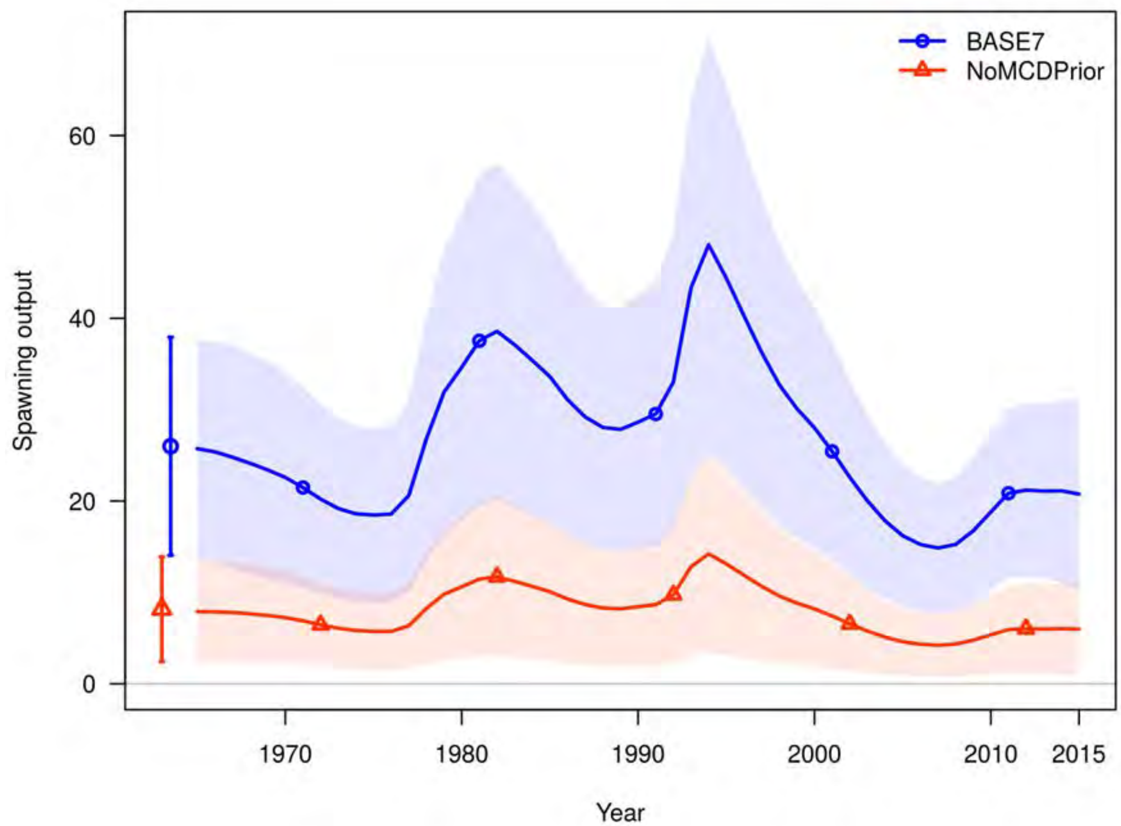

Figure 136: Biomass scale in a model sensitivity run for Atlantic surfclam in the southern area in which the prior for the MCD survey was not used compared to the base model (BASE7). The scale differs between the two but the trend is similar.

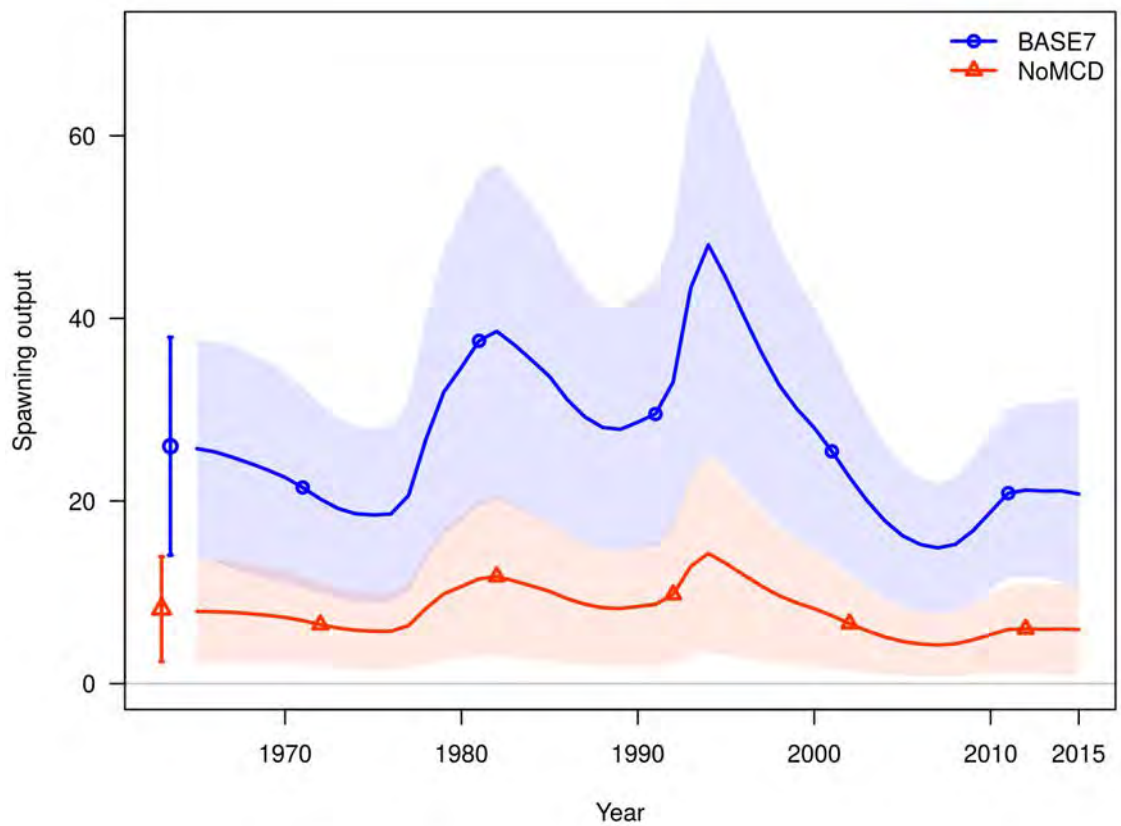

Figure 137: Biomass trend in a model sensitivity run for Atlantic surfclam in the southern area in which the likelihood component associated with the fit the MCD survey was reduced to 0, compared to the base model (BASE7). The scale differs between the two but the trend is similar.

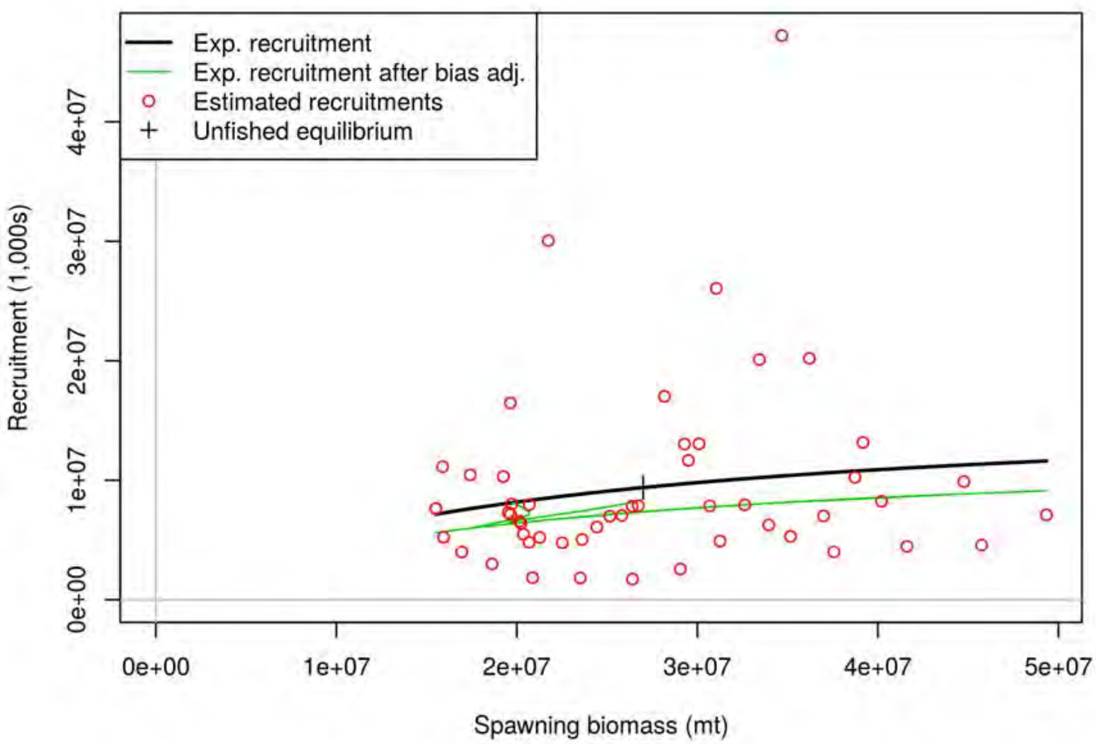

Figure 138: Stock recruit relationship with steepness estimated in a model sensitivity run for Atlantic surfclam in the southern area. There is no information to inform the left side of the stock recruit curve because no low stock sizes have been observed.

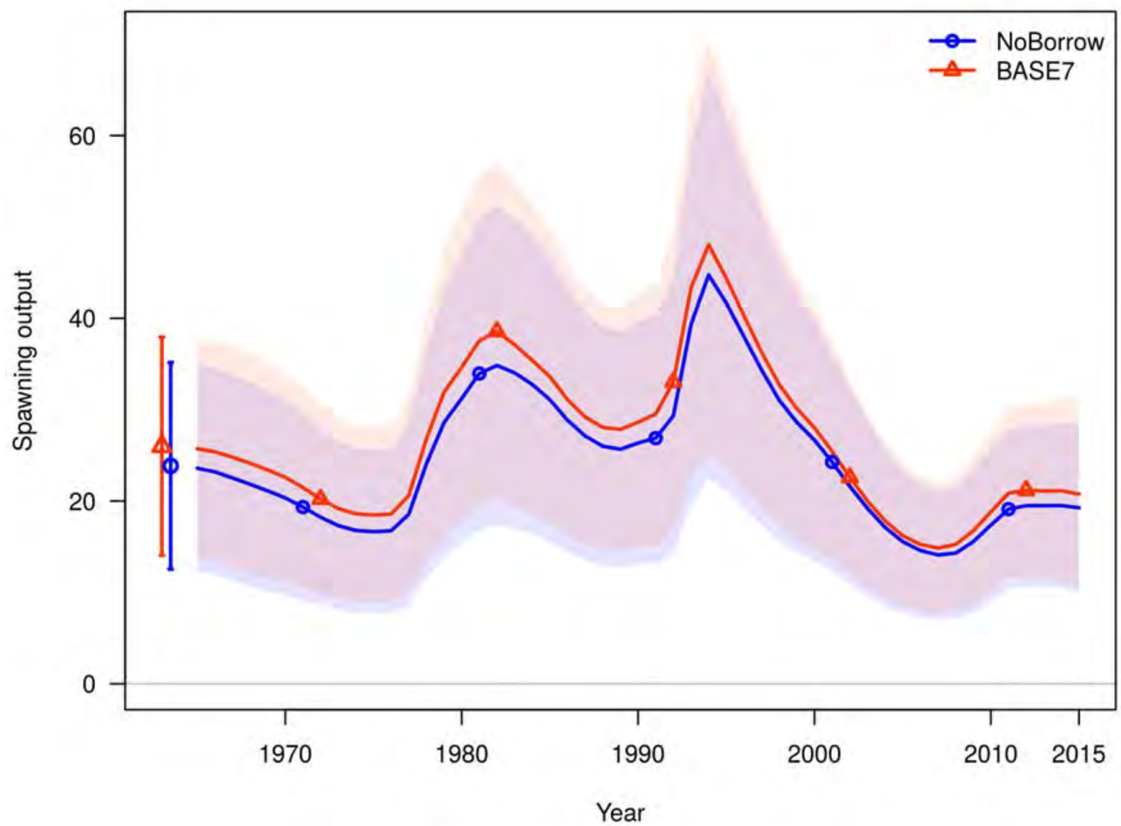

Figure 139: Biomass scale and uncertainty from 2 model runs, one in which the conditional age at length data was not borrowed from 2013 to 2012 (NoBorrow) and the other being the base model run for Atlantic surfclam in the southern area (BASE7). The biomass trajectories from each run were nearly identical.

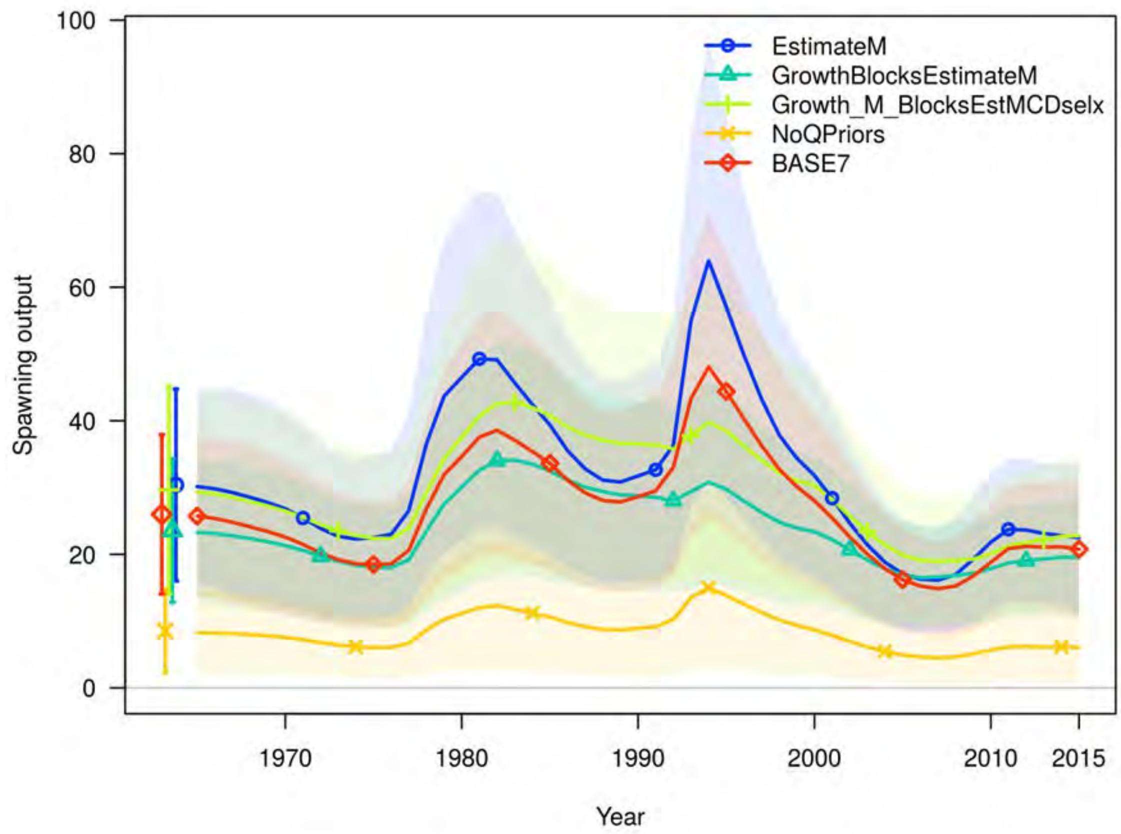

Figure 140: Biomass scale and uncertainty from several sensitivity model runs compared to the base run (BASE7) for Atlantic surfclam in the southern area. Each of the runs produced similar trends and only the run in which no prior distributions for catchability were used produced large differences in scale.

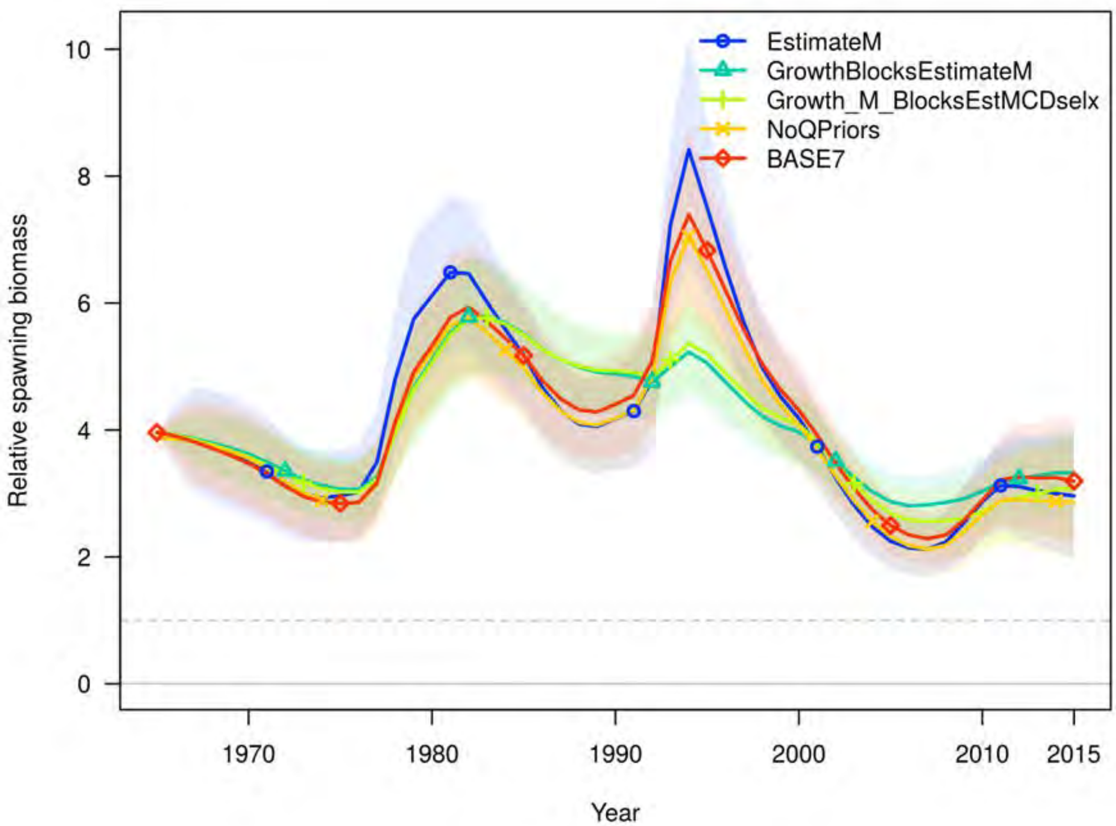

Figure 141: Relative spawning biomass and uncertainty from several sensitivity model runs compared to the base run (BASE7) for Atlantic surfclam in the southern area. Each of the runs produced similar trends. There was very little difference between the two runs. The trends depict the ratio of the biomass in each year to B_0 and include a dashed line at $\frac{B}{B_0} = 0.25$.

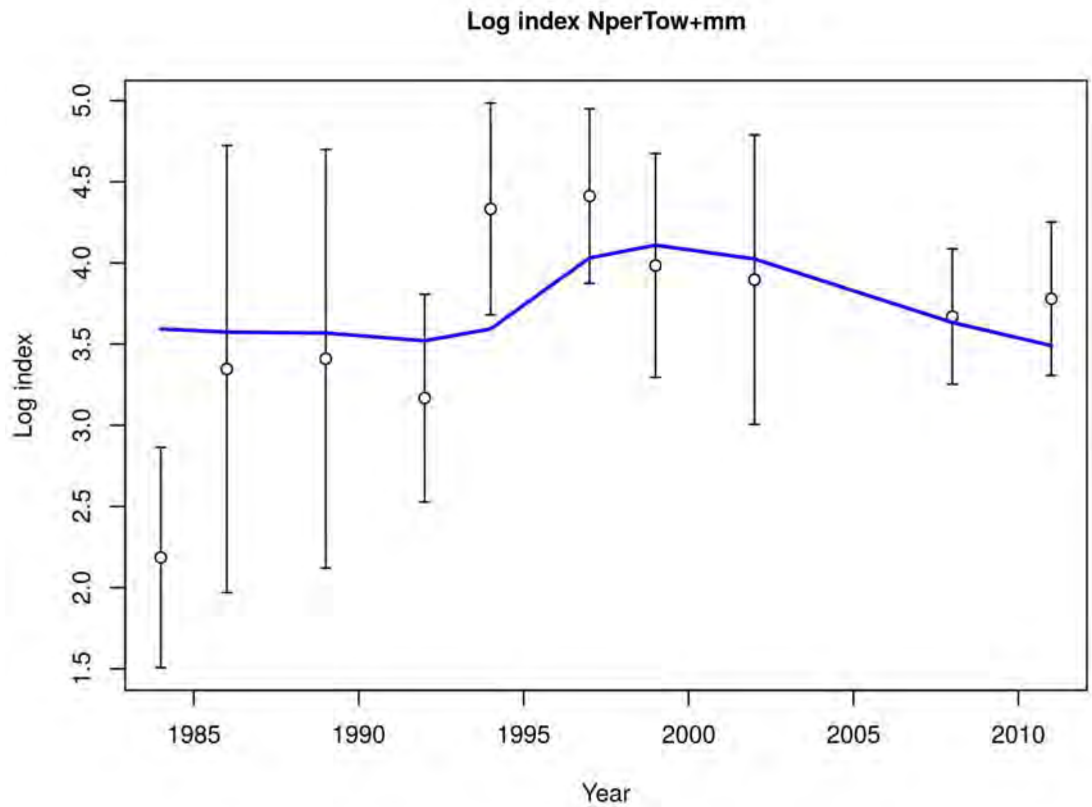

Figure 142: Model fit to the log of the RD survey index estimated in a model sensitivity run for Atlantic surfclam in the northern area in which the R_0 parameter was allowed to vary over time in two blocks (before and after 1995).

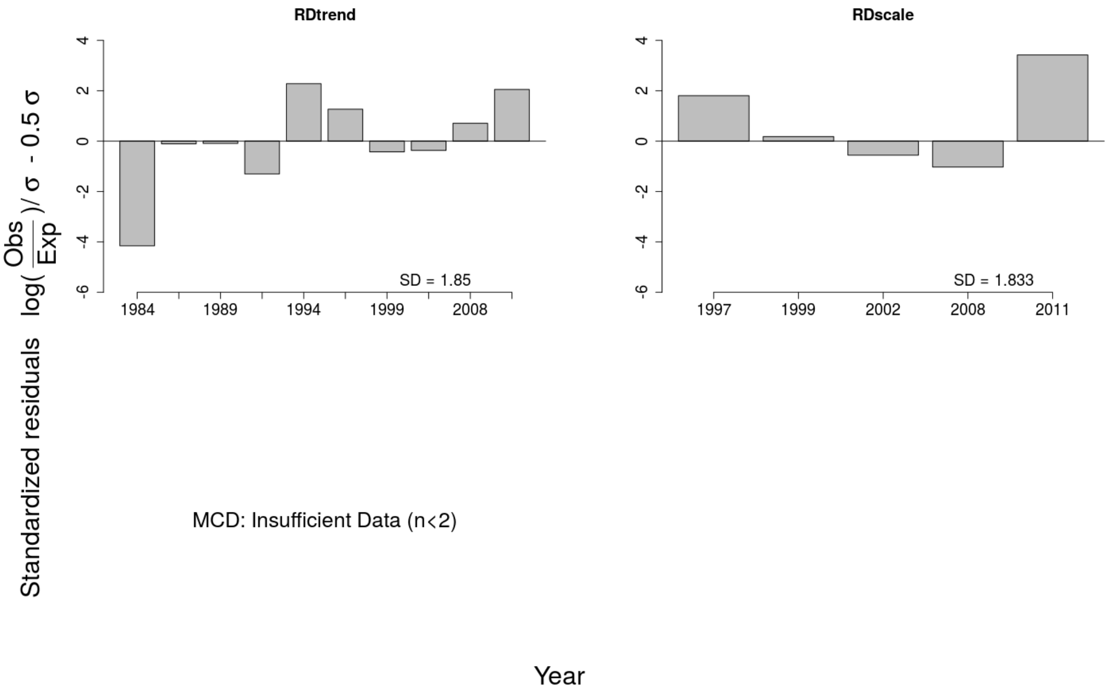

Figure 143: Standardized residuals from the model fit to the RD survey index estimated in a model sensitivity run for Atlantic surfclam in the northern area in which recruitment variance was increased by 100%.

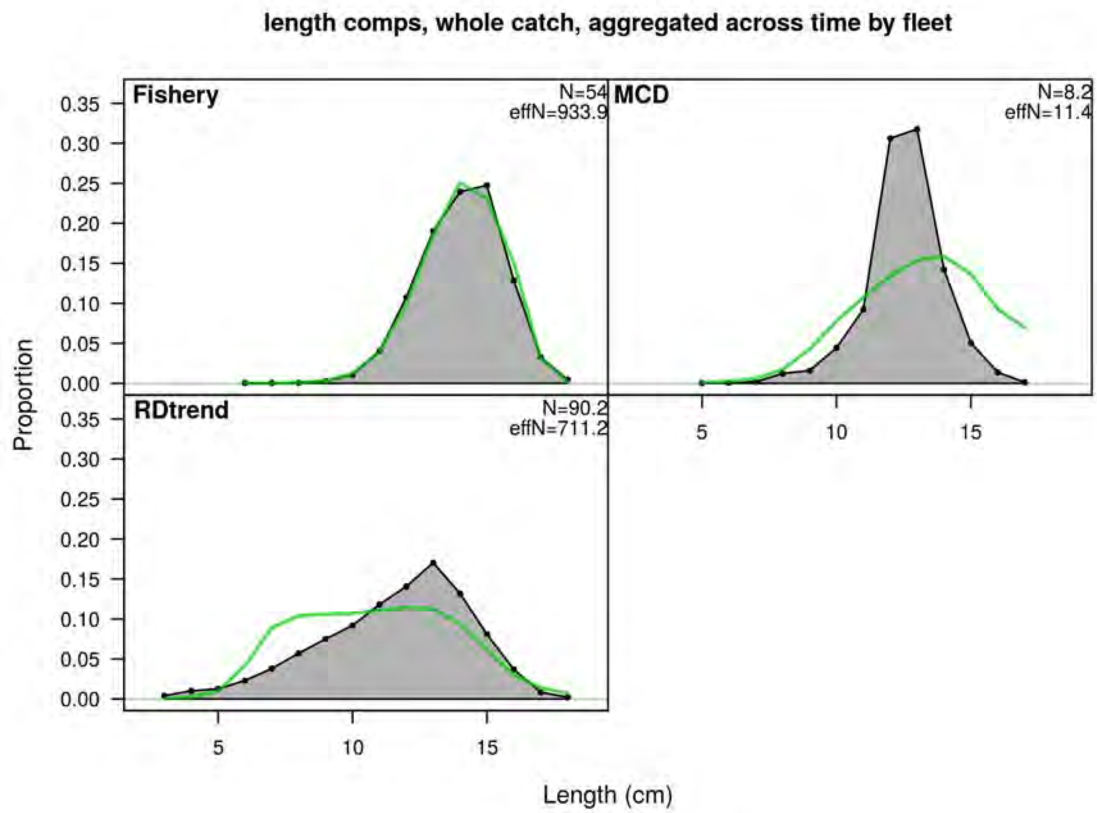

Figure 144: Length composition fits in a model sensitivity run for Atlantic surfclam in the northern area in which the weight of the likelihood component associated with the RD survey was increased by 1000%.

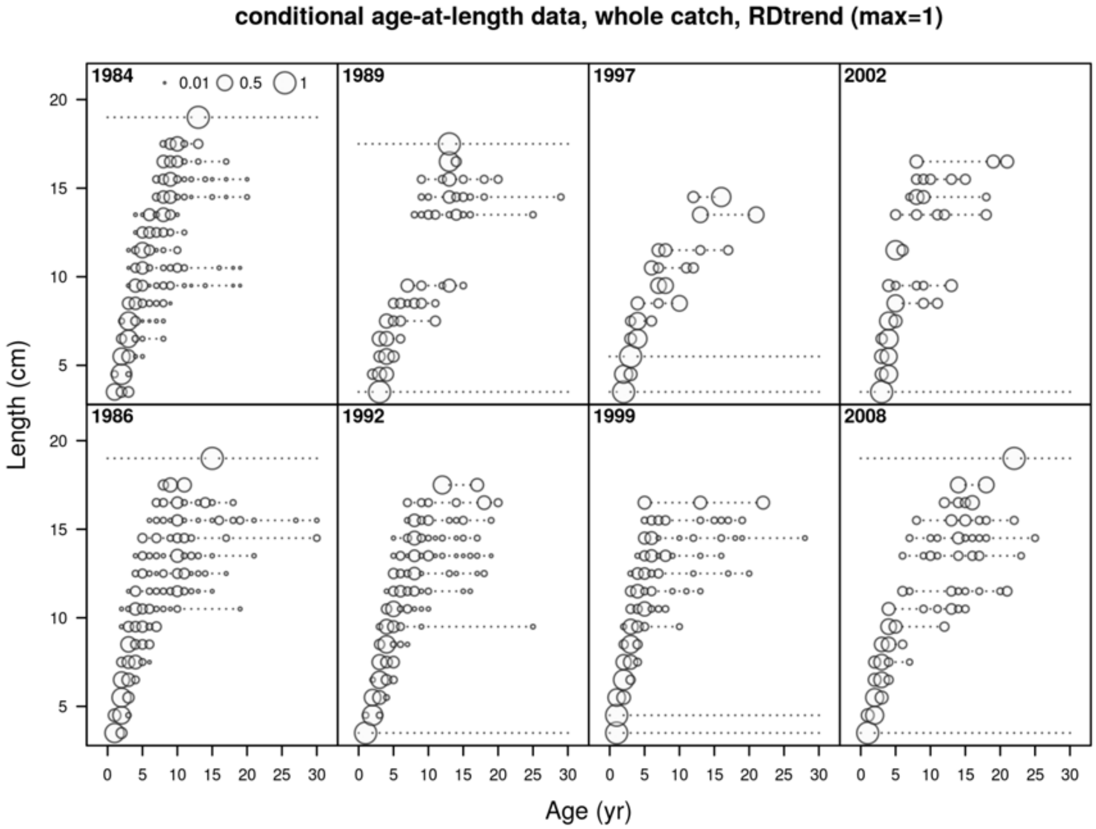

Figure 145: Standardized residuals from conditional age at length composition fits in a model sensitivity run for Atlantic surfclam in the northern area in which the weight of the likelihood component associated with the RD survey was increased by 1000%.

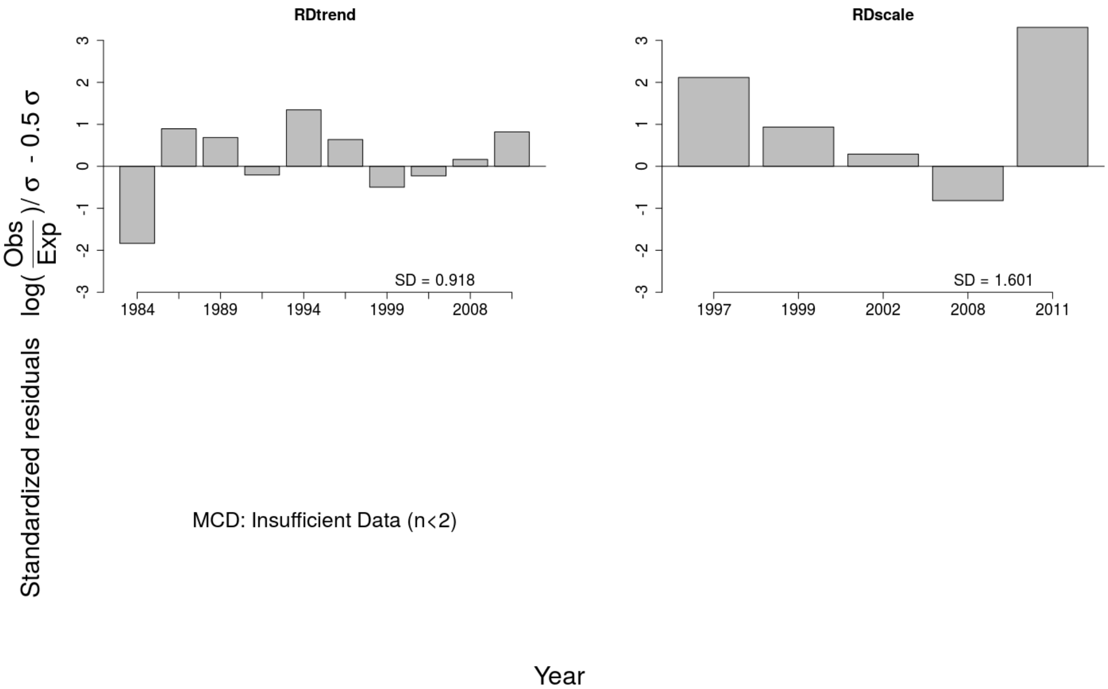

Figure 146: Standardized residuals from the model fit to the RD survey index estimated in a model sensitivity run for Atlantic surfclam in the northern area in which recruitment variance was increased by 100%.

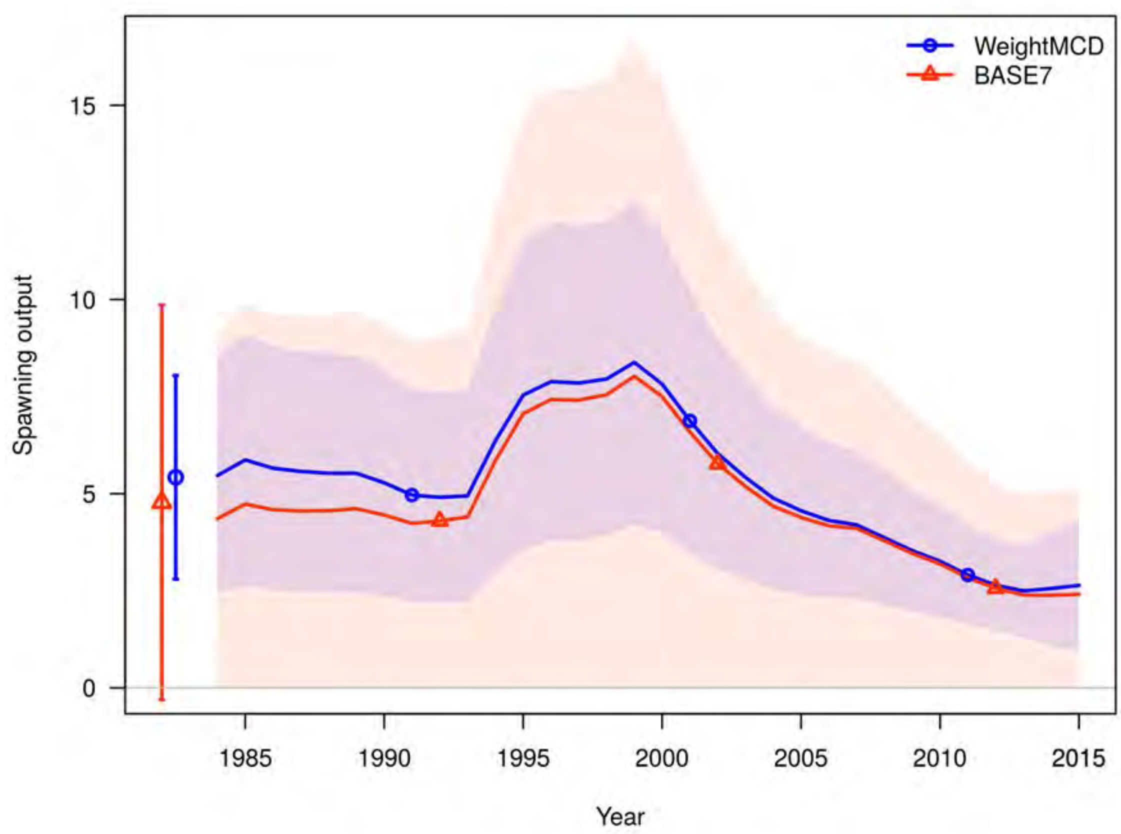

Figure 147: Estimated biomass from a model sensitivity run for Atlantic surfclam in the northern area in which the relative variance associated with the MCD survey index was reduced by about 50%, compared to estimated biomass from the base model run (BASE6).

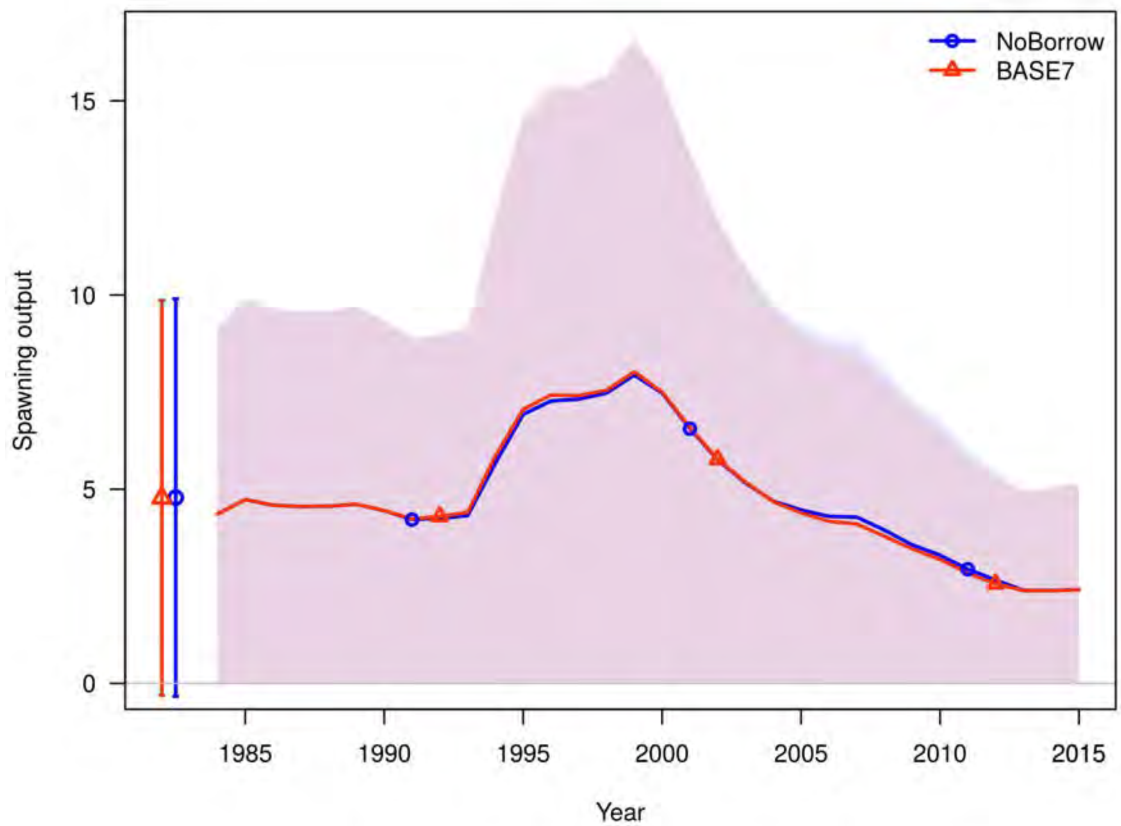

Figure 148: Biomass scale and uncertainty from 2 model runs, one in which the likelihood weight on the MCD survey trend information was set to 0 (RemoveMCD) and the other being the base model run for Atlantic surfclam in the northern area (BASE6). The biomass trajectories from each run were similar but the scale was not.

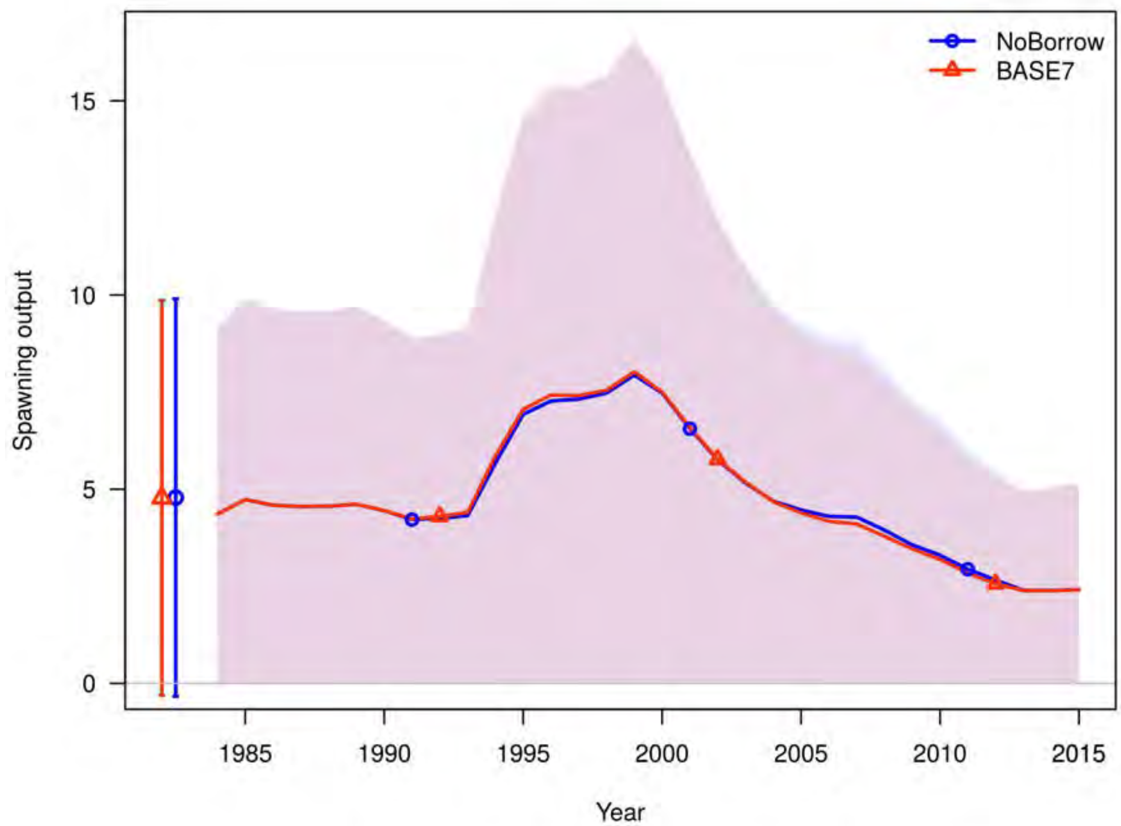

Figure 149: Biomass scale and uncertainty from 2 model runs, one in which the conditional age at length data was not borrowed from 2014 to 2013 (NoBorrow) and the other being the base model run for Atlantic surfclam in the northern area (BASE6). The biomass trajectories from each run were similar and the confidence regions overlapped.

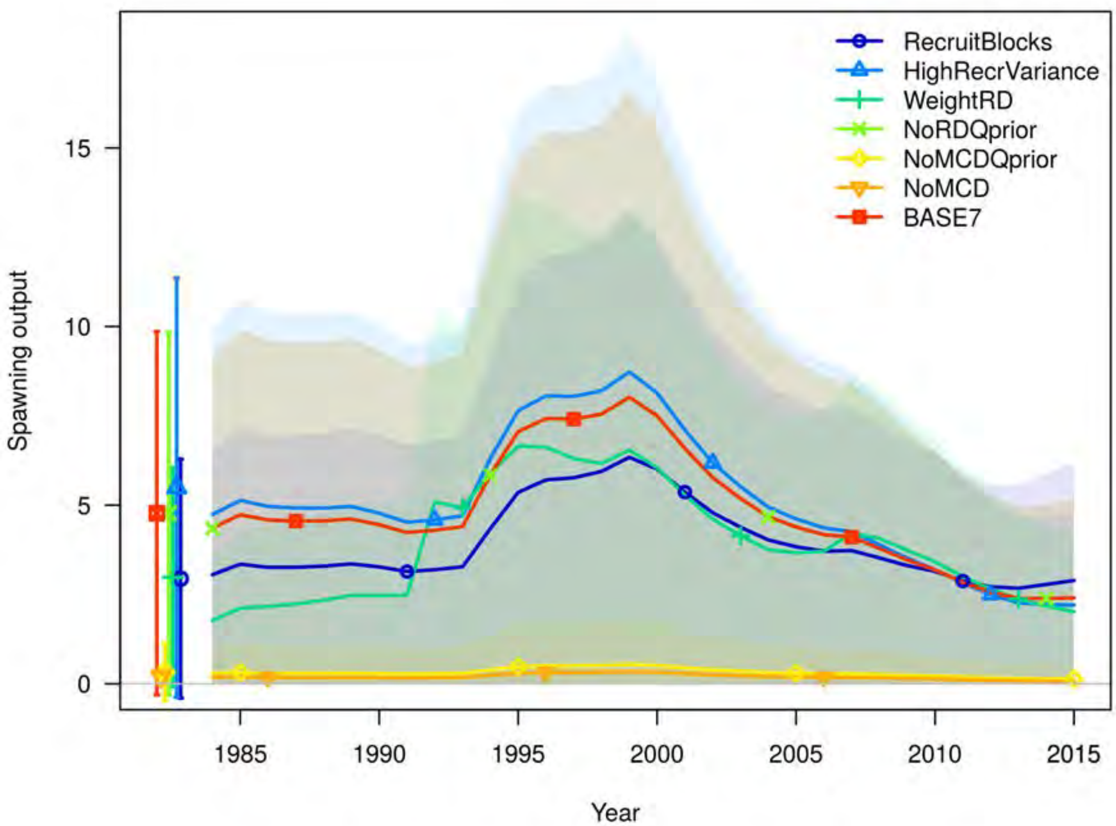

Figure 150: Biomass scale and uncertainty from several sensitivity model runs compared to the base run (BASE6) for Atlantic surfclam in the northern area. Each of the runs produced similar trends except when the model was forced to fit the early survey time series (WeightRD), but different scales when the information from the MCD survey was removed (NoMCD) or when the prior distribution for the catchability of the MCD was turned off (NoMCDprior).

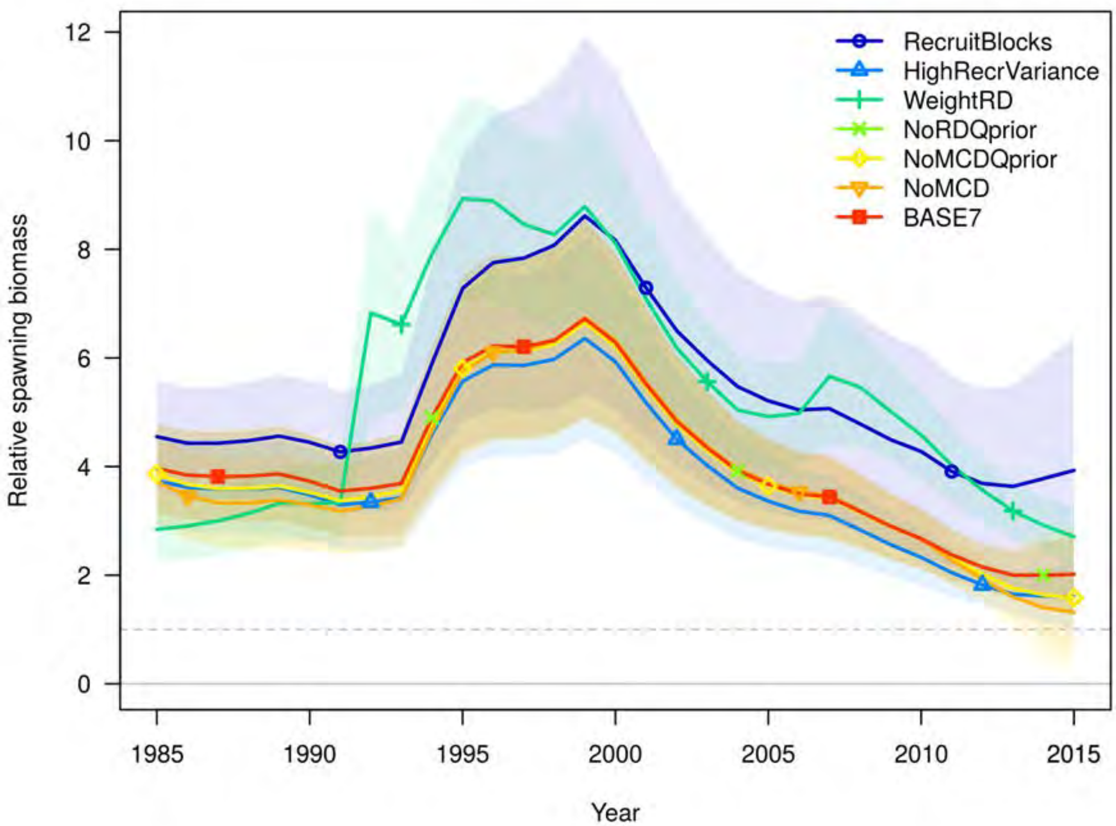

Figure 151: Relative spawning biomass and uncertainty from several sensitivity model runs compared to the base run (BASE6) for Atlantic surfclam in the northern area. Each of the runs produced similar trends except when the model was forced to fit the early survey time series (WeightRD). The trends depict the ratio of the biomass in each year to B_0 and include a dashed line at $\frac{B}{B_0} = 0.25$.

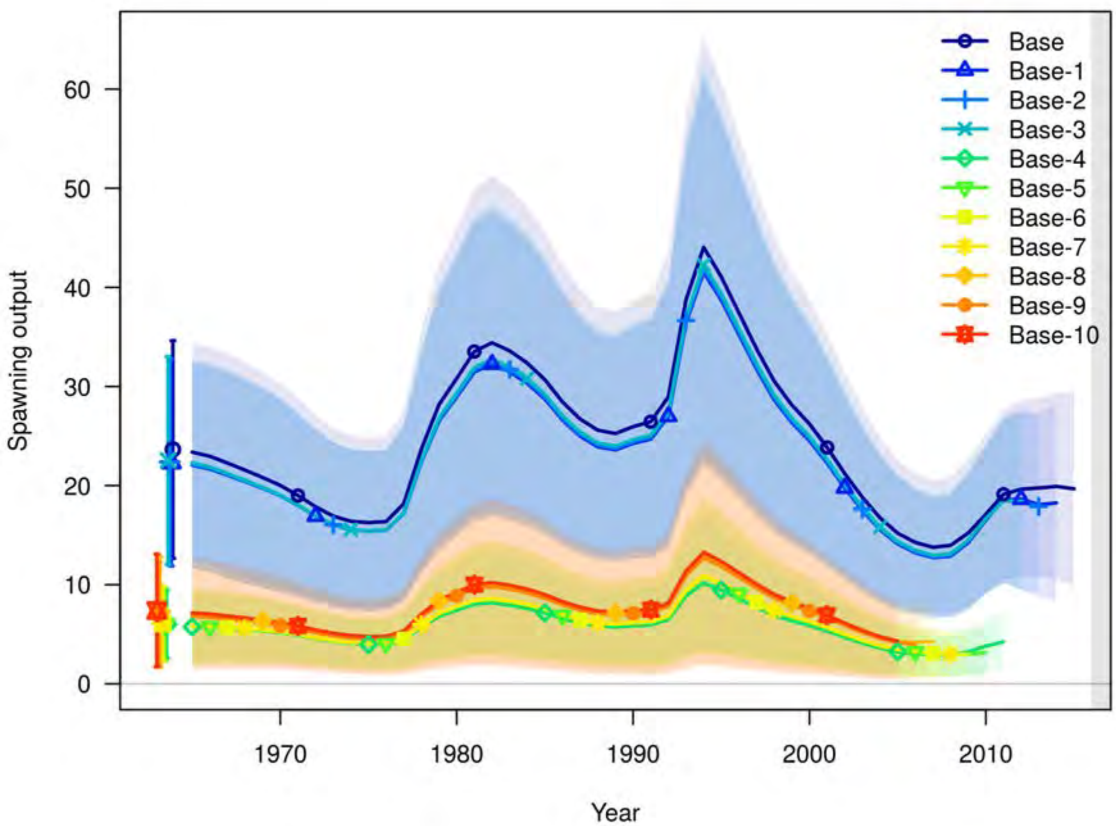

Figure 152: Biomass scale and uncertainty from 10 retrospective runs of the model for the southern area. The biomass scale shifts when the MCD survey is removed from the model. The dashed line represents a theoretical threshold value where the biomass is equal to 25% of the virgin biomass estimated in each retrospective run.

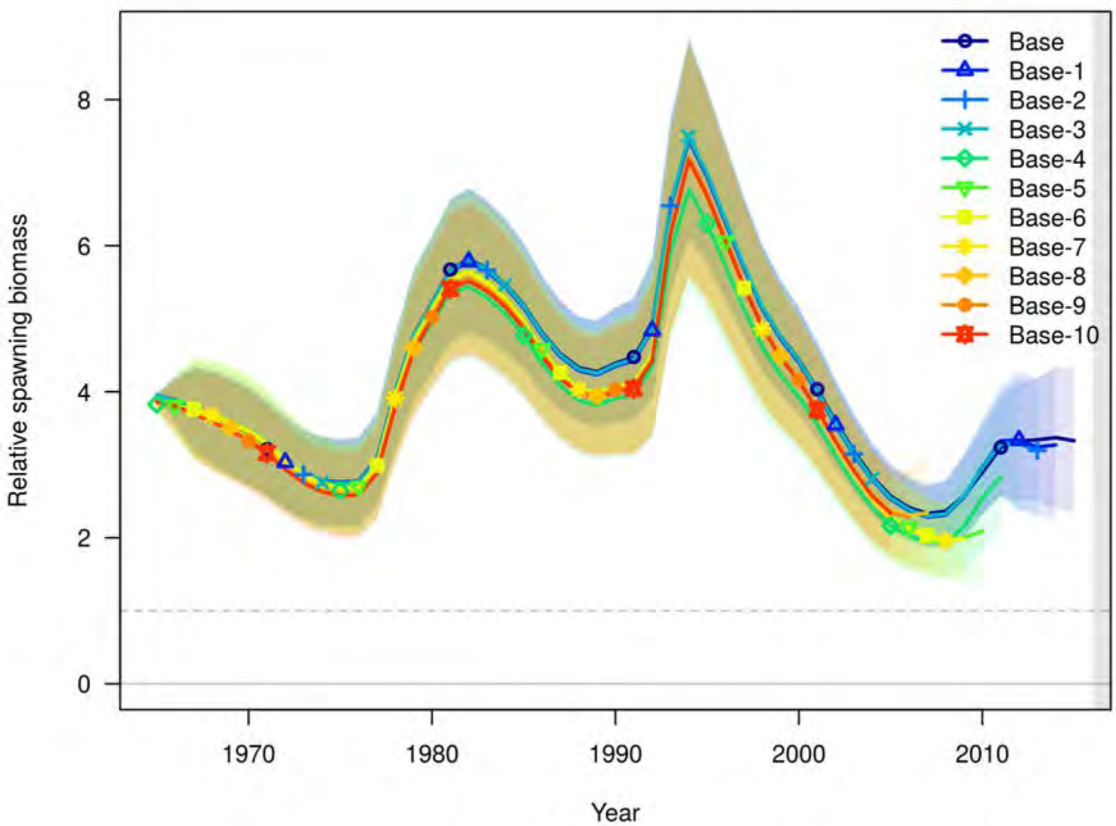

Figure 153: Relative spawning biomass and uncertainty from 10 retrospective runs of the model for the southern area. The trend in biomass is robust to the removal of data from recent years.

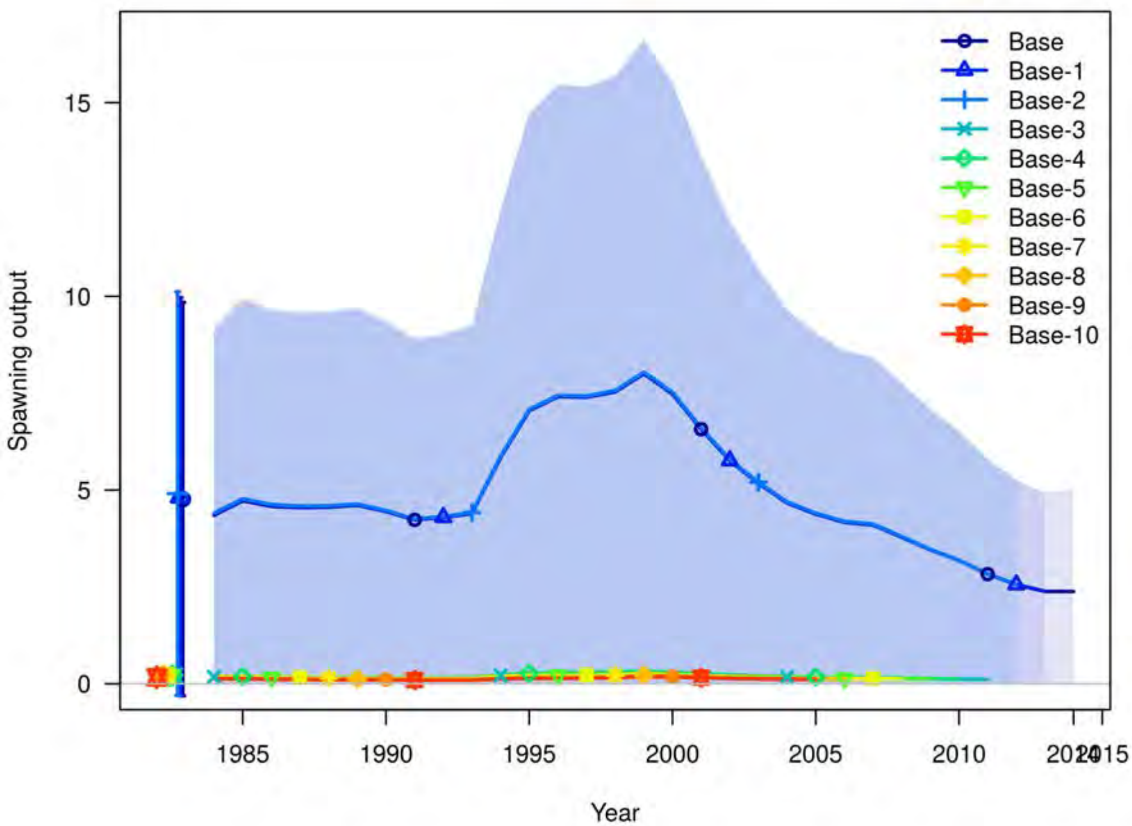

Figure 154: Biomass scale and uncertainty from 10 retrospective runs of the model for the northern area. The biomass scale shifts when the MCD survey is removed from the model.

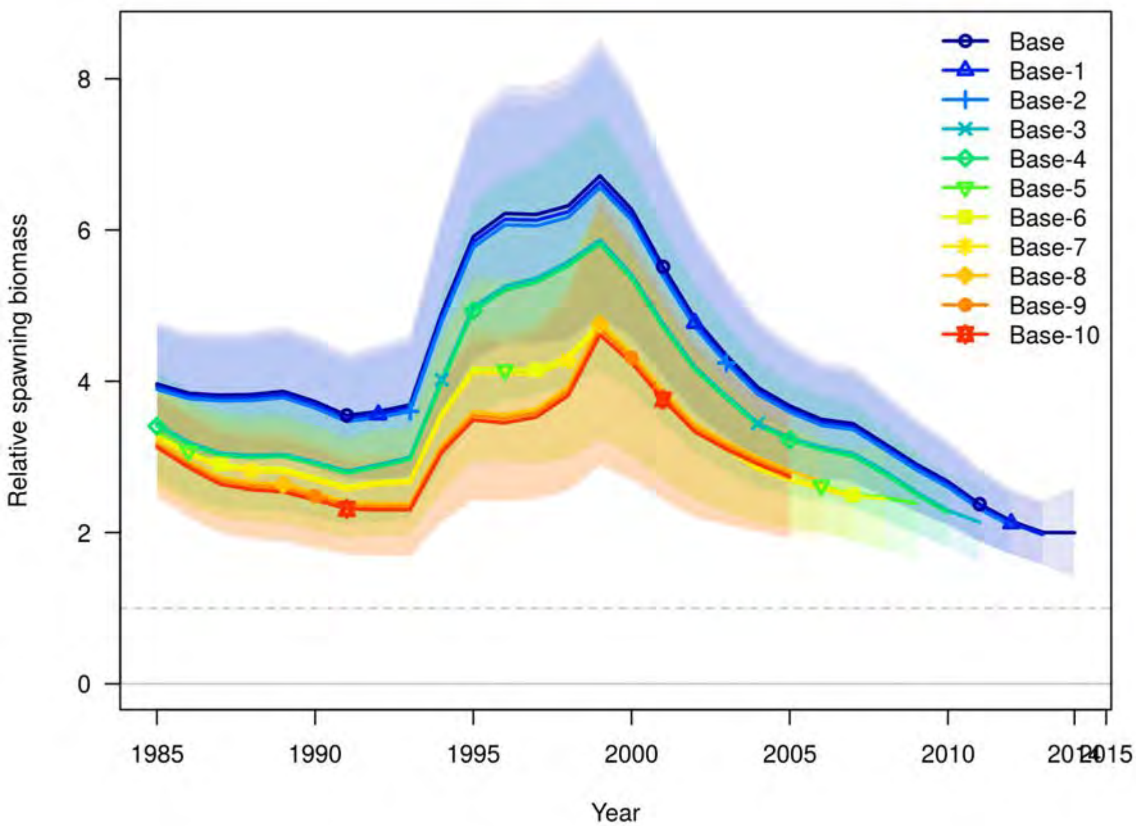

Figure 155: Relative spawning biomass and uncertainty from 10 retrospective runs of the model for the northern area. The dashed line represents a theoretical threshold value where the biomass is equal to 25% of the virgin biomass estimated in each retrospective run.

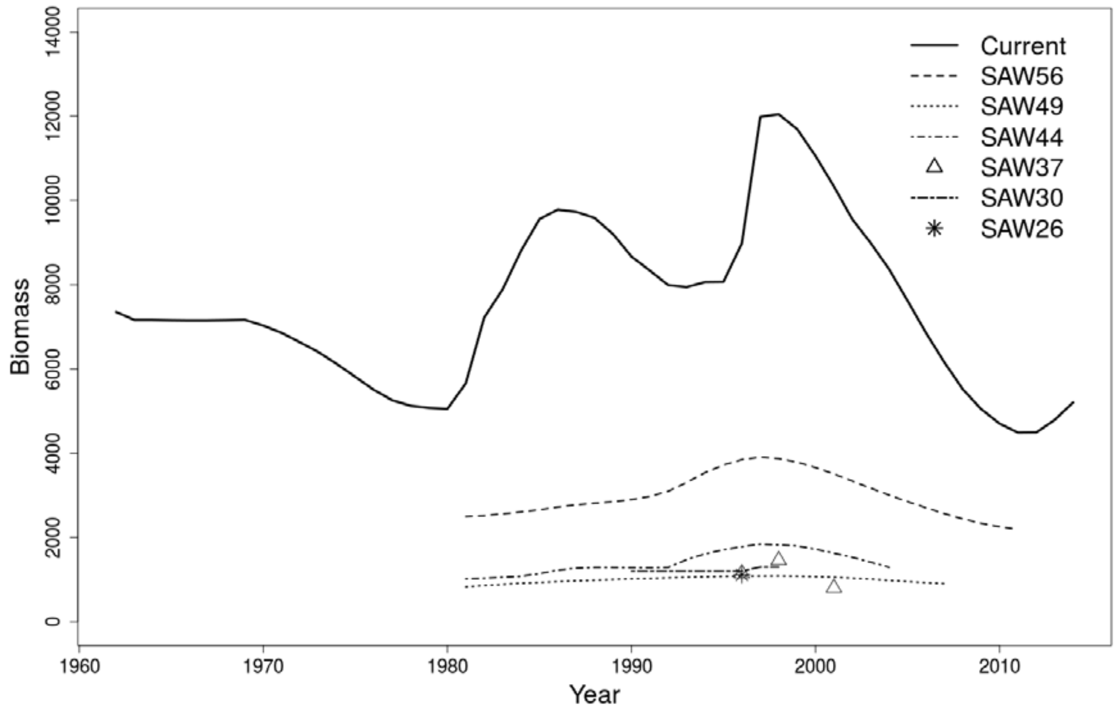

Figure 156: Historical retrospective plot showing the biomass trajectory from each of the previous Atlantic surfclam assessments.

Figures

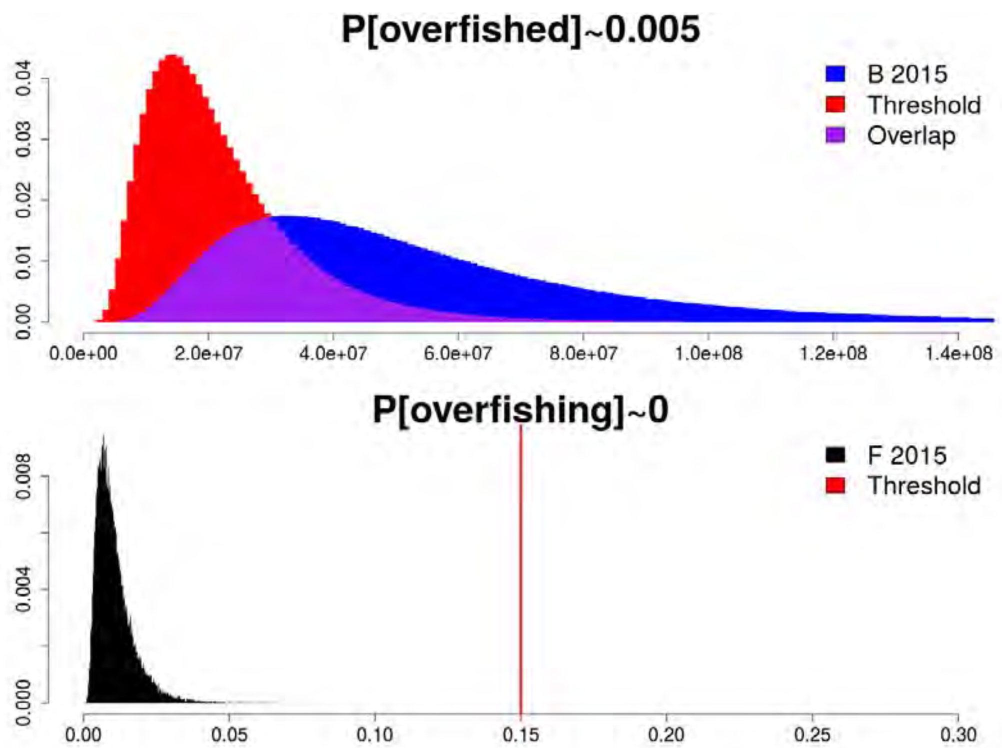

Figure 157: Probability of overfished and overfishing status during 2015 using the current reference points from the previous assessment. The overfished probability (upper panel) presented in this figure accounts for the positive correlation between the reference point ($\frac{B_{1999}}{4}$) and the biomass in 2015, which results in a probability of overfished status that is less than the apparent overlap between the two distributions. The current $F_{Threshold}$ is a point estimate and uncorrelated to F_{2015}. Therefore, the probability of overfishing was equal to the probability of overlap between the distribution of F_{2015} and the point estimate of $F_{Threshold}$.

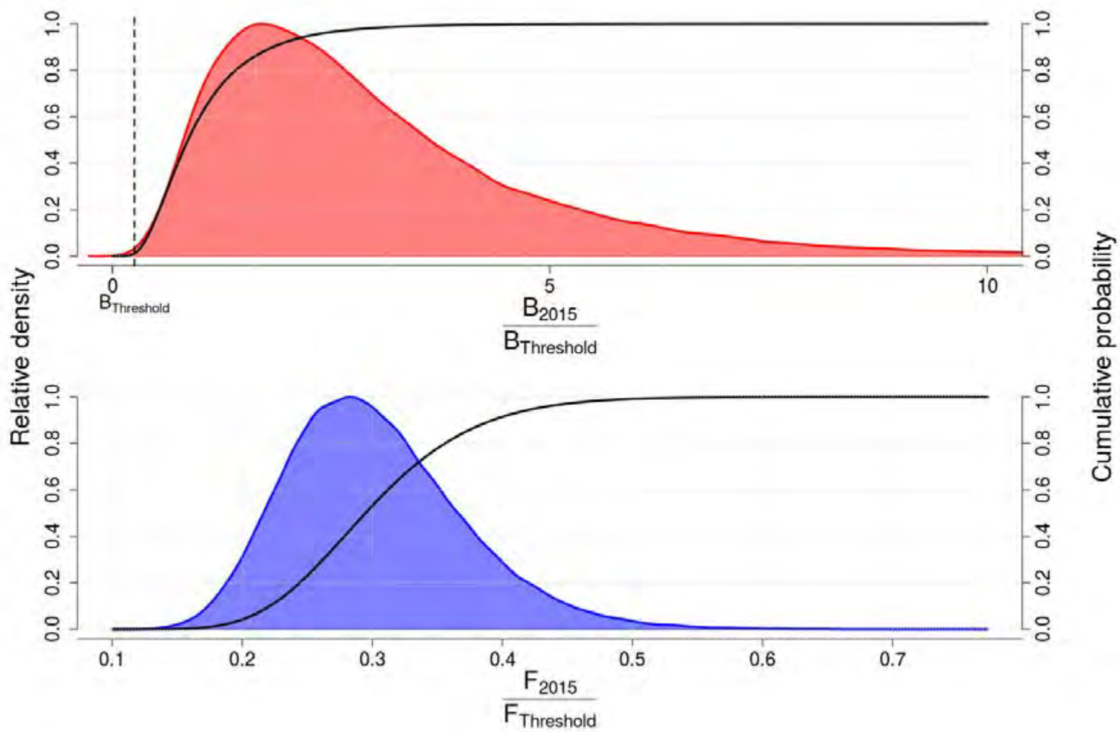

Figure 158: Probability distributions of $\frac{B_{2015}}{B_{Threshold}}$ and $\frac{F_{2015}}{F_{Threshold}}$, using the recommended reference points. The probability of overfished status during 2015 is equal to the area of the red, upper curve that is less than $B_{Threshold}$. The probability of overfishing status during 2015 is equal to the area of the blue, lower curve that is greater than $F_{Threshold}$. The probability of overfished and overfishing status can be approximated by the elevation (y axis scale) at which the solid line representing the cumulative probability distribution crosses the dashed vertical line representing the reference point in each plot. The probability distributions presented in this figure account for the positive correlation between the reference points ($B_{Threshold} = \frac{B_0}{4}$ and $F_{OFL} = F_{Threshold} = F^* \frac{F_{MSY}}{F^*_{Max}}$) and the fishing mortality and biomass estimates in 2015, as well as the uncertainty in the estimation of both the point estimates and their respective reference points.

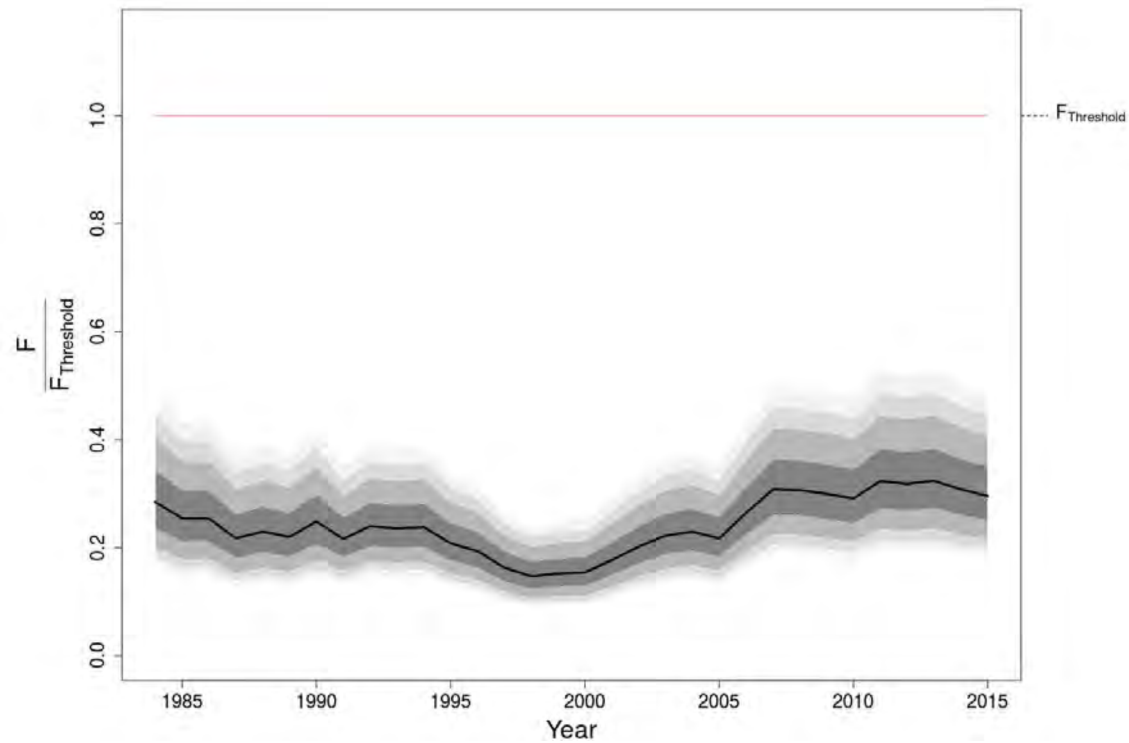

Figure 159: The time series of the ratio of fishing mortality estimates to the recommended F threshold, with the 50, 80, 90, and 95 % lognormal confidence intervals in shades of gray. The confidence intervals account for the correlation between F and $F_{Threshold}$. Over fishing would occur if the ratio exceed 1.0.

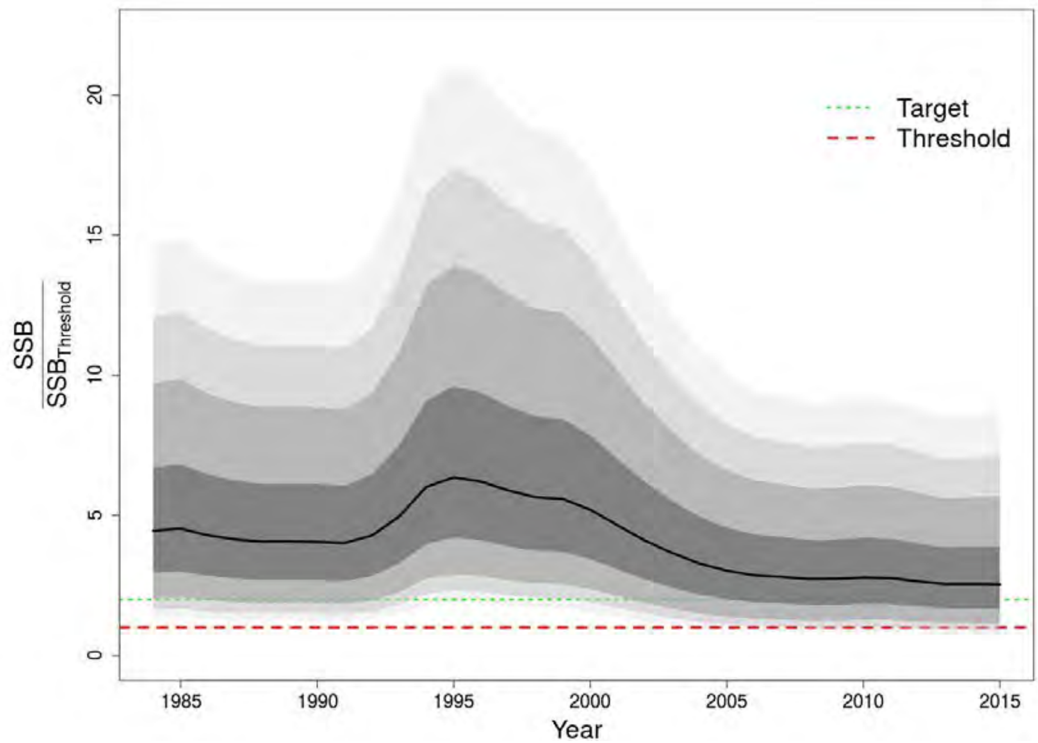

Figure 160: The time series of the ratio of biomass estimates to the unfished biomass (B_0), with the 50, 80, 90, and 95 % lognormal confidence intervals in shades of gray. The confidence intervals account for the correlation between B and B_0. Overfished status would occur if the ratio went below 0.25.

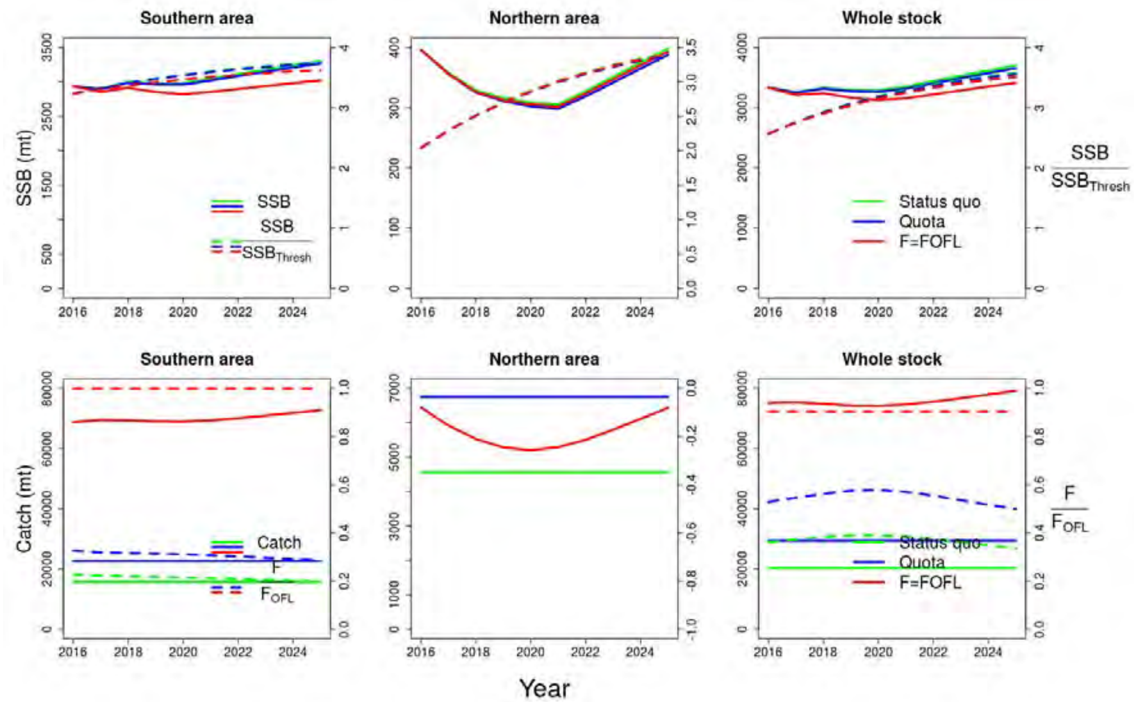

Figure 161: Projections using three different catch scenarios in the southern, northern and whole stock areas. The upper row of plots show the biomass trends over time (solid lines) and the ratio of biomass to biomass threshold (dashed lines). The lower plots show the landings (solid lines) and the ratio of F to F_{OFL}. In all plots the status quo catch scenario is green, the quota catch scenario is blue and the $F = F_{OFL}$ scenario is red. Determination of $\frac{F}{F_{OFL}}$ for the northern area was not possible due to a lack of the exploitation history required to generate an area specific fishing mortality threshold.

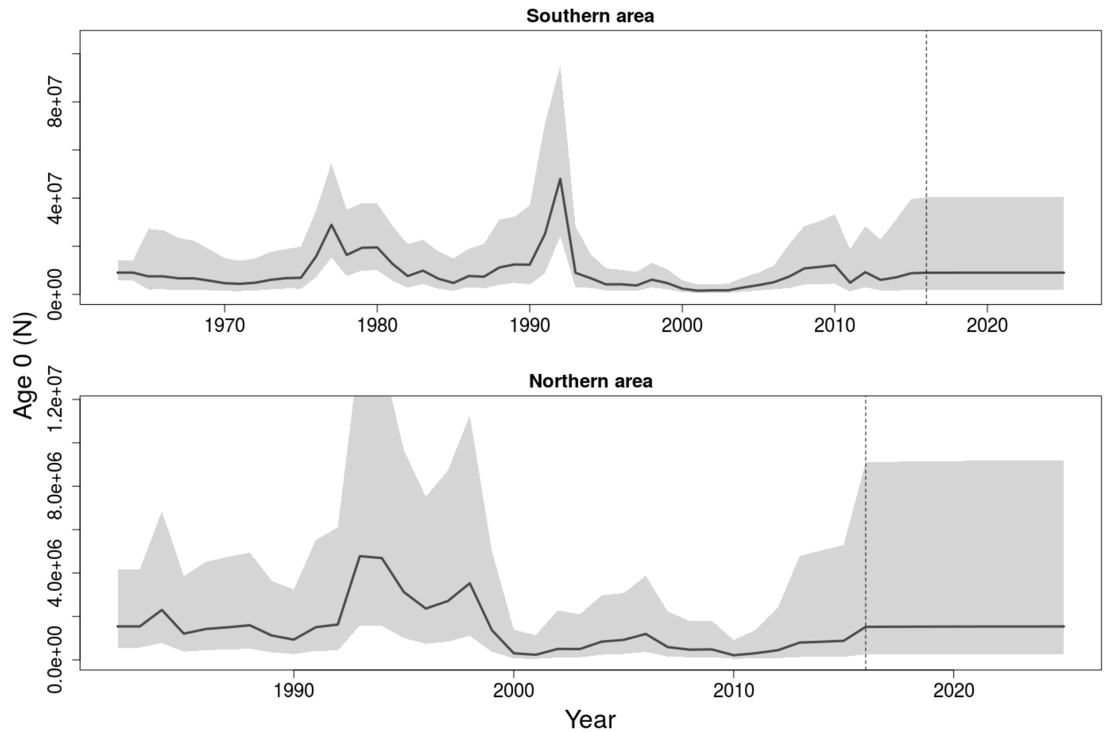

Figure 162: Forecast and time series recruitment estimates for the southern, and northern areas. Projections begin at the vertical dashed line. Note the different ranges of the vertical axes.

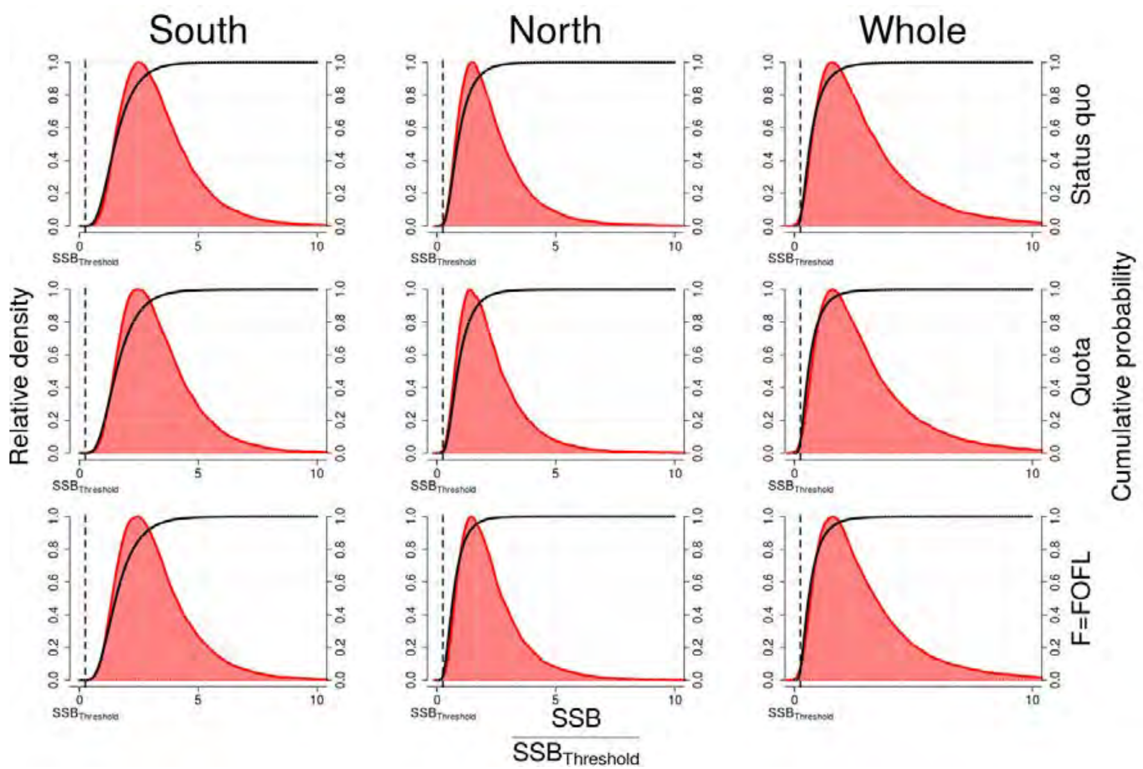

Figure 163: Probability of overfished status for Atlantic surfclam during the projection year with the lowest biomass from 2016-2025. The different catch scenarios are in rows and the different areas are in columns.

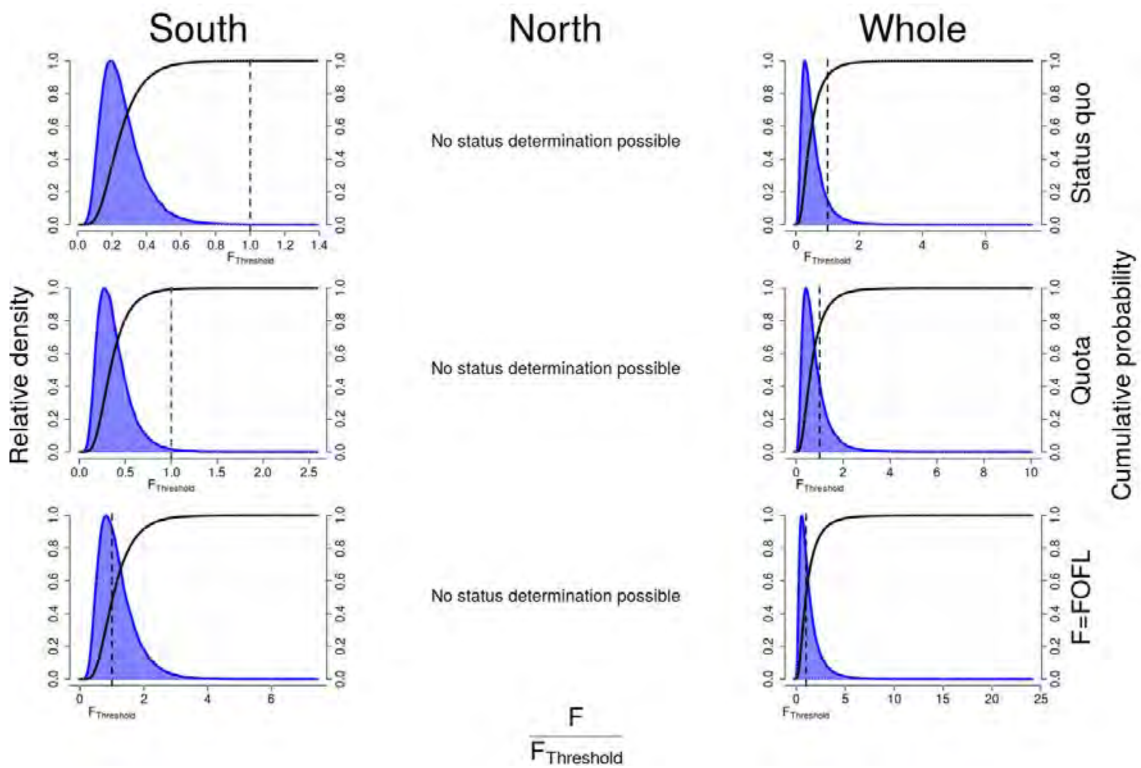

Figure 164: Probability of overfishing status for Atlantic surfclam during the projection year with the highest F from 2016-2025. The different catch scenarios are in rows and the different areas are in columns. Determination of F_{OFL} for the northern area was not possible due to a lack of the exploitation history required to generate an area specific fishing mortality threshold.

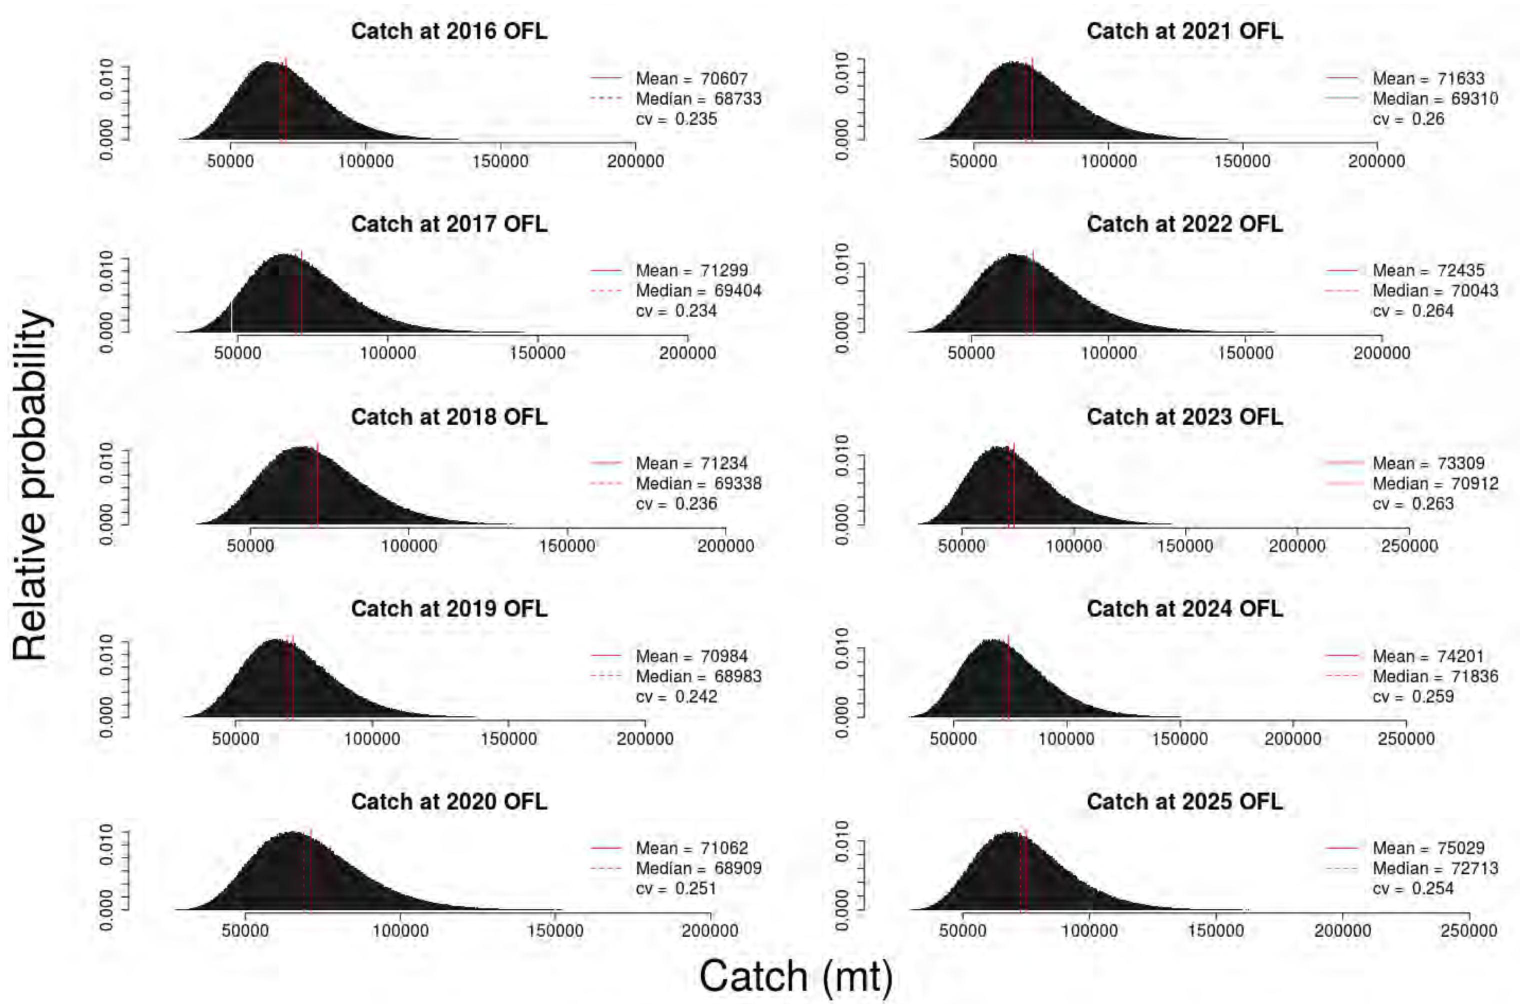

Figure 165: Distribution of catch (landings + incidental mortality) at the Over Fishing Limit (OFL) from 2016-2025 for Atlantic surfclam in the southern area.

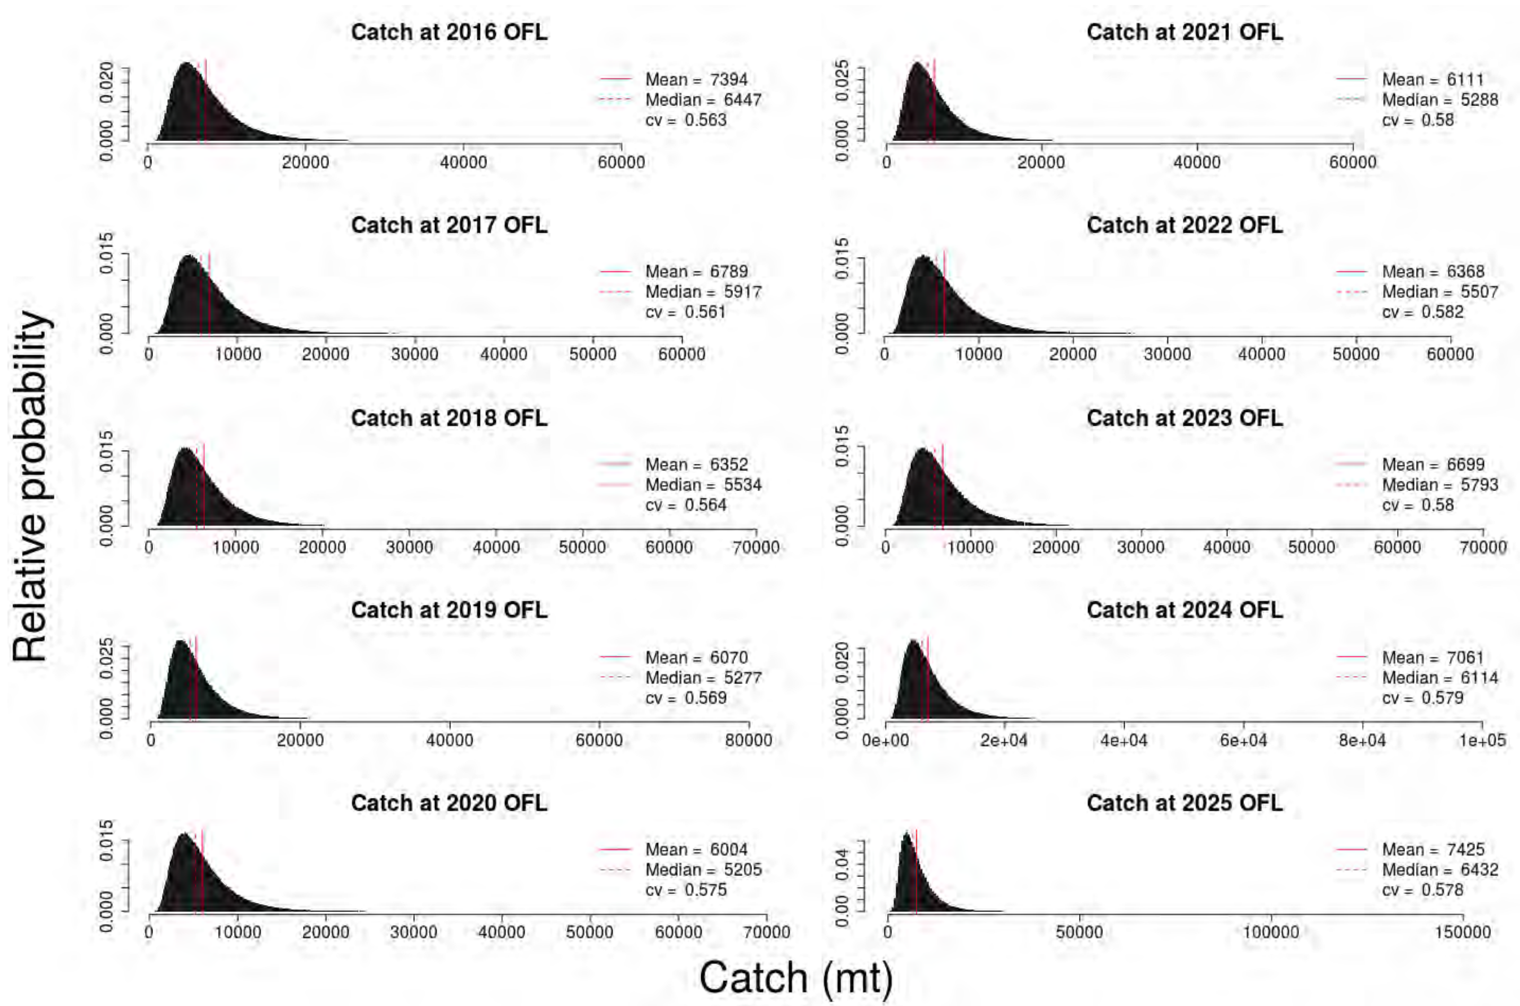

Figure 166: Distribution of catch (landings + incidental mortality) at an approximation of the Over Fishing Limit (OFL) from 2016-2025 for Atlantic surfclam in the northern area. There was not sufficient catch history to generate an OFL for the northern area, so one was approximated based on the average F during years in which fishing occurred.

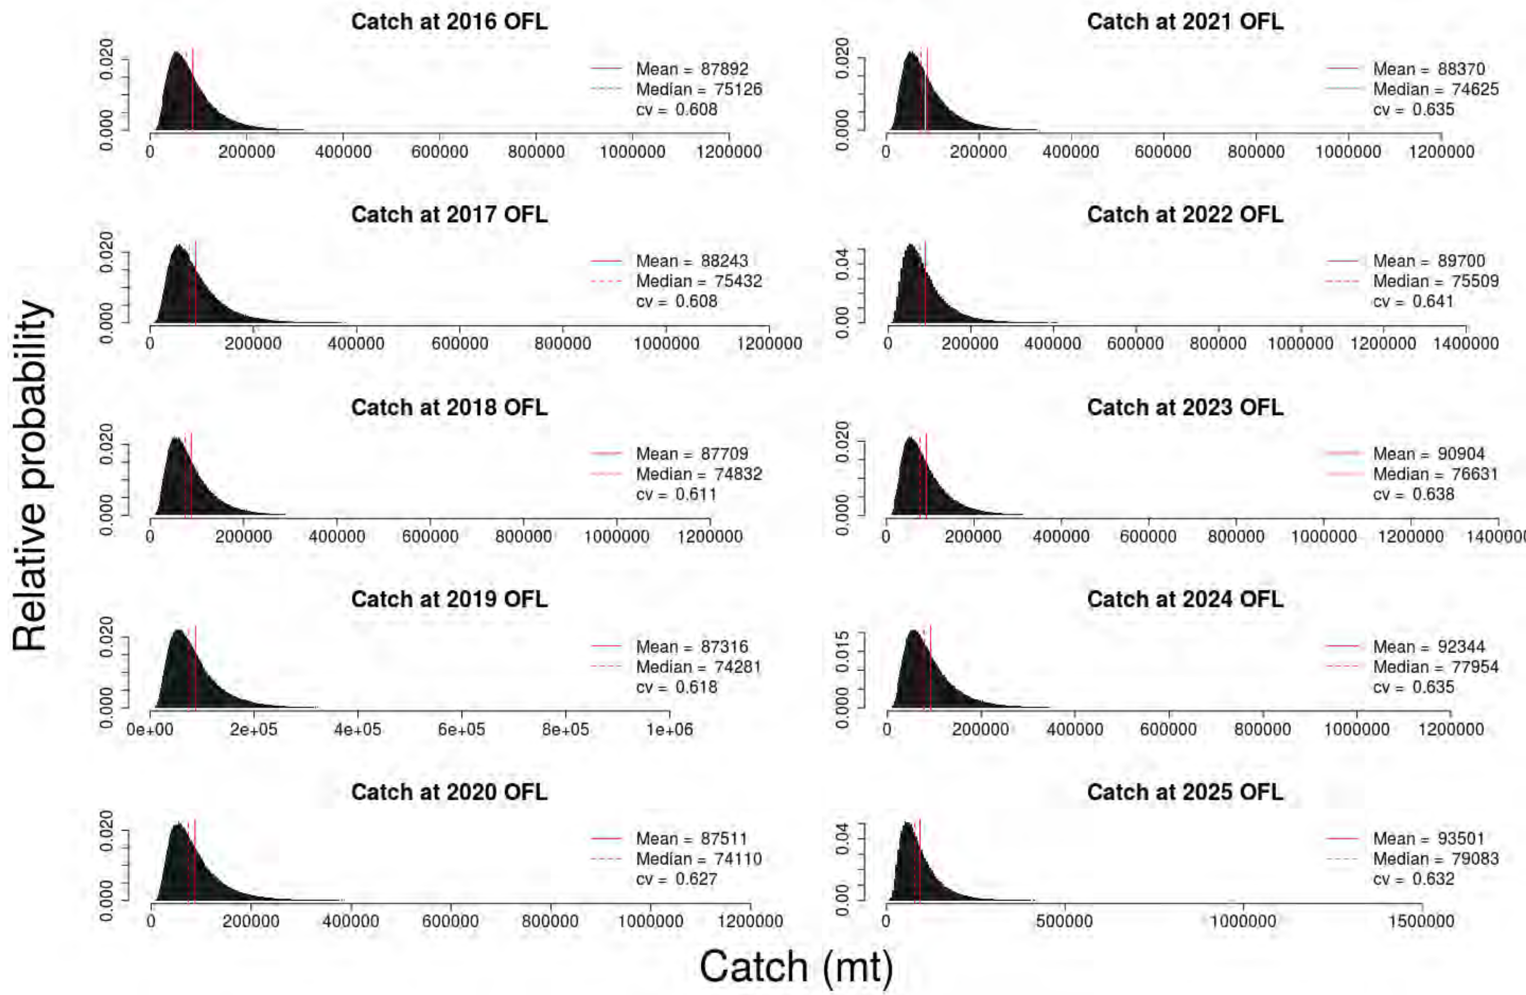

Figure 167: Distribution of catch (landings + incidental mortality) at the Over Fishing Limit (OFL) from 2016-2025 for Atlantic surfclam in the whole stock.

Spatial Patterns in Biological and Other Characteristics		
Growth curves and shell length-meat weight differ markedly between GBK and the southern region.	The differences are clinal or continuous and the split could be made elsewhere or not at all.	Table Table A14, Table A16, Figure A57, A58-62; Kim and Powell (2004); Marzec, et al. (2006); Weinberg (2005)
Post-settlement survival has decreased in the south but not on GBK.	Southern and northern portions of a large stock should respond differently to environmental change. The differences are clinal or concentrated in shallow water south of New Jersey and the split could be made elsewhere or not at all.	NEFSC 2010
Georges Bank tends to retain larvae spawned there due to a persistent gyre current. Published larval drift models for scallops show substantial movement of larvae from GBK to the south, but none from the south to GBK. A detailed unpublished surfclam larval drift presented to the Working Group indicates no movement of larvae from GBK to Southern New England and other southern areas occurs or *vice-versa* assuming no daily mortality during the assumed 35 day larval lifetime observed in culture (X. Zhang and D. Haidvogel, IMCS, Rutgers).	Larval drift models are not definitive and do not cover the whole time period of interest or all possible oceanographic conditions when substantial interchange may occur, particularly between GBK and Southern New England which is directly to the south. In certain circumstances, up to 10% of GBK larvae would reach Southern New England and these larvae would be 'unsuccessful' in the model, but near a reasonable size for metamorphosis in a biological sense.	Miller et al 1998; Werner et al 1993; Gilbert et al 2010; Tian et al 2009; Table A19
Georges Bank and MAB surfclam habitats are entirely within different and well recognized eco-regions.		Fogarty et al. (2011)

Figure 168: Points made to support splitting the Atlantic surfclam into two stocks with counterpoints (Copied directly from Table A17 in (Northeast Fisheries Science Center 2013)). The status quo is a single stock and the alternative is two stocks with the break southwest of Georges Bank. Under this option, the Georges Bank stock in the north would be separated from the rest of the resource in the south. Points made to support the status quo and counterpoints are listed in Figure 169. The tables presented here have not been updated with any new information since the last assessment.

The split south of GBK crosses an area that separates the two major concentrations of the resource in the south (off New Jersey) and on GBK.	The split could be made elsewhere or not at all.	Appendix A7
	Population Dynamics	
Surfclams in GBK and south resemble two independent populations based on abundance, recruitment and life history trends.	The northern and southern portions of SVASNE differ as well, why not identify three stocks?	POPULATION DYNAMICS (Figures A26, A27, A74, A75, A77 and A78)
Strong year classes occur independently and more often in the south and often over wide areas within the region.	Recruitment patterns are regional and the split could be made elsewhere or not at all.	Fig A67
	Fishery Patterns	
The split south of GBK crosses an area of relatively low fishing activity and catch.		See Table A3, Figures A3,A4, and A8
	Practical	
The new cooperative survey cannot sample the whole resource in one year but can be extended to include all of the SVASNE area.	Does not mean the split has to be made at GBK. Spatially explicit assessment models could be developed to handle areas incompletely sampled in annual surveys.	
Including GBK in a whole stock assessment model means that certain survey years cannot be included because GBK was not sampled in all years.	Areas can modeled separately but managed together, with results combined.	
Previous reviews of the surfclam assessment have been critical of the current stock definition.	Restoration of fishing on GBK invalidates some of these previous criticisms.	
The proposed boundary is along lines historically used to assess the stock and to collect survey data.	Historical use and best practice are not necessarily the same.	
	Utility of Biological Reference Points	
"Average" biological reference points for two quasi-populations with different population dynamics do not result in MSY for either population unit, particularly when differences are as large as for GBK and the southern region.	The same argument can be made with respect to different portions of the southern area.	Hart, D. R. 2001. Can. J. Fish. Aquat. Sci. 58:2351–2358.

Figure 168 cont.

The surfclam stock could be removed entirely in the south or on GBK without triggering an overfishing or overfished status determination because biomass would remain > Bmsy/2 for the combined areas.	This scenario is unlikely to occur in either GBK or the southern area now that GBK is open to fishing	
Combining two quasi-populations with different population dynamics obscures the condition of both.	Assessments should contain information about both stock components and other important regions, regardless of stock definitions.	

Figure 168 cont.

Pro	Con	References
Split is a needless departure from historical precedent.	Historical precedent is not necessarily best practice particularly given biological and ecological changes.	
Scallops and ocean quahogs (other sessile bivalves) are managed as one stock	Many species (lobsters and relatively sessile fish such as goosefish and flounders) with interconnected meta-populations are managed as separate stocks. Precedent does not define best practice.	
Split made at the proposed point is not optimal - this aspect should be studied further before management action occurs	GBK is the most distinct region based on biological characteristics, oceanography, geography, larval dispersal and general ecological classifications. Additional divisions in the south can be made later if warranted.	
No genetic differences were found among samples of surfclams from Georges Bank to Virginia.	Lack of significant differences in genetic studies does not prove population homogeneity.	Weinberg, J.W. 2005. Mar. Biol. 146(4): 707-716
Recruitment in SNE may come from GBK at periods that have not been observed in models	There is insufficient age data for SNE to evaluate this hypothesis. However, the limited available data indicate that recruitment patterns differ between the major population centers (GBK in the north and New Jersey and Delmarva in the south).	TABLE A19

Figure 169: . Points made to support maintaining the status-quo (single) stock definition for Atlantic surfclam, with counterpoints (copied from Table A18 in (Northeast Fisheries Science Center 2013)). The status quo is a single stock and the alternative is two stocks with the break just southwest of Georges Bank.

Appendix 1 Atlantic surfclam assessment working group members

The working group met February 1-3, March 28-30 and May 31-June 2 at the NEFSC in Woods Hole, MA to work on the Atlantic surfclam stock assessment. Members, contributors and attendees are listed alphabetically below.

Working group:

Jessica Coakley (MAFMC)
Bob Glenn (Mass. DMR)
Dan Hennen (NEFSC, Assessment Lead)
Tom Hoff (Wallace and Associates)
Larry Jacobson (NEFSC, Subcommittee Chair)
Roger Mann (VIMS)
Daphne Munroe (Rutgers)
Eric Powell (University of Southern Mississippi)

Contributors/attendees:

Tom Alspach (SeaWatch International)
Nicole Charriere (NEFSC)
Toni Chute (NEFSC)
Wendy Gabriel (MAFMC SSC, NEFSC)
Scott Gallagher (WHOI)
Jon Hare (NEFSC)
Deborah Hart (NEFSC)
Robert Johnston (NEFSC)
Chris Legault (NEFSC)
Michael Martin (NEFSC)
Vic Nordahl (NEFSC)
Jeff Normant (NJ DFW)
Loretta O'Brien (NEFSC)
Jennifer O'Dwyer (NY DEC)
Doug Potts (GARFO)
Mark Terceiro (NEFSC)
Dave Wallace (Wallace and Associates)
Jim Weinberg (NEFSC)

Appendix 2 Changes to assessment inputs

Commercial

The commercial length compositions were altered from the last assessment. The length compositions come from samples taken from landed catch (port samples). Each port samples consists of approximately 25 lengths (selected randomly) per landed catch from a single boat (trip). Boats are randomly selected from the vessels available on the day of sampling. Port samples are designed to be roughly proportional to the landings from each region. Port samples are systematic relative to time (evenly distributed over each quarter). The port sampler also collects information from the vessel landings sampled, including the approximate location of the area fished and the weight of the total landings.

In the 2013 assessment (Northeast Fisheries Science Center 2013), each port sample was attributed to a region (using the location data) and then the pooled proportion at length (averaging over all samples) from each region were expanded by the total landings from that region in that year.

$$\hat{P}_{r,y,l} = P_{r,y,l}C_{r,y}$$

where $\hat{P}_{r,y,l}$ was the expanded proportion at length (l), in region (r) and year (y), $P_{r,y,l}$ was the unexpanded proportion and $C_{r,y}$ was the catch by region and year. In order to get the length composition for the southern area, the $\hat{P}_{r,y,l}$ were summed over the regions that compose the southern area (SVA to SNE). The length compositions did not sum to one but that is not important for the assessment model which requires relative, but not true proportions.

The implied assumption of expanding the length composition by total landings in a region is that the port samples are randomly distributed in time and space relative to the landings from a region (random stratified sampling where the strata are the regions). Because the vessels selected for port sampling are randomly selected, random selection relative to space within a region is probably a reasonable assumption. Port samples are systematic relative to time however (they are stratified by quarter year), which is a violation of random selection relative to time. Therefore, it may be better to use cluster sampling techniques (see Cochran (1977)). Port samples are subsamples of samples (a single trip of many trips taken that quarter and landed at that port). They can be considered as 2 stage cluster samples (Cochran 1977). The estimate of the population mean is unbiased when the second stage sampling units are chosen with equal probability. The estimate of the population mean consists of a simple ratio based expansion, where the subsample is expanded to reflect the size of total sample from which it was drawn.

In the new assessment, the $P_{r,y,l}$ were expanded by the weight of the haul from which they came and then summed over each region and year (similar to the process for calculating a weighted average).

$$\hat{P}_{r,y,l} = \sum_{y} \sum_{r} P_{v,l}C_{v}$$

where $P_{v,l}$ and C_v are the vessel specific proportions and landings, respectively. Weight was the unit of measure chosen because the total number of animals landed was not recorded.

The change had the strongest effect on commercial catch at length during 1995 - 1999 and very little effect in most other years (Figure 170). 1995 - 1999 were years with relatively few port samples taken from relatively few regions.

Survey

The change to a cooperative survey using the *FV Pursuit* beginning in 2012 affected the way random tows from adjacent years were borrowed to fill holes (strata with no random tows) during 2011 and 2013 for calculation of abundance indices. In particular, it was not possible to use 2011 tows to fill 2012 holes or vice-versa because different vessels, gear and protocols were used starting in 2012. In addition, the new survey in 2012 and 2015 was meant to exclude the northern area while the survey in 2013 was meant to be on the northern area only. The 2014 survey was used primarily for gear testing and only a few strata were sampled in random survey mode. Survey data for 2012 and 2015 were therefore used to calculate abundance indices only for the southern area while survey data for 2013 was used to calculate abundance indices for the northern area only. No 2014 abundance indices were calculated. Therefore, northern area tows during 2013 were not borrowed to fill the intentional northern area 2012 holes although 2013 tows in other areas were used to fill 2012 holes. Northern area tows in 2014 tows were used to fill 2013 the northern area holes where necessary. The plan to survey areas south of the northern area in year one, survey the northern area in year two and take year three off was not followed perfectly during 2012-2014. It was followed in 2015 and is expected to be followed in future to the extent possible so that borrowing imputation and other approaches to filling holes are not necessary.

The ageing error vector in the assessment model was updated. The previous values could not be reproduced and the method used to generate them was unclear. The new values were based on the same data (with additional years added). The new ageing error vector was generated as a linear model fit to

$$\epsilon_a = sd(a_{prod,i,a} - a_{check,i,a})$$

where ϵ_a is the standard deviation of the ageing error for age a, $a_{prod,i}$ is the production age for individual i at age a and $a_{check,i,a}$ is the re-age of the same individual.

The standard deviation of ageing error increased with production age (Figure 171). The ageing error vector used in the assessment model was the linear fit to all of the non-zero ϵ_a. Because all zero values of ϵ_a had low sample sizes (Figure 172).

Figures

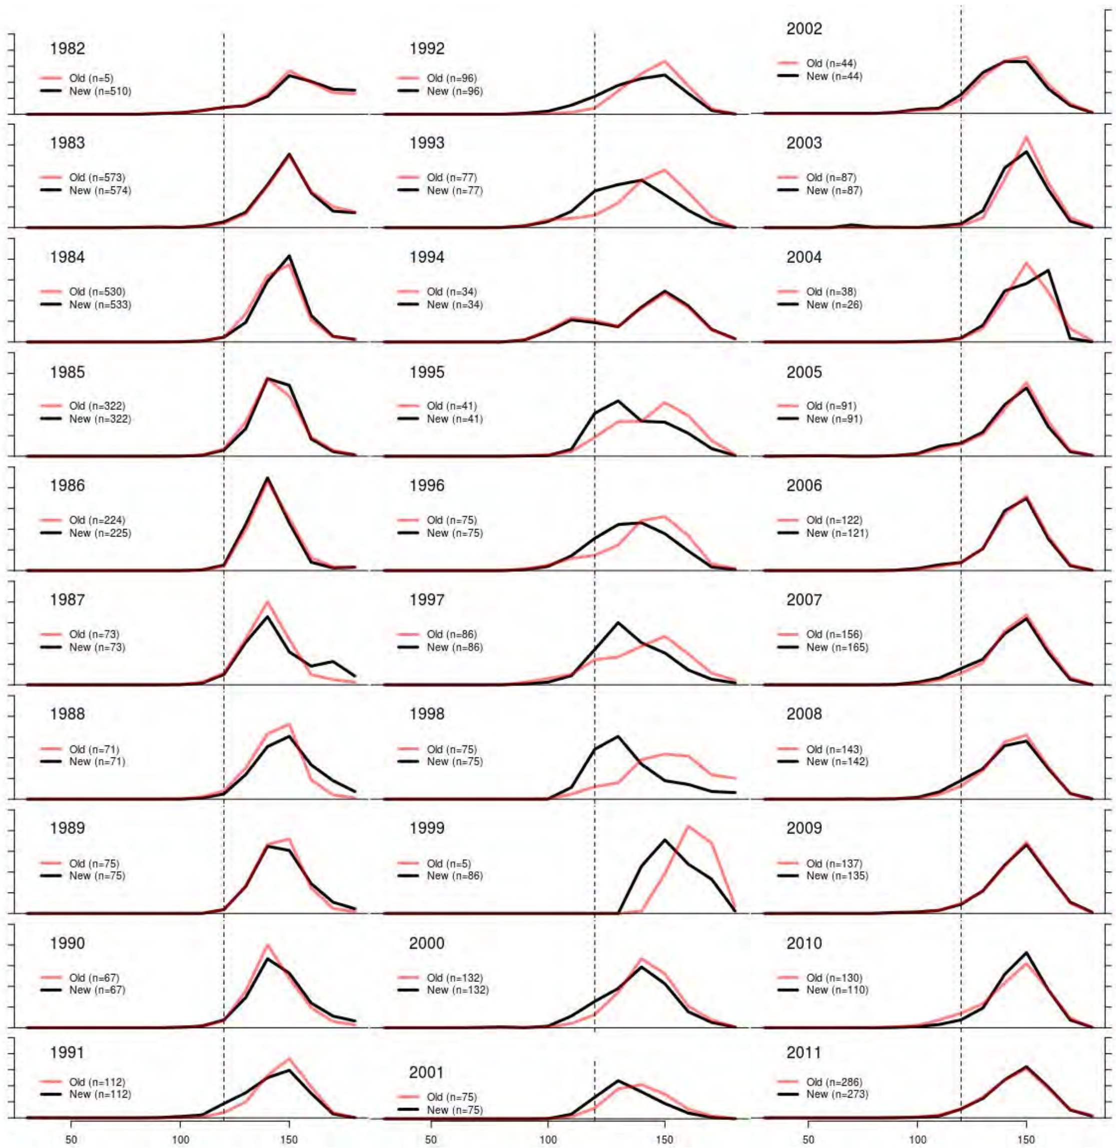

Figure 170: A comparison of the length compositions used on the surfclam assessment model in the last assessment (Old) vs. the current assessment (New). The x axis shows the shell length in mm and the y axis shows the relative frequency at each shell length. The sample sizes (n=) in the previous assessment are not the number of trips sampled (as in the current assessment). The sample sizes in the old assessment are the values used for data weighting of each component in the assessment. The vertical line at 120 mm is for reference only.

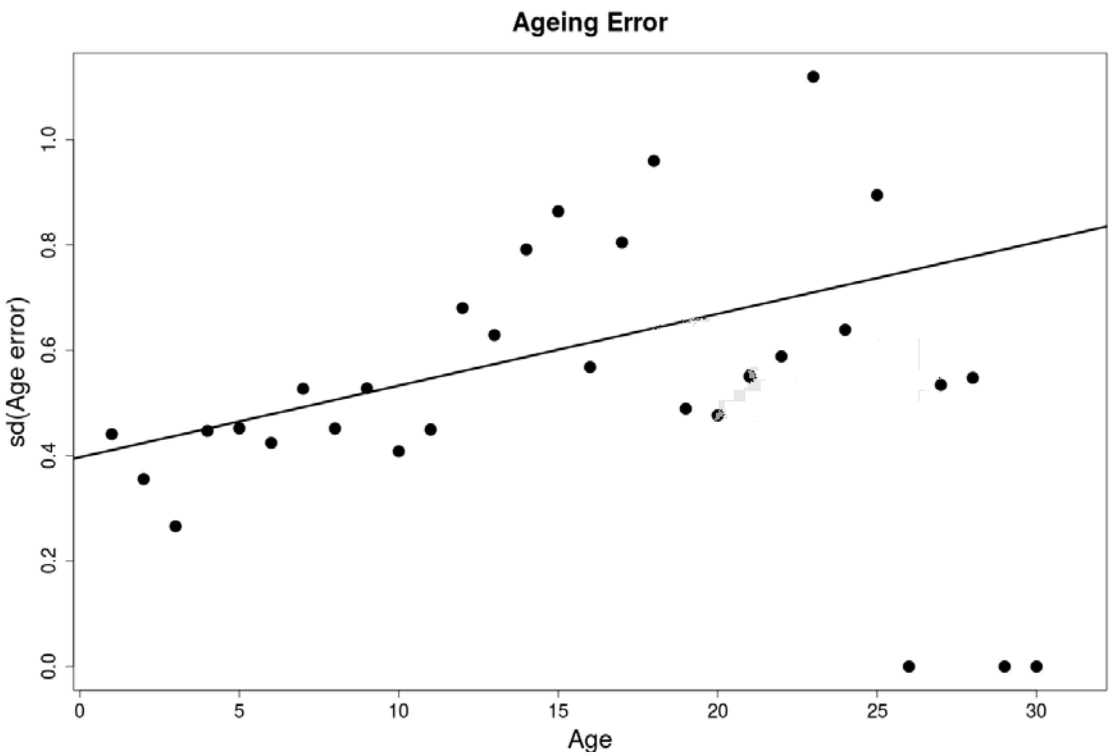

Figure 171: The standard deviation of the difference between production age and the re-age done to test ageing error against a linear fit.

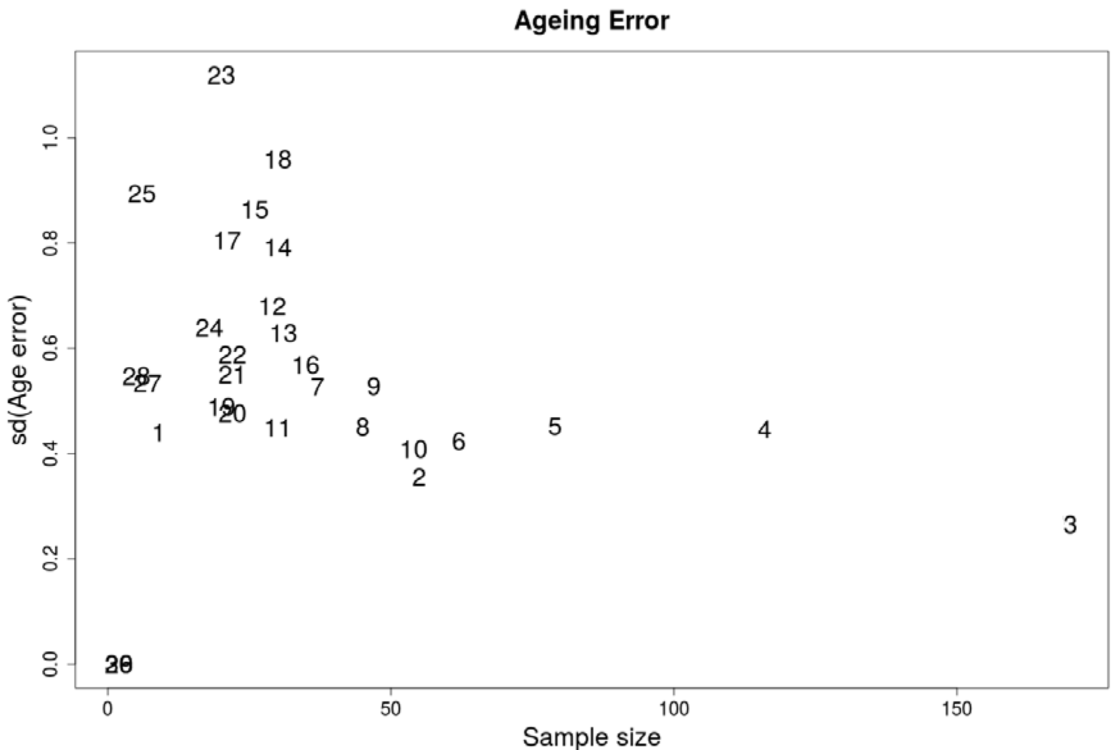

Figure 172: The sample size at age for standard deviation of the difference between production age and the re-age done to check ageing error. Each age is plotted as a numeral.

Appendix 3 Selectivity and assessment model performance

Introduction

In 2012 NMFS moved the clam survey from a research platform to a commercial one. All surveys previous to 2012 used a specially designed research dredge (RD). In 2012 the survey was conducted with a commercial dredge modified to retain smaller animals (MCD). The two dredges differ in selectivity (Figure 173) and efficiency (Figure 174). The MCD retains small animals at a reduced relative rate (lower selectivity at small sizes), and there was concern about loss of important information in future assessments.

Preliminary investigations of the data from the partial survey (4 of 6 regions were sampled) conducted with the MCD in 2012 show length composition similar to what would be expected based on selectivity. Comparing the length composition of the animals sampled by the MCD and RD reveal some differences between them (Figure 175).

The age composition of the animals surveyed with the MCD should not be as different from the age composition of those sampled with the RD (compared to length composition). The animals used for aging are stratified by length, which will mask selectivity differences because each length has representation in both dredges. Animals from the 2012 survey have not been aged so comparisons must be made based on the length of the animals that will be aged. So far, there appears to be some undersampling of small animals in the aging subsample (Figure 176). This issue bears watching as the survey continues in 2013.

There is no *apriori* reason to believe that the MCD will be less useful than the RD in providing informative data to the assessment. A reduced sample of a particular length should not theoretically pose a problem for the assessment model as long as the sample is representative of the general population and can be scaled up to population level values through selectivity. In fact, we expect that the increase in survey catchability should make the MCD a much more reliable tool for surveys.

Here, we examine the probable effects of changing dredges by comparing the results of the 2013 Atlantic surfclam assessment model (NEFSC 2013) with a mock model run using simulated MCD survey data. This exercise is intended to show how much the results of the current assessment would have differed had we conducted the survey from a commercial platform and used the MCD throughout the time series.

Methods

A SS3 model for the southern area (all regions south of GBK) was run using data from the 2013 Atlantic surfclam assessment, which was modified to simulate the MCD sampling properties as follows: 1) the selectivity of the survey index was altered, 2) the length composition data was altered and 3) the prior distribution on survey catchability was altered. All three of these changes represent likely differences in both data and model configuration corresponding to the shift in survey platform.

Selectivity

The assessment model used in the 2013 Atlantic surfclam assessment fixed (RD) selectivity at values estimated in a series of field experiments. Because we conducted selectivity experiments on the MCD simultaneously, we were able to substitute the field values estimated using the MCD for the values estimated using the RD (Figure 173).

Length composition data

Length composition data were altered as

$$L_{i,new} = L_{i,old} + (D_{s,i} * L_{i,old}) * c \tag{5}$$

where $L_{i,new}$ is the altered proportion at length for length bin i, $L_{i,old}$ is the proportion at length for length bin i used in the assessment, $D_{s,i}$ is the difference between the MCD selectivity, and RD selectivity for length bin i and c is a constant scaler used to increase the effect of the alterations (Table 35). The value of $c = 2$ was chosen to maximize the simulated effect of switching dredges. It would not be possible to increase the effect much further without losing some length classes entirely. It should be noted that (5) allows for both increases and decreases in the number of clams caught within a length bin. That is, for length bins in which the MCD catches clams at a higher rate than the RD, the number of animals in that length bin was increased. The opposite was true for length bins in which the MCD was less efficient than the RD (Table 35).

Prior on survey catchability

The prior on survey catchability was based on a log normal fit to variance weighted bootstrapped estimates of MCD efficiency (Figure 177). The estimates came from patch model analysis of depletion experiments. The methods used in patch model analysis are explained in Rago et al. (2006) and Hennen et al. (2012). The methods used in generating the prior distribution are explained in detail in Northeast Fisheries Science Center (2013).

Projections

The projection run examined here assumes that total catch will be equal to the average catch over the last 5 years. It also assumes that approximately 0.3 of the total catch will be fished in GBK and not the southern area. This scenario is identical to the ”status quo” fishing scenario in the 2013 Atlantic surfclam assessment (Northeast Fisheries Science Center (2013)).

Results

The SS3 model using altered inputs converged and diagnostics did not indicate any problems. Differences between the model used in the 2013 Atlantic surfclam assessment and the current exercise in selectivity (Figure 173), and fits to length composition data (Figures 175 and 180) were relatively minor. The scale, trend and terminal year status of estimated biomass was preserved with the altered inputs (Figures 181 and 182). Precision of the estimates improved with the altered data (Table 36). Conclusions about stock status with regard to fishing mortality were unchanged (Figures 181 and 182). Projections were somewhat more precise, but generally similar in trend, scale and probable stock status, to the projections from the 2013 Atlantic surfclam assessment (Table 36).

Discussion

The results of this exercise show that using data similar to what would have been observed had the survey always been conducted with the MCD produced assessment results that were similar to what was seen in the 2013 Atlantic surfclam assessment.

The expected effect of switching to the MCD on length composition was exaggerated in this study to make it a stringent test. In some cases, the length bin relative proportions were reduced by as much as 95% (Table 35). If the scaler c from 5 was increased much further we would have lost length classes all together, which would have made modeling difficult and reduced the comparability of the results. Setting $c = 2$ was considered to be a reasonable upper bound on the likely effects of switching dredges.

The increase in precision of this model over the 2013 assessment model is potentially spurious and may result from the somewhat artificial agreement between the selectivity and the length composition data (because length composition was adjusted using selectivity). It is likely however that the increase in precision is largely due to the reduction in the variance of the prior distribution on survey catchability and therefore a real result and an endorsement of the new dredge.

The results of this study indicate that switching to the MCD is not likely to diminish the performance of the assessment model, and may in fact increase the precision of model estimates.

Tables

Table 35: Size composition (cm) comparison between 2013 surfclam assessment and a size composition similar to what would have come from the survey using the MCD.

Appendix 4 Survey dredge efficiency

Increasing survey dredge efficiency, defined as the probability of capturing an animal if the dredge is towed over the bottom where that animal is buried, was an important consideration in switching to a commercial vessel as a platform for the NEFSC clam survey. The relatively small survey dredge deployed by the *RV Delaware II* had an estimated mean efficiency of approximately 0.23 and high variability in performance, with an estimated cv for efficiency of 1.32. A low mean dredge efficiency coupled with high variability resulted in high variance catches, which in turn increased the variability in estimates of mean abundance for survey strata, and ultimately for estimated biomass in the assessment.

The complex process for estimating survey dredge efficiency (described in detail in Northeast Fisheries Science Center (2013)) included 27 direct estimates of the efficiency of modified commercial dredges (MCD) similar to those that have been used in the NEFSC clam survey since 2012, including 8 estimates using the actual MCD used for the post-2012 surveys (Table 37). The efficiency of the MCD and the Pursuit dredge are substantially higher and more precisely estimated than the RD (Figure 53).

The depletion experiments have thus far been conducted in the southern area, with the most effort concentrated in the NJ region (Figure 183)

Tables

Table 37: Estimated dredge capture efficiency from depletion experiments. All experiments were conducted using a modified commercial dredge similar to, though somewhat smaller than the dredge that has been used for the NEFSC clam survey since 2012. Experiments after 2007 were conducted using the same dredge used in the survey.

Figures

Figures

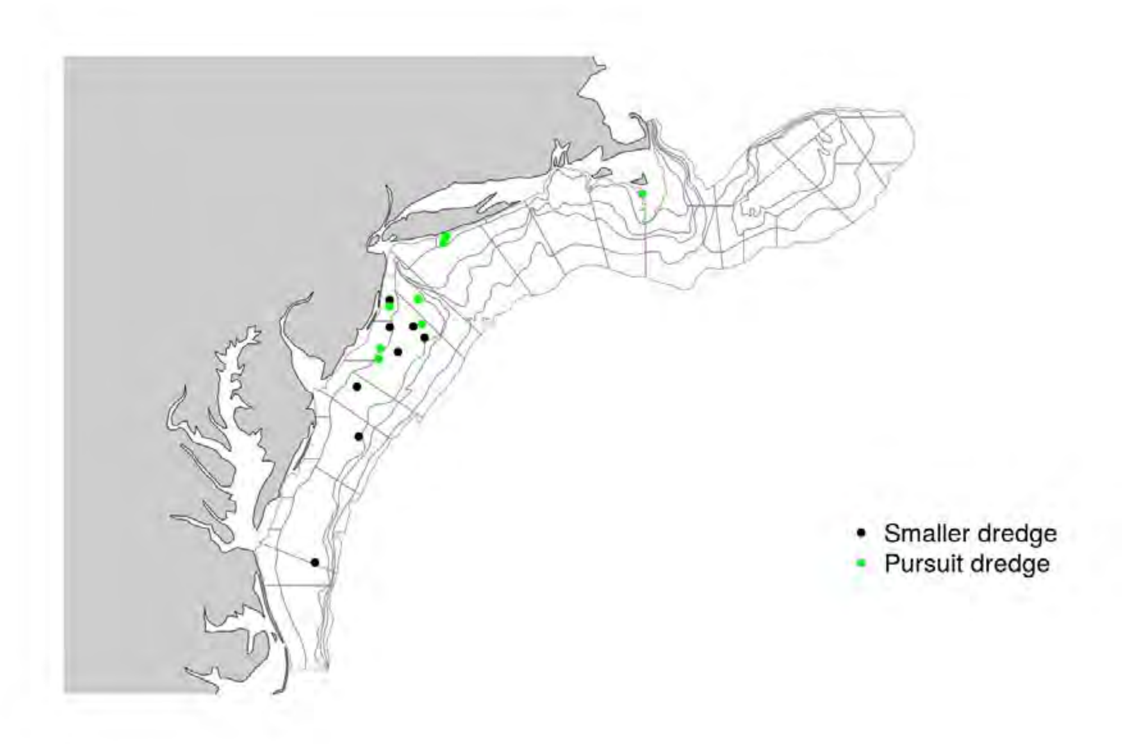

Figure 183: Position of each depletion experiment. The different colors represent the depletion experiments done with different dredges. The green dots are the experiments done with the dredge being used currently on the NEFSC clam survey.

Appendix 5 Appendix: Are broken clams a problem?

The mechanical sorting equipment employed on the ESS Pursuit results in higher sampling efficiency in terms of the number of animals processed per unit time, but also tends to increase breakage. The volume, mass and approximate length of broken clams is routinely recorded, but there has been concern that a size bias in the tendency to break could skew the size composition of the survey catch. A simple size composition comparison indicates that if there is size bias in the broken clams, it is unlikely to bias the size composition. Plots of length compositions (Figures 184 - 185) demonstrate that there is very little difference between compositions composed of whole animals and those composed of whole and broken animals. All survey analyses currently include both whole and broken clams.

There is also the possibility that clams are broken more often in smaller catches, as there would be less detritus to cushion the clams as they dropped from the dredge into the hopper for sorting. This could potentially bias the survey if the length composition of clams in "clean" habitat with less detritus were skewed by a high proportion of broken animals. Bias produced by this affect would probably not be very important to the assessment unless there was some reason to suspect that clean bottom resulted in some inherent difference in the length composition of clams caught there (e.g. clams grow more slowly on clean bottom). Nonetheless it may be worth evaluating, to determine if more clams are broken in smaller catches.

Although "trash" volume is no longer recorded on the NEFSC clam survey, we can compare the proportion of broken clams to the total number of clams caught in each tow. The relationship was weakly negative (Figure 186) implying that smaller catches do indeed produce a slightly higher proportion of broken clams. The effect was small enough however, to be unlikely to warrant much concern.

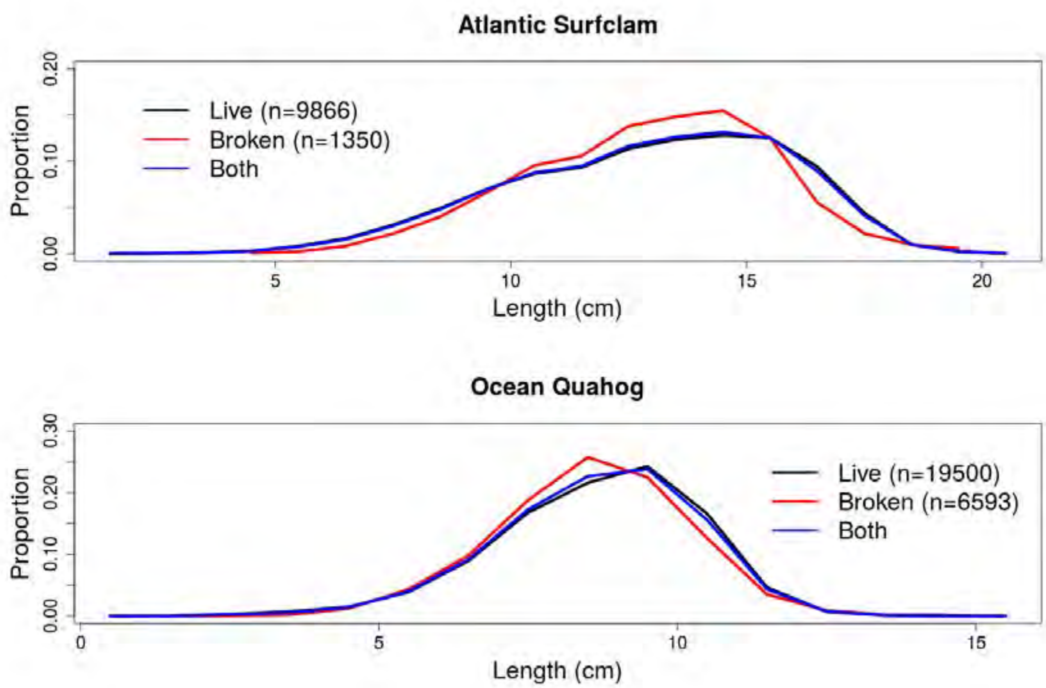

Figure 184: Length compositions from clam surveys on the ESS Pursuit through 2014. Proportion at length using only live (whole) clams, only broken clams, and live and broken clams together. There is very little difference between the length composition based only on live animals and the length composition using both whole and broken animals for both Atlantic surfclam and ocean quahog.

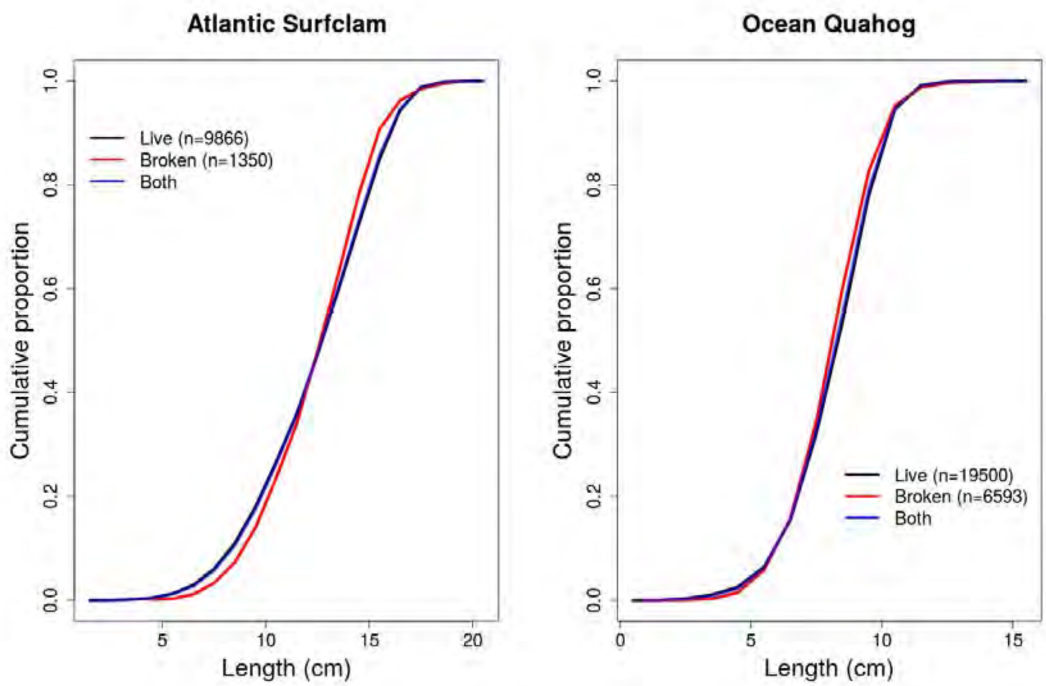

Figure 185: Cumulative length compositions from clam surveys on the ESS Pursuit through 2014. Cumulative proportion at length using only live (whole) clams, only broken clams, and live and broken clams together. There is very little difference between the cumulative length composition based only on live animals and the length composition using both whole and broken animals for both Atlantic surfclam and ocean quahog.

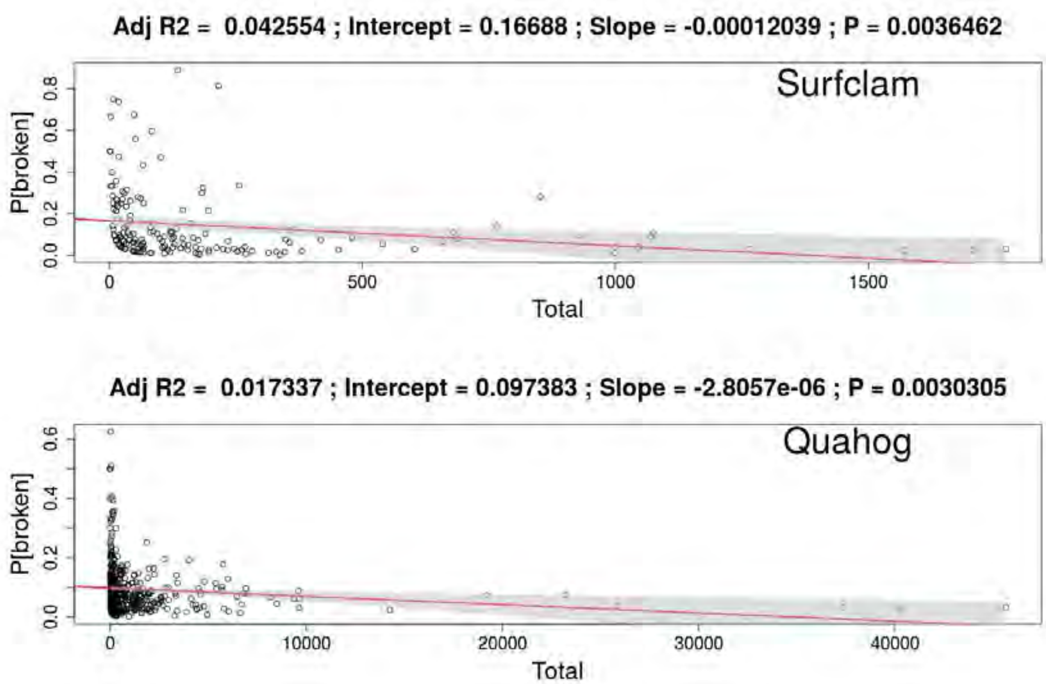

Figure 186: Correlation between the proportion of broken clams to the total clams caught in each tow from clam survey on the ESS Pursuit through 2014. The relationship was weak for both Atlantic surfclam and ocean quahog.

Appendix 6 Build a bridge

Southern area

The current assessment model for the southern area was based on the configuration of the assessment model for the southern area from the previous assessment (Northeast Fisheries Science Center (2013)). The alterations listed below illustrate step wise changes to the previous assessment model that result in the current assessment model. The sequence of these steps is not important, nor is it the actual sequence in which the changes occurred.

The first change was to incorporate new data (Figure 187). This required the addition of several new parameters (not estimated here, and left for illustrative purposes at previous values) because the new data came from a new survey (MCD). The MCD survey used a different dredge and required different selectivity parameters (Figure 188). The MCD also required a different prior probability distribution on catchability (Figure 189). The error around the growth curve was adjusted to follow a constant cv rather than a constant standard deviation (Figure 190). The relative weighting, in terms of assumed variance, of the composition data was decremented. This implicitly increased the weighting associated with the survey data and caused a shift in the trend in biomass (Figure 191) as the model began to fit the survey more closely. The ageing error was estimated, incorporating precision data from recent surveys (Figure 192). The cv of growth for young and old animals was estimated, rather than assumed (Figure 193). The number of recruitment deviations being estimated was increased to account for the additional years of data in the model, and the recruitment bias adjustment curve was altered to better fit the current data (Figure 194). The selectivity parameters for the MCD were adjusted in order to make the curve more flat topped and thus have higher selectivity for larger animals (Figure 195). Finally, the prior distribution for catchability on the RD was adjusted slightly to bring it more in line with the values estimated in the previous assessment ((Northeast Fisheries Science Center 2013); Figure 196). All of these adjustments together describe the sum of the changes made to the previous assessment model and build a bridge to the current model (Figure 197).

Northern area

The current assessment model for the northern area was based on the configuration of the assessment model for the northern area from the previous assessment (Northeast Fisheries Science Center (2013)). The alterations listed below illustrate step wise changes to the previous assessment model that result in the current assessment model. The sequence of these steps is not important, nor is it the actual sequence in which the changes occurred.

The first change was to incorporate new data (Figure 198). This required the addition of several new parameters (not estimated here, and left for illustrative purposes at previous values) because the new data came from a new survey (MCD). The previous assessment mistakenly allowed the swept area number per tow survey (SWAN) to contribute to the likelihood for estimating trend, that was corrected in this assessment (Figure 199). The MCD required a different prior probability distribution on catchability (Figure 200). The number of recruitment deviations being estimated was increased to account for the additional years of data in the model, the recruitment bias adjustment curve was altered to better fit the current data, and the variance around the recruitment deviations was fixed rather than estimated (Figure 201). The relative weighting, in terms of assumed variance, of the composition data was decremented. This implicitly increased the weighting associated with the survey data and caused a shift in the trend in biomass (Figure 202) as the model began to fit the survey more closely. The error around the growth curve was adjusted to follow a constant cv rather than a constant standard deviation (Figure 203). The MCD survey used a different dredge and required different selectivity parameters (Figure 204). The cv of growth for young and old animals was reduced to field estimated values (Figure 205). All of these adjustments together describe the sum of the changes made to the previous assessment model and build a bridge to the current model (Figure 206).

Appendix 7 Atlantic surfclam in Massachusetts, New York and New Jersey state waters

Thanks to Robert Glenn of the Massachusetts Division of Marine Fisheries, Jeff Normant of the New Jersey Division of Fish and Wildlife Bureau of Shellfisheries, and Jennifer O'Dwyer of the New York State Department of Environmental Conservation for data and assistance with this report.

The states of Massachusetts, New York, and New Jersey support and manage commercial Atlantic surfclam fisheries in their territorial waters (defined as from the shoreline to three nautical miles offshore) not covered by the NEFSC clam survey or assessment process. Commercial and survey data from state waters complement the assessment of the Federally managed EEZ stock given the biological linkage between state waters and the EEZ, and the possibility that environmental effects in inshore Atlantic surfclam habitat will be mirrored in the offshore population or vice versa.

Massachusetts, New Jersey and New York state waters have historically been excellent habitat for Atlantic surfclam and supported robust fisheries. In recent years, however, there is evidence of declining recruitment to the fishable population and mortality of large clams in New Jersey and New York based on size frequencies and total biomass estimates. This could be happening for any number of reasons including not enough successful spawning leading to reduced larval supply, or because newly settled Atlantic surfclam are not surviving due to predation, environmental conditions, or disease.

The percentage of total Atlantic surfclam landings (EEZ plus state waters) harvested from within state waters has been falling since the late 1980s (Figure 207). Commercial landings have also fallen dramatically in each of the three states. As recently as the 1990s, landings from state waters were around 500,000 bushels per year from New Jersey (all along the coast), 400,000 bushels per year from New York (off the south side of Long Island) and 260,000 bushels from Massachusetts (mostly from around Cape Cod Bay, Martha's Vineyard, and Nantucket). Since then, landings have been down about 90% in New Jersey, 70% in New York, and 75% in Massachusetts.

Each state has a shellfish management plan in place involving various methods of assessing the population. New Jersey and New York conduct annual or semi-annual surveys of the Atlantic surfclam resource in their territorial waters and track landings by subarea. Massachusetts has tracked Atlantic surfclam landings from subareas within its state waters since 1994. For details and results from each state see below.

New Jersey

The New Jersey State Atlantic surfclam survey has been conducted each summer by the New Jersey Bureau of Shellfisheries since 1988. The survey platform is a commercial clam vessel using a hydraulic dredge lined with 2x2 inch steel mesh; since 2010 either the F/V Ocean Bird or the FV Jersey Girl (Figures 208 - 209). The survey has followed a stratified random sampling protocol since 1994. The survey area includes the New Jersey territorial waters off the whole east coast of the state facing the Atlantic Ocean. The survey area is divided into 5 regions, and each region is divided into three one-mile-wide strata running parallel to the coast, covering Atlantic surfclam habitat out to the 3-mile limit of state waters (Figure 210). Surveys have generally completed between 250 and 330 five minute tows each year.

In preparation for the 2013 field season, a new survey station allocation plan was established to deliver the information needed for less money and time by emphasizing key strata. Unfortunately, hurricane Sandy struck in the fall of 2012, disrupting the coast to such a degree that there were virtually no Atlantic surfclam left in the reduced strata set, and the newly streamlined survey could not be considered a viable part of the time series. During the summer of 2014 the survey resumed sampling almost the whole strata set with a reduced number of stations.

After each survey tow, the volume of the total Atlantic surfclam catch is measured in bushels, and all the clams from one bushel are counted and measured for calculation of population estimates and length frequencies. For swept-area biomass estimates, the dredge efficiency is assumed to be 1.0, which yields a conservative population estimate. Abundance estimates are made using the mean number of clams per bushel from any given stratum multiplied by the biomass estimate in bushels. Grab samples of the sediment are also taken and juvenile Atlantic surfclam too small to be retained by the dredge are sorted out and counted.

Data from the state of New Jersey available for this appendix include survey biomass estimates, survey length frequencies, an index of juveniles from sediment grab samples through 2015, and landings from 1988 through the 2014-2015 fishing year (October 1 through May 31). The survey data from 2015 are considered preliminary.

Estimates of Atlantic surfclam biomass for all the survey strata combined since the first survey year rose to a peak in 1997, then fell to the lowest estimate of the time series in 2014. Rough estimates of exploitation rate (landings over biomass estimate for the year) in New Jersey state waters have been between about 2 and 12 percent (Figure 211). Whether overexploitation contributed to the biomass decline is unclear, but the population did recover from a time of high exploitation in the 1980s. The impact of Hurricane Sandy can be seen in the estimates following 2012.

In the 2000s, the length composition of Atlantic surfclam in New Jersey was narrow and composed of only larger Atlantic surfclam, indicating a lack of new recruitment. However, recent survey data shows some smaller clams recruiting to the population (Figure 212). Grab sample data collected regularly since 1994 from the area of the survey show that juvenile Atlantic surfclam are consistently setting successfully (Figure 213). Some years have been better than others with occasional larger sets such as the ones seen in 2005 and 2009, a typical pattern for bivalve recruitment. These data do not show any downward trend in production of juvenile Atlantic surfclam that might occur as the result of unsuccessful spawning due to a decline in spawning stock.

Atlantic surfclam landings for human consumption from New Jersey state waters have fallen from a high of about 700,000 bushels in 2003 to less than 100,000 in 2005 and to zero or near-zero levels since 2006. Since the early 2000s, a small fraction of landings came from “prohibited waters” - fishing areas where landings can only be sold as bait due to contamination (Figure 214). Since 2008 the percentage of estimated Atlantic surfclam standing stock in prohibited waters has varied from 5 to 26 percent (Figure 215). As of 2005 the landings of bait Atlantic surfclam surpassed edible Atlantic surfclam, and during the 2014-2015 season the only Atlantic surfclam harvested were less than 300 bushels for bait. As the standing stock of edible Atlantic surfclam has declined, the quota has been cut to levels prohibitive to fishing. There is no quota for bait Atlantic surfclam harvested from prohibited waters.

Temperature change may be at least partly to blame for the rapid decline in adult Atlantic surfclam off New Jersey, whether directly or indirectly (such as changes in the timing, location or type of phytoplankton blooms). Increased predation on juvenile clams may also be occurring as the result of temperature-driven changes in predator species or densities.

New York

The New York state Atlantic surfclam surveys are conducted by the New York Department of Environmental Conservation. Surveys took place in 1992, 1993, 1996, 1999, 2002, 2005, 2006, 2008 and 2012. Plans for running the survey in 2014, and then plans for 2015, were set aside due to problems with contracting the survey vessel. The surveys from 1992-1996 were conducted and analyzed using different methods than the later surveys, so the results may not be directly comparable to more recent surveys and thus are usually not included in plots and summaries in this report.

The survey area comprises four regions spanning the southern shore of Long Island. The three westernmost regions are subdivided into three mile-wide strata running parallel to the coast, reaching the limit of state waters. The remaining easternmost region consists of a single stratum from the shore to one mile out (Figure 216). The area further offshore in this region is not surveyed as the bottom is extremely rocky and incompatible with hydraulic clam dredges.

The survey is conducted using a commercial clam vessel, most recently the FV Ocean Girl (Figure 217), using a hydraulic dredge lined with 1 in. inch plastic mesh to retain smaller clams. The 1999-2012 surveys were conducted in the summer or fall, had an average of 236 stations, and used a random stratified sampling technique. Survey tows are three minutes long, the total volume of Atlantic surfclam from each tow is measured in bushels, and half a bushel of Atlantic surfclam from each tow is measured and counted for population estimates and length frequencies.

Data from the New York State surveys include total numbers, densities and length frequencies for all surveys and ages from all surveys except 2012. Atlantic surfclam landings from New York state waters are available through 2015 (although not all 2015 reports were in when we received these data so they are considered preliminary).

Population estimates from the survey years show that the Atlantic surfclam abundance increased through the 1990s and peaked in the early 2000s. After that begins a decline that is just as fast as the increase, and in 2012 the population was estimated to be about what is was in 1994 (Figure 218). The decline has been especially pronounced in the inshore and western strata. The simple catch/biomass exploitation rate has been less than 6% since the population increase so it does not seem like overfishing is responsible for the decrease (Figure 219). Just like New Jersey but to a lesser degree, it seems that New York Atlantic surfclam are declining mostly as the result of environmental stress.

Recruitment to the population has declined, but the 2008 and 2012 survey age frequencies both suggest there were more young clams than the two previous surveys (Figure 220), but many fewer than in 2002. There has also been an increase in very old Atlantic surfclam over the time series, so even though there are fewer clams overall the old ones do not seem to be dying disproportionally. The three main cohorts seen in the age frequency plots can all be followed from 2002 through 2012 but no new cohorts of any size seem to be making it past the age of five or six. The percentage of the Atlantic surfclam less than 100mm shell length caught (considered seed) caught on the survey is also a measure of recruitment. Many seed Atlantic surfclam were caught in the 2002 survey, especially in the western strata where up to 54% of clams caught were seed (Figure 221). The percentage of seed taken in the survey in years since has been falling. Survey length frequencies also indicate poor recruitment (Figure 222). Length at age plots do not seem to suggest New York Atlantic surfclam are growing more slowly in recent years (Figure 223), although all regions and strata were lumped together so spatial changes may be masked.

Despite the decline, Atlantic surfclam continue to be harvested in New York state waters at about 33 percent of the 1994-2014 mean (Figure 224). There was a very large harvest limit set in 2004 (930,000 bushels) and it was almost reached, making the landings from New York from that year almost double what they had been the year before, and since then there has been a downward trend. The harvest limit based on the results of the 2012 state survey is the lowest since 1994.

The Atlantic surfclam fishery in New York state waters has been limited entry since 1993 when 25 boats qualified, and as of 2015 there were 17 vessels still fishing. In 2003 an FMP was implemented, requiring the harvest limit not to exceed 5% of the biomass estimated by the most recent survey, and dividing it into equal quotas for each permitted vessel.

Massachusetts

The Massachusetts Department of Marine Fisheries has been logging total Atlantic surfclam landings from state waters since 1994, and since 2008, the location harvested. Landings are recorded as having been harvested in one of over 75 contiguous Designated Shellfish Growing Areas (DSGAs) surrounding the Massachusetts coast including Boston Harbor, Cape Cod, Buzzards Bay and the islands of Marthas Vineyard and Nantucket (Figure 225). Because there are so many small areas, these data give the DMF an overview of how both the resource and the fishing are distributed and where the particularly productive areas are (Figure 226). The data are also used to calculate landings per unit effort and track fishing effort and its impact in specific areas. The numeric data per DSGA are often confidential due to a small number of harvesters using the area and not available for publication, so they are reported by the larger statistical reporting areas SRAs (Figure 227). Even then much data remain confidential (Figure 228).

There is a cap on the number of commercial permits issued, a daily harvest limit of 200 bushels and a minimum size of 5.0 in. shell length. Catches must be reported using daily trip reports. Some of the Atlantic surfclam harvested are from contaminated areas and are only used for bait. A special permit must be issued for this and only 50 bushels can be landed per day. Landings of all Atlantic surfclam from Massachusetts have declined since the early 1990s and have varied without trend since 1997 (Figure 229).

Figures

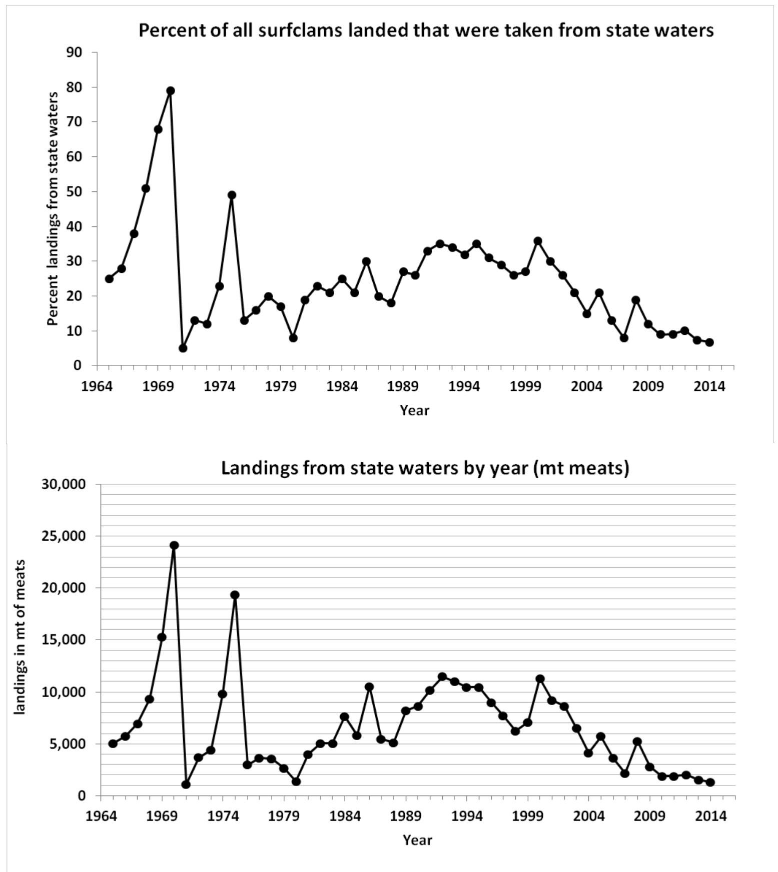

Figure 207: Percentage of total Atlantic surfclam landings harvested from state waters, almost entirely from New York, New Jersey and Massachusetts (top), and landings from state waters in metric tons of meats by year (bottom). There may be differences between the landings shown above and landings attributed to state waters in the main assessment report. The report has historically used dealer-reported landings minus logbook-reported landings (from EEZ - permitted vessels) to estimate state landings, which is not as accurate as the landings reported directly from the states. However, the assessment time series begins well before the states were keeping track of their landings and the subtraction method is still used for consistency.

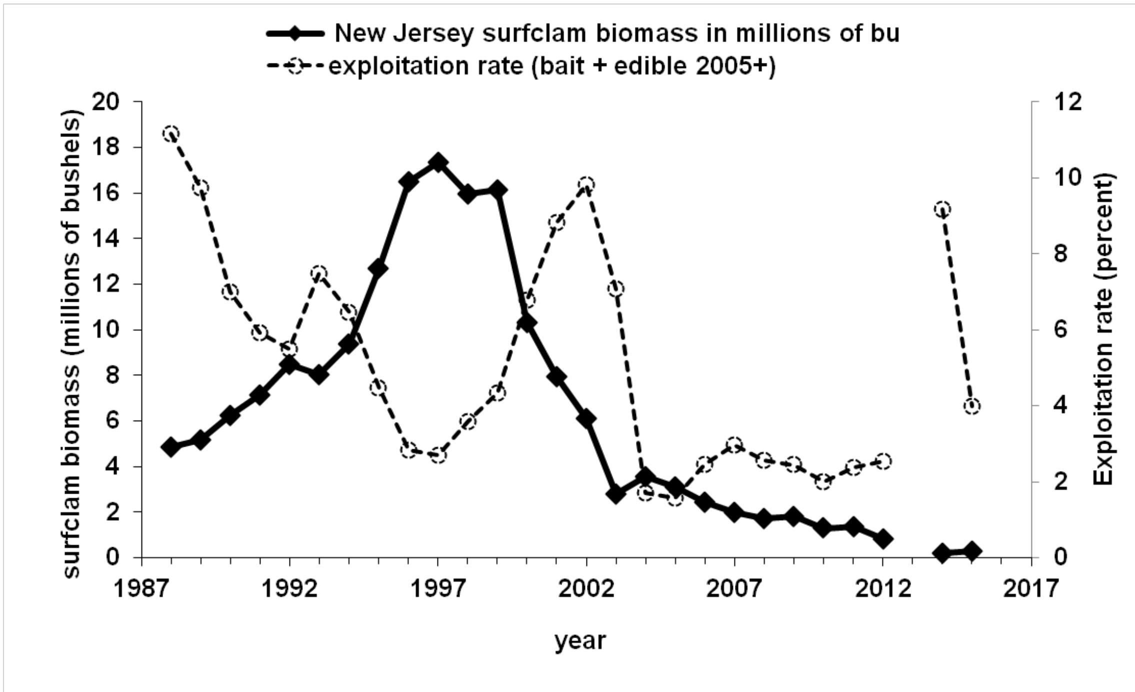

Figure 211: Exploitation rates (expressed as landings as a percentage of estimated biomass) and population biomass for New Jersey state Atlantic surfclam.

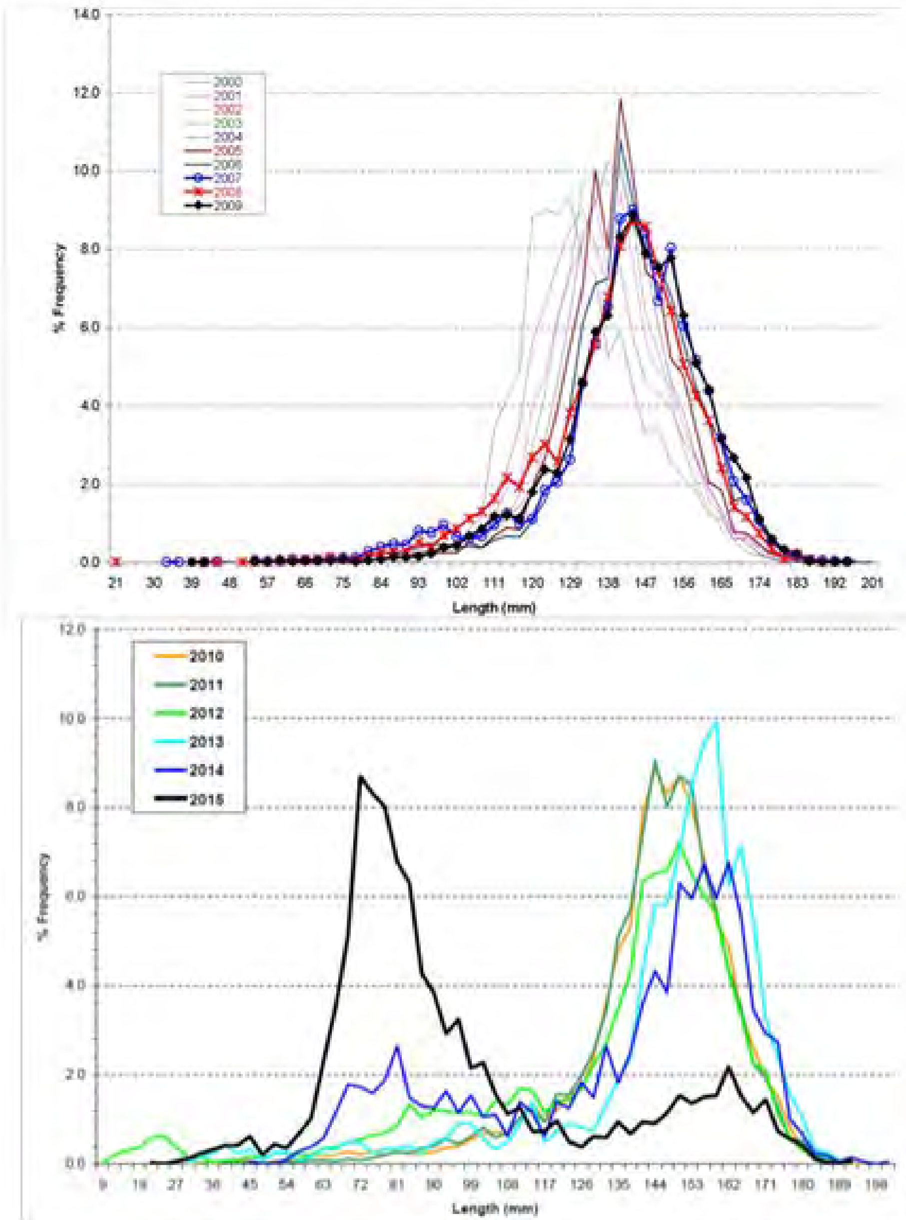

Figure 212: Length frequencies from the 2000-2009 (top) and 2010-2015 (bottom) New Jersey state Atlantic surfclam surveys. Not all strata were sampled in 2013 and 2014 but the most populous ones were. Note scales are different on both axes. Plots courtesy of Jeff Normant.

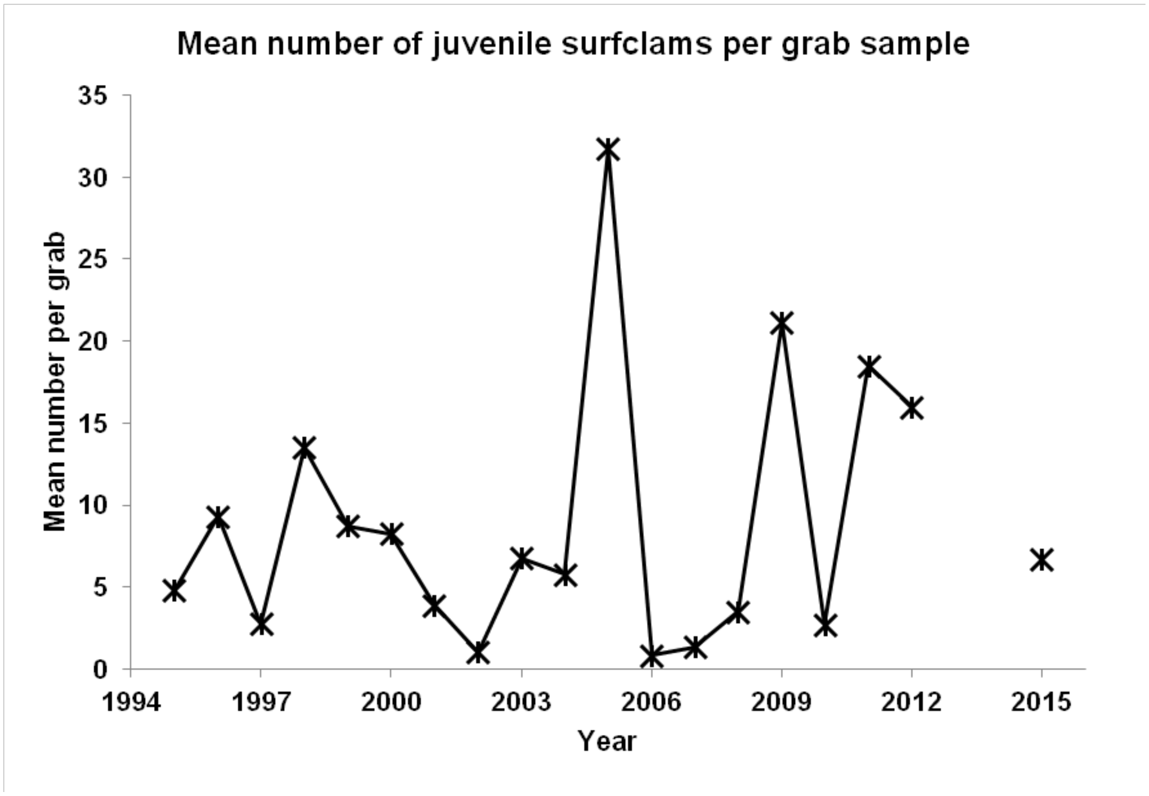

Figure 213: As part of the Atlantic surfclam survey, the state of New Jersey takes sediment grab samples, which contain juvenile Atlantic surfclam too small to be retained in the survey dredge. The clams are generally less than 10mm. About 300 grab samples were taken each year up until 2012, in 2013 and 2014 there were no grabs done, and 186 grabs were done in 2015. The area sampled is 1/10 of a square meter.

Appendix 8 Appendix: Management strategy evaluation

Introduction

The Atlantic surfclam (*Spissula solidissima*) has supported an important US fishery for many years (Northeast Fisheries Science Center 2010). There are, however, outstanding questions regarding the optimal biological targets and thresholds for Atlantic surfclam management, which warrant additional exploration through this management strategy evaluation.

The current maximum fishing mortality rate threshold is $F = 0.15$, which is a proxy for F_{MSY} and was derived by setting it equal to the current estimate of natural mortality (M). The Atlantic surfclam fishery has historically been lightly fished; therefore, the dynamics of the resource under fishing pressure near threshold intensity are unknown. There are also regional dynamics to the fishery and biology (*i.e.*, recruitment, growth, and M), and changes in fishing pressure across regions over time. Given the levels of exploitation and what is known about the dynamics of this resource, is $F = 0.15$ an appropriate overfishing threshold for Atlantic surfclam? The current control rule biomass target, also a proxy, is a fraction (0.5) of the biomass estimated in an earlier year (1999), and the minimum stock size threshold is set at a fraction (0.5) of the current control rule target. The current control rule applies to the entire stock in the US EEZ, but the biomass for a segment of the population called the southern area, which runs from Southern Virginia to Southern New England, is below target (as of the last assessment Northeast Fisheries Science Center (2013)), while the remainder of the population, the northern area located on Georges Bank is above target. Are these control rule reference points appropriate for Atlantic surfclam?

The current stock assessment models the two segments of the population separately (southern and northern areas), and then combines them for management purposes. The basis for separating the stocks were differences in exploitation patterns, growth, recruitment and the timing of surveys. Given the differences between areas, would the management of the resource be improved if the stocks were also managed separately? These questions have not been formally evaluated.

Methods

Simulation model

The population simulation model was age structured, such that for ages a

$$N_{t,a} = \begin{cases} R_t & \text{if a=1} \\ N_{(t-1),(a-1)} * e^{-Z_{(t-1),(a-1)}} & \text{if } 1 < a < a_{max} \\ N_{(t-1),a_{max-1}} * e^{-Z_{(t-1),a_{max-1}}} + N_{(t-1),a_{max}} * e^{-Z_{(t-1),a_{max}}} & \text{if } a = a_{max} \end{cases} \quad (6)$$

where $a_{max} = 30$, $N_{t,a}$ was the number of animals in year t at age a, R_t was the number of recruits in year t (see below). $Z_{t,a}$ was the instantaneous total mortality defined by

$$Z_{t,a} = F_t * S_a + M \tag{7}$$

where F_t was the fully selected fishing mortality, S_a was the fishery selectivity in age a, converted from selectivity at length (see below) and M was the natural mortality rate, which was constant over time and age.

The spawning stock biomass for each age in each year $SSB_{t,a}$ was determined by

$$SSB_{t,a} = N_{t,a} * Mat_{t,a} * W_{t,a} \tag{8}$$

Maturity $Mat_{t,a}$ was 0.5 at age 1 and 1 at all other ages.

Weight at age was modelled as a function of mean length and age

$$W_a = \begin{cases} e^{-9.27} L_a^{2.73} & \text{southern area} \quad (9) \\ e^{-9.16} L_a^{2.73} & \text{northern area} \quad (10) \end{cases}$$

where W is the weight (g) and L_a is the predicted mean length at age a (mm) such that

$$L_a = \begin{cases} 162.6(1 - e^{(-0.23(a+0.14))}) & \text{southern area} \quad (11) \\ 145(1 - e^{(-0.29(a-0.64))}) & \text{northern area} \quad (12) \end{cases}$$

The parameters used in eq. (9 and 11) were averaged values for each region derived as in Northeast Fisheries Science Center (2013). W_a and L_a refer to weight and length at age a, respectively.

Fishery selectivity at age (S_a) measures the relative impact of fishing on different age groups. It was defined as the relative proportion of age a animals in the population encountered and caught. The selectivity curve was logistic and taken directly from the previous Atlantic surfclam assessment for the northern area (Northeast Fisheries Science Center 2013).

The yield from the fishery was calculated as

$$Y_t = \sum_a \frac{F_{t,a}}{F_{t,a} + M} * N_{t,a} * W_a * (1 - e^{-(F_{t,a}+M)}) \tag{13}$$

where $F_{t,a} = F_t * S_a$ (Baranov 1918).

Recruitment (R_t) followed Beverton Holt (Beverton and Holt 1957)

$$R_t = \frac{SSB_{t-1}}{\frac{SSBR_{f=0}(1-h)}{4h} + \frac{5h-1}{4hR_0} * SSB_{t-1}} \tag{14}$$

or Ricker (Ricker 1954) dynamics.

$$R_t = \alpha SSB_{t-1} e^{-\beta SSB_{t-1}} \tag{15}$$

where

$$\alpha = \frac{log(h) - log(0.2)}{0.8 R_0 SSBR_{f=0}} \tag{16}$$

$$\beta = \frac{e^{\alpha R_0 SSBR_{f=0}}}{SSBR_{f=0}} \tag{17}$$

and $SSBR_{f=0}$ was the equilibrium unfished spawning stock biomass per recruit, R_0 was equilibrium unfished recruitment and steepness (h) was a simulation specific random variable (Table 38). The bounds on h were based on He et al. (2006) and further modified based on the results of sensitivity testing in the assessment model. Half of the total simulation runs used Beverton Holt stock recruitment dynamics and the other half used Ricker.

Control rule

The current process for setting catch and associated landings limits (i.e., quotas) for the Atlantic surfclam fishery is complicated. For Mid-Atlantic Fishery Management Council (Council) managed stocks, acceptable biological catch limits (ABC) are set at a level less than the catch associated with the maximum fishing mortality threshold rate ($F = 0.15$) using a control rule that is a combination of the predetermined Councils risk policy (i.e., maximum tolerance for overfishing under specific conditions) and Scientific and Statistical Committee (SSC) decisions on the degree of uncertainty associated with the stock assessment. Because setting these catch limits involves a committee decision on the degree of uncertainty in the assessment, and is not a purely formulaic control rule, it is difficult to apply directly and requires some simplification for simulation in this MSE. The Councils risk policy which is used in the derivation of the Atlantic surfclam ABC is described on page 51 of Amendment 16 to the fishery management plan (MAFMC 2011; Figure 230). The risk policy is conditioned on the ratio of current stock biomass relative to the control rule (stock replenishment) threshold, and whether the life history is considered to be typical or atypical[5]. The policy includes a stock replenishment threshold defined as the ratio of $\frac{B}{BMSY} = 0.10$, to ensure the stock does not reach low levels from which it cannot recover. The probability of overfishing is 0 percent at $\frac{B}{BMSY} = 0.10$ and increases linearly until the inflection point of $\frac{B}{BMSY} = 1.0$, where a 40 percent probability of overfishing is utilized for stocks defined as typical, and a 35 percent probability for those defined as atypical. In addition, the risk policy has associated regulations that govern setting ABC for stocks under rebuilding plans and in instances where no maximum fishing mortality rate threshold has been identified. Neither of these cases apply to Atlantic surfclam.

[5]An atypical stock has a life history strategy that results in greater vulnerability to exploitation, and whose life history has not been fully addressed through the stock assessment and biological reference point development process.

Simulation set up

Simulations of a managed population like Atlantic surfclam must account for management actions, because the actions of managers will affect population dynamics. Management actions were simulated by including a simple control rule (based on a simplified version of the current Atlantic surfclam control rule) with target (the control rule inflection point described above) and stock replenishment threshold levels of SSB in the base simulation routine. The target was the desired level of SSB. The threshold was the minimum acceptable SSB. If SSB_t fell below SSB_{target}, F_{target} was reduced linearly, finally reaching 0 where $SSB_t = SSB_{threshold}$ (Restrepo and Powers 1999; Figure 231). This framework allowed a comparison of various candidate control rule reference points ($SSB_{threshold}$ and SSB_{target}) as well as an examination of the response of the population to management. Control rule reference points were $\frac{SSB_{target}}{SSB_0}$ and $\frac{SSB_{threshold}}{SSB_0}$, the fraction of unfished biomass (SSB_0) that correspond to target and threshold biomass levels respectively. $\frac{SSB_{threshold}}{SSB_0}$ levels between 0.05 and 0.5 and $\frac{SSB_{target}}{SSB_0}$ levels between 0.1 and 1.0 (in increments of 0.05) were tested by drawing randomly with replacement from the candidate values (Table 38).

Although the true Atlantic surfclam control rule is based on the probability of overfishing, rather than the fraction of SSB_0 remaining, and acts on the ABC, rather than the F_{target}, the functional response of the stock to management is similar. In both cases, the catch will be reduced in proportion to biomass, when biomass drops below a target value (the probability of overfishing depends on F_{target} and biomass; when biomass is low, F_{target} must be reduced proportionately to reduce the probability of overfishing). In both cases, fishing will no longer be allowed when the biomass drops below a threshold value.

All simulations included lognormal autocorrelated assessment error. Assessment error was included to mimic the uncertainty around biomass estimates from an assessment, and that error was autocorrelated to reflect a situation where an error in the assessment in one year was more likely to produce an error in the following assessment(s) (Deroba and Bence 2008). Assessment error was described by

$$S\hat{S}B_t = SSB_t * e^{\epsilon_t - \frac{\sigma^2_{At}}{2}} \tag{18}$$

$$\epsilon_t = \epsilon_{t-1} * \varphi * \eta + \sqrt{1 - \varphi^2} \tag{19}$$

where $\eta \sim N(0, \sigma^2_{At})$ was the assessment error, φ was the autocorrelation coefficient, and ϵ_t was the year specific autocorrelated random deviation. The parameterization of eq. 19 makes $S\hat{S}B_t$ an unbiased estimate of SSB_t (Deroba and Bence 2012).

A manager may decide on a particular F_{target} for a fishery, but that F_{target} may not be achieved exactly. This discrepancy is often referred to as implementation error. Implementation error was included by modifying F_t (where $F_1 = F_{target}$) such that

$$\hat{F}_t = F_t * e^{\epsilon_{Ft} - \frac{\sigma^2_{Ft}}{2}} \tag{20}$$

where $\hat{F}_t$ was an unbiased estimate of F_t, including lognormal implementation error ϵ_{Ft} with error variance σ^2_{Ft}.

Simulated management included an "assessment" at the end of each 3 years. That is, a decision to reduce F_t from it's initial value (F_{target}) was made at the end of each 3 year period depending on the value of $S\hat{S}B_t$ relative to SSB_{target} and $SSB_{threshold}$. The actual fishing mortality experienced by the simulated population ($\hat{F}_t$) was then based on the (potentially) reduced F_t using eq. 20.

Simulated management over different spatial scales

Recruitment, growth, and natural mortality in the US Atlantic surfclam population are not uniform across space. Simulation results might be altered by combining the results from independently recruiting areas experiencing different life history parameters. Because the Atlantic surfclam stock is assessed using two distinct areas, simulations were set up to mimic the biological parameters measured in each area. Simulations combined the two regions, which had independent growth, weight at age, steepness, and natural mortality parameters, using two contrasting spatial management scenarios. In all cases, recruitment events occurred separately in each region according to eq. 15. Growth in each region was determined by

$$L_a = \begin{cases} (162.6 + N(0, \sigma_{L\infty,S})) * & (21) \\ (1 - e^{((-0.23+N(0.0,\sigma_{k,S}))(a+(0.14+N(0.0,\sigma_{t0,S}))))}) & \text{southern area} \\ (145.6 + N(0, \sigma_{L\infty,N})) * & (22) \\ (1 - e^{((-0.29+N(0.0,\sigma_{k,N}))(a+(-0.64+N(0.0,\sigma_{t0,N}))))}) & \text{northern area} \end{cases}$$

where N were normally distributed random variables with parameters $(0,\sigma_{x,a})$, where x represents either k, $t0$ or $L\infty$, the growth parameters describing the curvature, location and asymptote (respectively) of the growth curve (von Bertalanffy 1938), and the subscript a represents the southern area (S) or the northern area (N). Simulation specific regional growth and natural mortality parameters were selected from the distributions described in Table 38 and then held constant for each region over that simulation. All other parameters (F_{target}, φ, σ_t^{A2}, σ^2_{Ft}, $\frac{SSB_{threshold}}{SSB_0}$ and $\frac{SSB_{target}}{SSB_0}$; Table 38) were simulation specific, but shared between the regions.

In the first management scenario, each region was managed separately (separate stocks, SS). Under SS, each region had its own assessment in which the biomass in that region was compared to the control rule reference points ($\frac{SSB_{threshold}}{SSB_0}$ equal for each region, though the SSB_0 for each might be somewhat different depending on regional life history parameters and stochastic recruitment variability during the unfished portion of each simulation) and then the F_t for that region was adjusted from F_{target} if necessary. SS regions were then fished according to their individual $\hat{F}_t$ after application of eq. (20). In the second management scenario (one stock, 1S), the sum of the biomasses from each region was compared to the control rule reference points ($\frac{SSB_{threshold}}{SSB_0}$ multiplied by the sum of the SSB_0 in the case of $B_{threshold}$), and F_t for all regions was adjusted if necessary. 1S regions were all fished according to the resulting $\hat{F}_t$ and yield was extracted from each according to eq. (13), but using the region specific M, $N_{t,a}$ and W_a. SS and 1S total yield and total biomass were the sum of the yield and biomass in each region, and the cv of yield was the mean of the cv of yield in each region. In both scenarios the period between assessments, and subsequent adjustments to fishing mortality rates, were 5 years to mimic a realistic assessment interval.

Simulation

Some parameters in the model had unknown true values, such as steepness (h) and natural mortality (M). Other parameters, such as potential values for management quantities like F_{target} or $\frac{SSB_{threshold}}{SSB_0}$, had unknown affects on biomass and yield. To understand how these parameters affected the outcome of simulations, a range of values for each was examined.

In each new simulation run a random variable was drawn for: h, M, F_{target}, φ, σ^2_{At}, σ^2_{Ft}, $\frac{SSB_{threshold}}{SSB_0}$ and $\frac{SSB_{target}}{SSB_0}$ (Table 38). These were constant for the duration of the run. The simulation was initialized by running a cohort based on the simulation specific M out to a_{max}. The proportion at age was then multiplied by R_0. All simulations included a period of 100 years without fishing intended to allow the population to stabilize. The simulation continued through 100 years with fishing and then new values were drawn for 49,999 subsequent runs.

Results from simulations (both with and without spatial complexity) were compared to values of F_{target}, $\frac{SSB_{threshold}}{SSB_0}$ and $\frac{SSB_{target}}{SSB_0}$, while considering the effects of φ, σ^{A2}_t, σ^2_{Ft}, M and h, to determine how reference points affected biomass and yield.

Analysis

To understand how the stochastic parameters affected simulation results, mean scaled biomass ($\frac{\overline{SSB}}{SSB_0}$), mean scaled yield ($\frac{\overline{Y}}{SSB_0}$), coefficient of variation in yield $cv(Y)$ and time without fishing due to implementation of the control rule ($t_{F=0}$) were compared to natural mortality M, steepness (h), target fishing mortality (F_{target}), $\frac{SSB_{threshold}}{SSB_0}$, $\frac{SSB_{target}}{SSB_0}$, φ, σ^2_{At}, and σ^2_{Ft}. Interactions and main effects were examined with generalized linear models (McCullagh and Nelder 1989). In an example predicting mean biomass, the saturated model contained all the main effects and selected interactions between the predictor variables as

$$(\frac{\overline{SSB}}{SSB_0}) = f(\overrightarrow{b}(1 + (h * F_{target} * \frac{SSB_{threshold}}{SSB_0} * M) + \sigma^2_{At} + \varphi + \sigma^2_{Ft}) \qquad (23)$$

where f represents the link function and $\overrightarrow{b}$ is the vector of coefficients estimated in the model. Models predicting biomass and yield were overdispersed relative to the Poisson distribution so the error structure for the models described generally by eq. 23, was quasipoisson with a log link function (R Core Team 2013; McCullagh and Nelder 1989). This distribution includes a dispersion parameter for variance and reduces the degrees of freedom for estimation accordingly.

The relative importance of predictors (e.g. h, F_{target}, and M) was determined using deviance tables. The number of simulations was large and simulation results are not data in the traditional sense. Therefore model selection approaches based on AIC would result in very complicated models in which nearly all covariates and interactions tested would be significant. The deviance table approach may also be better than conventional χ^2 tests, which are more sensitive to the order in which explanatory variables are tested (Ortiz and Arocha 2004).

Variables tested included each categorical and continuous predictor variable, and several interactions between them. Linear models for deviance table analyses were fitted by sequentially adding main effects and interactions. Explanatory variables were judged statistically significant as they entered the model if they reduced model deviance by at least 5% of the deviance associated with the null (intercept only) model. This allowed the exclusion of the explanatory variables that least affected the response variables of interest from further consideration.

Simulation results were also plotted and inspected visually for indications of nonlinearity. In particular after initial results showed that steepness was not an important predictor of biomass or yield, results were binned over steepness values to determine if the effects of steepness were being masked by the stronger effects such as fishing mortality.

Results

Simulations

Because $\frac{SSB_{target}}{SSB_0}$ and $\frac{SSB_{threshold}}{SSB_0}$ were highly correlated, results using each were similar and results showing $\frac{SSB_{threshold}}{SSB_0}$ only are discussed here for simplicity.

Deviance tables show that the effects of F_{target}, steepness (h), control rule (stock replenishment) threshold ($\frac{SSB_{threshold}}{SSB_0}$) and M were better predictors of mean biomass, yield, variation in yield and time without fishing than any of the other candidate predictors and interactions tested (Table 39). Biomass tended to decrease with F_{target}, while variation in yield and time without fishing tended to increase (Figures 232 – 233). Yield increased initially with F_{target} before decreasing at higher values of F_{target}. Increasing natural mortality resulted in higher yields, more variation in yield and less time without fishing. Higher steepness resulted in higher biomass and yield and less variation in yield and time without fishing. Higher control rule (stock replenishment) thresholds produced higher biomass, more time without fishing, and more variation around less yield.

An interactions involving $\frac{SSB_{threshold}}{SSB_0}$ and steepness was an important predictor time without fishing (Table 39). At high $\frac{SSB_{threshold}}{SSB_0}$ and low h, the population was not productive enough to trigger recovery and a cessation of the management actions that shut down the fishery. At low $\frac{SSB_{threshold}}{SSB_0}$ and high h, the population was productive enough and the control rule (stock replenishment) threshold low enough to never trigger a shut down.

Stock recruitment dynamics

The stock was more productive at higher F when recruitment dynamics were driven by the Ricker curve (Figure 234).

Simulated management over different spatial scales

The effect of spatial scale on management was substantial on average across most of the response variables tested (Table 40). Mean biomass was greater when the stocks were managed separately, but mean yield was greater under single stock management (Figure 235). The higher yields however, resulted in a tendency to over-harvest and a higher probability of fishery closures due to management intervention, as well as higher variability in yield.

Discussion

Management strategy evaluation can be a useful tool for determining reference points that work well for a variety of life history traits and possible states of nature. Currently, there are many aspects of Atlantic surfclam biology that are poorly understood. The response of the Atlantic surfclam stock to ocean warming is unknown, and the behavior of the fishery may change over time as well. This management strategy evaluation used a broad distribution of possible values intended to capture both the unknown biological parameters and a reasonable suite of potential fishery conditions. The F_{Target} and control rule reference points were simulated over 100 years using random combinations of important biological and fishery parameters. Therefore the results of these simulations should describe management quantities that will work well under many possible combinations of life history traits and fishery conditions.

Simulation

The simulations demonstrate the utility of potential reference points relative to metrics of fishery performance. For example, SSB is maximized at low F regardless of the control rule (stock replenishment) threshold or target used, while yield is maximized at intermediate levels of F and lower values of $\frac{SSB_{threshold}}{SSB_0}$ or $\frac{SSB_{target}}{SSB_0}$ (Figures 236 - 237). Examination of the relative SSB and yield at various F_{Target} and B_{Target} or $B_{Threshold}$ (Tables 41 - 44) allow for comparison of the likely performance of competing reference points.

Variation in yield and time without fishing due to closures were near minimum at all the values of $\frac{SSB_{threshold}}{SSB_0}$ or $\frac{SSB_{target}}{SSB_0}$ tested when $F < 0.15$. The current $F_{Threshold} = 0.15$. If we consider only $F_{Threshold} <= 0.15$ then there is no further need to concern ourselves with variation in yield or the probability of fishery closures.

The current $B_{Threshold}$ is $0.25 * B_{0,proxy}$ and the current B_{Target} is $0.5 * B_{0,proxy}$. Using these values, yield is maximized at $F_{Target} = 0.12$, while $SSB = 0.5 * B_0$ at $F_{Target} = 0.11$.

The Atlantic surfclam fishery is market limited and currently fished under quota (see 1.3). Therefore there is little interest from either industry or management to increase yield. Under these conditions, it might be advantageous to weight SSB somewhat more than yield when deciding on reference points.

Simulated management over different spatial scales

There does appear to be an advantage to managing the Atlantic surfclam population as separate stocks. In general it results in higher yield and biomass, less variability in yield, less fishery closures over all values of h and $\frac{SSB_{threshold}}{SSB_0}$. Managing for separate stocks also results in higher biomass over all values of F, but higher yield only when F is over approximately 0.12, a high value, relative to what the fishery is currently experiencing. The advantages in variation in yield and time without fishing due to closures also appear to accrue only at values of F that are somewhat higher than the Atlantic surfclam population is currently experiencing. Therefore, while it appears to be advantageous to manage the population as separate stocks, those advantages are less clear at low F and the switch to management as separate stocks may not be important unless the fishing mortality rate increases relative to its current state.

Tables

Table 38: Sampling distributions of random variables used in simulation. The variable h was steepness, M was natural mortality, F_{target} was fully selected fishing mortality target, φ was the autocorrelation coefficient for assessment error, σ_{At}, σ_{Ft} were the standard deviation of annual assessment and implementation error, respectively, $\sigma^S_{L\infty}$, $\sigma^{GBK}_{L\infty}$, σ^S_k, σ^{GBK}_k, σ^S_{t0}, σ^{GBK}_{t0} were standard deviations of the growth parameters for each area, $\frac{SSB_{threshold}}{SSB_0}$ was the control rule (stock replenishment) threshold, and $\frac{SSB_{target}}{SSB_0}$ was the control rule target for fishery management. A random value for each variable was drawn from the sampling distributions shown for each simulation run.

Variable	Sampling distribution
	Continuous
h	$Unif(0.3, 0.99)$
M	$Unif(0.1, 0.25)$
F_{target}	$Unif(0.0001, 0.5)$
φ	$Unif(0.0, 0.5)$
σ_{At}	$Unif(0.0, 0.25)$
σ_{Ft}	$Unif(0.0, 0.5)$
$\sigma^S_{L\infty}$	$Unif(0.0, 1.95)$
$\sigma^{GBK}_{L\infty}$	$Unif(0.0, 3.9)$
σ^S_k	$Unif(0.0, 0.025)$
σ^{GBK}_k	$Unif(0.0, 0.061)$
σ^S_{t0}	$Unif(0.0, 0.249)$
σ^{GBK}_{t0}	$Unif(0.0, 0.59)$
	Discrete

Table 39: Deviance table results for models predicting mean Atlantic surfclam biomass ($\frac{\overline{SSB}}{SSB_0}$), mean ($\frac{\overline{Y}}{SSB_0}$), and cv of yield ($cv(Y)$) and years without fishing due to management ($t_{F=0}$), over ($n = 50,000$) 100 year simulations. The candidate predictors were fishing mortality target (F_{target}), steepness (h), natural mortality (M), the fraction of SSB_0 that corresponds to the control rule (stock replenishment) threshold ($\frac{SSB_{threshold}}{SSB_0}$), assessment error ($\sigma_{At}$), amount of auto correlation in assessment error (φ), implementation error (σ_{Ft}) as well as interactions of potential interest. Only predictors that explained $\geq 5\%$ of the deviance relative to the null model are shown.

Response	Significant predictors (% dev. explained)
	Biomass
$\frac{\overline{SSB}}{B_0}$	F_{target} (43.5), h (27.5), M (11.0)
	Yield
$\frac{\overline{Y}}{B_0}$	h (36.0), $\frac{SSB_{threshold}}{SSB_0}$ (22.9), M (20.4), SR (5.6)
$cv(Y)$	F_{target} (57.4), $\frac{SSB_{threshold}}{SSB_0}$ (10.4), h (11.8), M (7.9)
	Years without fishing
$t_{F=0}$	F_{target} (48.3), h (13.6), $\frac{SSB_{threshold}}{SSB_0}$ (14.2), h:$\frac{SSB_{threshold}}{SSB_0}$ (5.8)

Table 40: Deviance table results from simulations testing possible spatial structures of management. Inputs were models predicting mean Atlantic surfclam biomass, mean, and cv of yield and years without fishing due to management, over ($n = 50,000$) 100 year simulations. The total biomass and yield were based on summed values from two separately managed stocks and from two regions managed as one, each assessed every five years. The candidate predictors were fishing mortality target (F_{target}), steepness (h), natural mortality (M), the fraction of SSB_0 that corresponds to the control rule (stock replenishment) threshold ($\frac{SSB_{threshold}}{SSB_0}$), assessment error ($\sigma_{At}$), amount of auto correlation in assessment error (φ), implementation error (σ_{Ft}) and several interactions between them.

Figures

Alternative Risk-G (Council-Preferred): Stock Status/Life History, Inflection at B/B_{MSY} = 1.0

Under this alternative, a stock replenishment threshold defined as the ratio of $B/B_{MSY} = 0.10$, will be utilized to ensure the stock does not reach low levels from which it cannot recover. The probability of overfishing will be 0 percent if the ratio of B/B_{MSY} is less than or equal to 0.10. Probability of overfishing increases linearly for stock defined as typical as the ratio of B/B_{MSY} increases, until the inflection point of $B/B_{MSY} = 1.0$ is reached and a 40 percent probability of overfishing is utilized for ratios equal to or greater than 1.0. Probability of overfishing increases linearly for stock defined as atypical as the ratio of B/B_{MSY} increases, until the inflection point of $B/B_{MSY} = 1.0$ is reached and a 35 percent probability of overfishing is utilized for ratios equal to or greater than 1.0. The SSC will determine whether a stock is typical or atypical each time an ABC is recommended. Generally speaking, an atypical stock has a life history strategy that results in greater vulnerability to exploitation, and whose life history has not been fully addressed through the stock assessment and biological reference point development process.

In addition, under this alternative for managed resources that are under rebuilding plans, the upper limit on the probability of exceeding $F_{REBUILD}$ would be 50 percent unless modified to a lesser value (i.e., higher probability of not exceeding $F_{REBUILD}$) through a rebuilding plan amendment. In instances where the SSC derives a more restrictive ABC recommendation, based on the application of the ABC control rule methods framework and risk policy, than the ABC derived from the use of $F_{REBUILD}$ at the MAFMC-specified overfishing risk level, the SSC shall recommend to the MAFMC the lower of the ABC values.

In addition, if no OFL is available (i.e., No F_{MSY} or F_{MSY} proxy provided through the stock assessment to identify it) and no OFL proxy is provided by the SSC at the time of ABC recommendations, then an upper limit (cap) on allowable increases in ABC will be established. ABC may not be increased until an OFL has been identified.

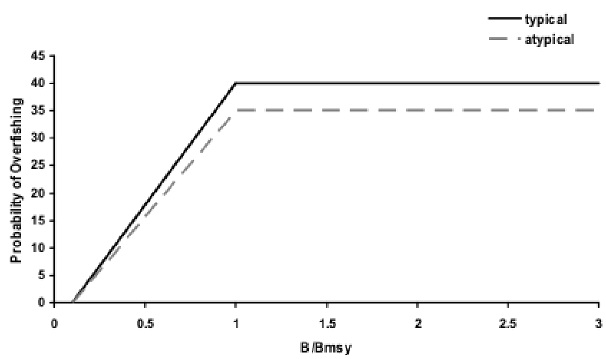

Figure 230: Mid-Atlantic Fisheries Management Council risk policy MAFMC 2011 (p. 51).

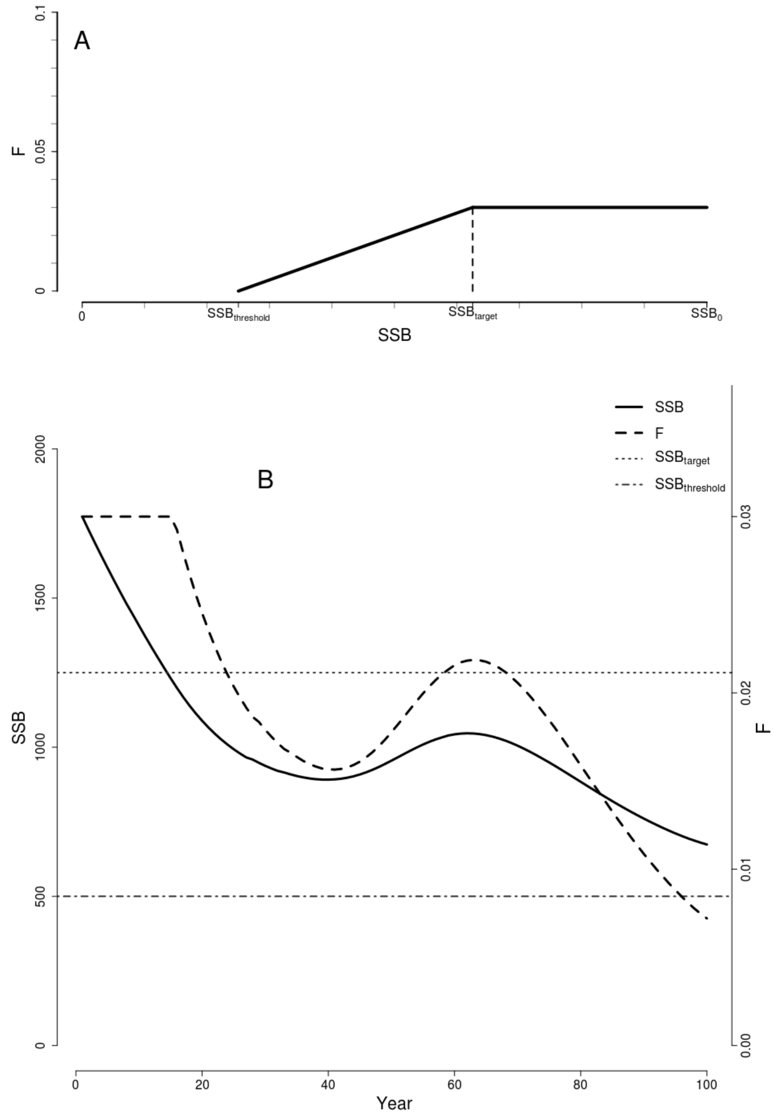

Figure 231: Panel (A) Control rule for Atlantic surfclam in terms of F and SSB. Fishing mortality is constant unless SSB drops below SSB_{target}, it then declines linearly until it reaches 0 at $SSB_{threshold}$. Panel (B) The control rule applied in a simulation run. Fishing mortality was constant when $SSB_t > SSB_{target}$, and was reduced when $SSB_t < SSB_{target}$. Simulated SSB units are 000 mt.

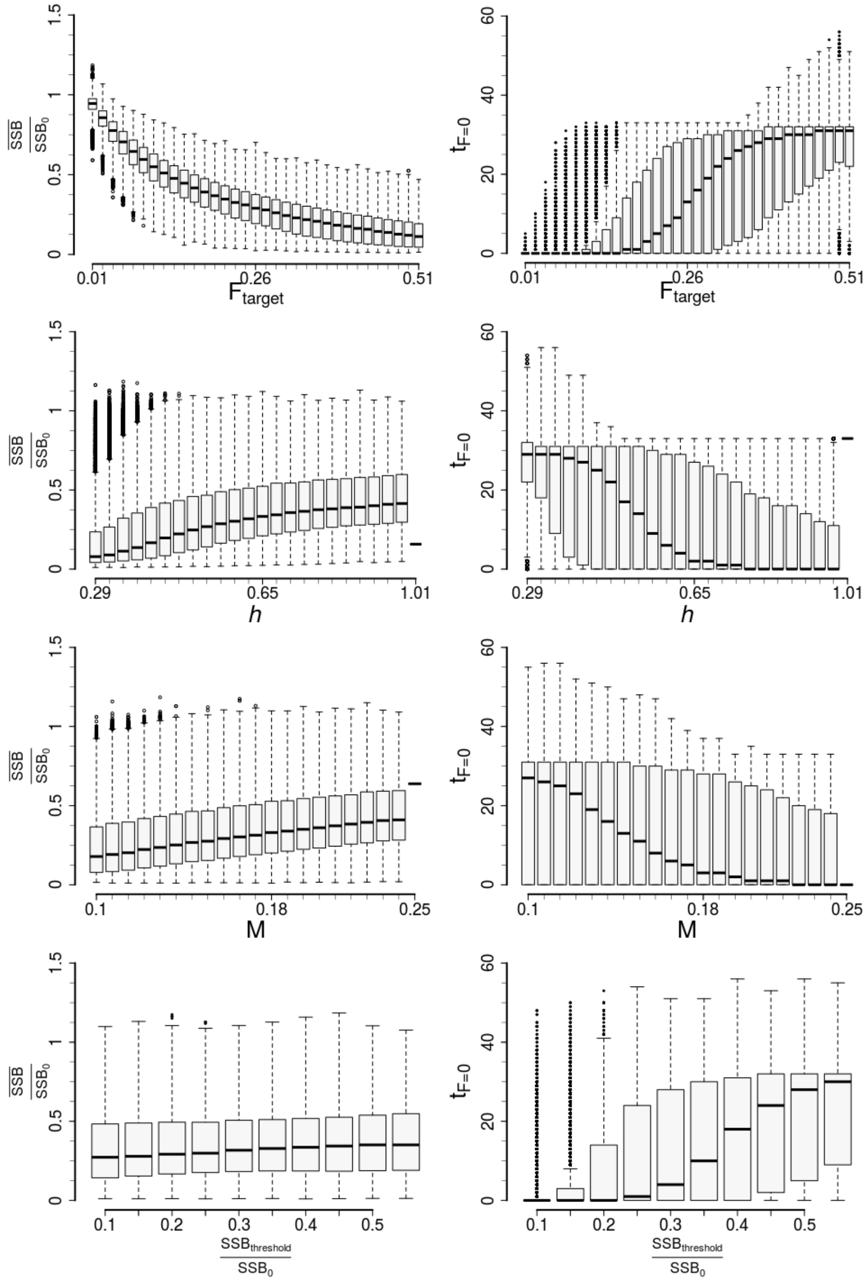

Figure 232: Mean biomass ($\frac{\overline{SSB}}{SSB_0}$), and time not fished due to management intervention ($t_{F=0}$) in 100 year simulations, by values of target fishing mortality (F_{target}), steepness (h), assessment error (σ_{At}), natural mortality (M) and the fraction of SSB_0 that corresponds to the control rule (stock replenishment) threshold ($SSB_{threshold}$). The boxes represent interquartile range, solid horizontal lines in each box are the medians, and the whiskers indicate the range between the 0.025 and 0.975 quanitles ($n = 500000$).

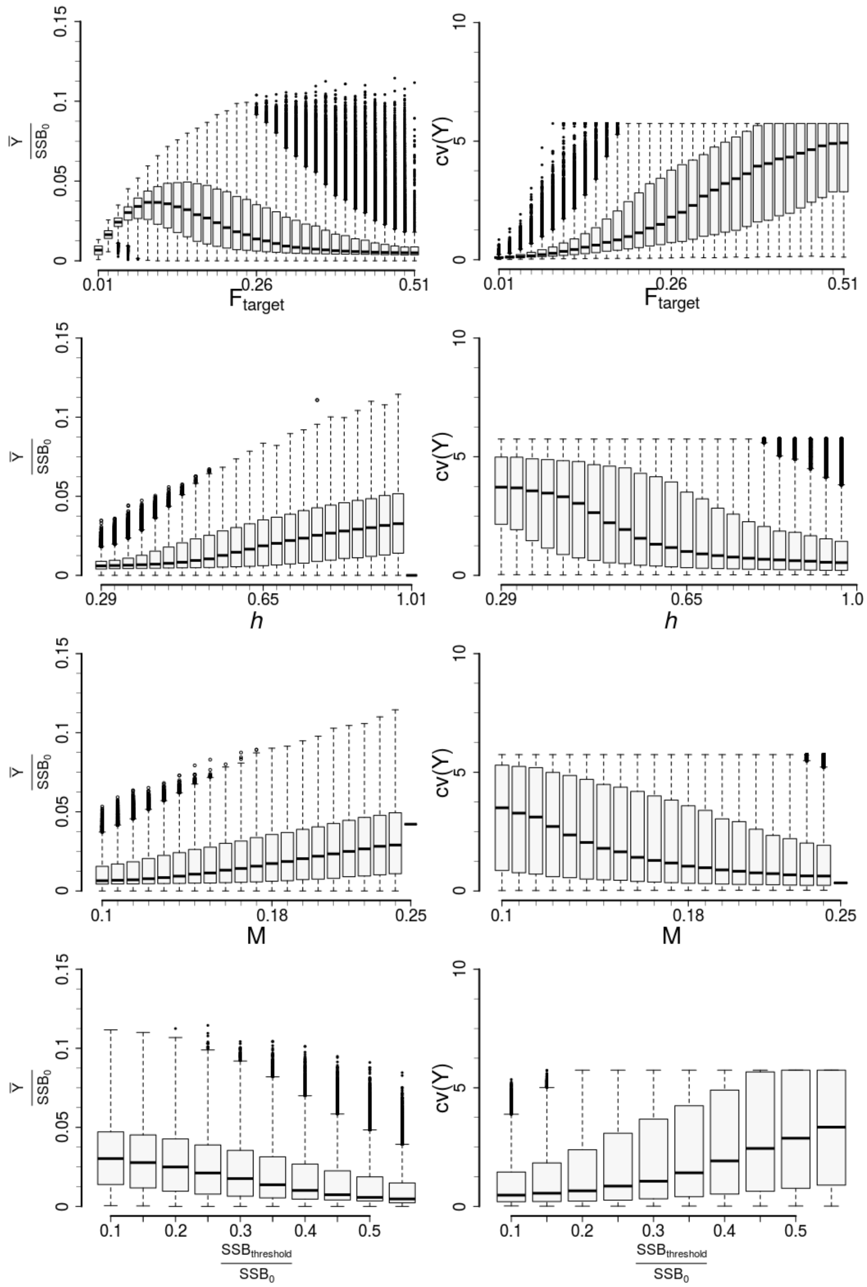

Figure 233: Mean yield ($\frac{\overline{Y}}{SSB_0}$) and cv yield in 100 year simulations, by values of target fishing mortality (F_{target}), steepness (h), natural mortality (M) and the fraction of SSB_0 that corresponds to the control rule (stock replenishment) threshold ($\frac{SSB_{threshold}}{SSB_0}$) ($n = 500000$).

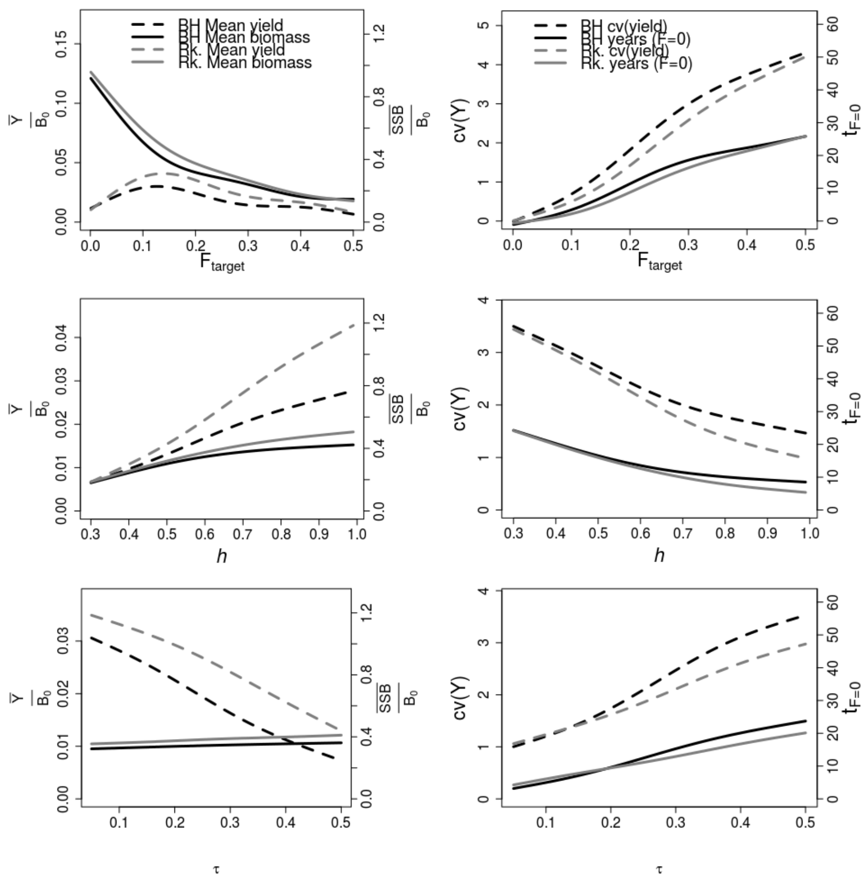

Figure 234: Mean yield, mean biomass, cv yield and years without fishing by F_{target}, h and $\frac{SSB_{threshold}}{SSB_0}$ from 100 year simulations for simulations where recruitment was driven by Beverton Holt (BH; $n = 60000$ for each) or Ricker (Rk) dynamics. The solid and dashed lines are fits to simple univariate generalized additive models (splines with basis dimension, $k = 5$). These are used to illustrate trends only.

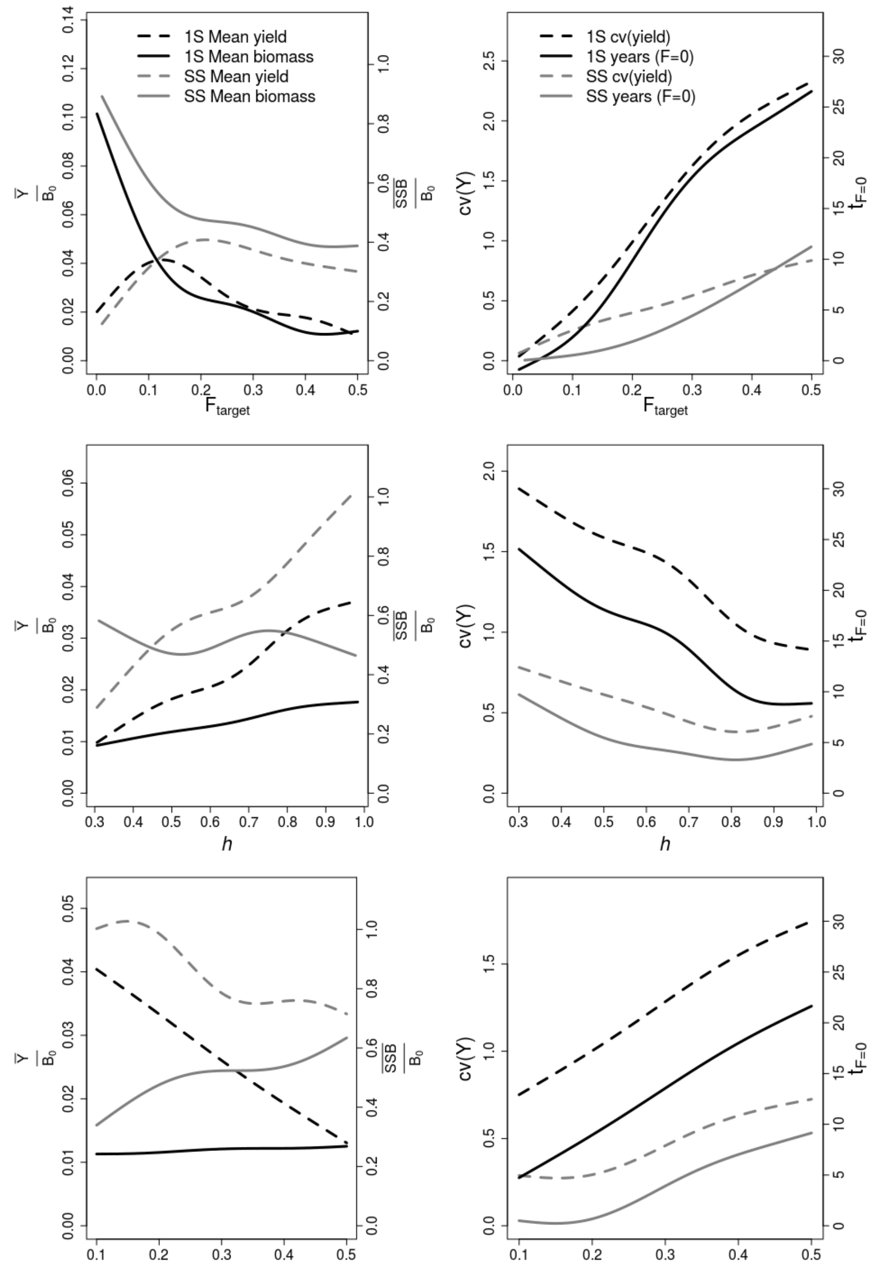

Figure 235: Mean yield, mean biomass, cv yield and years without fishing by F_{target}, h and $\frac{SSB_{threshold}}{SSB_0}$ from 100 year simulations for two regions with independent recruitment managed together, either as separate stocks (SS) or as a single stock ($1S$; $n = 60000$ for each). Both stocks were assessed every five years. The solid and dashed lines are fits to simple univariate generalized additive models (splines with basis dimension, $k = 5$). These are used to illustrate trends only.

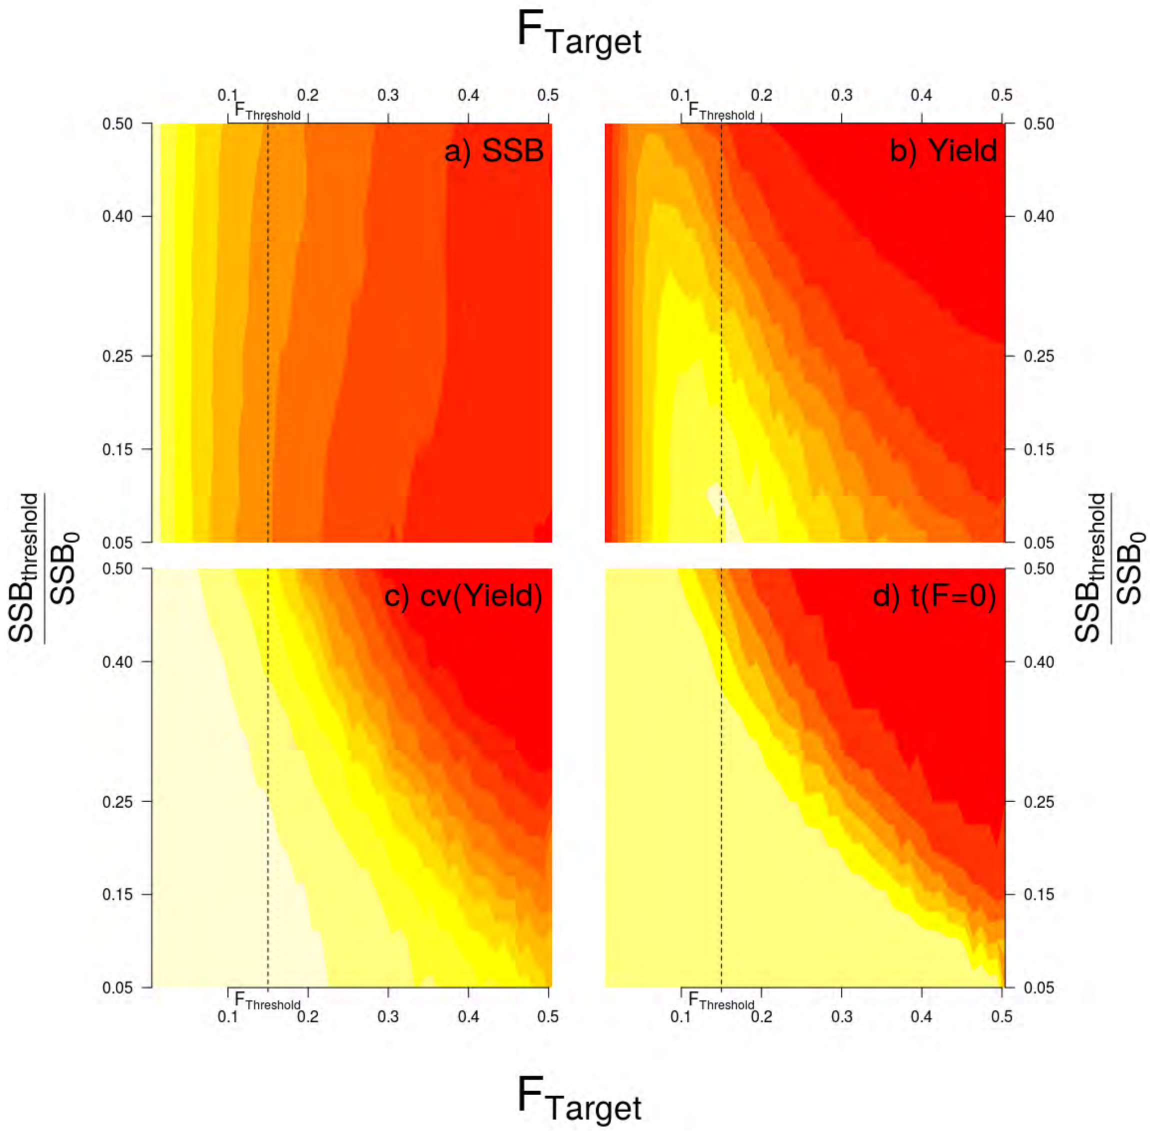

Figure 236: Contour plots showing the combined effects of F_{target} and the fraction of SSB_0 that corresponds to the control rule (stock replenishment) threshold ($\frac{SSB_{threshold}}{SSB_0}$) on: (a) $\frac{\overline{SSB}}{SSB_0}$, (b) $\frac{\overline{Y}}{SSB_0}$, (c) cv(Y) and (d) $t_{F=0}$. In each plot the darker colors are associated with less preferred values (*e.g.* in plot (a) the lowest $\frac{\overline{SSB}}{SSB_0}$ occurs on the right side, where F_{target} is high, and in plot (c) the highest variation in yield occurs on the right side, where F_{target} is high). The current $F_{threshold}$ (0.15; Northeast Fisheries Science Center 2013) is marked with a dashed line. These simulations were based on a single stock where recruitment followed either Beverton Holt or Ricker stock recruitment dynamics.

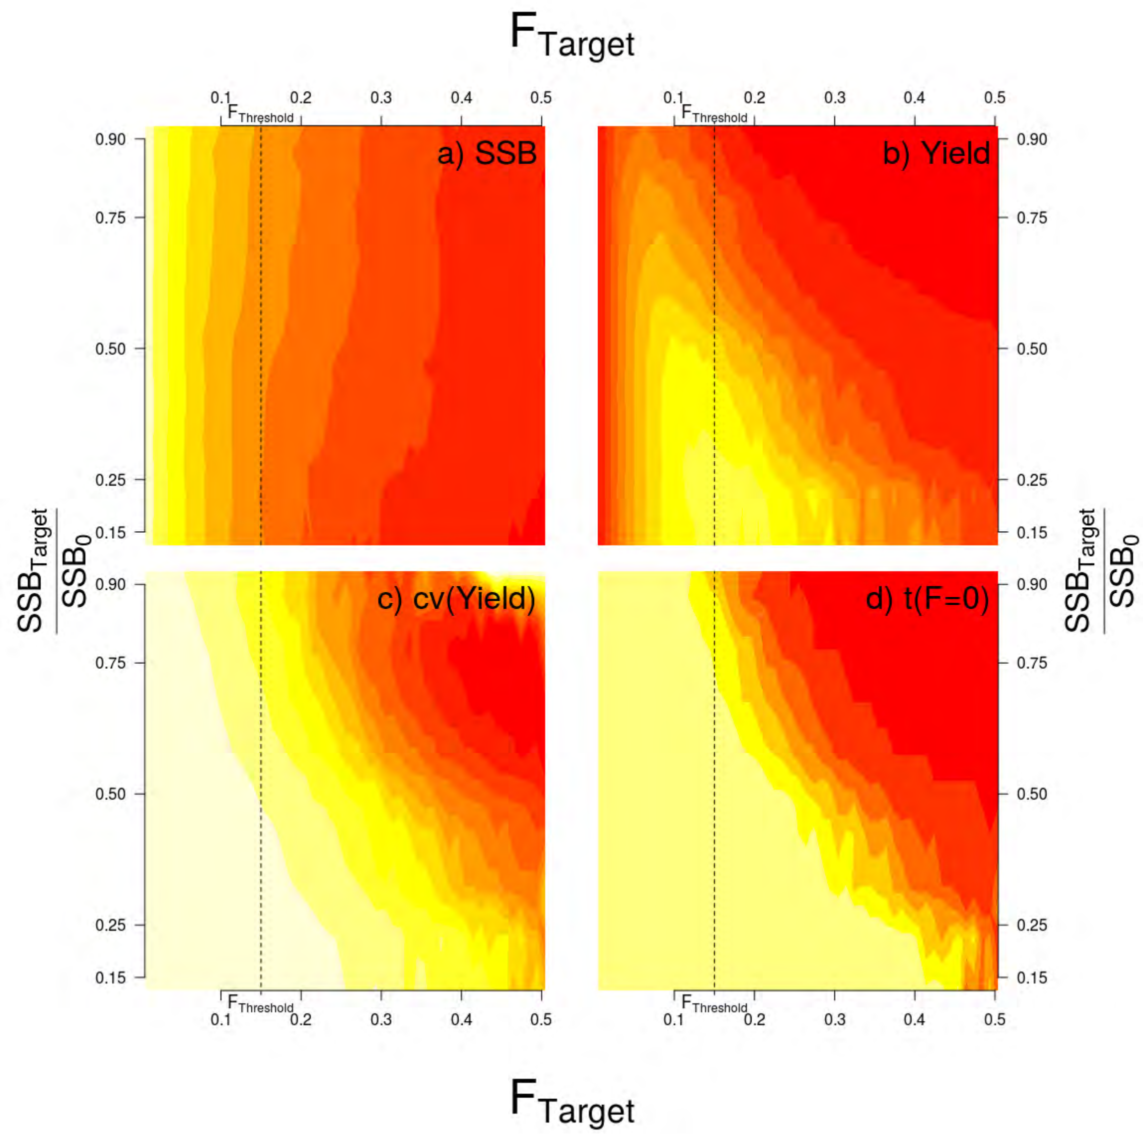

Figure 237: Contour plots showing the combined effects of F_{target} and the fraction of SSB_0 that corresponds to the control rule target ($\frac{SSB_{targer}}{SSB_0}$) on: (a) $\frac{\overline{SSB}}{SSB_0}$, (b) $\frac{\overline{Y}}{SSB_0}$, (c) cv(Y) and (d) $t_{F=0}$. In each plot the darker colors are associated with less preferred values (*e.g.* in plot (a) the lowest $\frac{\overline{SSB}}{SSB_0}$ occurs on the right side, where F_{target} is high, and in plot (c) the highest variation in yield occurs on the right side, where F_{target} is high). The current $F_{threshold}$ (0.15; Northeast Fisheries Science Center 2013) is marked with a dashed line. These simulations were based on a single stock where recruitment followed either Beverton Holt or Ricker stock recruitment dynamics.

Appendix 9 Comparing methods for combining F from different areas

Four different methods for combining estimates of fishing mortality from different areas were compared. The methods were: the arithmetic mean

$$\widehat{F_{W,arith}} = E[F_S + F_N] \tag{24}$$

where F_W is the whole stock fishing fishing mortality and F_S and F_N are the F form the southern and northern areas, respectively. The geometric mean

$$\widehat{F_{W,geo}} = e^{E[log(F_S)+lof(F_N)]} \tag{25}$$

the harmonic mean

$$\widehat{F_{W,har}} = \frac{2}{F_S^{-1} + F_N^{-1}} \tag{26}$$

and the abundance weighted mean

$$\widehat{F_{W,wt}} = \frac{N_S}{N_S + N_N} F_S + \frac{N_S}{N_S + N_N} F_N \tag{27}$$

where N_S and N_N are the abundances form the southern and northern areas, respectively.

Correlated lognormal random variables (n=10000) were drawn for F and N for each of two areas where

$$F_a \sim lognormal(\mu_{F,a}, \sigma_{S,a}) \tag{28}$$
$$N_a \sim lognormal(\mu_{N,a}, \sigma_{N,a}) \tag{29}$$

$\mu_{i,a}$ and $\sigma_{i,a}$ were the mean and variance of the parameter i (N or F) and simulated area a. The correlation between F_a and N_a (ρ) was varied experimentally. The distribution of each of $\widehat{F_{W,method}}$ from each of the different methods for combining F was compared to the true combined $F_W = E[\mu_{F,a}\mu_{N,a}]$.

The simulations showed that $\widehat{F_{W,arith}}$ is biased high and $\widehat{F_{W,har}}$ is biased low at all values of ρ (Figure 238). $\widehat{F_{W,wt}}$ was biased low when $\rho < -0.6$ and biased high when $\rho > -0.4$. $\widehat{F_{W,geo}}$ was close to F_W at all values of ρ and deemed the best choice for the combining the F in the Atlantic surfclam assessment where the correlation between biomass (and abundance) and fishing mortality is high (for example, from the base run for the southern area $\rho_{max} = -0.78$ and $\rho_{min} = -0.97$).

The results depended on the level of F. In particular when $F \cong 0.0$, the geometric and harmonic means were strongly negatively biased (Figure 239). When $F \cong 0.0$, the preferred method for combining F from different areas was the abundance weighted mean, based on less bias at all levels of correlation between F and abundance.

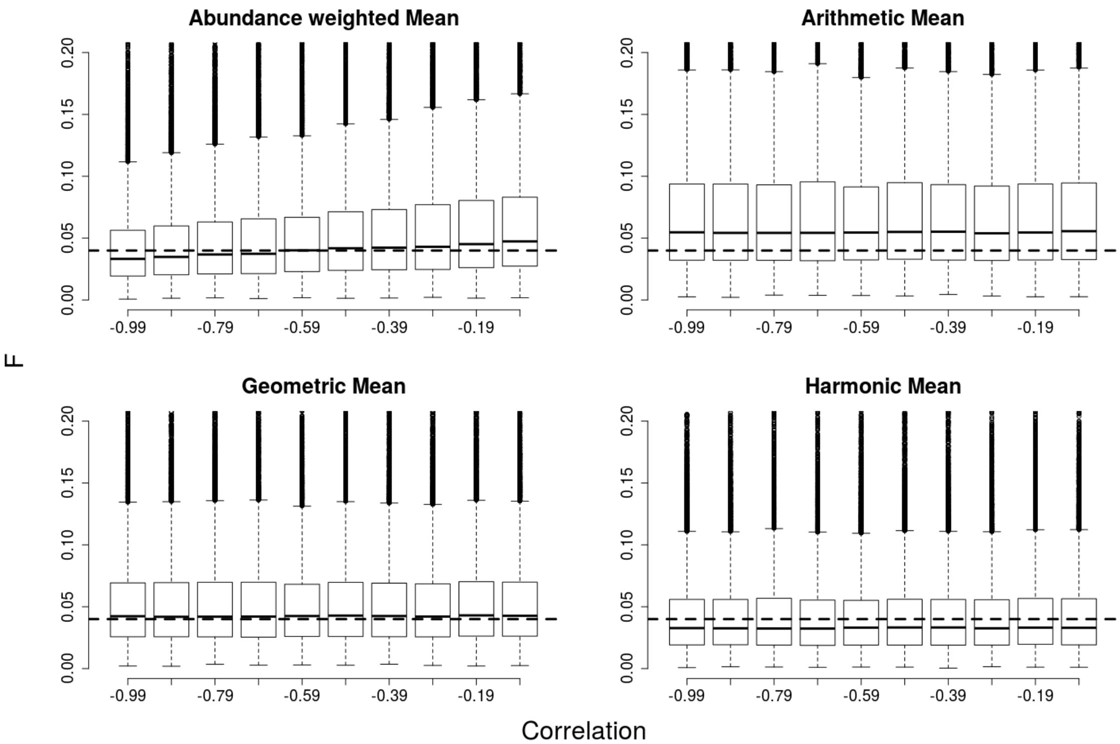

Figure 238: The distribution of estimates of the combined fishing mortality from two regions at varying levels of correlation between abundance and F, compared to the true combined fishing mortality (dashed line). The geometric mean was nearly unbiased at all correlation levels, while the bias in abundance weighted mean depended on the correlation between F and abundance.

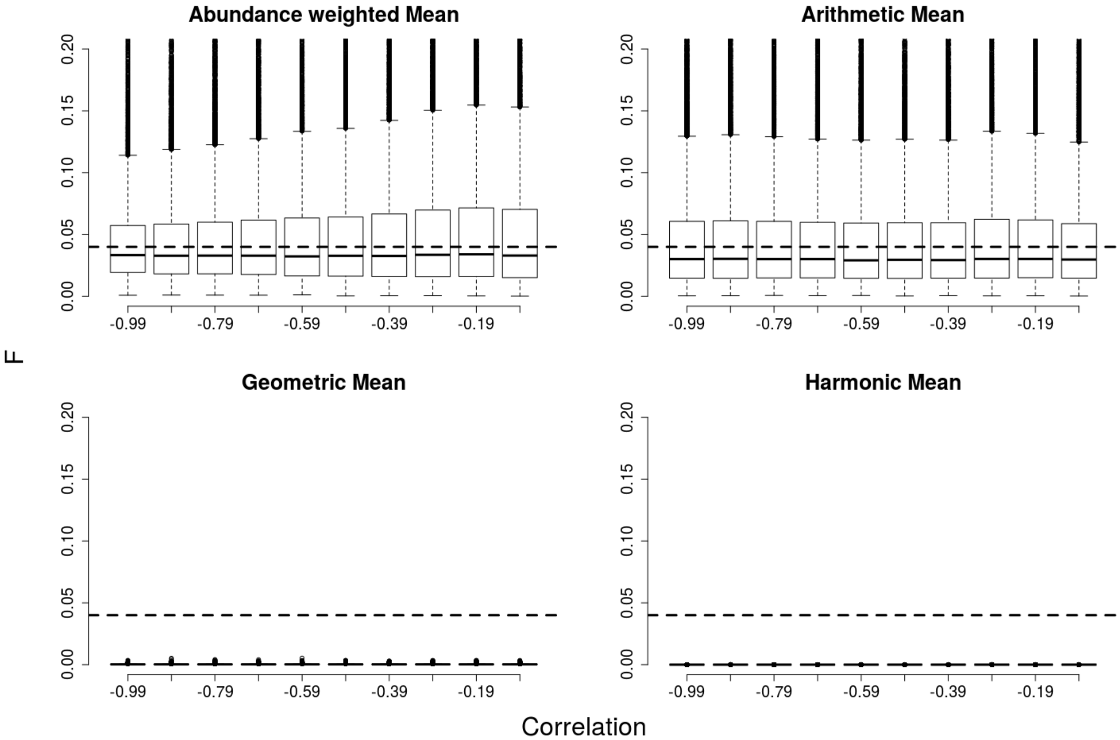

Figure 239: The distribution of estimates of the combined fishing mortality from two regions at varying levels of correlation between abundance and F, compared to the true combined fishing mortality (dashed line), when one the true F values is near 0 ($F = 0.00001$). In this case the geometric and harmonic means were strongly negatively biased and the abundance weighted average was the preferred method

Appendix 10 Sampling properties of presence-absence data for from NEFSC clam surveys

Changes in habitat overlap and co-occurrence of Atlantic surfclam and ocean quahogs affect the fisheries for both species because mixed catches are harder and more expensive to process for sale. Co-occurrence may be a simple metric for tracking climate change effects on habitat for both species. Here, we develop some mathematics that describe occurrence and co-occurrence of Atlantic surfclam and ocean quahogs in dredge survey tows as a function of individual densities using the RD clam survey as an example. In summary, occurrence and co-occurrence are sensitive indicators that one or both species are found in an area. However, they are insensitive to changes in density once encounter rates for both species reach about 15 individuals per tow (roughly 0.013 per m^2). Calculations are based on the RD, but the overall result applies to the MCD, which has higher capture efficiency for both species and sweeps a larger area, so that it is even more sensitive to the presence of either species and less useful as a measure of density (in the context of presence-absence).

The data used in this analysis are from random tows during NEFSC clam surveys during 1982-2011. The nominal area swept is 423 m^2 per tow, but varies with depth. We assume that the area swept by the survey dredge (1.82 m or 5 ft wide) is about 1140 m^2 per tow, based on a tow distance of about 700 m, where both species might be found (see Figure 240; Weinberg et al. (2002)). This crude approximation aids interpretation but does not affect the overall conclusion.

The probability of catching at least one Atlantic surfclam and one ocean quahog in the same tow depends on depth, species, and/or time dependent factors including: 1) capture efficiency of the gear, 2) area swept (tow distance x dredge width, m^2), 3) encounter rate and density (individuals per tow or m^2) and 4) the statistical distributions of the number of clams encountered in a tow (with parameters for the mean, variance and, implicitly, patchiness). The probability of catching at least one Atlantic surfclam (s) and one quahog (q) in a dredge tow is:

$$p(s, q \mid d) = p(s \mid d)p(q \mid d) \tag{30}$$

where $p(s \mid d)$ and $p(q \mid d)$ are the conditional probabilities of catching at least one Atlantic surfclam or quahog at depth d as independent events. These probabilities might depend on time, region, etc. but subscripts for such factors are not included. Using Atlantic surfclam as an example:

$$p(s \mid d) = \sum_{n=1}^{\infty} \left[P(E_s = n \mid d) \sum_{m=1}^{n} \binom{n}{m} e_s^m (1 - e_s)^{n-m} \right] \tag{31}$$

where $p(E_s = n \mid d)$ is the probability that the dredge encounters n individual Atlantic surfclam, e_s is capture efficiency ($0 < e_s < 1$), $\binom{n}{m}$ are binomial coefficients giving the number of ways to catch m clams if n are encountered, and $e_s^m(1-e_s)^{n-m}$ is the probability of catching m and missing $n - m$ individuals in the path of the dredge when n clams are encountered. The formula can be simplified because the

$$\sum_{m=1}^{n} \binom{n}{m} e_s^m (1 - e_s)^{n-m}$$

used to calculate the probability of catching at least one clam is the complement of the probability of catching none with probability $(1 - e_s)^n$, so that:

$$p(s \mid d) = \sum_{n=0}^{\infty} P(E_s = n \mid d)[1 - (1 - e_s)^n] \tag{32}$$

Note that the possibility that the dredge will not encounter any clams (even though they may be in the general area) is included. Such an event does not contribute to the probability of any catch because $1 - (1 - e_s)^0 = 0$. Thus, the probability of catching no clams could be omitted from the calculation without changing the results.

The encounter probability $P(E_s = n \mid d)$ is from an unknown statistical distribution with mean $(\mu_{s,d})$ and variance $(\sigma^2_{s,d}\ )$ parameters that may depend on any of the factors listed above. Patchiness is an inherent property of the statistical distribution that also affects the encounter probability because patchy organisms are captured less frequently than randomly distributed ones. The mean number of encounters per tow depends directly on the density of Atlantic surfclam (and overall abundance) and the area swept by the tow.

Using the Poisson distribution with parameters $\lambda_{s,d} = \mu_{s,d} = \sigma^2_{s,d}$, the probability distribution for encountering n individuals would be:

$$P(E_s = n \mid d) = \frac{\lambda^n_{s,d} e^(-\lambda_{s,d})}{n!} \tag{33}$$

The negative binomial distribution is another candidate distribution which may be appropriate given that Atlantic surfclam and ocean quahog catches during depletion experiments have been modeled successfully based on the distribution:

$$P(E_s = n \mid d) = \frac{\Gamma(n + k_{s.d})}{n!\Gamma(k_{s.d})} \left(\frac{k_{s.d}}{\mu_{s,d} + k_{s.d}}\right)^{k_{s.d}} \left(\frac{\mu_{s,d}}{\mu_{s,d} + k_{s.d}}\right)^{n} \tag{34}$$

where $k_{s.d}$ is a dispersion parameter and $\sigma^2_{s,d} = \mu_{s,d} + \frac{\mu^2_{s,d}}{k}$. By the method of moments, $k_{s.d} = \frac{\mu_{s,d}}{\left[\frac{\sigma^2_{s,d}}{(\mu_{s,d} - 1)}\right]}$.

It is important to remember that the probability density function for co-occurrence $p(s, q \mid d)$ can decline, for example, if either or both of $p(s \mid d)$ and $p(q \mid d)$ decline, if $p(s \mid d)$ declines substantially while $p(q \mid d)$ increases slightly, or if $p(s \mid d)$ increases substantially while $p(q \mid d)$ declines slightly. The probability may remain constant despite large ecological changes if a decline in density of Atlantic surfclam, for example, is offset by an increase in density of ocean quahogs. Very small changes in $p(s \mid d)$ are possible despite large changes in density if $(s \mid d)$ is close to one initially (and vice-versa). The probability of co-occurrence is therefore nearly the same as the probability of occurrence for a species at low density in a habitat where the other species is at high density.

The sampling characteristics of co-occurrence data can be evaluated using eq. (32) with assumed statistical distributions and parameter values (Table 45). The mean of 21 Delaware II dredge capture efficiency estimates in NEFSC (2013) for Atlantic surfclam 150+ mm SL was 0.413 (SE 0.098). The mean of 15 Delaware II dredge capture efficiency estimates in NEFSC (2009) for ocean quahogs 90+ mm SL was 0.263 (SE 0.057). The mean dispersion parameter (k) for catches in depletion studies was 9.83 (SD 11.6, SE 2.37) for Atlantic surfclam and 8.00 (SD 4.03, SE 0.88) for ocean quahogs.

The mean Atlantic surfclam catch (all sizes) was 83 (SD 237, SE 7.13) and the mean quahog catch was 239 (SD 895, SE 26.9) in random survey tows that caught both species during 1982-2011 (Table 45). The distributions of observed catches were highly skewed for both species. Based on catch and capture efficiency, the mean number of Atlantic surfclam encountered in tows that caught both species was mean catch/efficiency=83/0.413=201 (about 0.18 Atlantic surfclam per m^2) and the mean number of quahogs encountered was 239/0.263=909 (about 0.8 quahogs per m^2). These figures are under-estimates because of reduced capture efficiency for Atlantic surfclam $<$ 150 mm SL and for quahogs $<$ 90 mm SL.

The probabilities of catching at least one Atlantic surfclam, one ocean quahog or at least one of each species in a hypothetical survey tow is nearly one given the typical values described above using either the negative binomial or Poisson distribution (Table 45 and Figures 241-242). The probabilities are high because numbers encountered tend to be high ($>$ 100) for both species based on typical values and particularly because the probability of catching at least one clam is high for even modest numbers of encounters. Considering Atlantic surfclam with capture efficiency $e_{s.d} = 0.413$, the probability of capturing at least one individual with only five encounters (0.01 m^2) is $1-(1-0.413)^5 = 0.93$. For ocean quahogs, the corresponding probability is $1-(1-0.263)^5 = 0.78$.

The calculations above show that the probability of capture for both species and for co-occurrence is likely to be high at relatively low densities for both species and suggest that co-occurrence is a sensitive indicator that both species are present. To test this hypothesis, we calculated the probability catching at least one individual of both species, and the probability of co-occurrence for mean encounter rates ranging from 1 to 15 clams of each species per tow (0.0009 to 0.013 per m^2). Results indicate that the probability of co-occurrence is 0.10-0.15 when only one Atlantic surfclam and ocean quahog are encountered, 0.55-0.65 for five individuals of both species and at least 0.85 for ten individuals per tow (0.009 per m^2) of both species (Figure 240). However, the results also show that co-occurrence is insensitive to changes in encounter rates and density beyond fifteen individuals per tow. Average co-occurrence over many tows is unlikely to be useful for tracking trends in density of either species because typical catches in tows that caught both species were usually above 15 clams per tow for both Atlantic surfclam and ocean quahogs (Table 45).

Table 45: Typical parameters used in simulating occurrence and co-occurrence of Atlantic surfclam and ocean quahogs in survey tows. The probability of capturing at least one individual from eq. (32) under conditions in the table is shown in the last row. Statistic.

Statistic	Atlantic surfclam	Ocean quahogs
Mean number encountered	201	909
Approximate density assuming 500 m^2 per tow (see text)	0.40 per m^2	1.8 per m^2
Dispersion parameter	9.83	8.00
Capture efficiency	0.413	0.263
P(catch > 0)	1	1

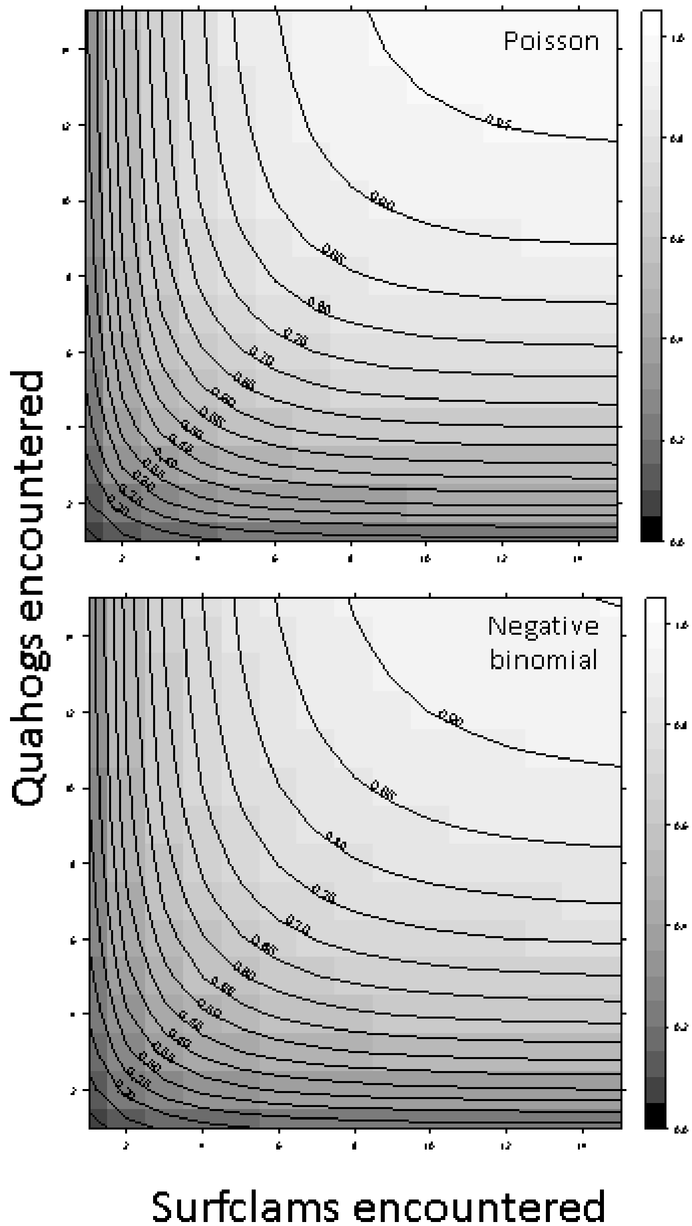

Figure 240: Isopleths for the probability of co-occurrence (at least one Atlantic surfclam and one ocean quahog in a hypothetical survey tow) given the number of Atlantic surfclam and ocean quahogs encountered.

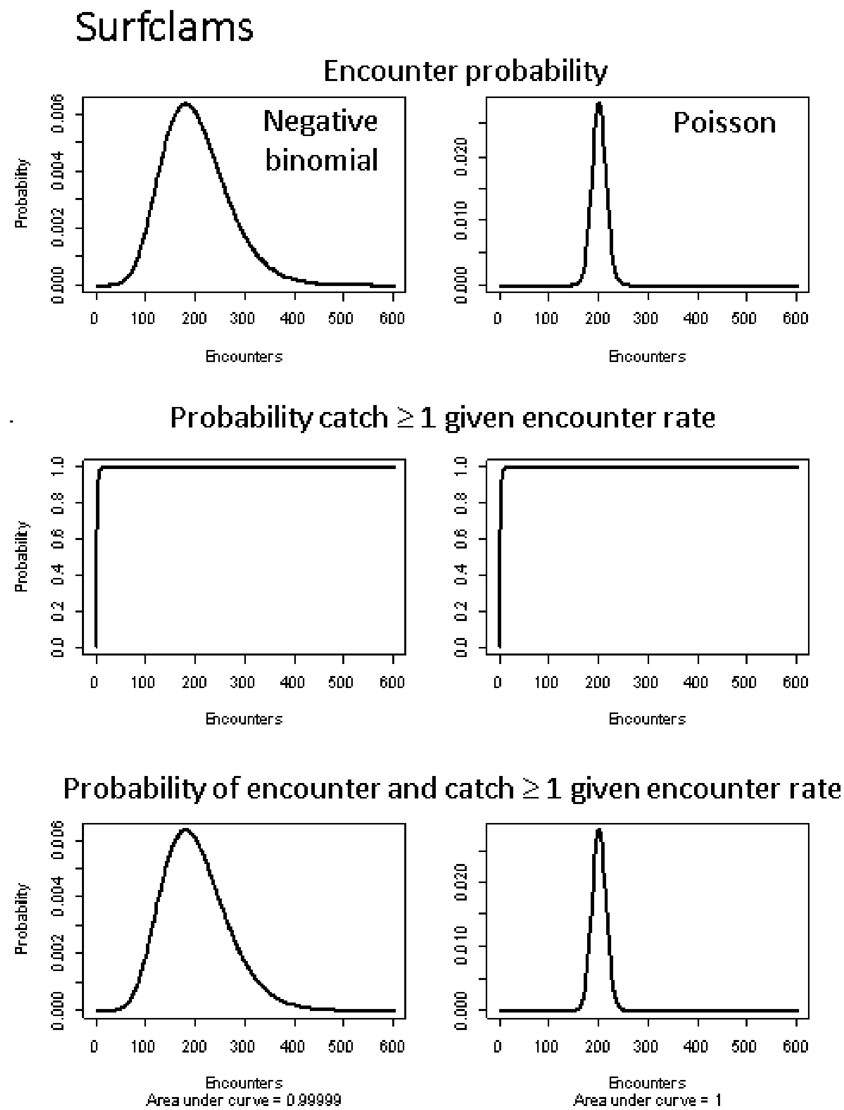

Figure 241: Intermediate calculations in calculating the probability that at least one individual is captured in a hypothetical survey tow assuming typical parameter values and either a negative binomial (left) or Poisson (right) distribution for encounter probability. The top row gives the probability density functions $P(E_s = n \mid d)$ for the number of clams encountered by the dredge given the assumed mean encounter rate (density) and statistical distribution. The middle row (same on left and right) shows the conditional probability $[1 - (1 - e_s)^n]$ that at least one clam is captured given the number of encounters on the x-axis. The bottom row shows the joint probability of the encounter rate and capture of at least one clam (the product of the curves in the top and middle rows). The area under the bottom curve is the total probability of catching at least one clam. The range of encounters on the x-axis differs markedly for the two species because ocean quahog densities are higher than Atlantic surfclam densities based on survey catches and because of capture efficiency assumptions.

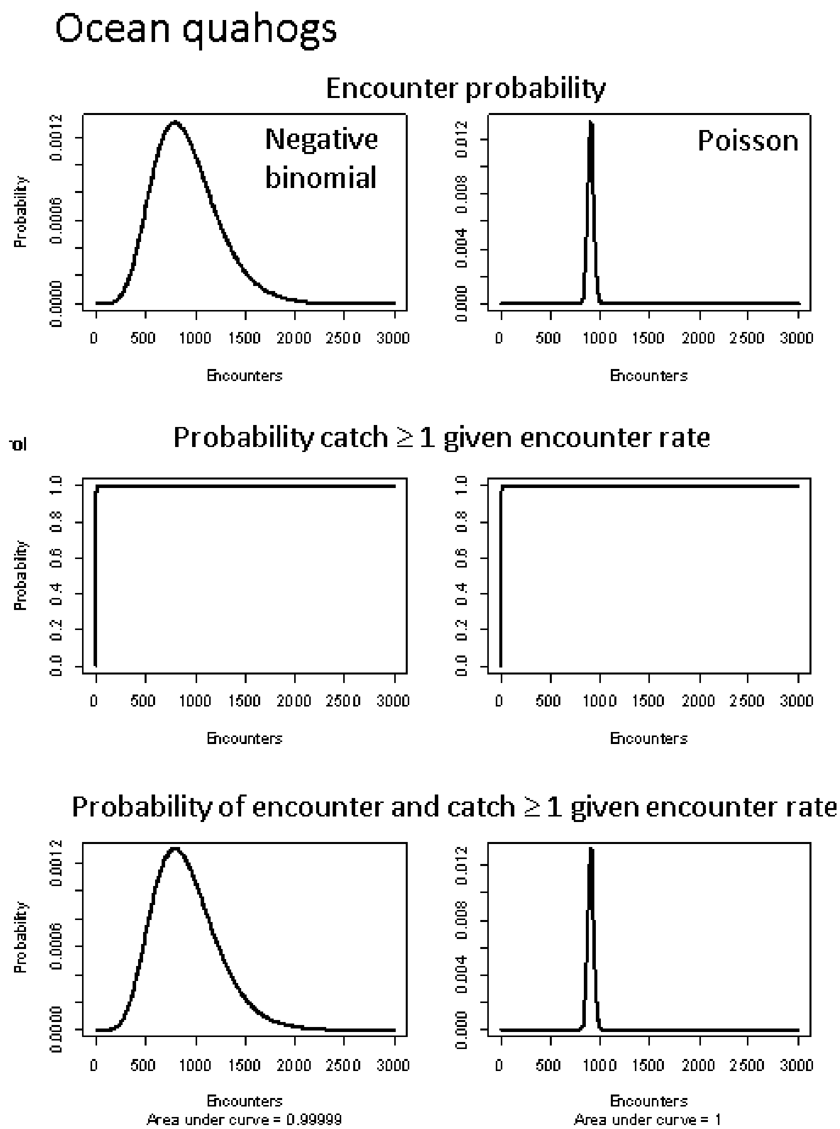

Figure 242: Intermediate calculations in calculating the probability that at least one individual is captured in a hypothetical survey tow assuming typical parameter values and either a negative binomial (left) or Poisson (right) distribution for encounter probability. The top row gives the probability density functions $P(E_s = n \mid d)$ for the number of clams encountered by the dredge given the assumed mean encounter rate (density) and statistical distribution. The middle row (same on left and right) shows the conditional probability $[1 - (1 - e_s)^n]$ that at least one clam is captured given the number of encounters on the x-axis. The bottom row shows the joint probability of the encounter rate and capture of at least one clam (the product of the curves in the top and middle rows). The area under the bottom curve is the total probability of catching at least one clam. The range of encounters on the x-axis differs markedly for the two species because ocean quahog densities are higher than Atlantic surfclam densities based on survey catches and because of capture efficiency assumptions.

Appendix 11 Trends in probability of Atlantic surfclam-ocean quahog co-occurrence in NEFSC clam surveys

Logistic regression models were used to detect trends in the probability of co-occurrence (Atlantic surfclam and ocean quahogs taken in the same tow) in NEFSC clam surveys during 1982-2011. Survey data collected after 2011 were not included because they involved different survey gear, were not comparable (Appendix 10), and because too few survey years were available for independent use. Only data from successful random tows were used. Poorly sampled strata with > 2 missing years were omitted. The dependent variable for each tow was a dummy variable for co-occurrence (1 if both Atlantic surfclam and ocean quahogs were captured and zero otherwise). In the R programming language, the models were specified $glm(d \sim y, family = binomial)$ where d is the dummy variable and y is year. The null hypothesis of no trend was rejected if $p \leq 0.1$.

Results show that the probability of co-occurrence decreased almost linearly during 1982-2011 in SNE while increasing almost linearly in the LI and NJ regions (Figure 243). Significant trends were detected for individual survey strata within each region except SNE (Table 46).

Table 46: Summary of strata with significant trends ($p \leq 0.1$) in co-occurrence of Atlantic surfclam and ocean quahogs in NEFSC clam surveys during 1982-2011.

Region	Stratum	Direction of trend	p-value	Strata depth range (m)	Area (nm2)
GBK	55	decline	0.08	55-73	364
GBK	69	increase	0.1	0-46	938
LI	29	increase	0.01	27-46	1096
LI	33	increase	0.01	27-46	363
NJ	22	increase	< 0.01	46-55	312
NJ	25	increase	0.01	27-46	648
DMV	9	decline	< 0.01	27-46	2171
SVA	6	decline	0.08	46-55	62

Appendix 12 Changes in habitat area for Atlantic surfclam in the Mid-Atlantic and GBK regions based on NEFSC clam survey data and presence-absence modeling

Survey data and model results suggest that habitat area declined in the south off DMV area due to losses in shallow water, increased along the central Mid-Atlantic Bight (NJ and LI areas) due to increases in deep water and varied without trend in the north (SNE and GBK areas). These changes were likely due to water temperatures increasing above the preferred range for Spp in nearshore coastal areas off DMV and above the lower bound of the preferred range in deep offshore waters off NJ and LI.

Presence-absence data for Spp in NEFSC clam survey tows are a sensitive indicator of whether clams exist in an area (Appendix 10). If clam habitat is defined as areas where clams are present, then statistical analysis and mapping based on presence-absence data can be used to study changes in habitat size over time. Habitat area estimates from presence-absence data amount to estimates of the total area in which Atlantic surfclam are found with almost no adjustment for differences in density or habitat quality. For example, carrying capacity in terms of abundance might change dramatically without changing the total habitat area based on presence-absence data as long as Atlantic surfclam were found on the same grounds in both cases.

Separate modeling analyses were carried out for each region. Only well sampled years and strata were used in the analysis (Table 47, Figure 244 and Appendix 10). Tows at locations beyond depths where Atlantic surfclam were observed were omitted in each region. The maximum depths used for each region were GBK=75 m, SNE=70 m, LI=60 m, and DMV=55 m.

The proportion of positive tows in each year and area were plotted as a rough check on model based trends (Figure 245). Trends in this simple measure of habitat area are variable or ambiguous for GBK and SNE in the north, increasing for LI Sound and NJ along the middle of the Mid-Atlantic Bight and decreasing off DMV in the south. Three coordinate systems were used to specify the location of survey stations for modeling, including one system that used depth to measure position across shelf. However, only results for latitude and longitude (decimal degrees) are shown because results were similar and because latitude and longitude are easy to visualize.

Seven logistic regression type GAM models (dependent variable 0/1 for presence/absence of Atlantic surfclam, logit link, binomial maximum likelihood) were tested for each region (Table 48). Models with and without year effects were included and there would be evidence of changes in habitat area over time if the best model chosen by AIC included year effects. Preliminary analyses showed that sample sizes were too low to reliably estimate spatial patterns for each year independently. It was therefore necessary to "borrow" data from adjacent surveys by smoothing over years. Thus, all models with year effects included spatial patterns that were the same every year or smoothed over time. Location effects in models were smooth functions with different levels of interaction between latitude and longitude.

Maps and trends in habitat area were made by constructing a "large" grid made up of cells which combined the full range of coordinates across each region (all possible combinations of the cells for each coordinate). Cells for latitude and longitude were about 0.45o on a side. Next, the coordinates of the stations actually sampled (years combined) were gridded in the same way to produce a list of the first and last longitude cell actually sampled along each row of latitude cells. The list was used to omit cells from the large grid outside of the range sampled. The best GAM model was then used to predict the probability of a positive tow across the remaining grid cells. The predictions at each cell were plotted to produce maps (Figures 246-250) .

Trends in total habitat were calculated by summing the predicted probabilities for each year and cell from the best model (Figures 246-250). Habitat area computed in this way is essentially a sum of cell areas weighted by the predicted probability.

The best models for each region and coordinate system included year effects with the exception of DMV where Model 4 (with a two dimensional smooth on latitude and longitude but no year effects) had the lowest AIC indicating insignificant changes in habitat over time (Table 48 and Figure 250). However, Model 5 (with year effects) had nearly the same AIC score (878.1 vs 877.8). We therefore chose to identify Model 4 as the best model and Model 5 as the best model for trends in the DMV region. Spatial patterns in results from the two models with latitude and longitude for DMV were similar.

Trends in habitat area estimates from GAM models (Figures 246-250) were similar to trends in proportion positive tows (Figure 2). Trends for Atlantic surfclam on GBK (where sampling was relatively sporadic) and in SNE were variable. Estimated habitat area increased dramatically in LI after 1986 and steadily in NJ after 1982 based on model estimates. Maps indicate that the increases were due to increasing utilization of offshore areas, probably due to warming (Figures 248-249). The best model for trends in DMV suggests that habitat area declined due to losses in shallow coastal areas (Figure 250).

Table 47: Sample size (number of survey tows) used to measure Atlantic surfclam habitat area.

Region	1982	1983	1984	1986	1989	1992	1994	1999	2002	2005	2008	2011	
GBK				31		48	51	47	40			32	79
SNE	19	34		18	18	21	24	21	19	16		21	30
LI	30	29		29	28	28	32	28	30	29	29	60	52
NJ	86	85		91	99	98	103	112	120	115	92	109	61
DMV	68	61	79	70	78	77	83	82	78	81	72	63	63

Table 48: AIC for models used to predict the probability of a positive tow and estimate habitat area for Atlantic surfclam. Bold font identifies the best model (lowest AIC) for each region. Terms in the formulas for each model (column 2) are "yr" for year as a continuous covariate, "yrf" for year as a categorical factor, "lat" for latitude and "lon" for longitude. The term "s()" is a smooth one- or two dimensional nonlinear spline function of the variables inside the brackets.

ID	Model	GBK	SNE	LI	NJ	DMV
1	s(lon) + s(lat)	625	228	361	760	971
2	s(lon) + s(lat) + yrf	614	223	359	757	974
3	s(lon) + s(lat) + s(yr)	608	221	349	753	966
4	s(lon,lat)	621	210	356	727	877.8
5	s(lon,lat) + yrf	603	201	357	721	878.1
6	s(lon,lat,yr)	625	245	392	910	993
7	s(lon,lat,yr) + yrf	631	124	399	915	1,004

Appendix 13 Appendix: Potential methods for locating and quantifying good Atlantic surfclam habitat and untowable ground/poor Atlantic surfclam habitat on Georges Bank

With the planned redesign of the NEFSC clam survey, the working group spent time discussing how to improve the survey in general and especially on Georges Bank. With Atlantic surfclam vessels now regularly fishing on Georges Bank after a hiatus of many years due to closures for health concerns, it is of renewed importance to estimate biomass as accurately as possible and monitor the affects of the fishery.

Unlike the mid-Atlantic, Georges Bank is a patchwork of sand, gravel, cobble and boulder bottom. This presents a challenge as the sandy areas are considered good Atlantic surfclam habitat, but patches of rough, rocky bottom, considered "untowable" and probably marginal habitat, often occur within the same strata. The new survey design will likely include some restratification of these areas into units of similar bottom. Areas composed of sandy substrate are more likely to contain higher densities of Atlantic surfclam, than areas composed of harder substrate. In order to increase the efficiency of the survey and the accuracy and precision of abundance estimates, good habitat should be sampled more frequently. Restratifying by substrate should result in fewer "untowable" survey stations and a more precise and accurate estimate of abundance, as well as a more targeted and perhaps less expensive survey.

An additional aspect of improving the survey on Georges Bank is determining what overall area is inhabited by Atlantic surfclam, and the fraction that is untowable (and probably poor clam habitat) and should be discounted when estimating swept-area biomass. For instance, if the overall Atlantic surfclam habitat area on Georges Bank is found to be 100 nm2 and there are 20 nm2 of untowable rocky bottom within that area, then the swept-area biomass would be extrapolated to 80% of the overall Atlantic surfclam area for a more accurate estimate.

To demarcate the overall area inhabited by Atlantic surfclam it is desirable to identify the limits of the population on Georges Bank, whether physical (temperature, depth, substrate) or ecological (food, predators, competition for habitat). An indicator of the presence of Atlantic surfclam would also serve to define habitat both in and outside the surveyed areas. Simply mapping survey catches is helpful, but the region analyzed needs to encompass areas outside the current Atlantic surfclam strata set as well, in case there is significant Atlantic surfclam habitat that should be added to the surveyed area. An example of this (although not on Georges Bank) is northern Nantucket shoals (see Part H).

Years of experience surveying the bank with a clam dredge has led to general knowledge of where there are boulder fields, and how to read the ship's depthfinder before a tow and know to move on to a new location. This hit or miss method can waste time and potentially damage equipment. However, detailed maps of the bottom have not been available to actually quantify the number of square miles inhospitable to both Atlantic surfclam and dredges. Today, with constantly improving technology and a new emphasis on habitat, the sea floor on Georges Bank is becoming known in more and more detail. It should be possible to bound the zones of bad bottom and calculate their areas for both restratification and biomass estimation.

In anticipation of the survey redesign the assessment working group reviewed several potential methods of evaluating habitat for the presence of Atlantic surfclam and for the delineation of areas of rough bottom, and they are summarized below. Some methods might work best in conjunction with others, and there will likely be suggestions of other techniques. This work is ongoing, and a formal committee experienced with survey design will be formed to make final decisions on any improvements or changes to the NEFSC clam survey.

Analysis of ancillary survey data for the Georges Shoals and Cultivator Shoals area of Georges Bank[6]

The following is a near-final analysis of ancillary survey data for the region of Georges Bank encompassing Cultivator Shoals and Georges Shoals. The analysis was funded by the NSF I/UCRC Science Center for Marine Fisheries (SCeMFiS). SCeMFiS has also funded a full analysis of Georges Bank. This update will be available some time in September.

Data Resources

Atlantic surfclam and ocean quahog survey data from 1982 to 2014 were obtained from the NMFS-NEFSC assessment database. These data included standardized catch of Atlantic surfclam, haul and gear codes, and, for years after 1999, comments for each tow with a non-zero haul and gear code. Additional information was obtained from survey data sheets for Atlantic surfclam and ocean quahog surveys from 1978 to 1999. All of these data sheets were digitized into PDF documents and the data obtained were entered into excel spreadsheets. Additional data from 2002 to 2014 were obtained from NEFSC survey electronic archives.

Analytical approach

Mapping the locations of various variables was carried out at the scale of an *ESS Pursuit* survey tow. This is a distance of approximately 0.29 minutes of latitude or 0.39 minutes of longitude. Survey tows within this distance apart were considered to be replicates even if taken in different years. In general, the most extreme value amongst replicates was taken for further analysis. Most non-living variables can be considered to be stable constituents over much, if not all, of the entirety of the survey time series. For shells, for example, taphonomic loss rates are low for Atlantic surfclam and ocean quahog shells and likely to be low for lesser clam constituents. Stability over time would not be the case for live animals, all but one of which has a life span less than the survey time series. These temporally more ephemeral variables should be interpreted to indicate the potential for occupation of a site. Regardless, no temporal variations have been tracked in this analysis.

[6]Contributed by: Eric Powell, University of Southern Mississippi

Haul and Gear Codes

These codes encompass a range of incidents that might have compromised the tow. Generally, these incidents fell into two broad categories: issues associated with the proper functioning of the dredge itself and issues associated with bottom type that might compromise a successful tow. Our focus was on the latter set of incidences. Unfortunately, the haul and gear codes used by NMFS-NEFSC were developed for the trawl survey; thus, an analysis was required to determine how these codes were applied to clam dredge hauls and the degree of consistency in that application across surveys. This analysis relied on annotations for each of these tows in the survey database for the period 2002-2014. Unfortunately, no annotations occur in the survey database prior to 2002. In order to investigate the consistency and meaning of haul and gear codes, the data for 2002-2014 were sorted by haul and gear code combination and comments were examined. A total of nine combinations of haul and gear codes indicated problems with the tows stemming from bottom obstruction (e.g. damage to the dredge or location dropped from the survey after scouting bottom). These tows were consolidated into one of three categories: 1.) locations where "bad bottom" was identified, such that the dredge was not deployed; 2.) locations where dredge damage occurred, including broken nipples, broken or bent knife blades, torn hoses, or damage to the dredge frame; and 3.) locations where rocks were caught by the dredge in sufficient number to be judged to have compromised the tow, but which did not cause significant/any damage to the dredge.

Tows for surveys from 2002-2014 could be assigned to these three categories without qualification. Unfortunately, with a few exceptions, haul and gear codes were not used predictably over the survey time series and often tows influenced by non-bottom-contact events (e.g., clogged pump, power supply issues) were given haul and gear codes also used for bottom contact events. Thus, earlier tows (1982-1999) with haul and gear codes could rarely be assigned to one of the three categories without qualification. However, for essentially all of these tows, annotations were recorded on the original data sheets. Accordingly, the raw data sheets were examined for tows prior to 2002, for which haul and gear comments were missing. Comments recorded on the raw data sheets permitted extraction of tows falling into the 3 afore-mentioned categories, so that the entire survey time series was assembled. Plots of these data identify the locations where each of the three incident types occurred (Figures 251 and 252).

Bycatch data - substrate

The term "bycatch" was used in a general way on the 1978-1999 data sheets to apply to a series of materials obtained in the dredge including substrate, shell, and a selection of live animals. Some species of live animals were not included in the bycatch category. Bycatch data from 1978 to 1999 was present on each digitized data sheet. Electronic data were available in the FSCS database. Terminology and category were relatively consistent between 1978 and 1982 and essentially identical from 1982 to 2011. Data ceased to be collected at the end of the 2011 survey.

The bycatch data comprise three categories: shell, substrate, and other invertebrates. Information regarding tows where gravel, rocks, cobbles, and boulders were present in the haul was extracted into a common database. The category "cobbles" encompassed anything smaller than six inches and larger than gravel, the size of which, however, was not specified. The category "rocks" encompassed material between six and twelve inches and "boulders" were anything larger than twelve inches.

Over the history of the survey, the annotations regarding substrate varied considerably. From 1978 to 1980 substrate data were recorded in either liters or bushels. The survey dredge used during this time period was considerably smaller than the dredge used from 1982 to 2011. Due to the extreme variability of recorded data from 1978 to 1980, presence and predominance values were assigned to the data. A value of 0 indicates an absence of a particular substrate (e.g., cobbles). A value of 1 was given to volumes =1 bushel or where presence was indicated without a volume given (e.g., "trace" was recorded in the place of a numerical value). A value of 2 was given to any volume > 1 bushel.

From 1982 to 1999 substrate data were recorded on the data sheet in terms of check marks (1 check for present and 2 checks for predominant) and categories include gravel as well as finer-grained substrates such as sand, mud, and clay; however, these substrate types are not further defined. The categories "cobble", "rock", and "boulder" were defined by the same sizes as used on the 1978-1980 data sheets. The survey dredge for this time period was larger than the dredge used from 1978 to 1980. Volume of bycatch was routinely recorded, as was the percent composition of the various components. In order to provide more quantitative and consistent values for substrate, the total volume of substrate in bushels was calculated for each tow for the period 1982 to 1999 from the percent of total volume. The total substrate volume was then divided equally by the sum of presence and predominance values (i.e. number of checks) in order to estimate a number of bushels of gravel, cobble, rocks, and boulders. For instances where the percent composition for substrate or total bycatch volume was not recorded, the data were entered as presence and predominance values (i.e. number of checks seen on datasheet) because a total substrate volume could not be calculated. These instances were relatively rare, however. In most cases, a volumetric estimate could be made. The data were then coded as 0 for absence or < 1 bushel, 1 where the volume of a particular category was < 30 bushels, and 2 where the volume was =30 bushels. For 2002-2011, the data were entered into FSCS as 0, 1, or 2. Substrate volumes were given in bushels (2002) or liters (post-2002) and percent composition was recorded in each case. An assumption was made initially that the criteria for presence and predominance were consistent across the transition from data sheets to FSCS files. However, subsequent statistical analysis showed that the substrate volumes recorded in the FSCS database were consistently lower per tow than those values on the pre-2002 data sheets, by a factor of 10. Further investigation, including interviews with people who participated in the survey across the 1999-2002 transition, did not elucidate an explanation for the differential, but evaluation across a series of surveys showed that the differential coincided with the transition from data sheet to FSCS files and that the differential was relatively consistent forwards and backwards in time from that point. To standardize the data, the FSCS substrate volumes were increased by a factor of 10.

The divisions at 0 and 1 bushel and 29 and 30 bushels used to distinguish absent, present, and predominant were obtained by examining the FSCS data from 2002-2011 where the tows for the entire survey could be analyzed as they were already in electronic format . The median and 75th percentile for all tows was 0 (no substrate larger than gravel collected) for these tows. That is, cobbles, rocks, and boulders were rarely encountered by the survey. The value of 30 fell between the 95th and 99th percentiles of all tows for these substrate types. The value 1 fell at or above the 90th percentile of all tows for these substrate types. Thus, we include as present all tows where at least one bushel of material was obtained and list as predominant the rare tows where 30 or more bushels were obtained. (See Figures 253 and 254).

Bycatch data - shell and miscellaneous invertebrates

For shell and other invertebrates, abundance data were entered as presence and predominance values. This information was also recorded by check marks on the pre-2002 data sheets. Abundance of shell was recorded in either liters or bushels from 1978 to 1980. Presence and predominance values were then assigned where 0 indicated absence, 1 indicated presence of =50% of the total shell volume, and 2 indicated presence of > 50% of the total shell volume. From 1982 to 1999, each of the shell types of concern were listed separately and given presence and predominance values seen as checks on the datasheets. For 2002-2011, the data were entered into FSCS as 0, 1, or 2. An assumption was made that the criteria for presence and predominance were consistent across the transition from data sheets to FSCS files. Interviews of survey personnel were confirmatory.

Generally, shell volume as a percentage of total bycatch was recorded for each tow. The afore-described analysis for substrate could be recapitulated for shell. However, our approach was to focus on the relative importance of shell types at each location rather than comparing the absolute quantity across all tows; thus, we relied on the number of check marks to assign values of 0, 1, and 2 for absent, present, and predominant within-tow. Shells of a series of miscellaneous clams were tracked (e.g. Astarte, Pitar). For presentation, we took the maximum value amongst these species (0, 1, 2) and assigned that to the "Clam shell" category.

The four species selected from the "Other Invertebrates" category are epibionts that indicate presence of substrate that is of a size that might be colonized (i.e. anything gravel sized or larger). These four were sponges, tunicates, anemones, and barnacles. Specific species are not identified on the data sheets. As with the shells, a volumetric conversion is present for most tows; however, our focus once again was on real presence and a within-tow evaluation of predominance. Thus, values are assigned based on check marks as 1 for present and 2 for predominant within-tow. A value for total bionts was calculated as the sum of the four values. See Figures 255, 256, 257, 258.

Species data - live animals

The numbers per tow for a suite of clams, asteroids, crabs, and gastropods were also recorded by survey species code. For 1978 to 1999, data were recorded and entered into a common database as the number of individuals. For 2002 to 2011, data regarding the number of individuals were obtained from the NMFS-NEFSC survey database. The number of individuals of asteroid species, spider crabs and hermit crabs, and gastropods were placed in three bins and data were entered as the sum of individuals from each of the three categories. Placopecten and Modiolus were retained as separate species. Total numbers per category were converted into a qualitative scale of 0, 1, 2, and 3 using 0 for absent, 1-2 for 1 (present), 3-10 for 2 (some), and > 10 for 3 (many).

Interpretation Relative to Re-stratification

Re-stratification of Georges Bank focuses on the need to limit the survey abundance estimates to areas inhabited by Atlantic surfclam and to limit the incidence of dredge damage on the bottom. The following are likely to be of most importance in assigning specific locations to a Atlantic surfclam and non-Atlantic surfclam stratum, wherein we use the term "non-Atlantic surfclam" to indicate areas where Atlantic surfclam are likely to be uncommon or where the catch of Atlantic surfclam with routine efficiency by the dredge is compromised.

1. The haul and gear code analysis has generated a comprehensive and consistent database establishing four bottom types.
a. No haul and gear code indicates a substrate potentially habitable by Atlantic surfclam (or ocean quahogs).
b. Untowable bottom or locations where gear damage occurred indicate regions of potentially complex habitat that very likely either do not harbor Atlantic surfclam or for which abundances are low due to the presence of substrate types that preclude Atlantic surfclam (e.g., boulders). In addition, continuing to sample these location risks dredge damage. However, these locations are spotty, that is, patches of sand clearly containing Atlantic surfclam exist within e.g., boulder fields.
c. The retention of many rocks in the dredge is a common occurrence and may permit allocation of the site to a non-Atlantic surfclam stratum.

2. Of the live animals recorded, the one that may provide additional guidance is the horse mussel Modiolus. It is unlikely that horse mussels are found in areas harboring large numbers of Atlantic surfclam. Thus, the large catches of horse mussels might provide additional assignment of sites to a non-Atlantic surfclam stratum.

3. The absence of abundant Atlantic surfclam shells may also indicate locations assignable to a non-Atlantic surfclam stratum.

4. Perusal of the plots of these variables shows that low abundance of Atlantic surfclam, presence of tows with haul and gear codes, presence of tows with high catches of rocks and boulders, and locations where horse mussel catches were high are not randomly distributed. Rather, there is a strong tendency for all of these tow types to group together, and this grouping might provide the basis for re-stratification.

One suggestion is that the survey database might be used to compare Atlantic surfclam catches in tows with few Atlantic surfclam shells, high catches of rocks or boulders, high mussel catches, and non-zero haul and gear codes to tows without any of these four conditions to see if Atlantic surfclam are differentially abundant in these two tow types. A consideration is that dredge efficiency is also likely to differ between these two groups of tows, but, of course, this would be true regardless of how the "non-Atlantic surfclam" locations are incorporated into strata. If a similar analysis for the entirety of Georges Bank continues to demonstrate some coherency in the location of indicators of habitat conducive to and disfavoring the presence of abundant Atlantic surfclam, then strata might be defined thusly and a biased allocation of tows to the Atlantic surfclam stratum might be considered.

For the Georges Shoals/Cultivator Shoals plots provided, the domain which encompasses the area as shown contains 206 survey tow cells (defined by the length of an F/V Pursuit tow) of which 71 recovered some combination of predominant catches of horse mussels, cobbles, rocks, or boulders, or for which gear damage occurred. Reducing the cell size to the length of an R/V Delaware II tow modestly increases both counts (210 and 74, respectively) as a few "replicates" occur in the database. Replicates are tows taken at the same or nearly the same location as defined by the cell size. Accordingly, 34.5% of the tows occurred in potentially complex habitat.

Using split-beam multi-frequency acoustic data to calculate hardness, roughness and slope of the bottom to help determine the extent of untowable areas on Georges Bank

This is data which could be used in conjunction with optical information to map the size and shape of boulder fields and allow them to be measured more precisely.

Michael Martin, NEFSC: Split-beam multi-frequency data from NOAA ships is used to estimate the hardness, roughness and slope of the seafloor in the Gulf of Maine and Georges Bank using interferometric techniques. Split-beam tranducers allow the user to infer the direction from which the sound reflected from the seafloor is returning. This information, when used with the estimated range, allows the slope of the seafloor over the ensonified area to be estimated. As the slope increases, less reflected sound energy is returned from the seafloor. The properties of the reflected sound returned from the bottom also allow inference about the hardness and roughness of the bottom as different seafloor sediments exhibit differential properties when interacting with sound waves at different frequencies (see Figures 259 and 260 for examples of the plotted data). Depth of the water will affect the interaction as more area is ensonified, so the same level of response does not necessarily mean the same kind of bottom. Up to 5 frequencies (18, 38, 70, 120, 200 Khz) are available aboard the latest class of NOAA ships. The data examined were collected on the FRVs Bigelow, Delaware II, and Pisces between 2007 and 2015.

It is hoped that these estimates can be used to help with stratification issues in both the Georges Bank clam survey and the Gulf of Maine longline survey. This data set is attractive for this purpose because of its geographical extent, which covers all the areas of interest. Approximately 4 million records were generated over these areas. Acoustic noise or interference was a prominent feature of much of the data and prevented estimation in approximately 25% of cases.

The next step is to perform quality assurance checks, and attempt to ground truth this information using other data sources. Here some of the optical or bad tow data we have could help to verify the acoustic data (it is not always possible to determine the bottom type from acoustic data only) while the acoustic data could help determine the size of particular patches of boulders and rough ground since a similar signal at similar depth usually indicates the same bottom type.

Using HabCam to provide optical information on the extent of untowable ground

The HabCam (Habitat Characterization Camera System) is an underwater system that (among other things) takes high-resolution photographs of the ocean floor as it is towed behind a survey ship. The vehicle flies close to the bottom and photographs an area approximately a meter wide at a rate that allows the individual photographs to overlap and create an unbroken photographic record of what the ship has passed over. The images yield a wealth of fish, invertebrate and substrate data. The images are currently processed by people but the goal is to have an automated system be able to pick out features such as scallops independently. The HabCam has been deployed as part of the NEFSC scallop survey on Georges Bank for several years (Figure 261).

As can be seen in Figure 261, there are HabCam data from Atlantic surfclam habitat on Georges Bank which could provide information on the size and shape of the untowable areas within the overall Atlantic surfclam habitat. Some of the images have already been processed and substrate information has been recorded. If one image is found that contains rough bottom, then surrounding images can be viewed to measure the width of the feature in the direction of travel of the HabCam.

Using HabCam data to create a Habitat Suitability model

Expecting content from: Scott Gallagher, WHOI

HabCam data can also be used to model the extent of Atlantic surfclam habitat based on substrate characteristics and other variables measured by the HabCam such as depth and temperature. Known as a Habitat Suitability Model, it uses the presence or absence of the target organism under certain conditions to predict the extent of the population. The model has been used for other species and has potential to help define suitable habitat for Atlantic surfclam on Georges Bank.

Using surficial sediment data from Harris and Stokesbury (2010) to locate untowable ground

Using underwater video camera data collected during numerous different surveys over 11 years, Harris and Stokesbury created composite substrate maps of all of Georges Bank, which they published in 2010 (see reference below for details of methods). The maps use sediment size and dominance characteristics determined from video footage taken by a camera facing down from the peak of a pyramid-shaped frame. The frame rests on the bottom as the video records movement of fish and invertebrates as well as sediment type. Maximum sediment size, dominant sediment type, average coarseness (mean size of types present) and sediment heterogeneity data were collected at each station. Data from each station were interpolated onto a 1 km grid and Figure 262 shows a resulting map of maximum size sediment (GIS files to make this map can be found with the electronic version of the Harris and Stokesbury paper).

The positive Atlantic surfclam tows overlaid on the sediment map show the need to enlarge the figure and look to see if there is a relationship between predicted sediment size and Atlantic surfclam catch or if the map is too low resolution to catch the untowable areas, which is helpful in itself for determining scale (Figure 263). However, if the areas with large boulders that are not available to the survey are located, and together with another source of optical data, a more precise extent of the boulder areas may be calculated, and the resulting areas discounted, from the Atlantic surfclam survey total swept area.

Harris, B. P. and Stokesbury, K. D. E. 2010. The spatial structure of local surficial sediment characteristics on Georges Bank, USA. Continental Shelf Research 30:1840-1853.

Using presence of dead shell to delineate habitat

We used NEFSC scallop survey data from 2010 through 2015 to map areas where dead shell has collected to see if that would be a marker for the presence of the live Atlantic surfclam or ocean quahogs. The scallop dredge often retains shell substrate, and the type and estimated amount of dead shell is recorded in the station log. It is not an exact measure: the total volume of “trash” (non-living matter brought up in the tow) is recorded, then an estimated percent of the volume comprising shell is made, and finally which species of shell were present and which species was dominant are noted. We found stations where Atlantic surfclam, ocean quahog or scallop (scallop just for comparison of distribution) shell was present, then estimated a rough volume by multiplying the total amount of trash by the proportion that was shell, then assuming the species marked “dominant” was 50% of the shell volume and any other species present were 25%. We mapped where shells of the three species were found over where the live animals were found, and the results can be seen in Figures 264 - 266. The maps of the three species of dead shell looked very similar and did not appear to designate where the species were, but instead where shell was concentrated by oceanographic processes. However, the estimation of shell volume by species was not very accurate and it may be worth another look at the trash data in more detail.

Using oceanographic data to delineate the extent of Atlantic surfclam habitat on Georges Bank

Temperature and salinity data from the NEFSC oceanography database were plotted with positive tows for Atlantic surfclam and ocean quahogs. The database contains all the CTD results from NOAA ships and NOAA cruises over many years. All the bottom temperature and bottom salinity data points (elevation less than 10 m) from 2011-2015 available for the month of April (representing the usual thermal minimum) and the months of September and October combined (representing the usual thermal maximum) were plotted on separate maps. Much of Georges Bank is known as a well-mixed, dynamic system, but there were gradients evident between different parts. Salinity was lower and temperature was higher on top of the Bank (in the shallower areas) at both times of year (Figures 267 - 270). Temperature and salinity were plotted using two colors to show the pattern.

With some additional data from other times of year and analysis of more specific temperature ranges, we may be able to plot isotherms that bound the Atlantic surfclam area on the bank and provide support for a designated Atlantic surfclam habitat area. Temperature is well known to limit populations, and with evidence Atlantic surfclam are moving into deeper waters in the MAB we understand it plays a role in the distribution of Atlantic surfclam and ocean quahogs. For instance, it looks like ocean quahogs on Georges Bank are limited by temperature maxima exceeding $\sim 16^o$ C (Figure 270), which is not new information, but supports the existence of the pattern on Georges Bank.

Increasing the footprint of the NEFSC clam survey to cover more of Nantucket shoals

Nantucket Shoals is an area not completely covered by the NEFSC clam survey that is densely populated with Atlantic surfclam, and supports a productive local Atlantic surfclam fishery (Figure 271). As part of the survey redesign, it has been suggested that there be an additional stratum added here to fill in the gap in the survey. How this will be accomplished and folded into the survey time series is yet to be determined, but areas where Atlantic surfclam fishing occur are not always stable over time and there should be a mechanism in place, or at least a process, to add new ground to the survey.

Appendix 14 Empirical Atlantic surfclam assessment

Summary

Empirical stock assessment results from catch curves, exploitation rates ($E = \frac{Catch}{swept\,area\,biomass}$), and recruit abundance and biomass trends were provided for comparison to stock assessment model estimates. Empirical analyses were the main source of information about mortality, recruitment, and biomass in southern subregions (SNE, LI, NJ, DMV and SVA). Catch curve and other empirical analyses were complicated by domed survey size selectivity patterns before 2012, that caused a positive bias in mortality estimates, and survey gear changes after 2011, and low numbers of age samples for some years (particularly in the north).

Empirical results appear to support assessment model estimates. Total annual mortality estimates (probably biased high) from catch curves for the northern and southern areas averaged 0.14 y^{-1} and were near the current estimate of natural mortality (0.15 y^{-1}) indicating that fishing mortality rates were low (Figures 272-274). There was no clear evidence of trends in mortality over time. Empirical exploitation estimates for the south indicate that recent fishing mortality rates in the northern and southern areas were relatively low ($E < 0.05y^{-1}$, Figure 275).

Exploitation rates were low ($E < 0.06y^{-1}$) after 2011 in the LI NJ, DMV and SVA subregions regions but relatively high ($0.1 < E < 0.15$) in SNE (Figures 275–276). Biomass appears to be declining in in all areas south of SNE and in the south as a whole although changes in the survey complicate interpretation of trends (Figures 275–276). Results indicate that recruit abundance was relatively high in the south during 2015 and about average in the northern area during 2012 (Figures 278-279).

Catch curves

Catch curves based on survey age data were for individual cohorts (cohort catch curves) and for all of the cohorts captured during the same survey (snapshot catch curves). In both types of analyses, the logarithm of mean numbers per tow was regressed on age and the slope of the regression model was taken as an estimate of the average mortality rate (Z). Survey age composition data were based on age-length keys. Poorly sampled years with less than 300 ages per survey from the south or less than 200 ages from the north were omitted. Year classes observed less than five times in the generally triennial clam survey were omitted from cohort catch curve analyses.

Field estimates of size-selectivity for the survey dredge used during 1982-2011 are dome shaped with a broad peak from about 8 cm (about age 4 y) to 15 cm (Northeast Fisheries Science Center (2013)). The survey dredge used since 2012 has a logistic size selectivity shape with full selectivity at about 10 cm (about age 5 y). The change is survey selectivity means that 1982-2011 and 2012-2015 data cannot be combined.

The most important decision in catch curve analysis is the first age group included. Average fishery length composition data for the southern area indicate that Atlantic surfclam are fully recruited to commercial gear and should experience maximum mortality at about 15 cm SL. Based on the updated growth curve in this assessment, Atlantic surfclam in the southern area reach 15 cm at about age 11 y. It is difficult to translate 15 cm SL into age for Atlantic surfclam in the northern area because 15 cm is close to the maximum size predicted by the von Bertalanffy growth curve, but it appears that Atlantic surfclam in the northern area may be close to fully recruited at age 15 y or older. We therefore fit catch curves assuming full recruitment at age 11 y in the south and at age 15 y for the northern area. Sensitivity analyses (not shown) showed that mean mortality estimates from cohort and snapshot catch curves increased as starting age increased, probably due to the dome shaped size-selectivity in the survey.

Statistically significant ($p \leq 0.1$) cohort mortality rates for the south ranged 0.07-0.24 y^{-1} and averaged 0.14 (Figure 272). There was no clear trend in mortality rate estimates over time. Statistically significant ($p \leq 0.1$) snapshot mortality rates ranged 0.06-0.28 y^{-1} and averaged 0.14 (Figure 273). There was no clear trend in mortality rate estimates over time. Runs of positive and negative residuals were noted in some cases.

It was not possible to estimate cohort catch curves for Atlantic surfclam in the northern area because of limited sampling, but the data were sufficient to fit four snapshot catch curves from data collected during 1984, 1986, 1992 and 2008 (Figure 274). Statistically significant ($p \leq 0.1$) mortality rates ranged 0.09-0.18 y^{-1} and averaged 0.14. Catch was negligible in the northern area prior to 2010 so these estimates represent natural mortality and do not include fishing mortality. There was no clear trend in mortality rate estimates over time. Runs of positive and negative residuals were noted in some cases.

Catch/swept-area biomass estimates

As in the last assessment (Appendix A8 in Northeast Fisheries Science Center (2013)), swept-area biomass and exploitation rates were computed for Atlantic surfclam 12+ cm during 1997-2015 by assessment area and smaller regions. The survey data used here were adjusted for survey selectivity to compensate for the dome shaped survey selectivity pattern in Atlantic surfclam 12+ cm in the old survey during 1982-2011. Field experiments indicate that survey selectivity was flat at 12+ cm in the new survey after 2012 so that no selectivity adjustments were required. Sensor based tow distances and updated estimates for survey selectivity, shell length-meat weight and other parameters were used in calculating survey catch weight per tow. Swept-area biomass was calculated assuming median dredge efficiency estimates of 0.23 for 1997-2011 and 0.67 for 2012-2015 based on depletion and selectivity studies to provide an approximate empirical measure of relative scale. Only one set of swept-area estimates were available for the northern area after 2011. Two sets of surveys were available after 2011 for the southern area which may reflect recent trends and should be interpreted with care.

Swept-area biomass estimates for 1997-2011 and 2012-2015 were comparable in scale suggesting that efficiency and tow distance estimates for the two survey dredges are reasonably consistent (Figure 276-275). There is substantial uncertainty in interpreting the composite time series in recent years, but it appears that SNE biomass increased during 2012-2015. Atlantic surfclam biomass in the LI and NJ regions may have declined substantially during 2012-2015 while biomass in DMV remained steady and biomass in the SVA region remained low. Exploitation rates since 2011 were low ($E < 0.06y^{-1}$) in the LI, NJ, DMV, and SVA regions but relatively high (0.1 - 0.15 y^{-1}) in SNE. The high values in SNE may be due in part to the fact that a proportion of the catch is landed in an area (northern Nantucket Shoals) that is not surveyed. Empirical exploitation estimates for the south confirm assessment model estimates which indicate recent fishing mortality rates in both areas are low ($E < 0.05y^{-1}$).

Survey recruitment trends

Long term (1982-2015, but see below) trends in abundance of recruits (5-12 cm, before recruitment to the fishery) were computed by adjusting survey catch data based on nominal tow distances (distance traveled while the dredge was on the tow rope) and dredge efficiency (0.23 for 1997-2011 and 0.67 for 2012-2015). Selectivity curves based on field studies were used to adjust for differences in size selectivity during 1982-2011 and 2012-2015. Recruit abundance trends were similar ending in 2011 and starting in 2012 indicating that dredge efficiency and selectivity estimates were consistent (Figures 278-279).

Data are adjusted for size-selectivity and dredge efficiency based field study results. Survey gear changed in 2012 so that comparison of trends up to and after 2011 may be misleading. Note that y-scales differ in each plot.

Appendix 15 Appendix to the SAW Assessment TORs:

Clarification of Terms used in the SAW/SARC Terms of Reference

On “Acceptable Biological Catch” (DOC Nat. Stand. Guidel. Fed. Reg., v. 74, no. 11, 1-16-2009):

Acceptable biological catch (ABC) is a level of a stock or stock complex’s annual catch that accounts for the scientific uncertainty in the estimate of [overfishing limit] OFL and any other scientific uncertainty. . . ” (p. 3208) [In other words, OFL ABC.]

ABC for overfished stocks. For overfished stocks and stock complexes, a rebuilding ABC must be set to reflect the annual catch that is consistent with the schedule of fishing mortality rates in the rebuilding plan. (p. 3209)

NMFS expects that in most cases ABC will be reduced from OFL to reduce the probability that overfishing might occur in a year. (p. 3180)

ABC refers to a level of “catch” that is “acceptable” given the “biological” characteristics of the stock or stock complex. As such, [optimal yield] OY does not equate with ABC. The specification of OY is required to consider a variety of factors, including social and economic factors, and the protection of marine ecosystems, which are not part of the ABC concept. (p. 3189)

On “Vulnerability” (DOC Natl. Stand. Guidelines. Fed. Reg., v. 74, no. 11, 1-16-2009):

“Vulnerability. A stocks vulnerability is a combination of its productivity, which depends upon its life history characteristics, and its susceptibility to the fishery. Productivity refers to the capacity of the stock to produce MSY and to recover if the population is depleted, and susceptibility is the potential for the stock to be impacted by the fishery, which includes direct captures, as well as indirect impacts to the fishery (e.g., loss of habitat quality).” (p. 3205)

Participation among members of a SAW Assessment Working Group:

Anyone participating in SAW assessment working group meetings that will be running or presenting results from an assessment model is expected to supply the source code, a compiled executable, an input file with the proposed configuration, and a detailed model description in advance of the model meeting. Source code for NOAA Toolbox programs is available on request. These measures allow transparency and a fair evaluation of differences that emerge between models.

Appendix 16 Appendix: Survey performance 2013

Introduction

The 2013 survey covered a portion of the whole stock area including the SNE and most of GBK subareas. There were 149 total tows and four selectivity tows. One tow resulted in severe damage to the dredge and was aborted and eight other tows during which no sensor data was recovered. Therefore there were 136 standard survey tows on which sensors were deployed and sensor data was recorded.

The 2013 survey used a modified commercial dredge with 3 on board data recorders. There was an inclinometer (Star Oddi) and two (Madge Tech) pressure sensors: one in the pump manifold measuring the pressure in the hydraulic jets used to loosen the sediments around clams and one measuring the ambient pressure at fishing depth. The inclinometer measured the pitch roll and yaw of the dredge as it was towed and was used to determine if the dredge was in a fishing position, which was the basis for determining "time fishing" on each tow. The pressure sensors were used to make sure that the pump was achieving sufficient pressure to maintain capture efficiency.

Survey performance

Sensors deployed during the 2013 survey suggest that either the average pump pressure was some what less than 2012 (Figure 280), or the pressure sensor was mis-calibrated. The pressure sensor data was not analyzed until 2014, after the 2014 survey had been conducted and the sensors re-calibrated. Therefore there is no way to determine if the problem with the sensors was due to reduced pump pressure or sensor calibration. Speed over ground also appeared to be somewhat less than in previous years (Figure 280), but may be related to the type of substrate encountered and/or current strength. The ground fished was in some cases exceedingly rocky and difficult to dredge through, while currents on GBK and SNE are strong relative to areas further south. The tow speeds recorded were probably not sufficient in magnitude to cause concern regarding dredge efficiency and may represent the maximum advisable speed given the conditions. Neither pump pressure nor vessel speed appeared to be less than expected based on ship board instruments during operations, which may indicate problems with sensor calibration, but the discrepancy cannot be definitively resolved at this juncture.

Determination of time fishing

The determination of time fishing, the "fishing seconds" for each tow was based on a measurement of the pitch of the dredge during each second of the tow. Roll and yaw were relatively stable for the large modified commercial dredge and rarely fluctuated from baseline levels during fishing events. Pitch was recorded by a Star Oddi inclinometer which functioned consistently. Data from each instrument was smoothed using a 7 second moving average and then parsed for time above or below the median fishing angle for that tow.

In order to account for median pitch $> 0^o$, the determination of time fishing was based on a critical deviation from median pitch, rather than an absolute critical pitch angle. The choice of critical deviation has implications for the calculation of tow distance for each tow. When the dredge is above or below the critical deviation it is assumed to be pitched too steeply for the blade to penetrate the sediment. If the dredge is pitched within Δ_{crit} (the critical deviation) of $\tilde{\phi}_t$ (the median pitch for tow t), it assumed to be near enough to parallel to the bottom that the blade should penetrate and thus be actively fishing.

An ideal critical deviation is as close to zero as possible, but not so small that it includes poor dredge performance seconds. When the dredge is bouncing over rough terrain it is unlikely to be fishing effectively and those seconds should be excluded. There is however, a certain amount of pitch that is within fishing tolerance and a certain amount of noise in the data. If the critical deviation is too small, many seconds when the dredge is actually fishing would be excluded, which would tend to bias estimates of tow distance down. It is therefore important to find a critical deviation that is neither too small, nor too large.

The choice of Δ_{crit} was informed by an examination of the total and average tow distances based on different critical deviations. Total tow distance summed across all tow and average tow distance over all tows was compared when different values of Δ_{crit} were used. In general, higher values of Δ_{crit} result in longer tows because the dredge is considered to be in fishing position for a greater proportion of the tow (Figure 281). We selected a Δ_{crit} of $4°$ because it produced an average tow distance that was near the nominal tow distance (0.25 nm, a value equal to the nominal tow speed 3 kt multiplied by the nominal tow time 5 min) and because it seemed reasonable based on examination of the engineering schematic of the dredge being used (*Figure not yet available*)

Time fishing during the 2013 survey was less than the nominal tow time in most cases due to the lower average tow speed discussed above (Figure 282).

Effects of depth

Depth is typically associated with longer tows due to the scope of the towing wire that must be deployed to assure good dredge performance. Additional scope requires longer retrieval times and may result in some additional time fishing while the slack in the wire is spooled up. This effect was evident (though the data was noisy) during the 2013 survey (Figure 282).

Temperature

Temperature was recorded from the dredge and averaged over fishing seconds for all tows during the 2013 survey (Figure 283). Temperature was correlated with depth (Figure 283).

Figures

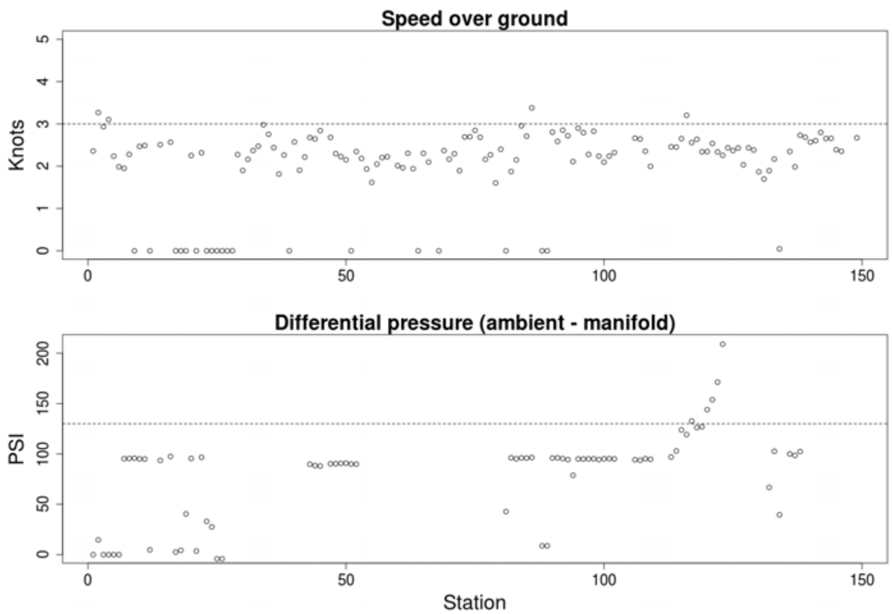

Figure 280: Speed over ground and differential pressure for each tow in the 2013 survey. The optimal speed over ground (3 kt) is marked with a horizontal dashed line. Differential pressure is the difference between the pressure in the dredge manifold, which indicates the absolute pressure realized by the dredges hydraulic jets, and the ambient pressure at fishing depth. The vertical line is plotted at 130 psi for reference only. Instrument failure or lost data are represented by differential pressure equal to 0.

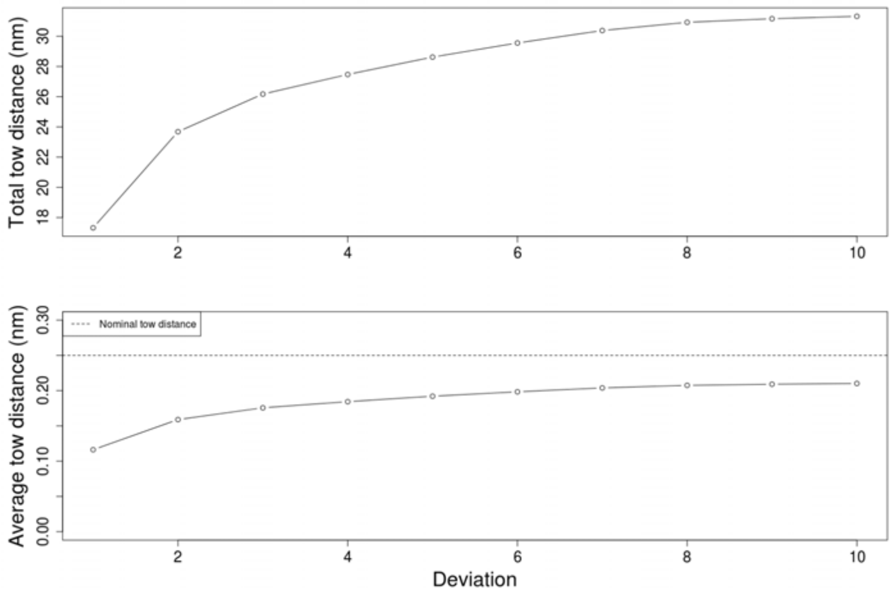

Figure 281: Average and total tow distance over all stations by critical deviation angle. The dashed line in the lower figure represents the nominal tow distance.

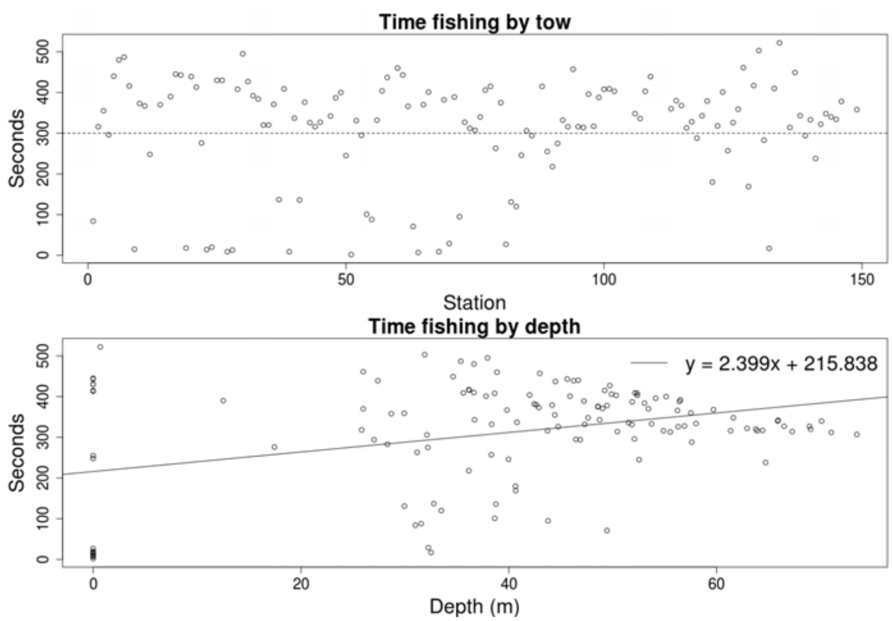

Figure 282: Time fished by station and depth. Depth significantly predicts tow time. The p value for slope was < 0.001, though the results were noisy and $R^2 < 0.14$ for the regression line shown.

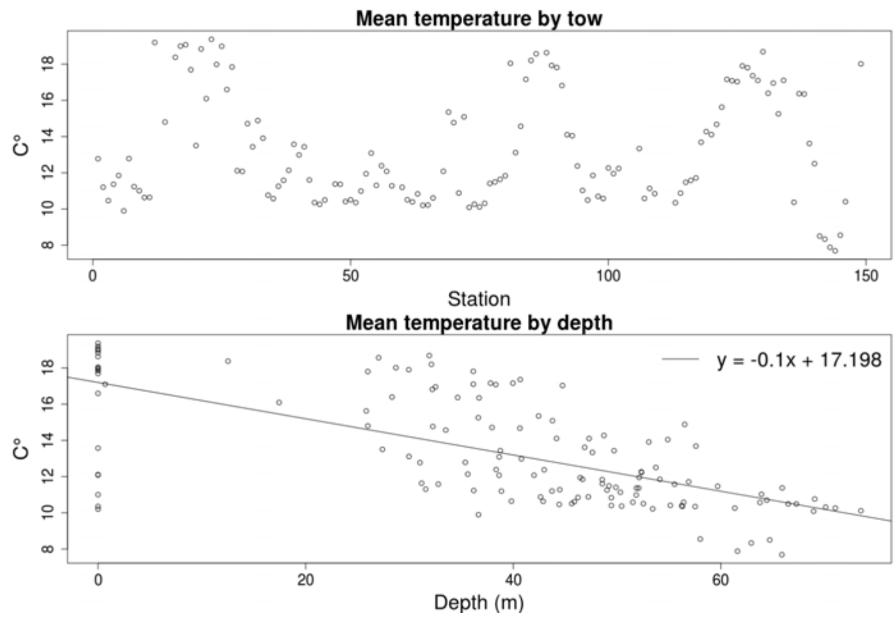

Figure 283: Temperature by station and depth. Depth significantly predicts temperature. The p value for slope was < 0.001 and $R^2 > 0.43$ for the regression line shown.

Appendix 17 Appendix: Survey performance 2014

Introduction

The 2014 survey covered portions of the SNE and GBK areas that were not sampled in 2013. There were 79 total tows and 49 experimental tows. Some sensor data was recorded on every completed tow except one. Therefore there were 29 standard survey tows on which sensors were deployed and sensor data was recorded.

The 2014 survey used a modified commercial dredge with 3 on board data recorders. There was an inclinometer (Star Oddi) and two (Madge Tech) pressure sensors: one in the pump manifold measuring the pressure in the hydraulic jets used to loosen the sediments around clams and one measuring the ambient pressure at fishing depth. The inclinometer measured the pitch roll and yaw of the dredge as it was towed and was used to determine if the dredge was in a fishing position, which was the basis for determining "time fishing" on each tow. The pressure sensors were used to make sure that the pump was achieving sufficient pressure to maintain capture efficiency.

Survey performance

Sensors deployed during the 2014 survey suggest that the average pump pressure was very close to the median pump pressure observed in 2012 (Figure 284). Speed over ground appeared to be somewhat less than in 2012 (Figure 284), but was well within the confidence bounds observed then and may be related to the type of substrate encountered and/or current strength. The ground fished was in some cases exceedingly rocky and difficult to dredge through, while currents on GBK and SNE are strong relative to areas further south. The tow speeds recorded were probably not sufficient in magnitude to cause concern regarding dredge efficiency and may represent the maximum advisable speed given the conditions. Neither pump pressure nor vessel speed appeared to be less than expected based on ship board instruments during operations. The values observed are probably well within normal operating tolerance and are probably not suggestive of changes in dredge performance.

Determination of time fishing

The determination of time fishing, the "fishing seconds" for each tow, was based on a measurement of the pitch of the dredge during each second of the tow. Roll and yaw were relatively stable for the large modified commercial dredge and rarely fluctuated from baseline levels during fishing events. Pitch was recorded by a Star Oddi inclinometer which functioned consistently. Data from each instrument was smoothed using a 7 second moving average and then parsed for time above or below the median fishing angle for that tow.

In order to account for median pitch $> 0^o$, the determination of time fishing was based on a critical deviation from median pitch, rather than an absolute critical pitch angle. The choice of critical deviation has implications for the calculation of tow distance for each tow. When the dredge is above or below the critical deviation it is assumed to be pitched too steeply for the blade to penetrate the sediment. If the dredge is pitched within Δ_{crit} (the critical deviation) of $\tilde{\phi}_t$ (the median pitch for tow t), it assumed to be near enough to parallel to the bottom that the blade should penetrate and thus be actively fishing.

An ideal critical deviation is as close to zero as possible, but not so small that it includes poor dredge performance seconds. When the dredge is bouncing over rough terrain it is unlikely to be fishing effectively and those seconds should be excluded. There is however, a certain amount of pitch that is within fishing tolerance and a certain amount of noise in the data. If the critical deviation is too small, many seconds when the dredge is actually fishing would be excluded, which would tend to bias estimates of tow distance down. It is therefore important to find a critical deviation that is neither too small, nor too large.

The choice of Δ_{crit} was informed by an examination of the total and average tow distances based on different critical deviations. Total tow distance summed across all tow and average tow distance over all tows was compared when different values of Δ_{crit} were used. In general higher values of Δ_{crit} result in longer tows because the dredge is considered to be in fishing position for a greater proportion of the tow (Figure 285). We selected a Δ_{crit} of 4° because it produced an average tow distance that was near the nominal tow distance (0.25 nm, a value equal to the nominal tow speed 3 kt multiplied by the nominal tow time 5 min) and because it seemed reasonable based on examination of the engineering schematic of the dredge being used (*Figure not yet available*)

Time fishing during the 2014 survey was less than the nominal tow time in most cases due to the lower average tow speed discussed above (Figure 286).

Effects of depth

Depth is typically associated with longer tows due to the scope of the towing wire that must be deployed to assure good dredge performance. Additional scope requires longer retrieval times and may result in some additional time fishing while the slack in the wire is spooled up. This effect was evident (though noisy) during the 2014 survey (Figure 286).

Temperature

Temperature was recorded from the dredge and averaged over fishing seconds for all tows during the 2014 survey (Figure 287). Temperature was correlated with depth (Figure 287).

Figures

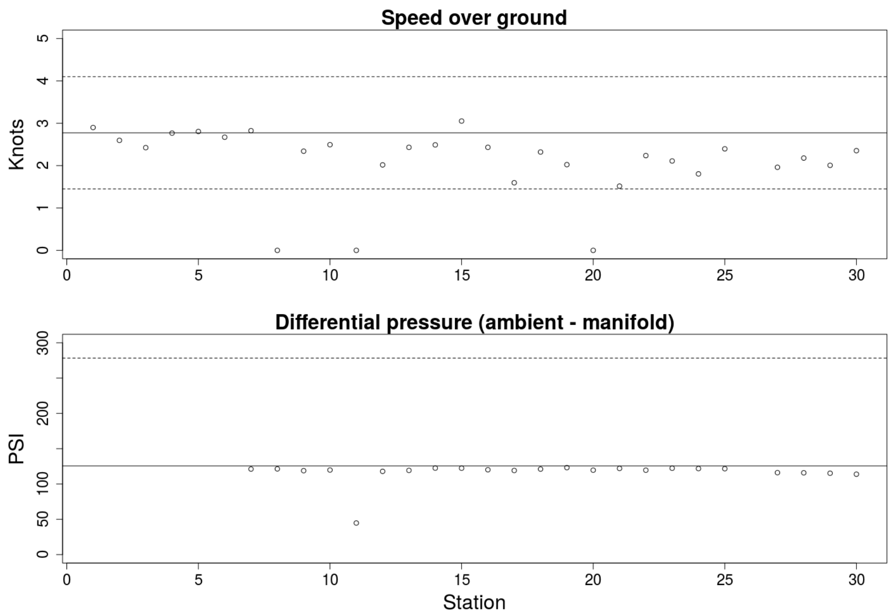

Figure 284: Speed over ground and differential pressure for each tow in the 2014 survey. The solid horizontal line is the median and the dashed horizontal lines are the 95% normal confidence bounds observed speed over ground in 2012. Differential pressure is the difference between the pressure in the dredge manifold, which indicates the absolute pressure realized by the dredges hydraulic jets, and the ambient pressure at fishing depth. The solid horizontal line is the median and the dashed horizontal lines are the 95% normal confidence bounds observed differential pressure in 2012. Instrument failure or lost data are represented by differential pressure equal to 0.

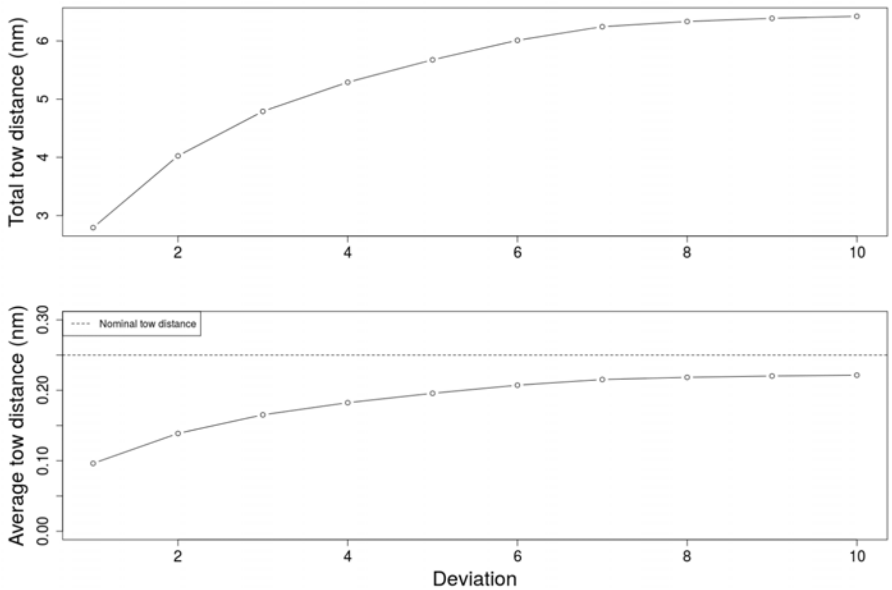

Figure 285: Average and total tow distance over all stations by critical deviation angle. The dashed line in the lower figure represents the nominal tow distance.

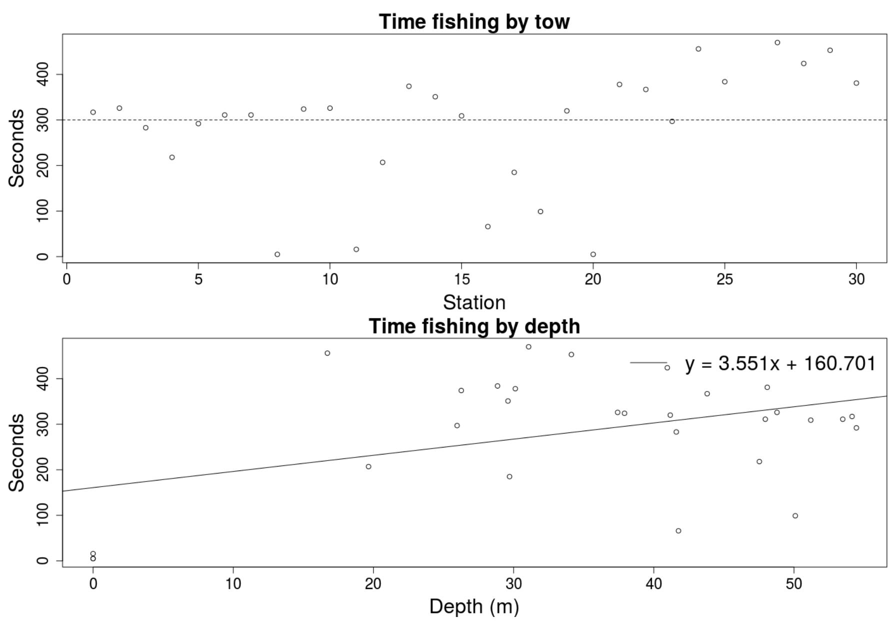

Figure 286: Time fished by station and depth. Depth significantly predicts tow time. The p value for slope was < 0.001, though the results were noisy and $R^2 < 0.14$ for the regression line shown.

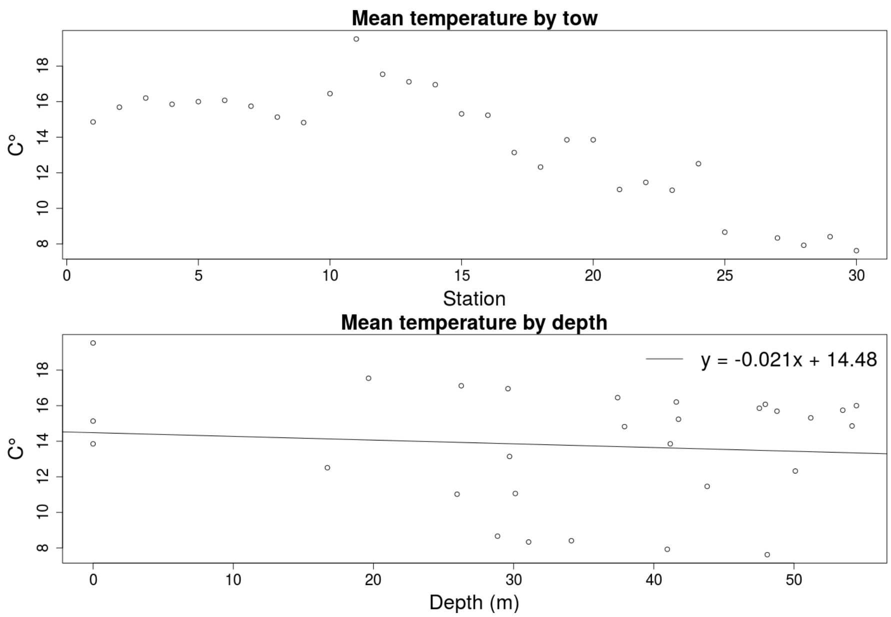

Figure 287: Temperature by station and depth. Depth significantly predicts temperature. The p value for slope was < 0.001 and $R^2 > 0.43$ for the regression line shown.

Appendix 18 Appendix: Survey performance 2015

Introduction

The 2015 survey covered a portion of the stock area including the SNE and most of GBK subareas. There were 189 total tows and two selectivity tows. At least some sensor information was recorded on every tow. Therefore there were 187 standard survey tows on which sensors were deployed and sensor data was recorded.

The 2015 survey used a modified commercial dredge with 3 on board data recorders. There was an inclinometer (Star Oddi) and two (Madge Tech) pressure sensors: one in the pump manifold measuring the pressure in the hydraulic jets used to loosen the sediments around clams and one measuring the ambient pressure at fishing depth. The inclinometer measured the pitch roll and yaw of the dredge as it was towed and was used to determine if the dredge was in a fishing position, which was the basis for determining "time fishing" on each tow. The pressure sensors were used to make sure that the pump was achieving sufficient pressure to maintain capture efficiency.

Survey performance

Sensors deployed during the 2015 survey suggest speed over ground was somewhat less than 2012, but consistent with the years since (Figure 288). Pump pressure was close to the 2012 median (Figure 288 and well within the confidence bounds observed then. Neither pump pressure nor vessel speed appeared to be less than expected based on ship board instruments during operations and the sensor data have substantial coefficients of variation. The values observed are probably well within normal operating tolerance and are probably not suggestive of changes in dredge performance.

Determination of time fishing

The determination of time fishing, the "fishing seconds" for each tow was based on a measurement of the pitch of the dredge during each second of the tow. Roll and yaw were relatively stable for the large modified commercial dredge and rarely fluctuated from baseline levels during fishing events. Pitch was recorded by a Star Oddi inclinometer which functioned consistently. Data from each instrument was smoothed using a 7 second moving average and then parsed for time above or below the median fishing angle for that tow.

In order to account for median pitch $> 0^o$, the determination of time fishing was based on a critical deviation from median pitch, rather than an absolute critical pitch angle. The choice of critical deviation has implications for the calculation of tow distance for each tow. When the dredge is above or below the critical deviation it is assumed to be pitched too steeply for the blade to penetrate the sediment. If the dredge is pitched within Δ_{crit} (the critical deviation) of $\tilde{\phi}_t$ (the median pitch for tow t), it assumed to be near enough to parallel to the bottom that the blade should penetrate and thus be actively fishing.

An ideal critical deviation is as close to zero as possible, but not so small that it includes poor dredge performance seconds. When the dredge is bouncing over rough terrain it is unlikely to be fishing effectively and those seconds should be excluded. There is however, a certain amount of pitch that is within fishing tolerance and a certain amount of noise in the data. If the critical deviation is too small, many seconds when the dredge is actually fishing would be excluded, which would tend to bias estimates of tow distance down. It is therefore important to find a critical deviation that is neither too small, nor too large.

The choice of Δ_{crit} was informed by an examination of the total and average tow distances based on different critical deviations. Total tow distance summed across all tow and average tow distance over all tows was compared when different values of Δ_{crit} were used. In general higher values of Δ_{crit} result in longer tows because the dredge is considered to be in fishing position for a greater proportion of the tow (Figure 289). We selected a Δ_{crit} of $4°$ because it produced an average tow distance that was near the nominal tow distance (0.25 nm, a value equal to the nominal tow speed 3 kt multiplied by the nominal tow time 5 min) and because it seemed reasonable based on examination of the engineering schematic of the dredge being used (*Figure not yet available*)

Time fishing during the 2015 survey was less than the nominal tow time in most cases due to the lower average tow speed discussed above (Figure 290).

Effects of depth

Depth is typically associated with longer tows due to the scope of the towing wire that must be deployed to assure good dredge performance. Additional scope requires longer retrieval times and may result in some additional time fishing while the slack in the wire is spooled up. This effect was evident (though noisy) during the 2015 survey (Figure 290).

Temperature

Temperature was recorded from the dredge and averaged over fishing seconds for all tows during the 2015 survey (Figure 291). Temperature was correlated with depth (Figure 291).

Figures

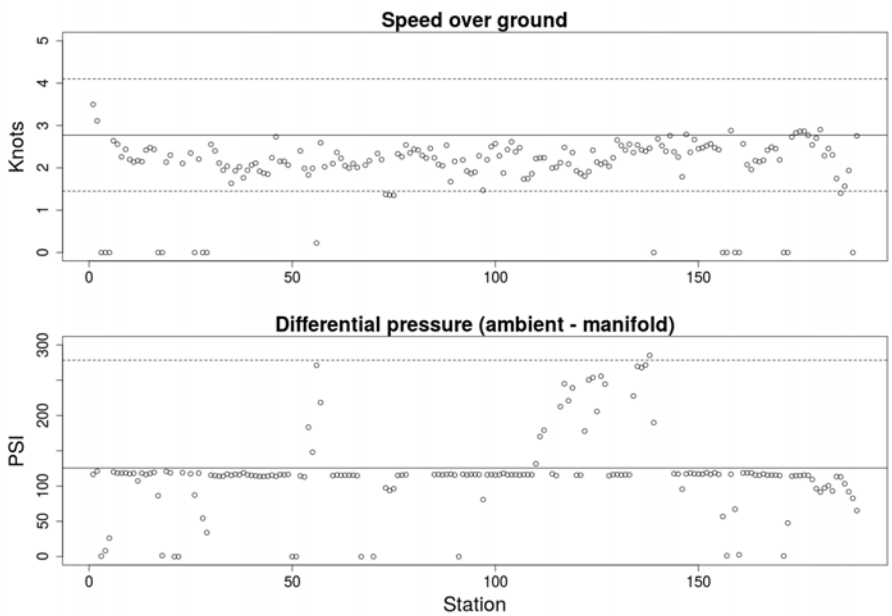

Figure 288: Speed over ground and differential pressure for each tow in the 2015 survey. The solid horizontal line is the median and the dashed horizontal lines are the 95% normal confidence bounds observed speed over ground in 2012. Procedures for Issuing Manuscripts in the *Northeast Fisheries Science Center Reference Document* (CRD) Series

Clearance

All manuscripts submitted for issuance as CRDs must have cleared the NEFSC's manuscript/abstract/webpage review process. If any author is not a federal employee, he/she will be required to sign an "NEFSC Release-of-Copyright Form." If your manuscript includes material from another work which has been copyrighted, then you will need to work with the NEFSC's Editorial Office to arrange for permission to use that material by securing release signatures on the "NEFSC Use-of-Copyrighted-Work Permission Form."

For more information, NEFSC authors should see the NEFSC's online publication policy manual, "Manuscript/abstract/webpage preparation, review, and dissemination: NEFSC author's guide to policy, process, and procedure," located in the Publications/Manuscript Review section of the NEFSC intranet page.

Organization

Manuscripts must have an abstract and table of contents, and (if applicable) lists of figures and tables. As much as possible, use traditional scientific manuscript organization for sections: "Introduction," "Study Area" and/or "Experimental Apparatus," "Methods," "Results," "Discussion," "Conclusions," "Acknowledgments," and "Literature/References Cited."

Style

The CRD series is obligated to conform with the style contained in the current edition of the United States Government Printing Office Style Manual. That style manual is silent on many aspects of scientific manuscripts. The CRD series relies more on the CSE Style Manual. Manuscripts should be prepared to conform with these style manuals.

The CRD series uses the American Fisheries Society's guides to names of fishes, mollusks, and decapod crustaceans, the Society for Marine Mammalogy's guide to names of marine mammals, the Biosciences Information Service's guide to serial title abbreviations, and the ISO's (International Standardization Organization) guide to statistical terms.

For in-text citation, use the name-date system. A special effort should be made to ensure that all necessary bibliographic information is included in the list of cited works. Personal communications must include date, full name, and full mailing address of the contact.

Preparation

Once your document has cleared the review process, the Editorial Office will contact you with publication needs – for example, revised text (if necessary) and separate digital figures and tables if they are embedded in the document. Materials may be submitted to the Editorial Office as email attachments or intranet downloads. Text files should be in Microsoft Word, tables may be in Word or Excel, and graphics files may be in a variety of formats (JPG, GIF, Excel, PowerPoint, etc.).

Production and Distribution

The Editorial Office will perform a copy-edit of the document and may request further revisions. The Editorial Office will develop the inside and outside front covers, the inside and outside back covers, and the title and bibliographic control pages of the document.

Once the Web version of the CRD is ready, the Editorial Office will contact you to review and submit corrections or changes before the document is posted online.

A number of organizations and individuals in the Northeast Region will be notified by e-mail of the availability of the document online.

MEDIA MAIL

Publications and Reports of the Northeast Fisheries Science Center

The mission of NOAA's National Marine Fisheries Service (NMFS) is "stewardship of living marine resources for the benefit of the nation through their science-based conservation and management and promotion of the health of their environment." As the research arm of the NMFS's Northeast Region, the Northeast Fisheries Science Center (NEFSC) supports the NMFS mission by "conducting ecosystem-based research and assessments of living marine resources, with a focus on the Northeast Shelf, to promote the recovery and long-term sustainability of these resources and to generate social and economic opportunities and benefits from their use." Results of NEFSC research are largely reported in primary scientific media (*e.g.*, anonymously-peer-reviewed scientific journals). However, to assist itself in providing data, information, and advice to its constituents, the NEFSC occasionally releases its results in its own media. Currently, there are three such media:

NOAA Technical Memorandum NMFS-NE -- This series is issued irregularly. The series typically includes: data reports of long-term field or lab studies of important species or habitats; synthesis reports for important species or habitats; annual reports of overall assessment or monitoring programs; manuals describing program-wide surveying or experimental techniques; literature surveys of important species or habitat topics; proceedings and collected papers of scientific meetings; and indexed and/or annotated bibliographies. All issues receive internal scientific review and most issues receive technical and copy editing.

Northeast Fisheries Science Center Reference Document -- This series is issued irregularly. The series typically includes: data reports on field and lab studies; progress reports on experiments, monitoring, and assessments; background papers for, collected abstracts of, and/or summary reports of scientific meetings; and simple bibliographies. Issues receive internal scientific review and most issues receive copy editing.

Resource Survey Report (formerly *Fishermen's Report*) -- This information report is a regularly-issued, quick-turnaround report on the distribution and relative abundance of selected living marine resources as derived from each of the NEFSC's periodic research vessel surveys of the Northeast's continental shelf. This report undergoes internal review, but receives no technical or copy editing.

TO OBTAIN A COPY of a *NOAA Technical Memorandum NMFS-NE* or a *Northeast Fisheries Science Center Reference Document*, either contact the NEFSC Editorial Office (166 Water St., Woods Hole, MA 02543-1026; 508-495-2350) or consult the NEFSC webpage on "Reports and Publications" (http://www.nefsc.noaa.gov/publications/). To access *Resource Survey Report*, consult the Ecosystem Surveys Branch webpage (http://www.nefsc.noaa.gov/femad/ecosurvey/mainpage/).

NOAA's National Marine Fisheries Service

NOAA Fisheries Toolbox

Welcome to AIM

Welcome to **An Index Method (AIM) Version 2.5**.

An Index Method (AIM) allows the user to fit a relationship between time series of relative stock abundance indices and catch data. Underlying the methodology is a linear model of population growth, which characterizes the population response to varying levels of fishing mortality. If the underlying model is valid, **AIM** can be used to estimate the level of relative fishing mortality at which the population is likely to be stable. The index methodology can used to construct reference points based on relative abundance indices and catches and to perform deterministic or stochastic projections to achieve a target stock size.

Note: Version 2.5 no longer supports Lowess Smoothing

Version 2.1 introduces an improved graphical interface. This version also allows the user to perform Sensitivity Analysis on the numbers of years used to smooth Indices of Abundance and Relative Fishing Mortality. Version 2.2 adds Envelope Analysis.

The user will begin using the program by either opening an existing input data file or by creating a new case. After editing the input data, the user may launch the AIM calculation engine module and then review the model results in tables and graphs, or view an output report file.

North Pacific Fishery Management Council

Groundfish Species Profiles

2015

Biology • Management • Catch History • Economics • Assessment• Fishery

Since 1976, the North Pacific Fishery Management Council has provided responsible stewardship of the groundfish resources under its jurisdiction, resulting in sustainable and profitable fisheries off Alaska. The foundation for this success is the scientifically based annual catch limits that are established for each target groundfish stock, species, or species complex. The NMFS Alaska Fisheries Science Center provides the necessary scientific information, ranging from basic research data on life history parameters to fishery independent surveys and rigorous stock assessments. These stock assessments are peer reviewed by the BSAI and GOA Groundfish Plan Teams and the Scientific and Statistical Committee. Using this information, the Council establishes total allowable catch levels that do not exceed biologically sustainable catch limits set by the scientists. All catch accrues towards the total allowable catch levels, and catches are closely monitored by the NMFS Alaska Regional Office during the season based on data from mandatory electronic reporting by vessels and processing plants, and a comprehensive observer program.

This publication was developed to provide the public with readily available and accessible information about the federally managed groundfish fisheries. For more information on the Council's management program, I invite you to visit the website at www.npfmc.org.

Dave Witherell

Deputy Director, NPFMC

This 2015 update was prepared by David Witherell and Jim Armstrong based on the annual Stock Assessment and Fishery Evaluation (SAFE) reports, which are assembled by the groundfish plan teams and include contributions from numerous assessment authors (see list of contributors at the end of the document). Front cover image courtesy of Julianne Curry, United Fishermen of Alaska, and back cover image courtesy of SeaAlliance and Alaska Groundfish Databank. Special thanks to those who provided editorial revisions and suggestions to improve the report: Sandra Lowe, Jim Ianelli, Grant Thompson, Steve Barbeaux, Jon Heifetz, Dana Hanselman, Chris Lunsford, Carey McGilliard, Olav Ormseth, Phil Rigby, Ingrid Spies, Paul Spencer, Cindy Tribuzio, Tom Wilderbuer, Elizabeth Conners, Martin Dorn, Teresa D'mar, Jack Turnock, and Diana Stram, as well as Mike Sigler who prepared many of the BSAI figures.

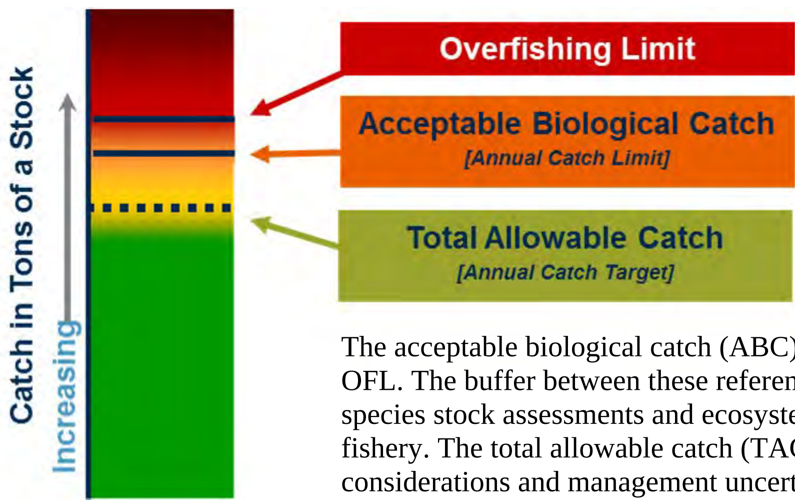
Forward

Strict annual catch limits for every target fishery have proven an effective management tool for achieving sustainable fisheries. In the North Pacific, a rigorous process in place for over 35 years ensures that annual quotas are set at conservative, sustainable levels for each of our managed groundfish stocks. Below is a brief summary of the process for setting annual catch limits for Gulf of Alaska groundfish (comprised of 141 species) Bering Sea and Aleutian Islands groundfish (comprised of 148 species).



Three reference points are used for management of groundfish fisheries in the North Pacific. The overfishing level (OFL) is the catch limit which should never be exceeded. It is based on the fishing mortality rate associated with producing the maximum sustainable yield on a continuing basis. The acceptable biological catch (ABC) is the annual catch limit, and is set lower than the OFL. The buffer between these reference points allows for scientific uncertainty in single species stock assessments and ecosystem considerations, and operational management of the fishery. The total allowable catch (TAC) is the target catch level that incorporates economic considerations and management uncertainty. The fishery management plans prescribe that TAC may equal but never exceed ABC, such that **TAC≤ABC<OFL**. The sum of TACs for all groundfish stocks must also remain within the optimum yield range defined in the FMP. In the BSAI, the upper limit is 2 million mt, which can be constraining. TAC may be set lower than ABC for a variety of reasons, such as to remain under the 2 million mt optimum yield limit; to increase a rebuilding rate or address other conservation issues; to limit incidental bycatch; or to account for state water removals. Fisheries are managed in-season to achieve the TACs without exceeding the ABC or OFL. All catch taken in directed fisheries or caught incidentally in other fisheries, whether retained or discarded, accrues towards the TAC.

Catch Limit Control Rules for North Pacific Groundfish.

Tier 1: Reliable point estimates of B and B_{MSY} and pdf of F_{MSY} .
- 1a) Stock status: $B/B_{MSY} > 1$
  - $F_{OFL} = mA$, the arithmetic mean of the pdf
  - $F_{ABC} \leq mH$, the harmonic mean of the pdf
- 1b) Stock status: $\alpha < B/B_{MSY} \leq 1$
  - $F_{OFL} = mA \times (B/B_{MSY} - \alpha)/(1 - \alpha)$
  - $F_{ABC} \leq mH \times (B/B_{MSY} - \alpha)/(1 - \alpha)$
- 1c) Stock status: $B/B_{MSY} \leq \alpha$
  - $F_{OFL} = 0$; $F_{ABC} = 0$

Tier 2: Reliable point estimates of B, B_{MSY} , F_{MSY} , $F_{35\%}$, and $F_{40\%}$.
- 2a) Stock status: $B/B_{MSY} > 1$
  - $F_{OFL} = F_{MSY}$
  - $F_{ABC} \leq F_{MSY} \times (F_{40\%}/F_{35\%})$
- 2b) Stock status: $\alpha < B/B_{MSY} \leq 1$
  - $F_{OFL} = F_{MSY} \times (B/B_{MSY} - \alpha)/(1 - \alpha)$
  - $F_{ABC} \leq F_{MSY} \times (F_{40\%}/F_{35\%}) \times (B/B_{MSY} - \alpha)/(1 - \alpha)$
- 2c) Stock status: $B/B_{MSY} \leq \alpha$
  - $F_{OFL} = 0$; $F_{ABC} = 0$

Tier 3: Reliable point estimates of B, $B_{40\%}$, $F_{35\%}$, and $F_{40\%}$.
- 3a) Stock status: $B/B_{40\%} > 1$
  - $F_{OFL} = F_{35\%}$; $F_{ABC} \leq F_{40\%}$
- 3b) Stock status: $\alpha < B/B_{40\%} \leq 1$
  - $F_{OFL} = F_{35\%} \times (B/B_{40\%} - \alpha)/(1 - \alpha)$
  - $F_{ABC} \leq F_{40\%} \times (B/B_{40\%} - \alpha)/(1 - \alpha)$
- 3c) Stock status: $B/B_{40\%} \leq \alpha$
  - $F_{OFL} = 0$; $F_{ABC} = 0$

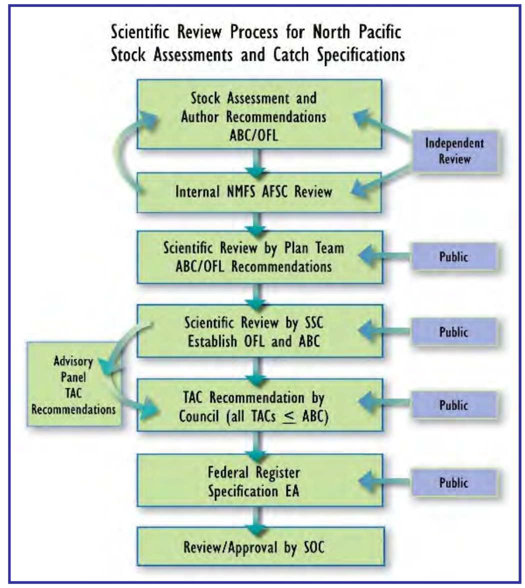
Tier 4: Reliable point estimates of B, $F_{35\%}$, and $F_{40\%}$.
- $F_{OFL} = F_{35\%}$; $F_{ABC} \leq F_{40\%}$

Tier 5: Reliable point estimates of B and natural mortality rate M.
- $F_{OFL} = M$; $F_{ABC} \leq 0.75 \times M$

Tier 6: Reliable catch history from 1978 through 1995.
- OFL = the average catch, unless an alternative value is established by the SSC.
- $ABC \leq 0.75 \times$ OFL

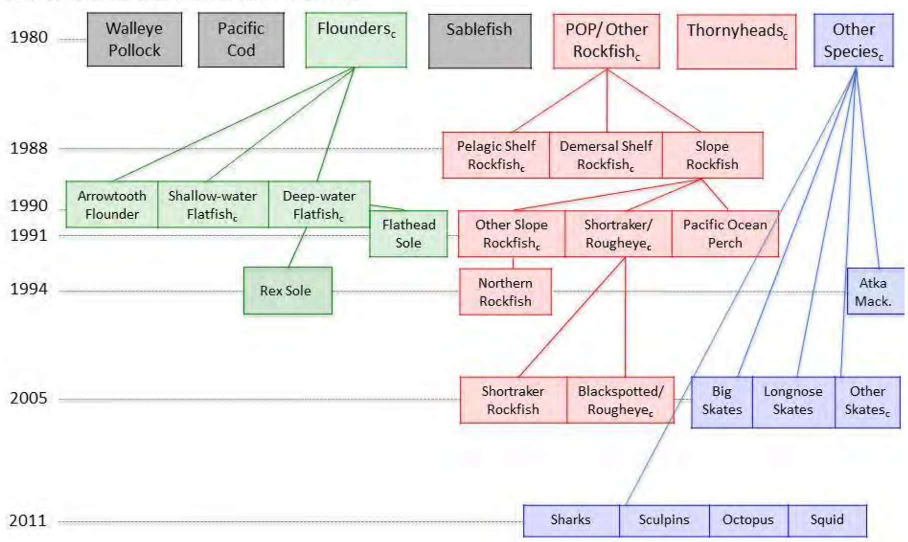
The catch limits are specified annually through an established public process. The annual process of determining OFL and ABC specifications begins with the assignment of each stock to one of six “tiers” based on the availability of information about that stock. Stocks in Tier 1 have the most information, and those in Tier 6, the least. Application of a control rule for each tier prescribes the resulting OFL and maximum ABC for each stock. For many groundfish stocks F_{ABC} is set at $F_{40\%}$. $F_{40\%}$ is the fishing mortality rate at which the spawning biomass per recruit is reduced to 40% of its value in the equivalent unfished stock. The control rules for Tiers 1-3 also provide for better chances of rebuilding, because if a stock falls below target biomass level, rates for computing ABC and OFL are reduced.

Scientists prepare an assessment of the status of each stock (or stock complex), and include alternate model simulations and tier assignments to arrive at recommendations for OFLs and ABCs. The Groundfish Plan Teams review the assessments and compile them into Stock Assessment and Fishery Evaluation (SAFE) reports, develop their own OFL and ABC recommendations (which may differ from the stock assessment author), and present this information to the Council and its Scientific and Statistical Committee (SSC) and Advisory Panel (AP). The SSC is responsible for setting the Council's OFLs and ABCs, using the SAFE reports and Plan Team recommendations. The SSC retains the flexibility to adjust ABC values downward from the control rule, based on factors such as multispecies interactions, ecosystem considerations, and additional scientific uncertainty. The Council then sets the TAC levels at or below the ABC levels, incorporating recommendations from the Advisory Panel and stakeholders. The public has an opportunity to provide input at each step in the process.

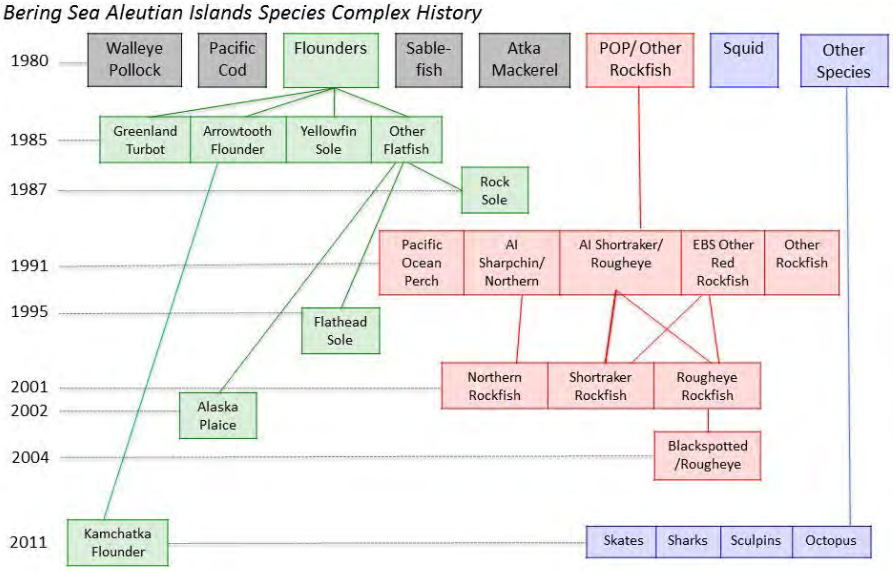


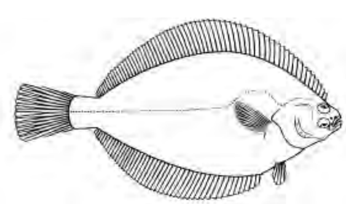
Groundfish stock groupings for establishing catch limits have evolved over time as new scientific information has become available and new markets have developed for certain species. The original fishery management plans set catch limits for the few major target species (e.g., Pollock, Cod, Sablefish), with the remaining species managed in a few complex groups (e.g., flounders, rockfish, other species). Over time, with new information and new fisheries developing, species were separated out from the complexes and assigned their own catch limits. Currently, there are nearly 50 separate single species groundfish stocks or species complexes that are assigned annual catch limits. For many of these stocks, catch limits are further subdivided into each regulatory area as a precautionary measure to prevent disproportionate exploitation rates in small areas, in case the stock consists of multiple populations.

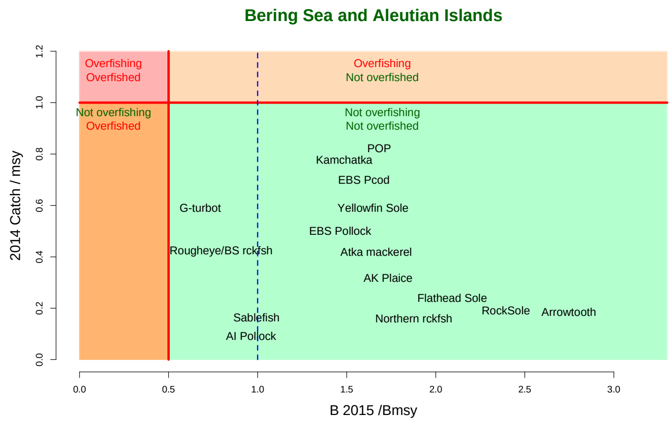
Gulf of Alaska Species Complex History

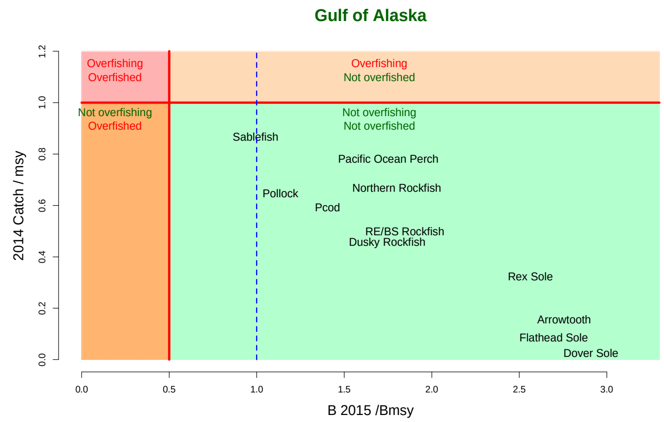


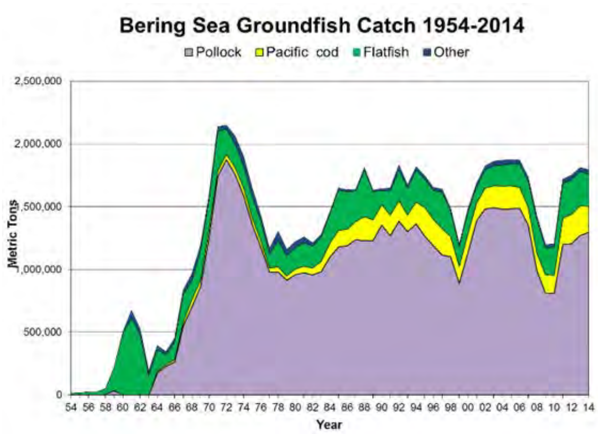
Bering Sea Aleutian Islands Species Complex History





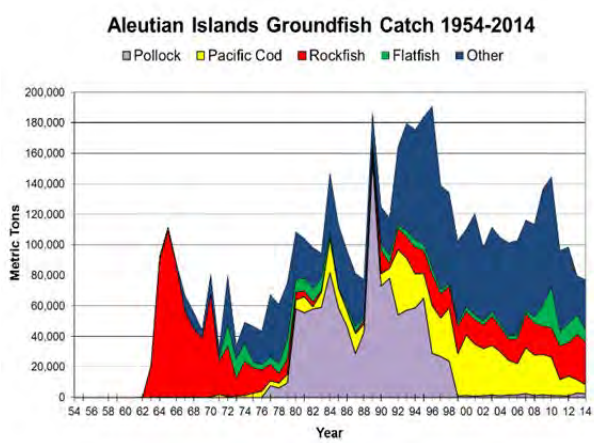


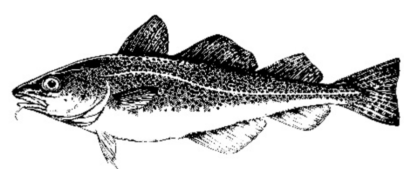


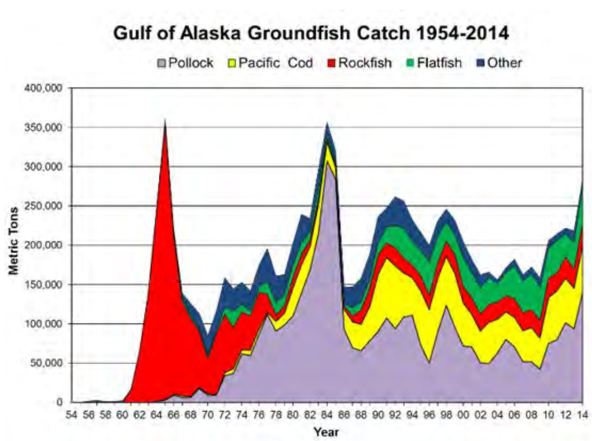


The Council's conservative catch limit policies, combined with favorable environmental conditions, have resulted in abundant fish stocks and sustainable fisheries. No groundfish stock is overfished or undergoing overfishing. Further, most stocks are well above the target biomass levels that produces maximum sustainable yield (B_{msy}).

The total catch and species composition of the catch has remained relatively stable since 1976 with the formation of the Council and development of the fishery management program. Prior to 1976, fisheries were only minimally regulated by bilateral agreements between the U.S. and foreign nations with fishing fleets off Alaska (Japan, USSR, South Korea, and Taiwan). Very high catches of Yellowfin Sole, rockfish, and Pollock were taken during this time. Catches and targets began to stabilize with the development of the U.S. fishing fleet through joint ventures in the 1980s. By the time the U.S. fishery was fully developed in 1991, the catch composition was more dependent on the TAC limits than on certain species being targeted. The variability in total groundfish catch in the Bering Sea and Gulf of Alaska is now due mainly to changes in Pollock biomass and resulting changes in annual catch limits.







Catch Specifications

At each December meeting, the Council specifies catch limits for a two year period, which when implemented (in early March) supersede the limits that were set the prior year to start the fishery (which opens January 1). For example, the adjacent specification tables adopted by the Council in December 2014 will be implemented for 2015 and 2016 fisheries, effectively replacing the catch limits that were previously recommended. The 2-year cycle allows for the use of the most recent biological information in the stock assessment while eliminating any potential delay or gap in setting the second year's limits.

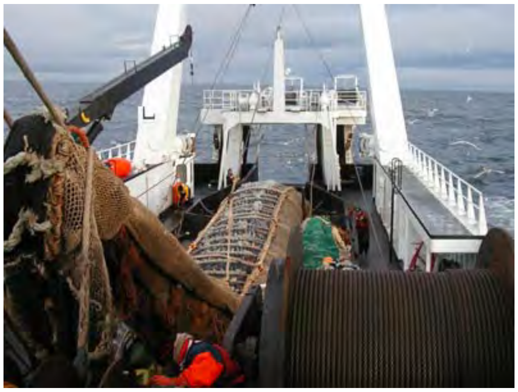
Walleye Pollock



Diana Stram, NPFMC

Biology: Walleye Pollock *Gadus chalcogrammus* is the most abundant fish species in the Bering Sea. In the Eastern Bering Sea (EBS), pollock are found throughout the water column and adults are concentrated along the outer continental shelf. Seasonal migrations occur from overwintering areas along the outer shelf to shallower waters to spawn. Pollock feed on copepods, euphausiids (krill) and fish (primarily juvenile pollock) and are prey for other fish, marine mammals and seabirds.

Pollock is a relatively fast growing and short lived species. They begin to recruit to the fishery at age 3 and longevity extends to 12 years or more. Annual natural mortality is estimated at 25% (M=0.30). Most fish reach maturity between ages 3 and 5. Females produce 60,000 to 400,000 pelagic eggs. Peak spawning occurs in the in the southeastern BS and eastern AI along the outer continental shelf in late February. Smaller spawning aggregations also occur in the northern Bering Sea in mid-late April.

Fishery Management: The U.S. manages pollock as 3 separate stocks; the Eastern Bering Sea stock (Unimak Pass to the U.S.-Russia Convention line), the Aleutian Islands stock (the Aleutian Islands shelf region from 170°W to the U.S.-Russia Convention line), and the Central Bering Sea - Bogoslof Island stock.

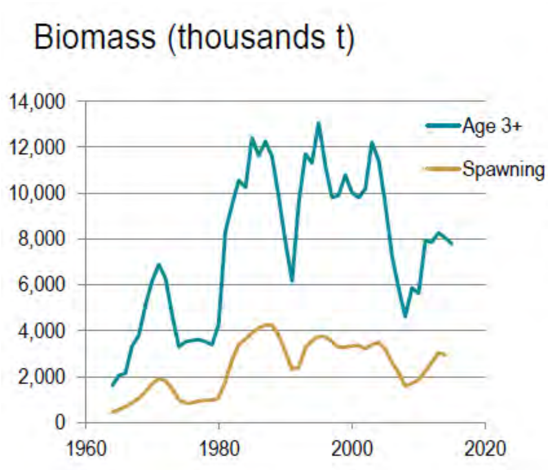
Stock assessment:

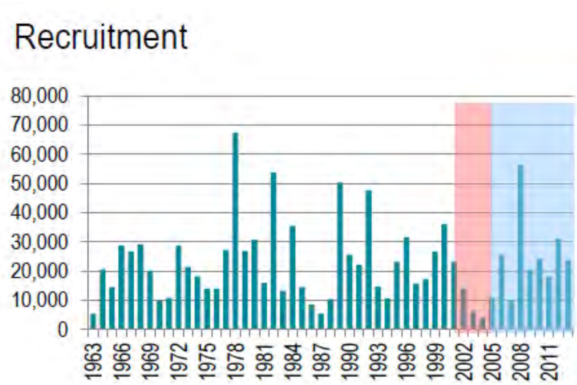
J. Ianelli, T. Honkalehto, S. Barbeaux, and S. Kotwicki. 2014. Assessment of Walleye Pollock in the Eastern Bering Sea.

www.afsc.noaa.gov/refm/stocks/assessments.htm

The American Fisheries Act (1998) established eligibility to participate in the BSAI pollock fishery and settled the contentious inshore/offshore allocation issue by establishing permanent allocations of pollock quota among sectors. CDQ groups are allocated 10% of EBS pollock TAC. The remaining TAC is divided up as follows; catcher vessels delivering inshore (50%), catcher processors offshore (40%) and catcher vessels delivering to motherships (10%). The 2004 Appropriations Act established that the non-CDQ pollock fishery in the AI is fully allocated to the Aleut Corporation, for the purpose of economic development in Adak, with a percentage allocated to vessels 60 feet or less in length overall.

The EBS pollock fishery has been redistributed spatially and seasonally to reduce the potential competition for prey with the endangered western stock of Steller sea lions, with fishery exclusion zones around sea lion rookeries. TACs have also been divided into





separate seasons since 2000; the "A-season" (Jan-Apr) and the "B-season" (Jun-Oct).

Catch History: Fisheries for Bering Sea pollock developed in 1964, and catches increased rapidly in the early 1970s and peaked in 1972 at 1.9 million mt. Early 1980s joint ventures were phased out by the domestic fleet by 1991. The international zone or "Donut Hole" also supported significant harvests of pollock through 1987, followed by a sharp decline and a fishing moratorium for the international zone beginning in 1993.

Stock Assessment: The EBS pollock assessment is based on a statistical age-structured model that incorporates fishery data and fishery independent data from annual bottom trawl surveys and biennial acoustic trawl surveys. Catch specifications for EBS pollock are established under Tier 1a of the ABC/OFL control rule. B_{msy} is equal to 1,948,000 mt. EBS catch specifications for 2015 are as follows; OFL=3,330,000, mt, ABC=1,637,000 mt, TAC=1,310,000 mt. The AI pollock ABC =29,659 mt and the Bogoslof ABC = 15,900 mt.

Biomass of EBS pollock declined steadily from 2004-2009 due to poor recruitment from the 2000-2005 year classes. The biomass is now increasing with recruitment of above average 2008 and 2010 year-classes.

Total catches, pre-season catch specifications, and exploitable biomass of age 3+ Walleye Pollock in the EBS 1980-2015.

[1]Catch data current through November 2014.
[2]TAC, ABC and OFL data from Federal Register Harvest Specifications.
[3]Biomass from annual SAFE report projections issued the previous year.

Fishery: The BSAI pollock fishery is prosecuted by relatively large vessels using pelagic trawls. A total of 77 catcher vessels delivering shoreside, 14 catcher vessels delivering to motherships, and 16 catcher processors participated in the 2014 fishery. The A-season fishery is focused in the southeast portion of the EBS and targets pre-spawning pollock. Roe, fillets and surimi are the main product forms of the A-season fishery, and approximately 40% of the TAC is caught during the A-season. The B-season fishery takes the remaining 60% of the quota and is distributed over the outer shelf edge of the Bering Sea extending to the Russian border.

Economics: Pollock fishery products include whole fish, head and gut, roe, deep-skin fillets, other fillets, surimi, minced fish, and fish meal. In 2013, production was 546,410 mt for all pollock products in Alaska, with a gross value of $1.33 billion. Surimi products comprised approximately 28% of the gross value of pollock products, roe comprised around 9%, and fillets about 42% of the gross value.

Ecosystem Components: Pollock are an important prey for fish, seabirds, and marine mammals (including Steller sea lions) in the BSAI.

Diana Evans, NPFMC

Pacific Cod

Biology: Pacific Cod *Gadus macrophalus* is a demersal species found in the EBS, the AI, and GOA south to California. Pacific Cod are distributed over the continental shelf at depths from shoreline to 500 m. Mature fish tend to concentrate on the outer continental shelf and prefer muddy or sandy soft sediment substrate. Juvenile Pacific cod feed primarily on small invertebrates and euphausiids, whereas adults feed on fish such as juvenile pollock, and invertebrates such as polychaetes, amphipods and crangonid shrimp. Predators of Pacific Cod include adult Pacific Cod, Pacific Halibut, salmon shark and Steller sea lions.

Pacific Cod are a relatively fast growing and short lived fish. Longevity can extend to 19 years. The size at 50% maturity is 58 cm (about 5 years). Females are highly fecund and can produce more than 1 million eggs. Adults form spawning aggregations from January to May in the BS. Natural mortality is estimated at M=0.34. Pacific Cod begin to recruit to the fisheries at age 3 and are 50% recruited by ages 4-5.

Catch History: Pacific Cod were taken by Japanese longline and trawl fisheries beginning in the early 1960s. Vessels from the USSR entered the fishery in 1971. Japanese and Russian fisheries harvested around 50,000 mt annually in the 1970s. Joint ventures became more prevalent in the early 1980s until they were entirely phased out by the domestic fleet a few years later. Catches have remained fairly stable since 1991, averaging just over 200,000 mt annually.

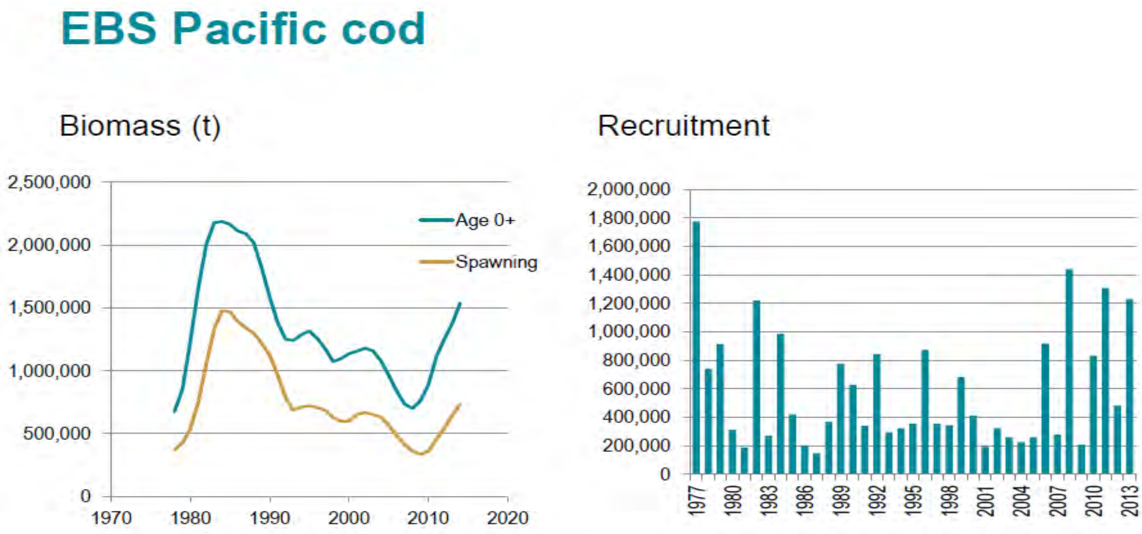
Jackie Patt, UAF

Fishery Management: Like most other groundfish, 10.7% of the TAC is allocated to CDQ fisheries. Since 2007 with implementation of Amendment 85, the remaining TAC is allocated among sectors as follows: 1.4% to jig gear; 2% to hook and line/pot catcher vessels < 60', 0.2% to hook and line/pot catcher vessels ≥ 60' LOA; 48.7% to hook and line catcher processors; 8.4% to pot catcher vessels > 60'; 1.5% to pot catcher processors; 2.3% to AFA trawl catcher processors; 13.4% to non-AFA trawl catcher processors; and 22.1% to trawl catcher vessels.

Stock assessment:

G. Thompson, 2014. Assessment of the Pacific Cod Stock in the Eastern Bering Sea.

www.afsc.noaa.gov/refm/stocks/assessments.htm



Stock Assessment: In the EBS, the Pacific Cod assessment is based on a Stock Synthesis model that uses both length-structured and age-structured data. This model incorporates fishery data and fishery-independent data from the NMFS EBS trawl surveys. Pacific Cod fall under Tier 3a of the ABC/OFL control rules. The 2015 Bering Sea Pacific Cod biomass is estimated at 1,680,000 mt. Catch specifications for Bering Sea cod in 2015 are as follows: OFL=346,000 mt (F_{OFL}=0.35), ABC=255,000 mt, TAC=240,000 mt. Catch specifications for Aleutian Islands stock of Pacific Cod in 2015 are: OFL=23,400 mt, ABC=17,600 mt, TAC=9,422 mt.

Estimated biomass of Pacific Cod has fluctuated over the last 40 years. The stock increased rapidly and peaked in the mid-1980s, then declined through 2008. Biomass has been increasing due to relatively good year classes produced in 2006, 2008, and 2011.

Total catches, pre-season catch specifications, and biomass of Pacific Cod in the BSAI, 1980-2013, and BS 2014 to present.

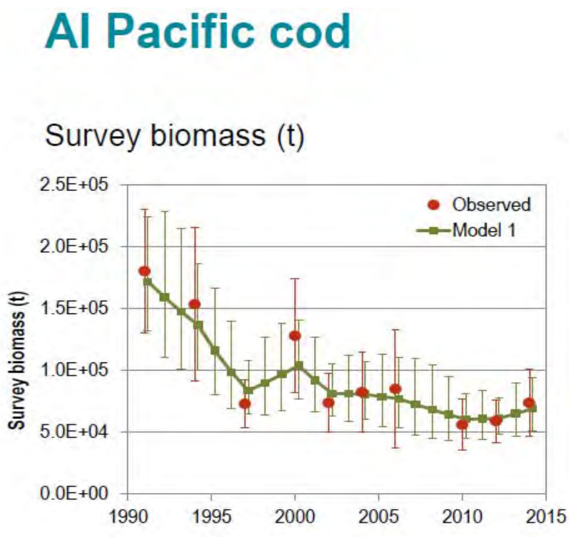
[1]Catch data current through November 2014. BS and AI specifications set separately beginning in 2014; all numbers combined in this table.
[2]TAC, ABC and OFL data from annual SAFE report.
[3]Biomass from annual SAFE report projections issued the previous year.

Fishery: Pacific Cod are taken with trawl, longline, pot and jig gear. In 2013, a total of 47 vessels using longline gear (18 catcher vessels, 29 catcher processors), 59 pot gear vessels (56 catcher vessels, 3 catcher processors), and 72 vessels using trawl gear (54 catcher vessels, 18 catcher processors) caught Pacific Cod in the BSAI.

Economics: In 2013, ex-vessel value of Pacific Cod catch in the BSAI was $130 million, and production for all Pacific Cod products in Alaska was 145,490 mt, worth $390 million. Primary products included whole fish, headed and gutted fish, and fillets. Exvessel price averaged $0.24/lb for trawl gear and $0.25/lb for fixed gear.

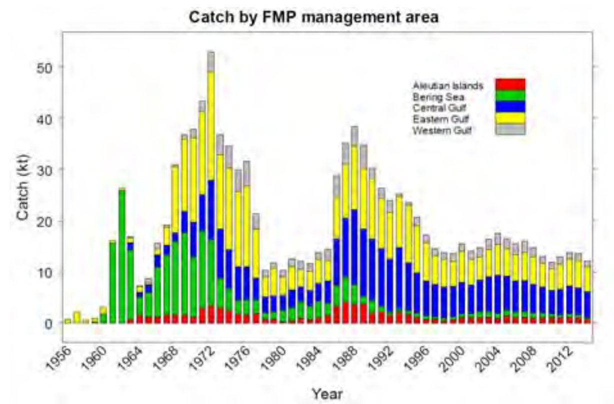
Ecosystem Components: Pacific Cod are an important prey item for SSLs, especially in winter months.



Sablefish

AFSC, NOAA Fisheries

Biology: Sablefish *Anoplopoma fimbria* distribution extends from the northern Mexico through the Gulf of Alaska, along the Aleutian Islands and into the Bering Sea. Adult Sablefish are generally found at depths greater than 200 m along the continental slope, shelf gullies and deep fjords. Juveniles (less than 40 cm) spend the first 2-3 years farther inshore along the continental shelf and begin to move out to the continental slope around age 4-5. Young-of-the-year feed primarily on euphausiids and copepods while adults are more opportunistic feeders, relying more heavily on fish such as pollock, Pacific Herring and Pacific Cod. Squid and jellyfish are important invertebrates in the adult Sablefish diet. Coho and Chinook salmon are the main predators of young-of-the-year.



Sablefish are relatively long lived. They begin to recruit to the fishery at age 4 or 5 and longevity often reaches 40 years (the oldest recorded Sablefish in Alaska was 94 years old). Female Sablefish size at 50% maturity is approximately 65 cm (age 6). Females are slightly larger than males, and fish in the BSAI generally tend to be smaller than in the GOA. Natural mortality is estimated at M=0.10. Off Alaska, Sablefish spawn near the edges of the continental slope at depths greater than 500 m between January and March.

Stock assessment:

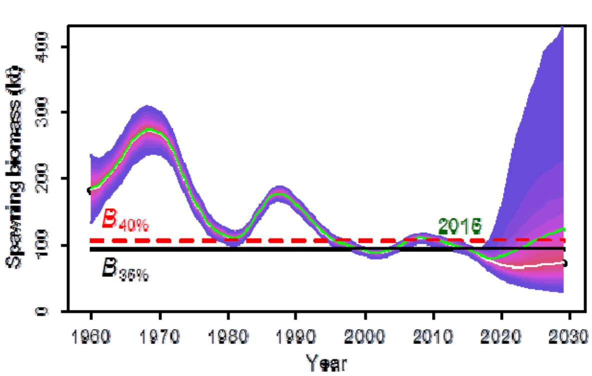
D. Hanselman, C. Lunsford, and C. Rodgveller. 2014. Assessment of the Sablefish stock in Alaska.

www.afsc.noaa.gov/refm/stocks/assessments.htm

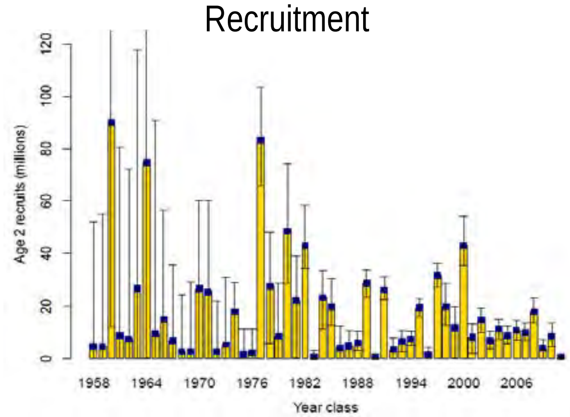
Catch History: U.S. fishermen have harvested Sablefish since the end of the 19th century as a byproduct of halibut fisheries. Harvests were relatively small, averaging 1,666 mt from 1930-1957. Japanese longlining began in the EBS around 1958 and expanded into the AI and GOA through the 1970s. Japanese fleet catches increased throughout the 1960s, and catch peaked 36,776 mt in 1972. High fishing pressure in the early 1970s may have resulted in a population decline of Sablefish in the mid-1970s. By 1988, U.S. fishermen took the majority of the Sablefish harvested in the GOA and BSAI. The fishery was a derby-style fishery in the late 1980s and early 1990s until Individual Fishing Quotas were implemented for the hook and line fishery in 1995.

Fishery Management: BSAI and GOA Sablefish are managed as one population in federal waters due to their highly migratory behavior during certain life history stages.

Biomass



Recruitment



In 1990, Amendment 13 to the BSAI FMP similarly allocated Sablefish quota by gear type; 50% to fixed gear and 50% to trawl gear in the BS; 75% to fixed gear and 25% to trawl gear in the AI. Amendment 20 to the GOA FMP and 15 to BSAI FMP established IFQ management for the Sablefish fishery and allocated 20% of the fixed gear quota to a CDQ reserve for the BSAI, effective 1990.

Stock Assessment: The Sablefish assessment is based on a statistical sex-specific age-structured model. This model incorporates fishery data and fishery independent data from domestic and Japan-U.S. cooperative longline surveys and the NMFS GOA trawl survey. Sablefish fall under Tier 3b of the ABC/OFL control rules. Specifications are apportioned among management areas based on a 5-year exponential weighting of the survey and fishery abundance indices. Catch specifications for 2015 Bering Sea Sablefish are as follows; OFL=1,575 mt, ABC=1,333 mt, TAC=1,333 mt. For the Aleutian Islands, OFL=2,128 mt, ABC=1,802 mt, TAC=1,802 mt.

Total catches, pre-season catch specifications, and exploitable biomass of Sablefish age 4+ in the BS and AI, 1980-2015.

2015	-	3,135	3,135	3,703	58,000

[1]Catch data current through November 2014.
[2]TAC, ABC and OFL from annual Federal Register.
[3]Biomass from annual SAFE report projections.

Biomass of Sablefish has fluctuated over time. There were two high points in biomass in the early 1970s and mid-1980s and two decreases in the late 1970s and the mid-1990s. Relative abundance is near an all-time but may increase with recruitment of an average 2008 year class.

Fishery: Sablefish are taken with trawl, longline and pot gear. Most Sablefish are taken with longline gear in the Aleutian Islands and pot gear in the Bering Sea. The Sablefish season is open 7 months beginning in April, concurrent with the halibut fishing season. Primary species taken incidentally in the Sablefish fishery include Shortaker, Rougheye and Thornyhead Rockfish.

Sperm whale and killer whale depredation occurs when whales remove Sablefish from longline gear, damage the fish and/or fishing gear. Killer whale depredation predominates in the BSAI and sperm whale depredation is more common the GOA. Depredation can lead to significant economic losses in the form of reduced catch, extended travel distances, and damaged gear. Depredation may also reduce the accuracy of Sablefish stock assessment models. Additionally, depredating whales may be at greater risk of mortality or injury through vessel strikes or entanglement in gear.

Economics: In 2013, the ex-vessel value of Sablefish catch from the BSAI was $9.7 million. Exvessel prices for BSAI Sablefish in 2013 averaged $2.84/lb for fish caught on longline gear and $1.17/lb for fish taken with trawl gear. For both gear types, the primary product is frozen, head and gutted fish.

Diana Evans, NPFMC

Yellowfin Sole

Biology: Yellowfin Sole *Limanda aspera* are distributed from the Sea of Japan to British Columbia, with the highest abundance in the Bering Sea. Yellowfin Sole are the target of the largest flatfish fishery in the U.S. and are one of the most abundant flatfish species in the EBS. Adult Yellowfin Sole occupy the benthos and have separate winter spawning and summertime feeding grounds on the EBS shelf. Adults over-winter near the shelf margins and then migrate to inner shelf areas in April/May each year for spawning and feeding. Yellowfin Sole predate on bivalves, polychaetes, amphipods, mollusks and fish. They are prey for Pacific Cod, Pacific Halibut and skates.

Yellowfin Sole are relatively slow-growing and long-lived. They begin to recruit to the fishery at age 6, are fully selected by age 13 and longevity extends to 30+ years. Females reach 50% maturity at 30 cm (10.5 years old) and are highly fecund, producing 1.3-3.3 million eggs depending on size. Annual natural mortality of adults is estimated at 0.12. Spawning occurs in June/July in shallow waters from Bristol Bay to Nunivak Island.

Diana Evans, NPFMC

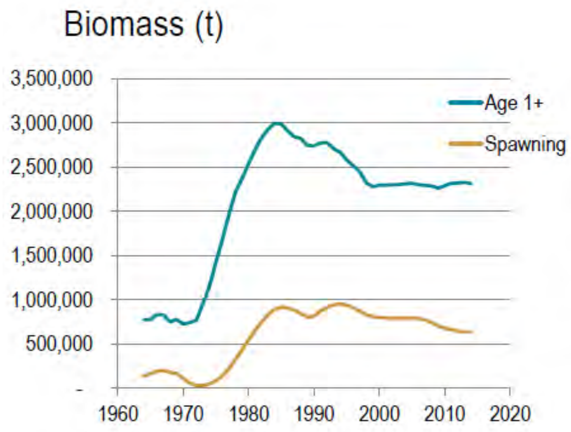
Fishery Management: BSAI Flatfish are regulated under the BSAI groundfish FMP through permits, limited entry, catch quotas (TACs), seasons, in-season adjustments, gear restrictions, closed waters, bycatch limits and rates (for halibut and crab), allocations, regulatory areas, record keeping, reporting requirements and observer monitoring.

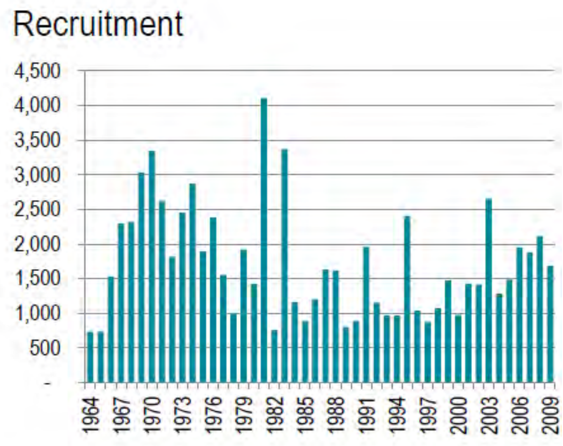
In 1985, the Flounder (Flatfish) category was broken into four management groups (Greenland Turbot, Arrowtooth Flounder, Yellowfin Sole, Other Flatfish) due to significant differences in stock robustness and product values. Northern Rock Sole was separated from the Other Flatfish complex in 1987. Flathead Sole was separated from the Other Flatfish complex in 1995, and Alaska Plaice was separated in 2002.

Stock assessment:

T. Wilderbuer, D. Nichol, and J. Ianelli. 2014. Assessment of Yellowfin Sole in the Bering Sea and Aleutian Islands.

www.afsc.noaa.gov/refm/stocks/assessments.htm





In 2008, BSAI FMP Amendment 80 established catch shares for the bottom trawl catcher-processor fleet. Flatfish resources were allocated among BSAI trawl harvesters according to their historic harvest patterns, monitoring requirements were increased, and fishermen were given the ability to form cooperatives. Up to 93% of the Yellowfin Sole TAC is allocated to the Amendment 80 fleet, depending on the TAC. Like other groundfish stocks except pollock, 10.7% of TAC is first allocated to CDQ groups.

Catch History: Yellowfin Sole have been harvested annually since the inception of the BS bottom trawl fishery in 1954. Overharvesting by foreign vessels occurred from 1959-1962, and catches averaged 404,000 mt annually during that period. Catches declined during the late 1960s and early 1970s as a result of reduced abundance. Domestic and joint venture fisheries for Yellowfin Sole emerged in the 1980s, and only domestic harvesting has occurred since 1990, and catches have increased in more recent years.

Total catches, pre-season catch specifications, and exploitable biomass of Yellowfin Sole in the BSAI, 1980-2015.

[1]Catch data current through November 2014.
[2]1988-2010 TAC, ABC and OFL data from annual Federal Register Harvest Specs. Pre-1988 TAC and ABC data from annual SAFE reports.
[3]Biomass from annual SAFE report projections.

Stock Assessment: The Yellowfin Sole assessment is a separable catch-age, sex-specific analysis. This model incorporates fishery data and fishery independent data from annual trawl surveys. Yellowfin Sole fall under Tier 1a of the ABC/OFL control rules. The 2015 projected age 6+ biomass is 2,127,800 mt. Catch specifications for 2015 are as follows; OFL=266,400 mt, ABC= 248,800 mt, TAC= 149,000 mt.

Yellowfin Sole biomass peaked in the early-1990s. The population has been in a slow decline as the strongest year classes have passed through the fishery, however, the population remains at fairly high/stable levels.

Fishery: Yellowfin Sole are primarily caught with trawl gear. Seven catcher vessel and 27 catcher processors participated in 2013 BSAI Yellowfin Sole fishery. Fishing effort is focused on the mid and inner BS shelf during ice-free conditions. A small area in Bristol Bay is open to bottom trawling from April 1 – June 15 to allow the fishery to target this species when they are aggregated and can be taken with low incidental catches of other species. Yellowfin Sole are usually headed and gutted or frozen whole for further processing. In 2013, the retention rate of Yellowfin Sole caught by the Amendment 80 sector was 97 percent.

Economics: In 2013, production was 169,150 mt for all flatfish products for a total gross value of $234 million. Ex-vessel value of all flatfish caught in the BSAI in 2013 was $96 million.

Arrowtooth Flounder

Arrowtooth Flounder
AFSC, NOAA Fisheries

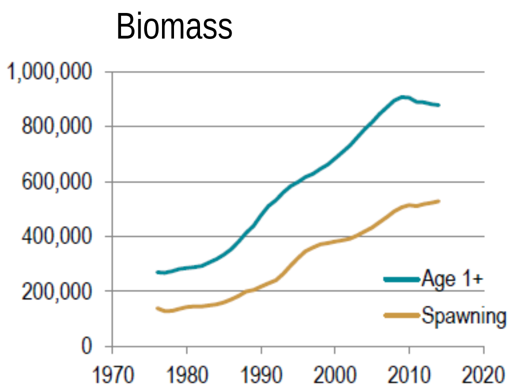
Biology: Arrowtooth Flounder *Atheresthes stomias* are distributed from the Kamchatka Peninsula to the BSAI south to central California. Adults migrate seasonally from shelf margins in the winter to the outer shelf in April/May with the onset of warmer waters temperatures. In the BSAI, Arrowtooth Flounder prey on juvenile pollock (47%), adult pollock (19%) and euphausiids (9%).

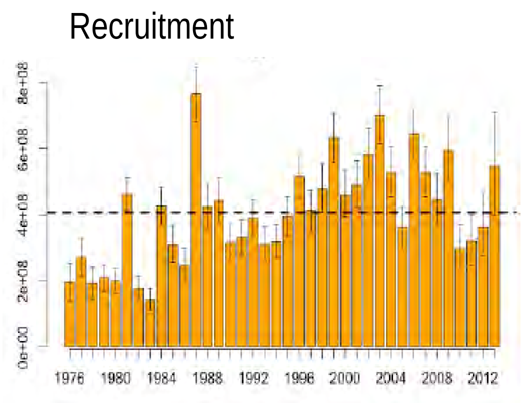
Arrowtooth Flounder length at 50% maturity is 28 cm for males (4 years) and 37 cm for females (5 years). Natural mortality is estimated at M=0.2 for females and M=0.35 for males. Adult males range in size from 30-50 cm, and females range in size from 30-70 cm. The spawning period for Arrowtooth Flounder is protracted and variable, ranging from September through March.

Stock assessment:

I. Spies, T. Wilderbuer, D. Nichol, and K. Aydin. 2014. Assessment of the Arrowtooth Flounder stock in the Bering Sea and Aleutian Islands.

www.afsc.noaa.gov/refm/stocks/assessments.htm





Catch History: USSR and Japan targeted Greenland Turbot and Arrowtooth Flounder during the 1960s. Catches peaked from 1974-1976 at 19,000-25,000 mt. Arrowtooth Flounder and Greenland Turbot were managed as a complex until 1985 due to their similar life history characteristics and distribution. Catches decreased following implementation of the Magnuson-Stevens Act in 1977.

Total catches, pre-season catch specifications, and exploitable biomass of Arrowtooth Flounder in the BSAI, 2000-2015.

Year	Catch[1]	TAC[2]	ABC	OFL	Biomass[3]

2014	18,119	25,000	106,599	125,642	1,023,440
2015	-	22,000	80,547	93,856	908,379

[1]Catch data current through November 2014.
[2]TAC, ABC and OFL data from Harvest Specifications. Kamchatka Flounder separated out in 2011; data not included thereafter.
[3]Biomass from annual SAFE report projections.

Stock Assessment: Arrowtooth Flounder and Kamchatka Flounder were assessed and managed together as a complex through 2010, when Kamchatka Flounder were split out as a separate target fishery. The assessment model is a length-based approach using survey and fishery lengths to estimate population numbers at age. Arrowtooth Flounder fall under Tier 3a of the ABC/OFL control rules.

Fishery: Arrowtooth Flounder has developed into a target fishery and retention rates have increased in response to developing markets and implementation of the Amendment 80 catch share cooperatives in 2008. From 2005-2007, at least 50% of Arrowtooth Flounder caught was discarded. In 2013, the retention rate of Arrowtooth Flounder caught by trawl gear was 85%.

Biology: Kamchatka Flounder *Atheresthes evermanni* are distributed from northern Japan to the Aleutian Islands and along the eastern Bering Sea slope. This species generally occurs in waters deeper than 200m, and the larger fish (> 50 cm) are most common at depths of 500m to 800 m.

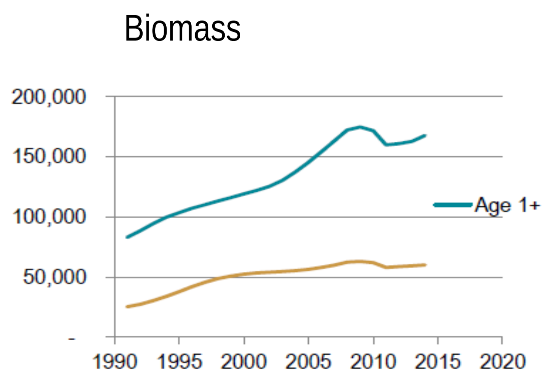
Kamchatka Flounder recruitment to the fishery begins at about 30 cm, and are fully recruited at about 45 cm. The age at 50% maturity is 10 years for females. Natural mortality is estimated at M=0.11. Kamchatka Flounder live to a maximum age of 35 years, and can grow to a maximum size of about 90 cm.

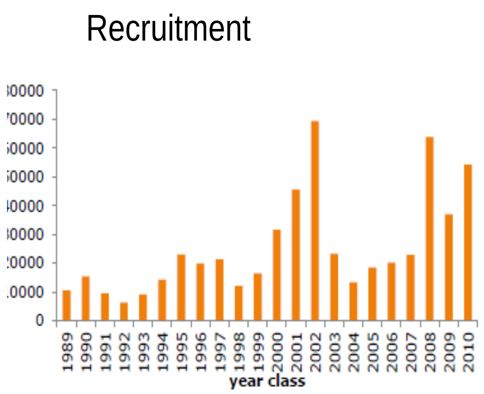
Catch History: From 1986 until 2011, Kamchatka Flounder and Arrowtooth Flounder were managed together under the Arrowtooth Flounder complex. However, a directed fishery for Kamchatka Flounder began to emerge, and catches were increasing. Because the ABC was based on the large amount of Arrowtooth Flounder relative to Kamchatka Flounder

Stock assessment:

T. Wilderbuer, J. Ianelli, D. Nichol, and R. Lauth. 2014. Assessment of Kamchatka Flounder in the Bering Sea and Aleutian Islands.

www.afsc.noaa.gov/refm/stocks/assessments.htm





(complex is about 93% Arrowtooth Flounder) the possibility arose of an overharvest of Kamchatka Flounder. So beginning in 2011, separate catch specifications were established.

Stock Assessment: The Kamchatka Flounder assessment uses a sex-specific length and age based approach. Kamchatka Flounder fall under Tier 3a of the ABC/OFL control rules. The 2015 projected biomass is 174,500 mt. Catch specifications for 2015 are as follows: OFL=10,500 mt, ABC= 9,000 mt, TAC= 6,500 mt.

Total catches, pre-season catch specifications, and exploitable biomass of Kamchatka Flounder in the BSAI, 2011-2015.

Year	Catch[1]	TAC[2]	ABC	OFL	Biomass[3]
2011	9,935	17,700	17,700	23,600	129,000
2012	9,514	17,700	18,600	24,800	125,000
2013	7,772	10,000	12,200	16,000	125,000
2014	6,395	7,100	7,100	8,270	136,600
2015	-	6,500	9,000	10,500	174,500

[1]Catch data current through November 2014.

[3]Biomass from annual SAFE report projections.

Fishery: The Kamchatka Flounder fishery developed in response to developing markets and implementation of the Amendment 80 catch share cooperatives. Retention rate of Kamchatka Flounder caught by trawl gear was 92% in 2013.

Ecosystem Components: Kamchatka Flounder prey on pollock, shrimp, and euphausiids.

Diana Evans, NPFMC

Rock Sole

Stock assessment:

T. Wilderbuer and D. Nichol. 2014. Assessment of Northern Rock Sole in the Bering Sea and Aleutian Islands.

www.afsc.noaa.gov/refm/stocks/assessments.htm

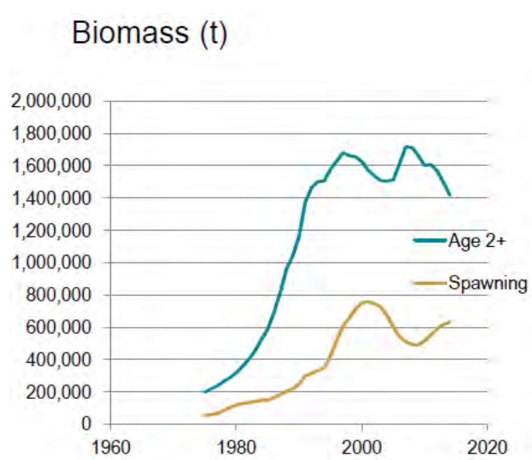
Biology: Two species of rock sole, Northern Rock Sole *Lepidopsetta polyxstra* and Southern Rock Sole *L. bilineatus*, occur in the North Pacific Ocean and are managed together as one complex in the BSAI, but separately in the GOA. Northern Rock Sole are the most commonly found species of rock sole in the BSAI. Adults are bottom dwellers and occupy separate winter and summer feeding ground along the continental shelf. As early juveniles, rock sole consume plankton and zooplankton, switching to bivalves, polychaetes, amphipods, mullosks and crustaceans as they age and become late juveniles and adults. Small rock sole are prey for Pacific Cod, Walleye Pollock, Yellowfin Sole, skates and Pacific Halibut.

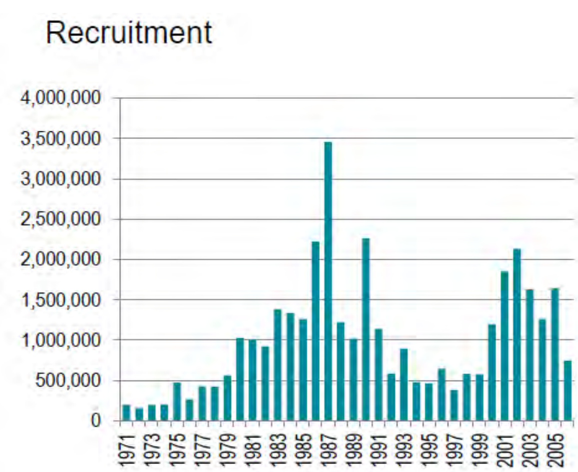
Recruitment to the fishery begins at age 4 and they are fully selected by age 11. Estimated length at 50% maturity is 31 cm (9 years). Natural mortality is estimated at M=0.15. Rock sole spawn from December to March in two separate concentrations in the BS along the continental shelf/slope break.

Catch History: Rock sole were harvested by Japanese and Soviet vessels beginning in 1963. Catches averaged 7,000 mt annually from 1963-1969 and increased during the early 1970s. Peak catch occurred in 1972 (61,000 mt). Catches declined until joint venture operations began in 1980. Catches again increased during the 1980s and peaked in 1988 (86,000 mt). The fishery was fully domesticated by 1990, and catches have remained fairly stable since 1990 (average 46,000 mt annually).

Fishery Management: Rock sole is regulated under the BSAI groundfish FMP through permits, limited entry, catch quotas (TACs), seasons, in-season adjustments, gear restrictions, closed waters, bycatch limits and rates, allocations, regulatory areas, record keeping, reporting requirements and observer monitoring. In 2008, BSAI FMP Amendment 80 modified rock sole fishery management, such that 100% of the directed fishery rock sole TAC is allocated among non-AFA trawl catcher processors according to their historic harvest patterns, groundfish retention standards were extended to catcher/processor fleet and fishermen were given the ability to form cooperatives. Like other groundfish, 10.7% of rock sole TAC is allocated to CDQ groups.

Stock Assessment: The rock sole assessment uses a separable catch-age analysis that estimates abundance, mortality and recruitment. This model incorporates fishery data and





fishery independent data from EBS and AI trawl surveys. Rock sole fall under Tier 1a of the ABC/OFL control rules. The 2015 projected age 6+ biomass is 1,233,400 mt and B_{msy}=260,000.

Strong recruitment and low fishing effort enabled rock sole biomass to increase significantly from 1985-1995. Estimated biomass peaked in the late 1990s and then declined by about 20% through 2005. The decline during the early 2000s was attributed to below average recruitment to the adult population during the 1990s. Estimated biomass began increasing again in 2005 as a result of a series of above average year-classes.

Fishery: Rock sole are caught by trawl catcher-processors targeting roe-bearing females. The primary product for the rock sole fishery is the high value roe. The fishery occurs from January-March and is focused in outer Bristol Bay and north of Unimak Island. A total of 7 catcher vessels and 27 catcher processors participated in the 2013 flatfish fisheries in the BSAI. From 1987-2000, over 50% of rock sole catch was discarded. Retention rate for rock sole by trawl gear increased to 87% by 2009, and to 95% in 2013.

Ecosystem Components: Northern Rock Sole recruitment has been linked to decadal scale climate variability, especially ocean forcing by onshelf/offshelf winds in the BS. After spawning in March, Northern Rock Sole larvae are subject to advection from wind, current and tidal forcing during the spring. Using an ocean surface current model, Northern Rock Sole larvae advection towards favorable nursery areas and resultant above-average recruitment occurred during years with onshelf (easterly) winds during the 1980s and again in 2001-2003. Conversely, periods of off-shelf (westerly) winds during the 1990s corresponded with average or poor recruitment.

Diana Evans, NPFMC

NOAA Fisheries

Greenland Turbot

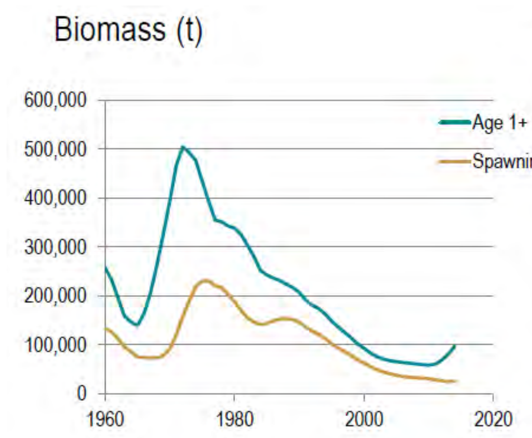
Biology: Greenland Turbot *Reinhardtius hippoglossoides* has a circumpolar distribution, occurring in both the North Pacific and North Atlantic Oceans. Juveniles inhabit shallow continental shelf waters (<200 m) for the first 3-4 years and move out to the deeper waters of the continental slope (200-1,000 m). Greenland Turbot predate on euphausiids, polychaetes and small fish (e.g. pollock) as they mature. In the North Pacific, juveniles are prey for Pacific Cod and Pacific Halibut.

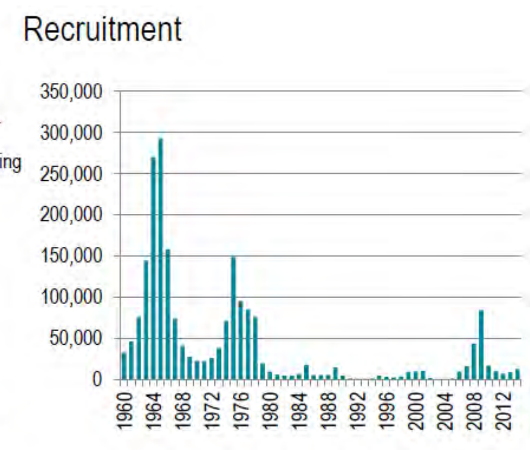
Greenland Turbot size at 50% maturity is around 60 cm (age 5-10). Greenland Turbot begin to recruit to longline fisheries at about 60 cm and are fully recruited at 90 cm. Natural mortality is estimated at M=0.112. Peak spawning period is from November – February in the EBS. Female fecundity is fairly low; females less than 83 cm release 25,000-150,000 eggs.

Stock assessment:

S. Barbeaux, J. Ianelli,, D. Nichol, and T. Hoff. 2014. Assessment of Greenland Turbot in the Eastern Bering Sea and Aleutian Islands Area.

www.afsc.noaa.gov/refm/stocks/assessments





Catch History: Catches averaged 30,000 mt annually during that during the 1960s when the USSR and Japan first targeted the Greenland Turbot fishery. Catches peaked in the mid-1970s, and declined after 1986 due to poor recruitment.

Total catches, pre-season catch specifications, and exploitable biomass of Greenland Turbot in the BS and AI, 2000-2015.

[1]Catch data current through November 2014.
[2]TAC, ABC and OFL from Federal Register Harvest Specifications.
[3]Biomass from annual SAFE report projections.

Stock Assessment: The Greenland Turbot assessment is based on a stock synthesis model that incorporates fishery data and fishery independent data from EBS slope and shelf bottom-trawl surveys and the NMFS longline survey. Greenland Turbot fall under Tier 3b of the ABC/OFL control rules. Catch limits are further apportioned into BS and AI components. Biomass had declined since the early 1970s, but strong year classes produced in 2007-2009 are contributing to a steep increase in abundance.

Fishery: The Greenland Turbot fishery is prosecuted by both trawls and longline gear. Predominantly a longline fishery from 1993-2007, the trawl fishery began harvesting a larger share of the TAC beginning in 2008. Fishing effort is concentrated on the continental slope throughout the EBS and on both sides of the AI.

Current Issues: Killer whale depredation is problematic for Greenland Turbot longline fisheries in the EBS.

Diana Evans, NPFMC

Alaska Plaice

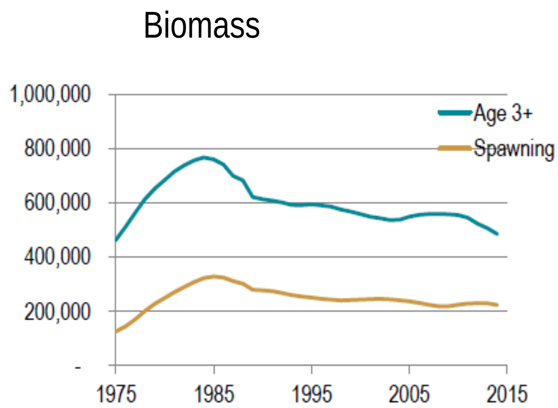
Biology: Alaska Plaice *Pleuronectes quadrituberculatus* distribution extends through the Sea of Japan, Chukchi Sea, BSAI and GOA. Alaska Plaice are generally found along the EBS continental shelf, with relatively few found in the AI region. Summer distribution of adults is generally confined to depths less than 110 m, with larger fish in deeper waters and smaller juveniles in shallower coastal waters. Alaska Plaice predate on polychaetes and amphipods and are prey for Pacific Cod, Pacific Halibut and Yellowfin Sole.

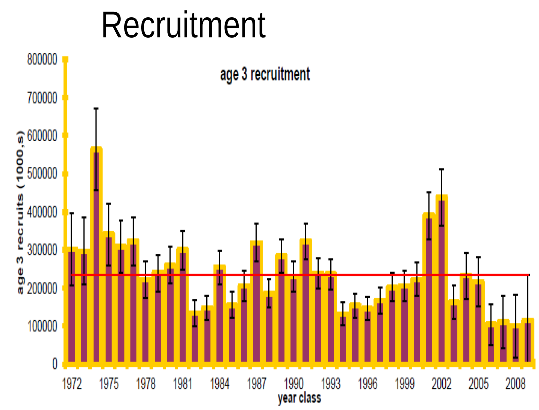
Alaska Plaice recruit to trawl fisheries at age 4, are full recruited by age 13. Females mature between ages 7 and 12. Natural mortality is estimated at M=0.13. Spawning usually occurs in March and April on hard sandy substrate in the EBS.

Stock assessment:

T. Wilderbuer, D. Nichol, and P. Spencer. 2014. Assessment of Alaska Plaice in the Bering Sea and Aleutian Islands.

www.afsc.noaa.gov/refm/stocks/assessments.htm





Catch History: Alaska Plaice were harvested by Japanese and Soviet vessels beginning in 1963. Catches increased from 1,000 mt in 1971 to a peak of 62,000 mt to in 1988. Joint ventures began in 1988, and the fishery was fully harvested by domestic vessels in 1991. Alaska Plaice are taken in a directed target fishery as well as a secondary catch in the Yellowfin Sole fishery.

Total catches, pre-season catch specifications, and exploitable biomass of Alaska Plaice* in the BSAI, 2002-2015.

2013	23,523	20,000	55,200	67,000	589,000
2014	19,000	24,500	55,100	66,800	576,300
2015	-	18,500	44,900	54,000	471,500

*Alaska Plaice removed from Other flatfish complex 2002.
[1]Catch data current through November 2014.
[2]TAC, ABC and OFL data from Federal Register.
[3]Biomass from annual SAFE report projections.

Stock Assessment: The assessment uses a sex-specific, age-structured model. This model incorporates fishery data and fishery independent data from trawl surveys. Alaska Plaice fall under Tier 3a of the ABC/OFL control rules. The 2015 projected biomass is 471,500 mt. Catch specifications for 2015 are as follows; OFL= 54,000 mt, ABC= 44,900 mt, TAC= 18,500 mt.

Fishery: Alaska Plaice are caught primarily by trawl catcher processors targeting higher-value flatfish species such as Yellowfin Sole. With the implementation of Amendment 80 in 2008, retention rates of Alaska Plaice increased from about 5% (2003-2005 average) to an average of 70% in the last few years.

AFSC, NOAA Fisheries

Flathead Sole and Bering Flounder

Stock assessment:

C. McGillard, D. Nichol, W. Palsson, and W. Stockhausen. 2014. Assessment of the Flathead Sole-Bering Flounder stock in the Bering Sea and Aleutian Islands.

www.afsc.noaa.gov/refm/stocks/assessments.htm

Biology: Flathead Sole is managed as a two-species complex including Flathead Sole *Hippoglossoides elassodon* and Bering Flounder *Hipogloissoides robustus.* Individuals of both species are morphologically similar; Flathead Sole are faster growing and achieve larger size. Flathead Sole are distributed in the Kuril Islands, BS, GOA and down to northern California. In the northern part of the Bering Sea, Flathead Sole distribution overlaps with Bering Flounder. Bering Flounder distribution extends from the Chukchi Sea into the northern BS. Bering Flounder generally represents less than 3% of the estimated survey biomass of the two species. Adult Flathead Sole overwinter near the shelf margins before migrating to the mid and outer continental shelf in April or May each year for feeding. Flathead Sole predate on pollock, polychaetes, brittle stars and crustaceans. They are prey for adult pollock and Pacific Cod.

Flathead Sole recruitment to the fishery begins at age 4, and longevity extends to 32 years. Estimated length at 50% maturity is 32 cm. Natural mortality is estimated at M=0.20. Flathead Sole spawn in March and April, primarily in deeper waters near the margins of the continental shelf. Females release from 70,000-600,000 eggs depending on size.

Catch History: Flathead Sole were harvested by Japanese and Soviet vessels beginning in 1963. Flathead Sole catches peaked in 1971 (51,000 mt). Catches declined to 15,000 mt in 1975 and remained under 10,000 mt until 1990. Catch levels have increased since the 1980s due to higher incidental catch rates and emerging markets for Flathead Sole, averaging 18,377 mt from 1995-2009.

Total catches, pre-season catch specifications, and exploitable biomass of Flathead Sole* in the BSAI, 1995-2015.

Year	Catch[1]	TAC[2]	ABC	OFL	Biomass[3]

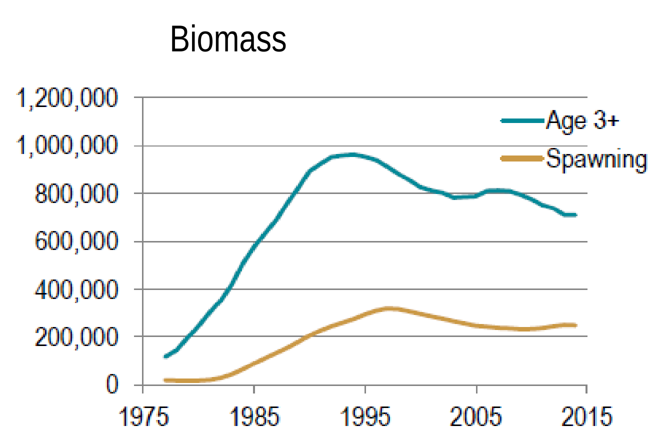
*Flathead Sole removed from Other Flatfish category 1995. Flathead Sole category includes Bering Flounder and Flathead Sole.
[1]Catch data from BSAI SAFE, through November 2014.
[2]TAC, ABC and OFL from annual Specifications.
[3]Biomass corresponds to the annual SAFE report projections.

Stock Assessment: The assessment uses a split-sex, age-based model with length-based formulations for fishery and survey selectivities. This model incorporates fishery data and fishery independent data from trawl surveys. Flathead Sole fall under Tier 3a of the ABC/OFL control rules.

Fishery: 100% of the directed fishery Flathead Sole TAC is allocated among non-AFA trawl catcher processors according to their historic harvest patterns. The fishery mainly occurs from January-June. Primary products are H&G with roe-in and kirimi.



Dover Sole
AFSC, NOAA Fisheries

Other Flatfish

Stock assessment:

T. Wilderbuer, and D. Nichol. 2014. Assessment of Other Flatfish in the Bering Sea and Aleutian Islands.

www.afsc.noaa.gov/refm/stocks/assessments.htm

Biology: The Other Flatfish complex consists of 15 species. Starry Flounder, Rex Sole, Longhead Dab, Dover Sole, and Butter Sole comprise the majority of harvested "Other Flatfish."

Data are limited for many of the species in this complex. Rex Sole and Dover Sole are distributed from Baja California, through the BSAI and widely throughout the GOA. Adult Rex Sole and Dover Sole are bottom dwellers and are generally found in water deeper than 300 m. Available natural mortalities are as follows; Rex Sole M=0.17, Dover Sole M=0.085, remaining Other Flatfish M=0.15.

Common Name	Scientific Name
Arctic Flounder	*Liopsetta glacialis*
Butter Sole	*Isopsetta isolepis*
Curlfin Sole	*Pleuronectes decurrens*
Deepsea Sole	*Embassichths bathybius*
Dover Sole	*Microstomus pacificus*
English Sole	*Parophrys vetulus*
Longhead Dab	*Limanda proboscidea*
Pacific Sanddab	*Citharichthys sordidus*
Petrale Sole	*Eopsetta jordani*
Rex Sole	*Glyptocephalus zachirus*
Roughscale Sole	*Clidodoerma asperrimum*
Sand Sole	*Psettichthys melanostictus*
Slender Sole	*Lyopsetta exilis*
Starry Flounder	*Platichthys stellatus*
Sakhalin Sole	*Limanda sakhalinensis*

Catch History: Other Flatfish have been incidentally captured in target flatfish fisheries since Japanese and Soviet fleets began fishing in the Bering Sea in 1963. Prior to its removal from the "Other Flatfish" complex in 2002, Alaska Plaice comprised the majority of harvested "Other Flatfish." Catch of Alaska Plaice and "Other Flatfish" peaked in 1988 at 137,418 mt. Since the removal of Alaska Plaice from the complex, annual catches have averaged about 3,500 mt from 2003-2010.

Stock Assessment: The Other Flatfish assessment is based on survey biomass estimates. Other Flatfish are managed under Tier 5 of the ABC/OFL control rules.

Fishery: Other Flatfish are caught primarily by trawl catcher processors targeting higher value flatfish species. Nevertheless, 47% of the other flatfish caught by trawl gear were retained in 2013.

Total catches, pre-season catch specifications, and exploitable of Other Flatfish* in the BSAI, 2002-2015.

Year	Catch[1]	TAC[2]	ABC	OFL	Biomass[3]

Pacific Ocean Perch

Stock assessment:

P. Spencer and J. Ianelli. 2014. Assessment of the Pacific ocean perch stock in the Bering Sea and Aleutian Island.

www.afsc.noaa.gov/refm/stocks/assessments.htm

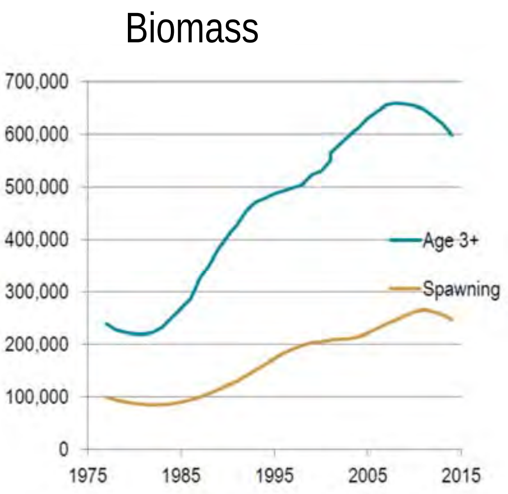
Biology: Pacific Ocean Perch (POP) *Sebastes alutus* distribution extends from Japan around the Pacific Rim south to California. POP are most abundant in AI, GOA and British Columbia and are found primarily offshore along the continental slope in depths from 180-420 m. POP are a demersal species found over cobble substrate. Seasonal changes in depth distribution occur, and adults migrate farther offshore to deeper waters during winter. During late spring and summer, POP migrate to shallower waters inshore for summer feeding. Populations often occur in patchy aggregations. Juveniles feed on calanoid copepods, whereas adults prey on euphausiids, shrimp and squids. POP are prey for Pacific Halibut, Sablefish, Pacific Cod and Arrowtooth Flounder.

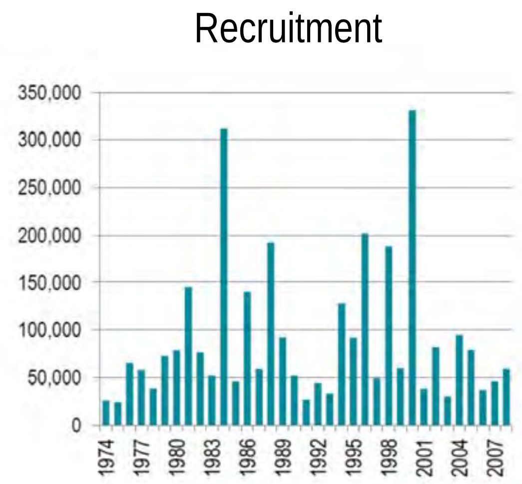
AFSC, NOAA Fisheries

POP is a slow-growing, long lived species. Recruitment to trawl fisheries begins at age 5, and they are fully recruited to the fishery around age 20 in recent years. Females reach 50% maturity at 9.1 years and longevity extends to 90 years (oldest recorded 98 years). Natural mortality is estimated to be M=0.062. Females are viviparous, retaining their fertilized eggs within the ovary until larval extrusion. Mating takes place in late fall, and larval extrusion occurs in early spring. Females release from 10,000-300,000 eggs each year, depending on size.

Stock Assessment: The assessment uses an age-structured population dynamics model that incorporates fishery data and fishery independent data from biennial trawl surveys. POP are managed under Tier 3a of the ABC/OFL control rules. The 2015 projected biomass (age 3+) is 577,967 mt. Catch specifications for 2015 are as follows; OFL=42,558 mt, ABC= 34,988 mt, TAC= 32,021 mt. Catch limits (ABC and TAC) are further apportioned by AI subarea.

Estimated biomass declined significantly from 1,131,000 mt in 1960 to 218,000 mt in 1981. Biomass recovered during the late 1980s due to above-average year classes in the AI and





reduced exploitation rates. Estimated biomass averaged 637,000 mt annually from 2004-2014.

Catch History: Soviet and Japanese trawl fisheries targeted POP throughout the 1960s. Catches in the EBS peaked at 47,000 mt in 1961 and in the AI in 1965 at 109,100 mt. Intense harvesting pressure reduced the stock biomass during that time, and catches declined through the mid-1980s. Foreign fisheries were replaced by joint ventures in the late1980s, and the fishery was fully domesticated by 1990, with catches reaching 18,324 mt. Catches averaged 14,4041 mt annually from 2004-2009.

Mark Fina, NPFMC

Fishery: POP are caught primarily in bottom trawl fisheries. Since 1996, the majority of the catch (by weight) occurred in the western Aleutians. In 2014, the discard rate for AI POP was <1%.

Fishery Management: In 1991, the POP and Other Red Rockfish complexes were separated from the POP/Other Rockfish complex. In 2001, the POP complex was separated into three management units; POP, Shortraker/Rougheye, and Sharpchin/Northern Rockfish. In 2002, Sharpchin Rockfish were dropped from the complex due to sparse catches, leaving Northern Rockfish as a single species management unit. In 2004, Shortraker and Rougheye Rockfish were split into single species management units. In 2008, the Rougheye Rockfish category was reclassified as a two species complex, Blackspotted and Rougheye Rockfish.

In 2008, BSAI FMP Amendment 80 allocated 90-98% (depending on sub-area) of the AI Pacific ocean perch TAC, along with flatfish and Atka Mackerel as catch shares among non-AFA trawl catcher processors according to their historic harvest patterns. Like other groundfish, 10.7% of rockfish is first allocated to CDQ groups.

Total catches, pre-season catch specifications, and exploitable biomass of Pacific Ocean Perch in the BSAI, 2004-2015.

Year	Catch[1]	TAC[2]	ABC	OFL	Biomass[3]
2004	11,896	12,580	13,300	15,800	375,000
2005	10,426	12,600	14,600	17,300	382,000
2006	12,859	12,600	14,800	17,600	385,000
2007	18,468	19,900	21,900	26,100	457,000
2008	17,436	21,700	21,700	25,700	453,000
2009	15,347	18,800	18,880	22,300	402,000
2010	17,852	18,860	18,860	22,400	403,000
2011	24,004	24,700	24,700	36,300	600,600
2012	24,143	24,700	24,700	35,000	594,000
2013	31,393	35,100	35,100	41,900	663,000
2014	25,889	33,122	33,122	39,585	639,505
2015	-	32,021	34,988	42,558	577,967

*POP removed from POP Complex 2004.
[1]Catch data current through November 2014.
[2]TAC, ABC and OFL data from annual Federal Register Harvest Specifications.
[3]Biomass from annual SAFE report projections.

Economics: In 2013, ex-vessel value of catch was $15.9 million for all BSAI Rockfish. Production was 29,170 mt for all rockfish products in Alaska, with a gross value $67.8 million. One catcher vessels and 16 catcher processor vessels participated in rockfish fisheries in the BSAI in 2013. Primary products are H&G and whole fish. Rockfish product price averaged $1.03/lb for at-sea processors and $1.16/lb for shoreside processors.

Ecosytem Components: POP habitat use shifts with ontogeny. Juveniles are thought to remain in more rugged, rocky benthic environments, whereas adults move into deeper, less rough habitats. POP were also found to be associated with epibenthic sea pens and sea whips along the BS slope.

AFSC, NOAA Fisheries

Northern Rockfish

Biology: Northern Rockfish *Sebastes polyspinus* distribution extends from the Kamchatka Peninsula, through the BSAI, GOA and British Columbia. This species is most abundant in the central GOA to the western end of the AI. Northern Rockfish are demersal and are generally found in discrete aggregations with patchy distributions along the outer continental shelf from 75-150 m. Northern Rockfish prey on calanoid copepods, euphausiids and chaetognaths. Based on stomach content data for POP, Pacific Halibut and Sablefish likely prey on Northern Rockfish.

Northern Rockfish is a relatively slow-growing, long lived species. Age at 50% maturity is 8.2 years, and longevity extends to 70 years (the oldest recorded Northern Rockfish was 72 years old). Natural mortality is estimated to be M=0.049. Females are viviparous, retaining their fertilized eggs within the ovary until larval extrusion.

Stock assessment:

P. Spencer and J. Ianelli. 2014. Assessment of Northern Rockfish in the Bering Sea / Aleutian Islands.

2015	-	3,250	12,488	15,337	218,901

*Northern Rockfish removed from Other Rockfish catetory 2001.
[1]Catch data current through November 2014.
[2]TAC, ABC and OFL from annual Federal Register.
[3]Biomass data corresponds to the annual SAFE report projections.

Catch History: Foreign trawl fisheries were replaced by joint ventures in the 1980s, and the fishery was fully domesticated by 1990. Catches of Northern Rockfish peaked in 1995 at 6,724 mt and ranged from 859-6,724 mt from 1990-2009. Catches from 2004-2009 averaged 3,800 mt annually.

Stock Assessment: The Northern Rockfish assessment uses an age-structured population dynamics model that incorporates fishery data and fishery independent data from biennial trawl surveys. Northern Rockfish are managed under Tier 3a of the ABC/OFL control rules.

Fishery: Northern Rockfish are generally caught in bottom trawl fisheries targeting other species. Catches in the BSAI primarily occur within the Atka Mackerel fishery, and historically, most (>80%) were discarded. Discard rates of Northern Rockfish have been decreasing over time, with an overall 2014 discard rate of 4% in the AI.

Blackspotted Rockfish
AFSC, NOAA Fisheries

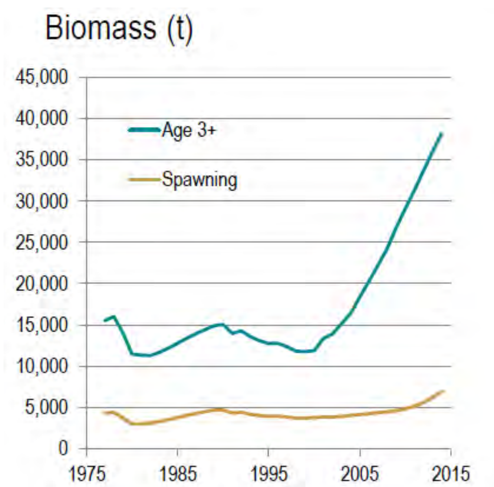
Blackspotted and Rougheye Rockfish

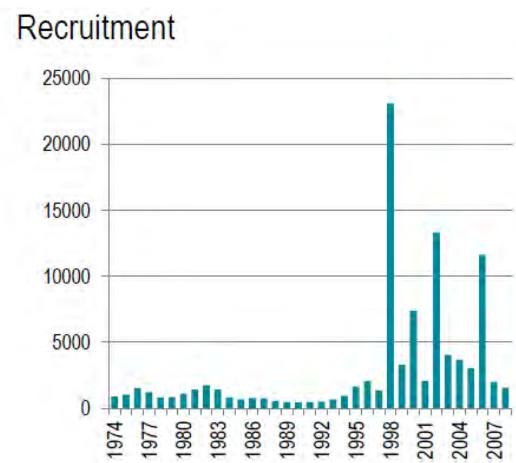
Biology: The Blackspotted and Rougheye Rockfish complex consists of 2 species: Blackspotted Rockfish *S. melanostictus* and Rougheye Rockfish *Sebastes aleutianus*. Blackspotted and Rougheye Rockfish are distributed from Japan, through the BSAI and GOA to southern California. Adults inhabit a narrow band along the upper continental slope at depths from 300-500 m. Data from recent bottom trawl surveys suggests that although the two species distributions overlap, Blackspotted Rockfish are predominant in the AI, while Rougheye Rockfish are more common in the GOA and southeastern BS. Blackspotted and Rougheye Rockfish length at 50% maturity is 44 cm. and longevity may extend to 200 years. Natural mortality is estimated at M=0.033. Blackspotted and Rougheye Rockfish prey primarily on shrimps, squids and myctophids.

Stock assessment:

P. Spencer and C. Rooper. 2014. Assessment of Blackspotted and Rougheye Rockfish Stock Complex in the Bering Sea and Aleutian Islands.

www.afsc.noaa.gov/refm/stocks/assessments.htm





Catch History: Rougheye Rockfish catches were relatively high during the late 1970s and peaked in 1979 at 3,553 mt. Catches then declined in the 1980s as the foreign fishery was reduced. Catches increased again during the 1990s with the domestication of the fishery, averaging 800 mt from 1990-1999. Catches have decreased since 2001, averaging 182 mt from 2004-2009.

Exploitable biomass (mt), pre-season catch specifications (mt), and total catches (mt, including discards) of Blackspotted and Rougheye Rockfish in the BSAI, 2004-2015.

Year	Catch[1]	TAC[2]	ABC	OFL	Biomass[3]

2015	-	453	453	560	41,666

*Rougheye Rockfish removed from Other Rockfish catetory 2003.
[1]Catch data current through November 2014.
[2]TAC, ABC and OFL from annual Federal Register.
[3]Biomass data corresponds to the annual SAFE report projections issued the preceding year.

Stock Assessment: The Rougheye Rockfish assessment uses an age-structured population dynamics model that incorporates fishery data and fishery independent data from biennial trawl surveys. Rougheye Rockfish are assessed under Tier 3, and Blackspotted Rockfish are assessed under Tier 5 of the ABC/OFL control rules. The catch limits are split into two units: AI (2015 OFL = 516 mt, ABC = 420 mt) and EBS (2015 OFL= 44 mt, ABC = 33 mt).

Fishery: There is no directed fishery for these rockfish species in the BSAI. In the AI, they are primarily taken as incidental catch in the POP trawl fishery, and to a lesser extent the Atka Mackerel trawl fishery and the Pacific Cod longline fishery.

AFSC, NOAA Fisheries

Shortraker Rockfish

Stock assessment:

I. Spies, P. Spencer, J. Ianelli, and C. Rooper. 2014. Assessment of the Shortraker Rockfish stock in the Bering Sea and Aleutian Islands.

www.afsc.noaa.gov/refm/stocks/assessments.htm

Biology: Shortraker Rockfish *Sebastes borealis* are distributed from southeastern Kamchatka, north through the BSAI, the GOA and south to California. Adults are concentrated along the 300-500 m depth interval along the continental slope. Shortraker Rockfish predate on shrimps, squids and myctophids. Shortraker Rockfish is one of the most long-lived species in the northeast Pacific. Age at 50% maturity is 45 cm, and longevity can exceed 140 years. Natural mortality is estimated to be M=0.03. Information on early life history stages of Shortraker Rockfish is limited.

AFSC, NOAA Fisheries

Catch History: Shortraker Rockfish were included in the BS "Other Rockfish" category and AI Shortraker/Rougheye category prior to 2004. Catches of Shortraker Rockfish averaged 300 mt annually from 2009-2014.

Stock Assessment: The Shortraker Rockfish assessment uses a random effects model incorporates fishery data and fishery independent data from biennial trawl surveys. Shortraker Rockfish are managed under Tier 5 of the ABC/OFL control rules.

Fishery: Shortraker Rockfish in the Aleutian Islands are primarily taken in rockfish trawl fisheries and longline fisheries targeting Greenland Turbot, Sablefish, and Pacific Cod. The central Aleutians comprised 24% of the 2004-2014 AI Shortraker catch, followed by the western Aleutians (23%) eastern Aleutians (13%), and EBS (35%). In the Eastern Bering Sea, catches of Shortraker Rockfish largely occur in midwater pollock trawl fisheries and longline fisheries for Pacific Cod, Greenland Turbot, and halibut. In 2014, 45% of the Shortraker Rockfish were discarded.

Total catches, pre-season catch specifications, and exploitable biomass of Shortraker Rockfish* in the BSAI, 2004-2015.

Year	Catch[1]	TAC[2]	ABC	OFL	Biomass[3]

Shortspine Thornyhead Rockfish
AFSC, NOAA Fisheries

Biology: The Other Rockfish complex consists of 24 species. The 7 most commonly caught species are listed in the adjacent text box. Shortspine Thornyhead and Dusky Rockfish are the two most abundant species for this complex, accounting for about 80% of the survey biomass and fishery catch. Data are limited for many of the "Other Rockfish" complex species.

Common name	Scientific name
Redbanded Rockfish	*Sebastes babcocki*
Dusky Rockfish	*Sebastes variabilis*
Redstriped Rockfish	*Sebastes proriger*
Yelloweye Rockfish	*Sebastes ruberrimus*
Harlequin Rockfish	*Sebastes variegatus*
Sharpchin Rockfish	*Sebastes zacentrus*
Shortspine Thornyhead	*Sebastolobus alascanus*

Dusky Rockfish distribution extends from Japan into the BSAI and down to central Oregon. Dusky Rockfish are found along the outer continental shelf in patchy distributions. Natural morality is estimated at M=0.09. Dusky Rockfish are viviparous. Dusky Rockfish longevity is approximately 60 years. Shortspine Thornyhead is distributed from Japan to the BSAI down to central California. Shortspine Thornyheads are commonly found at depths from 150-450 m. Natural morality is estimated at M=0.03, and Shortspine Thornyhead longevity extends to 100 years or more. In contrast to many other *Sebastes spp*., the Shortspine Thornyhead is oviparous.

Stock assessment:

I. Spies and P. Spencer. 2014. Assessment of Other Rockfish stock complex in the Bering Sea / Aleutian Islands.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Catch History: Other Rockfish have been caught in trawl fisheries since Japanese and Soviet fleets began fishing in the BS in the 1960s. Catches of "Other Rockfish" have been tracked since 1977. Catches were relatively high in the BSAI from 1977-1983, ranging annually from 700-2,300 mt. Catches have remained relatively stable from 1993-2009, averaging 677 mt annually.

Stock Assessment: Other Rockfish are managed under Tier 5 of the ABC/OFL control rules. Catch specifications for 2015 include further subdivision of ABC limits by area such that BS ABC= 695 mt, and AI ABC=555 mt.

Total catches, pre-season catch specifications and exploitable biomass of Other Rockfish in the BSAI, 1995-2015.

Year	Catch[1]	TAC[2]	ABC	OFL	Biomass[3]

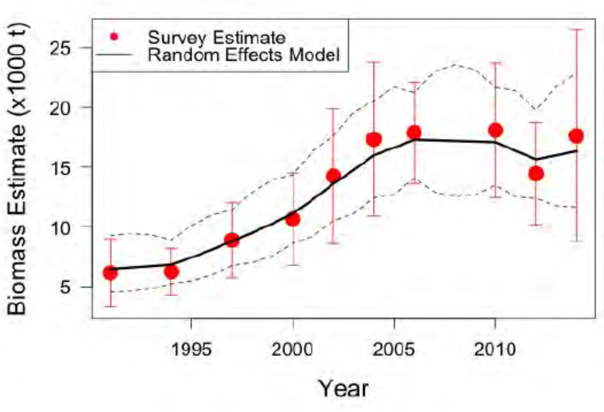
Fishery: There is no directed fishery for Other Rockfish in the BSAI. Dusky Rockfish are primarily taken in the Atka Mackerel fishery in the AI and the EBS Pacific Cod fishery. Shortspine Thornyhead are primarily taken in the AI Sablefish and Greenland Turbot longline fisheries and EBS pollock trawl fishery.

Aleutian Islands SST



Atka Mackerel

AFSC, NOAA Fisheries

Biology: Atka Mackerel *Pleurogrammus monopterygius* is a schooling, semi-demersal species most commonly found in the AI. Adults occur in large localized aggregations at depths less than 200 m over rough, uneven bottom areas with high tidal currents. Atka Mackerel move off the bottom during daylight hours presumably to feed on their main prey items, euphausiids and copepods. Predators of Atka mackerel include Pacific Cod, Arrowtooth Flounder, Steller sea lions and seabirds. They begin to recruit to the fishery at age 3 and longevity can extend to 15 years. Females reach 50% maturity at 34 cm (3.6 years). Natural mortality is estimated at M=0.30. Atka Mackerel are a substrate spawning fish with male parental care. . During spawning, territorial males become bright yellow. Spawning occurs from July to October, peaking in early September. Eggs are adhesive and deposited in rock crevices in nests guarded by males until hatching, which occurs about 40-45 days later.

Stock assessment:

S. Lowe, J. Ianelli, and W. Palsson. 2014. Assessment of the Atka Mackerel stock in the Bering Sea/Aleutian Islands.

[1]Catch data current through November 2014.
[2]1988-2010 TAC, ABC and OFL from Federal Register
[3]Biomass data from SAFE report projections.

Catch History: Beginning in 1970, USSR, Russia and Korea harvested Atka Mackerel; foreign catches peaked in 1978 at 24,000 mt. U.S. joint venture fisheries began in 1980 and dominated landings of Atka mackerel from 1982-1988. The last joint venture allocation of Atka mackerel off Alaska was in 1989. Peak domestic catch occurred in 1996 (104,000 mt).

Fishery Management: The Atka Mackerel fishery is heavily regulated to minimize the potential for prey competition with Steller sea lions, including seasonal allowances of TAC and spatial distribution of the fishery away from critical habitat. Since 2008, the fishery has operated as a catch share fishery, with participants operating as cooperatives.

Stock Assessment: The Atka Mackerel assessment model incorporates fishery data and fishery independent data from trawl surveys. Atka Mackerel fall under Tier 3a of the ABC/OFL control rules.

Fishery: Atka Mackerel are targeted by trawl catcher processors. Products include whole fish and H&G.

AFSC, NOAA Fisheries

Biology: There are 14 species in the "Squid" complex in the BSAI. The most commonly caught species in the BS is the Magistrate Armhook Squid *Berryteuthis magister*. Squid in the BSAI are generally pelagic, however, the North Pacific bobtail squid, and magistrate armhook squid are often found in close proximity to the bottom. Most species are associated with the slope and basin, with the highest species diversity along the slope region of BS between 200–1500 m.

Chiroteuthid sp.	*Chiroteuthis calyx*
Glass squid sp.	*Belonella borealis*
Glass squid sp.	*Galiteuthis phyllura*
Minimal Armhook Squid	*Berryteuthis anonychus*
Magistrate Armhook Squid	*Berryteuthis magister*
Armhook squid	*Eogonatus tinro*
Boreopacific Armhook Squid	*Gonatopsis borealis*
Berry Armhook Squid	*Gonatus berryi*
Armhook squid sp.	*Gonatus madokai*
Armhook squid sp.	*Gonatus middendorffi*
Clawed Armhook Squid	*Gonatus onyx*
Robust Clubhook Squid	*Moroteuthis robusta*
Boreal Clubhook Squid	*Onychoteuthis borealijaponicus*
North Pacific Bobtail squid	*Rossia pacifica*

Squids are productive, short-lived animals. Squid display rapid growth, patchy distribution and variable recruitment patterns. Populations of the Magistrate Armhook Squid are complex and are made up of multiple cohorts spawned throughout the year. Magistrate squid are dispersed throughout the summer months in the western BS but form large, dense schools over the continental slope between September and October. Three seasonal cohorts are identified in the region; summer-hatched, fall-hatched and winter-hatched. Growth, maturation and mortality rates vary between cohorts. Juvenile and adult magistrate squid also appear to be separated vertically in the water column. Most squid are generally thought to live less than 2-3 years.

Stock assessment:

O. Ormseth. 2014. Assessment of the squid stock complex in the Bering Sea and Aleutian Islands.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Catch history: Japanese and Korean trawl fisheries targeted squid during the 1960s and 1970s; catches peaked in 1978 at 9,000 mt. Catches have remained below 2,000 mt since 1984.

Stock Assessment: Squid fall under Tier 6 of the OFL/ABC control rules, and catch specifications are therefore based on the average catch of squid between1978-1995. Squid estimated biomass is unknown due to a lack of reliable survey data. Catch specifications for squid in 2015 are as follows: OFL= 2,620 mt, ABC= 1,970 mt, TAC= 400 mt.

Total catches and pre-season catch specifications of Squid in the BSAI, 2007-2015.

Year	Catch	TAC	ABC	OFL
2007	1,188	1,970	1,970	2,620
2008	1,542	1,970	1,970	2,620
2009	360	1,970	1,970	2,620
2010	410	1,970	1,970	2,620
2011	336	425	1,970	2,620
2012	688	425	1,970	2,620
2013	300	700	1,970	2,620
2014	1,668	310	1,970	2,620
2015	-	400	1,970	2,620

*Squid biomass data unavailable.

Fishery: Squid are not a target fishery, and are primarily taken as incidental catch in the pelagic trawl pollock fishery. Discard rates have ranged from about 40 to 70 % in recent years.

Ecosystem Components: Squid important components in the diets of many seabirds, fish and marine mammals. Overall fishing removals of squid are very low (especially relative to natural predation).

Bigmouth Sculpin
AFSC, NOAA Fisheries

Sculpins

Biology: There are a total of 48 species of sculpins in the BSAI, with 41 species identified in the Eastern Bering Sea and 22 species in the Aleutian Islands region. Sculpins occupy all benthic habitats and depths. The six species with the highest biomasses include Great Sculpin (*Myoxocephalus polyacanthocephalus*), Threaded Sculpin (*Gymnocanthus pistillger*) Plain Sculpin (*M. jaok*), Warty Sculpin (*M. verrucosus)*, Bigmouth Sculpin (*Hemitripterus bolini)*, and Yellow Irish Lord (*H. jordani*).

There is limited BSAI-specific data on age and growth, maturity, or reproductive biology for sculpins identified in this management region. Most if not all sculpins lay adhesive eggs in nests, and many exhibit parental care for eggs.

Stock assessment:

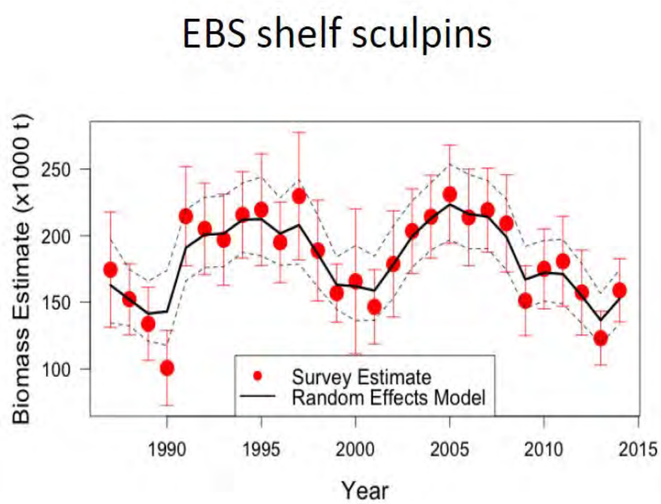
I. Spies, D. Nichol, O. Ormseth and T. TenBrink. 2014. Assessment of the sculpin stock comples in the Bering Sea and Aleutian Islands.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Catch history: Based on total catch estimates from 1998-2008, sculpins comprised 19-28% of the total Other Species catch during this time period. Catches from 2000-2008 ranged from 5,735 mt to 7,670 mt per year.

Stock Assessment: Prior to 2011, sculpins were managed as part of the BSAI Other Species complex that included sculpins, skates, sharks, and octopuses. Sculpins fall under Tier 5 of the OFL/ABC control rules. A complex wide natural mortality rate of M=0.29 is applied.

Fishery: There is currently no target fishery for sculpins in the BSAI, and virtually all are discarded or made into meal. Incidental catches of sculpins are taken in the Pacific Cod and Atka Mackerel fisheries in the AI, and in the Pacific Cod rock sole, and Yellowfin Sole fisheries in the BS.



Total catches, pre-season catch specifications, and exploitable biomass of Sculpins in the BSAI, 2008-2015.

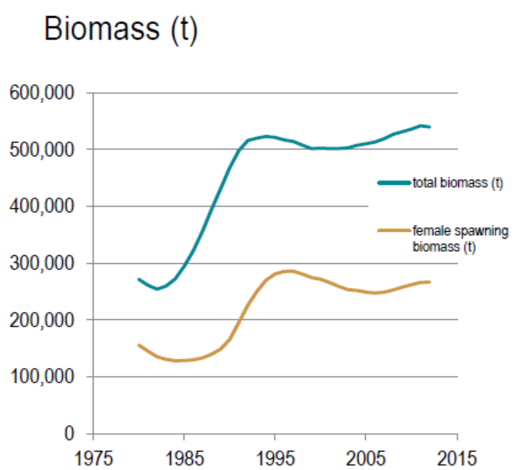
Alaska Skate
Beth Matta
AFSC, NOAA Fisheries

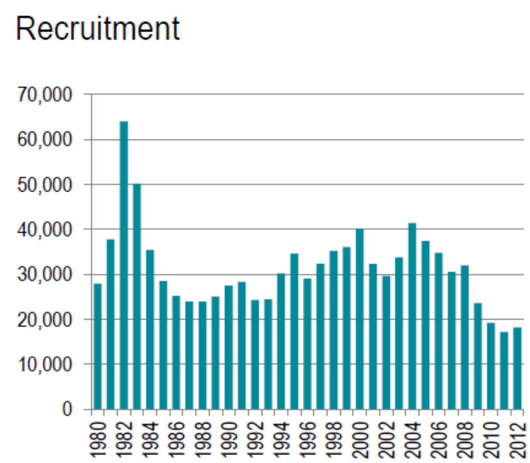
<u>Biology:</u> Skates are cartilaginous fishes with large pectoral "wings" attached to the sides of the head. There are 15 species of skates in the BSAI in four genera, *Raja*, *Bathyraja*, *Beringraja*, and *Amblyraja.* The EBS shelf skate complex is dominated by a single species, the Alaska Skate (*Bathyraja parmifera*), occurring at depths of 50 to 200 m. The Bering or sandpaper Skate (*B. interrupta*) is the next most common species on the EBS shelf, and is distributed on the outer continental shelf. The dominant species on the EBS slope is the Aleutian Skate (*B. aleutica*). A number of other species are found on the EBS slope in significant numbers, including the Alaska Skate, Commander Skate (*B. lindbergi*), Whiteblotched Skate (*B. maculata*), Whitebrow Skate (*B. minispinosa*), roughtail Skate (*B. trachura*), and mud Skate (*B. taranetzi*). Two rare species, the Deepsea Skate (*B. abyssicola*) and Roughshoulder Skate (*Amblyraja badia*), have only recently been reported from EBS slope bottom trawl surveys. The skate complex in the AI is quite distinct from the EBS shelf and slope complexes, with different species dominating the biomass, as well as at least one endemic species, the recently described Butterfly Skate, *Bathyraja mariposa*, as well as the newly identified Leopard Skate. In the AI, the most abundant species is the Whiteblotched Skate, *B. maculate.*

Stock assessment:

O. Ormseth. 2014. Assessment of the skate stock complex in the Bering Sea and Aleutian Islands.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm





Skate life cycles are similar to sharks, with relatively low fecundity, slow growth to large body sizes, and dependence of population stability on high survival rates of a few well developed offspring. Alaska Skates reach 50% maturity at ages 9-10 years, and have life spans of up to 17 years, based on observations to date.

Total catches, pre-season catch specifications, and exploitable biomass of Skates in the BSAI, 2008-2015.

Year	Catch[1]	TAC[2]	ABC	OFL	Biomass[3]
2008	20,469	-	-	-	-
2009	19,442	-	-	-	634,000
2010	16,515	-	-	-	608,000
2011	23,005	16,500	31,500	37,800	612,000

2013	26,165	24,000	38,800	45,800	745,000
2014	21,319	26,000	35,383	41,849	698,204
2015	-	25,700	41,849	49,575	628,314

[1]Catch data current through November 2014.
[2]TAC, ABC and OFL from SAFE
[3]Biomass from SAFE report projections.

<u>Stock Assessment</u>: Until 2011, skate species were managed as part of the "Other species" management category within the BSAI FMP. Catch specifications for the Alaska Skate is based on Tier 3a, and for other skates Tier 5 of the ABC/OFL control rules. Total skate biomass is projected at 628,314 mt in 2015.

<u>Fishery</u>: There is currently no target fishery for skates in the BSAI. Most of the skate is caught incidentally in the hook and line fishery for Pacific Cod, and trawl fisheries for pollock and flatfish. About 35% of the skate catch is retained.

Sharks

Salmon Shark
AFSC, NOAA Fisheries

Biology: The shark complex consists of 8 species. The species most likely to be encountered in BSAI fisheries and surveys are the Pacific Sleeper Shark (*Somniosus pacificus*), the Spiny Dogfish (*Squalus acanthias*), and the Salmon Shark (*Lamna ditropis*). Sharks are long-lived species with slow growth to maturity, a large maximum size, and low fecundity. Spiny Dogfish tend to segregate by sex and by size. Age-at-50%-maturity for Spiny Dogfish is estimated to be 35 years for females, and 19 years for males. Spiny Dogfish may live up to 100 years, and exhibit very slow growth rates. Spiny dogfish are aplacental viviparous, and embryos are nourished solely by their yolk sac, with a gestation period of 18-24 months. Pacific Sleeper Sharks can attain large size, with maximum lengths of 440 cm for females and 400 cm for males, although there are reports of individuals of 700 cm in length. Like Spiny Dogfish, Pacific Sleeper Sharks are aplacental viviparous. Salmon Sarks also grow relatively large, attaining a maximum length of 215 cm precaudal length for females and about 190 cm for males. Maximum ages for Salmon Sharks are 17 years for males and 30 years for females. They are thought to live up to 30 years.

Stock assessment:

C. Tribuzio, K. Echave, C. Rodgveller, and P-J. Hulson. 2014. Assessment of the shark complex in the Bering Sea and Aleutian Islands.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Catch history: Incidental catches of shark species in the BSAI fisheries have been very small compared to catches of target species. Sharks have only been reported to species in the catch since 1997. Pacific Sleeper Shark make up about 60% of the total shark catch in the BSAI, followed by unidentified sharks at 20%, Salmon Shark at 9% and Spiny Dogfish at 2%.

Fishery Management: Shark species were managed as part of the "Other species" management category until 2011, when sharks became a separate management complex with shark specific OLF, ABC, and TAC.

Stock Assessment: Sharks fall under Tier 6 of the OFL/ABC control rules, and catch specifications are based on the maximum catch from 1997-2007 (1,362 mt in 2002). Sharks estimated biomass is undefined due to a lack of reliable survey data. Directed fishing for this species has not been authorized.

Fishery: There is currently no target fishery for sharks in federally or state managed waters of the BSAI, and most incidentally captured sharks are not retained. Spiny Dogfish are at the northern edge of their range in the BSAI but a few are taken in Pacific Cod longline fishery. About majority of the salmon sharks are taken in the Pollock fishery. Sleeper Sharks are taken mainly in the Pacific Cod and Pollock fisheries.

Total catches, pre-season catch specifications, and exploitable biomass of Sharks in the BSAI, 2008-2015.

Giant Pacific Octopus
Rex Murphy

Biology: There are at least 7 species of octopus present in the BSAI, and the species composition both of natural communities and commercial harvest is unknown. Some species, particularly *G. boreapacifica*, are primarily distributed at greater depths than are commonly fished. At depths less than 200 meters *E. dofleini* appears to be the most abundant species.

Giant Pacific Octopus	*Enteroctopus dofleini*
Smoothskin Octopus	*Benthoctopus leioderma*
Flapjack Devilfish	*Opisthoteuthis californiana*
Small Pelagic Octopus	*Japatella diaphana*
Stubby Octopus	*Sasakiopus salebrosus*
A deepwater octopus	*Graneledone boreopacifica*
A deepwater octopus	*Benthoctopus oregonesis*

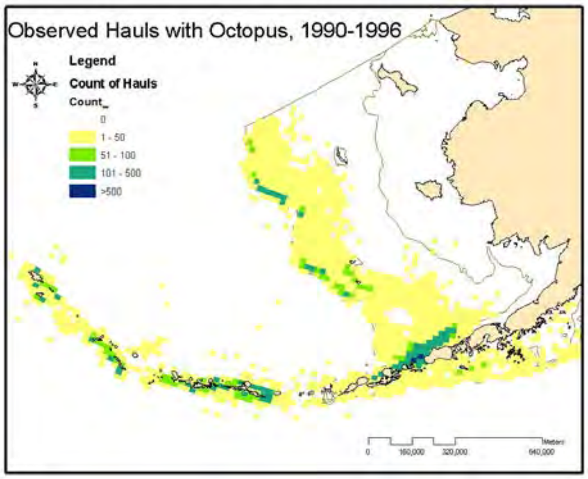
Octopus life spans are either 1-2 years or 3-5 years depending on the species. *E. dofleini* are estimated to mature at 1.5 – 3 years. *E. dofleini* is a terminal spawner, females die after the eggs hatch while males die shortly after mating. The fecundity of this species in Japanese waters has been estimated at 30,000 to 100,000 eggs per female. Based on larval data, *E. dofleini* is the only octopus in the Bering Sea with a planktonic larval stage.

Stock assessment:

M.E. Conners, C. Conrath, and K. Aydin. 2014. Assessment of the Octopus Stock Complex in the Bering Sea and Aleutian Islands.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Fishery Management: Until 2011, octopus were managed as part of the "Other species" management category within the BSAI FMP. Octopuses have been managed as a single complex with specific OFL, ABC, and TAC since 2011.



Stock Assessment: Octopus fall under Tier 6 of the OFL/ABC control rules. Catch specifications are based on a natural mortality approach using the geometric mean of annual consumption of octopus by its main predator, Pacific Cod. There are no historical catch records for octopus, and their biomass has not been estimated. Catch specifications for octopus in 2015 are as follows; OFL=3,452 mt, ABC=2,589 mt, TAC=400 mt. Directed fishing for this species is normally prohibited each year.

Total catches, pre-season catch specifications, and exploitable biomass of Octopus in the BSAI, 2008-2015.

[3]Biomass from SAFE report projections.

Fishery: There is currently no target fishery for octopus in the BSAI. Octopus are taken as incidental catch in trawl, longline, and pot fisheries throughout the BSAI; the highest catch rates are from Pacific Cod pot fisheries in the three statistical areas around Unimak Pass. The species composition of the octopus community is not well documented, but recent research indicates that the giant Pacific Octopus *Enteroctopus dolfleini* is most abundant in shelf waters and predominates in commercial catch.

Walleye Pollock
AFSC, NOAA Fisheries

Walleye Pollock

Biology: Walleye Pollock *Gadus chalcogrammus* is an abundant fish species in the GOA, found throughout the shelf regions at depths less than 300 m. Seasonal migrations occur from overwintering areas along the outer shelf to shallower waters (30-140 m) to spawn. Pollock feed on copepods, euphausiids and fish and are prey for other fish, marine mammals and seabirds. Pollock begin to recruit to the fishery at age 3 and live to 12 years or more (the oldest Pollock recorded in the GOA is 22 years). Females reach 50% maturity at approximately 43 cm (ages 4-6), and adults produce 60,000 to 400,000 pelagic eggs. Annual natural mortality is estimated to be M=0.30. Peak spawning in the GOA occurs from February to March in the Shumagin Islands and late March in the Shelikof Strait.

Stock assessment:

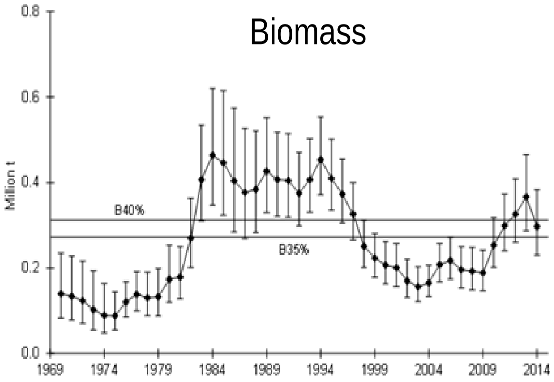
M. Dorn, K. Aydin, D. Jones, W. Palsson, K. Spalinger. 2014. Assessment of the Walleye Pollock stock in the Gulf of Alaska.

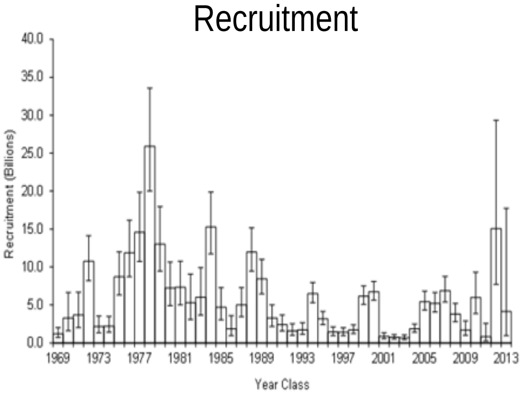
http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Catch History: Foreign fisheries for pollock developed in the GOA in the early 1970s and peak foreign catches occurred in 1981 at 130,324 mt. A late spawning aggregation was discovered in Shelikof Strait in 1981, and a valuable pollock roe fishery was established in the region. U.S. vessels entered the pollock fishery in 1977 and by 1988, the fishery was fully harvested by the domestic fleet.

AFSC, NOAA Fisheries

Fishery Management: The GOA pollock fishery is regulated under the GOA groundfish FMP through permits and limited entry, catch quotas (TACs), seasons, in-season adjustments, gear restrictions, closed waters, bycatch limits and rates, allocations, regulatory areas, record keeping, reporting requirements and observer monitoring. In 1993, 100% of GOA pollock was apportioned to the inshore sector (vessels that catch fish to deliver to shore based processing plants). In 1998, trawl gear was prohibited east of 140°W, and 100% retention was required for pollock.





Since 1992, GOA pollock catch has been apportioned spatially and temporally to reduce fishery impacts on Steller sea lions (SSLs). Additional SSL protection measures implemented in 2001 established 4 seasons in the Central and Western GOA beginning in January, March, August and October (25% TAC to each season). Additionally, a harvest control rule was implemented that requires suspension of directed pollock fishing if spawning biomass declines below 20% of unfished spawning biomass.

Stock Assessment: The GOA pollock assessment is based on an age-structured model. This model incorporates fishery data and fishery independent data from annual bottom trawl surveys and acoustic trawl surveys. GOA pollock fall under Tier 3b of the ABC/OFL control rules. The 2015 age 3+ biomass is estimated at 1,940,031 mt. Gulf wide catch specifications for 2015 are as follows; OFL=273,378 mt, ABC=203,934 mt, TAC=199,151 mt. The catch limits are further spatially apportioned into Western, Central area 62, Central area 63, West Yakutat, and Eastern GOA.

Total catches, pre-season catch specifications, and exploitable biomass of age 3+ Walleye Pollock in the GOA, 1980-2015 (in mt).

[1]Catch data through November 8, 2014.
[2]1988-2014 TAC, ABC and OFL data from annual Federal Register Harvest Specifications. Does not include EYAK and SEO.
[3]Biomass from annual SAFE report projections.

Age 3+ GOA pollock model-estimated biomass was high during the early 1980s. Biomass declined through the late 1980s and dropped below target as a result of below average recruitment. More recently, the stock size has shown a strong upward trend, and is now close to target.

Fishery: The directed fishery is prosecuted by vessels using trawl gear, primarily with pelagic trawls. Small amounts of pollock are also taken as bycatch in other fisheries. A total of 91 catcher vessels participated in the 2013 GOA directed pollock trawl fishery.

Economics: In 2013, ex-vessel value of the catch was $36.4 million for GOA pollock. Average ex-vessel price paid for GOA pollock in 2013 was $0.18/lb. round weight. Primary products were surimi, roe, fillets, H&G, and other products.

Ecosystem Components: In the GOA, the main predators of pollock are Arrowtooth Flounder, Pacific Halibut, Pacific Cod, and Steller sea lions. For pollock less than 20 cm, Arrowtooth Flounder represents close to 50% of total mortality, and the abundance of Arrowtooth Flounder has increased dramatically in the GOA since the 1980s.

Pacific Cod
Diana Evans, NPFMC

Biology: Pacific Cod *Gadus macrocephalus* is a demersal species found in the eastern BS, the AI, and GOA down to central California. Juveniles are typically distributed over the inner continental shelf at depths from 60-150 m. Adults are found at depths from shoreline to 500 m. Mature fish tend to concentrate on the outer continental shelf and prefer muddy or sandy sediment. Juveniles feed primarily on small invertebrates and euphausiids. Adult Pacific Cod feed on fish such as juvenile pollock, and invertebrates such as polychaetes, amphipods and crangonid shrimp. Predators of Pacific Cod include adult Pacific Cod, Pacific Halibut, Salmon Shark and Steller Sea Lion.

Pacific Cod are a relatively fast growing and short-lived fish. Longevity can extend to 19 years. Pacific Cod begin to recruit to the fishery around age 3 and are 50% recruited by age 7. Natural mortality is estimated at M=0.38. Females reach 50% maturity at 50 cm (4-5 years) and larger fish can produce more than 1 million eggs. Adults form spawning aggregations from January to May in the GOA.

Stock assessment:

T. A'mar and W. Palsson 2014. Assessment of the Pacific Cod stock in the Gulf of Alaska.

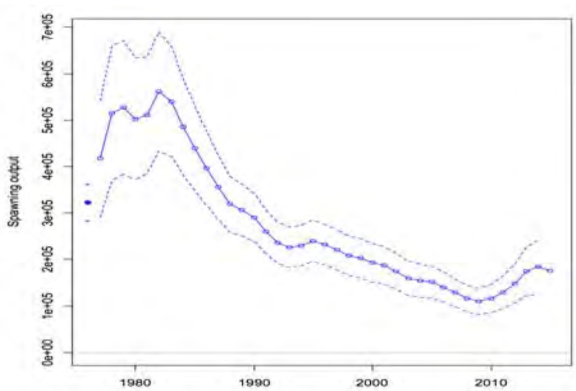
http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Catch History: Pacific Cod were harvested by foreign fleets targeting higher-value species during the 1970s. By 1976, catches increased to 6,800 mt, and the foreign fishery peaked in 1981 at 35,000 mt. A small joint venture fishery existed through 1988, averaging about 1,400 mt annually. The domestic fishery increased through 1986 and tripled its catch in 1987 to a catch of nearly 31,000 mt. The GOA Pacific Cod fishery was fully harvested by domestic vessels in 1987.

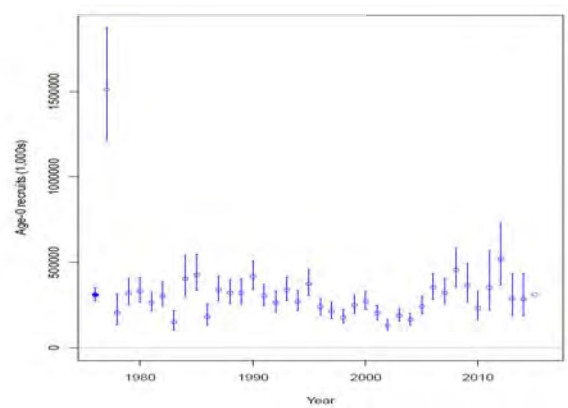
SeaAlliance/AGDB

Fishery Management: The Pacific Cod fishery is regulated under the GOA groundfish FMP through permits, limited entry, catch quotas (TACs), seasons, in-season adjustments, gear restrictions, closed waters, bycatch limits and rates, allocations, regulatory areas, record keeping, reporting requirements and observer monitoring. In 1992, Amendment 23 allocated 90% of GOA Pacific Cod to the inshore sector and 10% to the offshore sector. In 1998, 100% retention of Pacific Cod was required.

Biomass



Recruitment



Separate TACs are currently identified for Pacific Cod in the Western, Central and Eastern GOA regulatory areas. Within the Central and Western Regulatory Areas, 60% of each component's portion of the TAC is allocated to the A season (January 1 through June 10) and the remainder is allocated to the B season (June 11 through December 31). Longline and trawl fisheries are also associated with a Pacific Halibut mortality limit, which can constrain the magnitude and timing of harvests taken by these two gear types.

Stock Assessment: The Pacific Cod assessment is based on a Stock Synthesis model that uses both length-structured and age-structured data. This model incorporates fishery data and fishery independent data from the NMFS trawl surveys. Pacific Cod catch limits are set by a Tier 3a ABC/OFL control rule. The 2014 age 3+ biomass is estimated at 422,000 mt for GOA Pacific Cod. Since 1997, the Council has reduced the TAC in each area by up to 25% to account for removals in the State waters Pacific Cod fishery.

Total catches, pre-season catch specifications, and exploitable biomass of age 3+ Pacific Cod in the GOA, 1980-2015 (in mt).

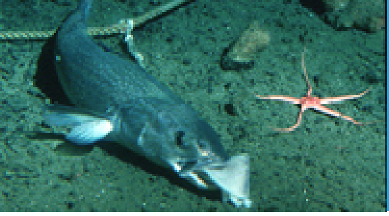
[1] Catch data f through November 2014, includes state waters fishery catch.
[2]TAC, ABC and OFL data from Federal Register.
[3]Biomass from annual SAFE report projections issued the preceding year.

Estimated biomass of Pacific Cod peaked in the early 1980s, and then slowly declined as the exceptional 1977 year class gradually exited the population. Estimated biomass appears to be increasing in the short term due to above average recruitment in recent years.

Fishery: The Pacific Cod fishery is the second major species (after pollock) targeted in the commercial groundfish catch in the GOA. Pacific Cod are taken with trawl, longline, pot and jig gear. Participants in the 2009 GOA directed fishery included 240 vessels using longlines or jig gear, 125 vessels using pot gear, and 64 vessels using trawl gear.

Economics: In 2013, ex-vessel value of Pacific Cod catch in the GOA was $37.2 million, and ex-vessel fixed-gear price averaged $0.27/lb round weight. Primary products include whole fish, H&G and fillets.

Ecosystem components: Pacific Cod are a prey item for Steller Sea Lions in the GOA and BSAI.



Sablefish

Sablefish
AFSC, NOAA Fisheries

Stock assessment:

D. Hanselman, C. Lunsford, and C. Rodgveller. 2014. Assessment of the Sablefish stock in Alaska.

www.afsc.noaa.gov/refm/stocks/assessments.htm

Biology: Sablefish *Anoplopoma fimbria* distribution extends from the northern Mexico through the Gulf of Alaska, the AI and into the BS. Adult Sablefish are generally found at depths greater than 200 m along the continental slope, shelf gullies and deep fjords. Juvenile Sablefish (less than 40 cm) spend the first 2-3 years farther inshore along the continental shelf and begin to move out to the continental slope around age 4. Young-of-the-year Sablefish feed primarily on euphausiids and copepods while adults are more opportunistic feeders, relying more heavily on pollock, Pacific Herring, Pacific Cod, squid and jellyfish. Coho and Chinook Salmon are the main predators of young-of-the-year Sablefish.

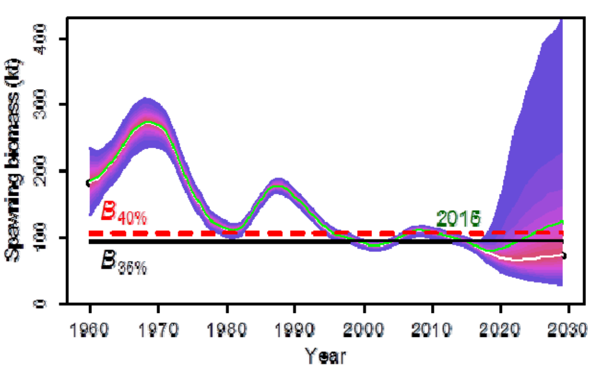
Sablefish are relatively long lived. They begin to recruit to the fishery at age 4 or 5 and longevity often reaches 40 years (the oldest recorded Sablefish in Alaska was 94 years old). Female size at 50% maturity is around 65 cm (approximately age 6.5). Females are slightly larger than males, and natural mortality is estimated at M=0.10. Off Alaska, Sablefish spawn at depths near the edges of the continental slope (500 m) between January and April.

Catch History: U.S. fishermen have harvested Sablefish (also called black cod) since the end of the 19th century as a byproduct of halibut fisheries. Harvests were relatively small, averaging 1,666 mt from 1930-1957. Japanese longlining began in the EBS around 1958 and expanded into the AI and GOA through the 1970s. Japanese fleet catches increased throughout the 1960s, and peak Sablefish catch reached 36,776 mt in 1972. High fishing pressure in the early 1970s by Japanese and USSR vessels may have resulted in a population decline of Sablefish in the mid-1970s. By 1988, U.S. fishermen took the majority of the Sablefish harvested in the GOA and BSAI. Sablefish was increasingly harvested as a derby-style fishery in the late 1980s and early 1990s until Individual Fishing Quotas were implemented for the hook and line fishery in 1995.

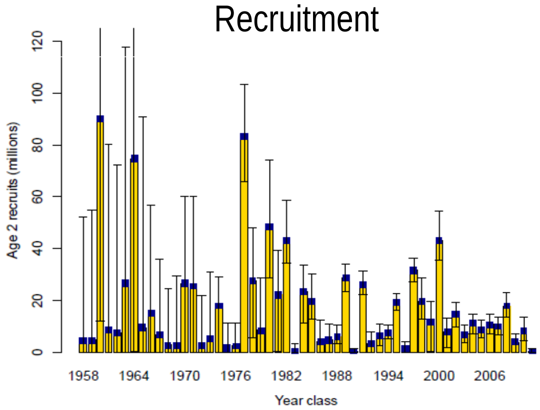
Fishery Management: BSAI and GOA Sablefish are managed as one population in federal waters due to their highly migratory behavior during certain life history stages. There are four management areas in the GOA; Western, Central West Yakutat and East Yakutat/Southeast Outside.

In 1985, Amendment 14 to the GOA FMP allocated Sablefish TAC by gear type; 80% to fixed gear (including pots) and 20% to trawl in the Western and Central GOA, 95% to fixed gear and 5% to trawl gear in the Eastern GOA. Amendment 20 to the GOA FMP established IFQ management for the GOA Sablefish fishery, which began in 1995.

Biomass



Recruitment



Stock Assessment: The Sablefish assessment is based on a statistical sex-specific age-structured model. This model incorporates fishery data and fishery independent data from domestic and Japan-U.S. cooperative longline surveys and the NMFS GOA trawl survey. Sablefish fall under Tier 3b of the ABC/OFL control rule. Separate ABCs and TACs are established for each GOA subregion: Western, Central, West Yakutat, and Southeast Outside.

Fishery: The Sablefish IFQ fishery season opening date is concurrent with the halibut fishery for the purposes of reducing bycatch and regulatory discards between the two fisheries. In the GOA, the directed fishery for Sablefish is prosecuted with longline gear (pot gear is prohibited for directed Sablefish fishing in the GOA). Sablefish are also taken by trawl gear in directed fisheries for rockfish and deepwater flatfish. Primary incidental catch species in the directed Sablefish fishery include Shortraker, Rougheye and Thornyhead Rockfishes.

Total catches, pre-season catch specifications and exploitable biomass of Sablefish in the GOA, 1980-2015 (in mt).

[1]Catch data through November 2014.
[2]TAC, ABC and OFL from annual Federal Register.
3Biomass from SAFE report projections for following year.

Economics: In 2013, the ex-vessel value of Sablefish catch from the GOA was $83.6 million. Ex-vessel prices for GOA Sablefish in 2013 averaged $3.22/lb for fish caught on longline gear and $2.43/lb for fish taken with trawl gear. For both gear types, the primary product is frozen, head and gutted fish.

Current Issues: Sperm whale and killer whale depredation is problematic for Sablefish fisheries in the GOA and BSAI. Depredation occurs when whales remove Sablefish from longline gear, damage the fish and/or fishing gear. Killer whale depredation predominates in the BSAI and sperm whale depredation is more common the GOA. Depredation can lead to economic losses in the form of reduced catch, extended travel distances, extended wait times and damaged gear. Depredation may also reduce the accuracy of Sablefish stock assessment models. Additionally, depredating whales may be at greater risk of mortality or injury through vessel strikes or risk of entanglement in gear.

Northern Rock Sole
Washington DFW

Shallow-water Flatfish

Stock assessment:

B. Turnock W. and T. A'mar. 2014. Assessment of Shallow Water Flatfish in the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Biology: The shallow-water flatfish complex is comprised of 8 flatfish species. Northern Rock Sole, Southern Rock Sole, Butter Sole and Yellowfin Sole account for the majority of the current biomass of shallow-water flatfish. All flatfish are demersal but have varying depth ranges. Shallow-water flatfish feed on euphausiids, bivalves, polychaetes, amphipods, mollusks and fish. They are prey for Pacific Cod, Pacific Halibut and skates.

Northern Rock Sole	*Lepidopsetta polyxystra*
Southern Rock Sole	*Lepidopsetta bilineata*
Butter Sole	*Pleuronectes isolepis*
Yellowfin Sole	*Pleuronectes asper*
Starry Flounder	*Platichthys stellatus*
English Sole	*Pleuronectes vetulus*
Alaska Plaice	*Pleuronectes quadrituberculatus*
Sand Sole	*Psettichthys melanostictus*

Yellowfin Sole distribution extends from the Sea of Japan, through the Chukchi Sea and south to British Columbia. Yellowfin Sole are the second most abundant finfish species (after pollock) in Cook Inlet and are also found in Prince William Sound. Yellowfin Sole spawning period is protracted and likely extends from May to August, occurring primarily in shallow water. Females are relatively fecund, ranging from 1.3-3.3 million eggs depending on size. Yellowfin Sole begin to recruit to the fishery at age 6 and are fully selected by age 13. The estimated age of 50% maturity is 10.5 years for females. Natural mortality is estimated at M=0.12-0.16, and longevity extends to 31 years.

The rock sole stock in the GOA consists of both Northern and Southern Rock Sole. The two species are similar in appearance but have different life history characteristics. Northern Rock Sole stock spawns beginning in midwinter and peaking during the spring, and the Southern Rock Sole stock spawns during the summer. The estimated age of 50% maturity is 9 years for Southern Rock Sole and 7 years for Northern Rock Sole. For both species, natural mortality is estimated to be M=0.18-0.20 for females, and M=0.25-0.26 for males, and longevity can extend to 30 years. Rock sole are most abundant in the Kodiak and Shumagin areas. Adults occupy separate winter spawning and summertime feeding distributions on the continental shelf margins.

Starry Flounder
AFSC, NOAA Fisheries

Catch History: The flatfish fishery was predominantly a foreign fishery targeting non-flatfish species until 1981. With the cessation of foreign fishing in 1986, joint venture fishing began to account for the majority of flatfish catch, and the fishery was fully domestic by 1988. Shallow-water flatfish catch was 5,455 mt in 1978. Catch declined to a low of 957 mt in 1986 then increased to 9,715 mt in 1993. Shallow-water flatfish catch is often constrained by Pacific Halibut bycatch limits.

Fishery Management: The Council divided the "Flatfish" complex into 3 categories (Deep-water flatfish, Shallow-water flatfish, and Arrowtooth Flounder) in 1990 due to significant differences in halibut bycatch rates, biomass and commercial value in directed fisheries for shallow and Deep-water flatfish. Flathead Sole was separated out from the Deep-water flatfish complex in 1991 due to its distributional overlap between both shallow and deep-water groups.

All flatfish species under the GOA groundfish FMP are regulated through permits, limited entry, catch quotas (TACs), seasons, in-season adjustments, gear restrictions, closed waters, bycatch limits and rates, allocations, regulatory areas, record keeping, reporting requirements and observer monitoring. GOA flatfish species or complexes are managed with area-specific ABC and TAC apportionments to avoid the potential for localized depletions.

Stock Assessment: The Northern and Southern Rock Sole stock assessments are based on Stock Synthesis models that use both length-structured and age-structured data. These models incorporate fishery data and fishery independent data from the NMFS trawl surveys. The Northern and Southern Rock Sole catch limits are set by a Tier 3a ABC/OFL control rule. The 2015 projected biomass is 287,534 mt. Catch specifications for 2015 are as follows; OFL=54,207 mt, ABC= 44,205 mt, TAC= 35,381 mt.

Survey biomass for all species in the shallow-water complex has declined from 2009 to 2013, except English Sole and Alaska Plaice, which have shown no trend. Northern Rock Sole survey biomass declined about 22% from 2009 to 2013, while Southern Rock Sole and Yellowfin Sole survey biomass declined about 31%.

Total catches, pre-season catch specifications and exploitable biomass of Shallow Water Flatfish* in the GOA, 1991-2015 (in mt).

*Separated from "Flounders" category 1990.
[1] Catch data through November 2014.
[2]Biomass from annual SAFE report projections.

Fishery: Since 1988 the majority of shallow-water flatfish harvest has occurred on the continental shelf and slope east of Kodiak Island in the Central regulatory area. Shallow-water flatfish are generally harvested with trawl gear. Rock sole is the predominant target species in the complex.

Economics: The bottom trawl fishery in the GOA primarily targets rock soles, Rex Sole and Dover Sole. Primary products include whole fish, H&G and fillets. Ex-vessel value of all flatfish caught in the GOA in 2013 was $8.6 million. The price per pound for GOA shallow water flatfish products averaged $0.98/lb for shoreside processors. A total of 31 catcher vessels and 5 catcher processors prosecuted the GOA flatfish fishery in 2013.

Butter Sole
Washington DFW

Deepwater Flatfish

Dover Sole
AFSC, NOAA Fisheries

Stock assessment:

C. McGilliard 2014. Assessment of Deepwater Flatfish stock in the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Biology: The GOA Deep-water flatfish complex is comprised of 3 flatfish species; Greenland Turbot *Reinhardtius hippoglossoides*, Dover Sole *Microstomus pacificus*, and Deep-Sea Sole *Embassichthys bathybius*. GOA Dover Sole constitutes the majority of the survey biomass and deep-water flatfish catch (generally over 98%). Dover sole move to deeper water as they age and older Dover sole migrate seasonally from deep water on the outer continental shelf and upper slope where spawning occurs to shallower water mid-shelf in summer time to feed. Dover Sole are especially adapted to feeding on small-detrital consuming invertebrates such as polychaetes, amphipods, mollusks, and brittle stars. Dover Sole are batch spawners, releasing around 83,000 advanced oocytes in about 9 batches per spawning season. The peak spawning period occurs from January through May. Female Dover Sole reach 50% maturity at 12-13 years of age. Dover Sole recruit to the fishery at 35 cm. The maximum age observed for Dover Sole in the GOA is 59 years. Greenland Turbot has a circumpolar distribution in the Atlantic and Pacific. Greenland Turbot are typically found from 200-1600 m. Biological data is limited for GOA Greenland Turbot and Deep-Sea Sole.

Catch History: Deep-water flatfish catches peaked in 1992 at 11,379 mt, and then declined in 1993, remaining fairly stable from 1993-1999 (average 2,800 mt). After 1999, catches declined, reaching a low of 225 mt in 2013.

Total catches, pre-season catch specifications, and exploitable biomass of Deep Water Flatfish* in the GOA, 1990-2015 (in mt).

2015		13,334	13,334	15,993	182,160

*Separated from "Flounders" category 1990.
[1] Catch data through November 2014.
[2] Biomass from annual SAFE report projections.

Stock Assessment: The Deep-water flatfish complex assessment uses a split-sex, age-structured model for Dover Sole and mean historical catch data from 1978-1995 for Greenland Turbot and Deep-Sea Sole. Dover Sole catch limits are set by a Tier 3a control rule, and Greenland Turbot and Deep-Sea Sole fall under Tier 6 due to highly variable survey biomass estimates. The 2015 projected Deepwater Flatfish biomass is 182,160 mt. Catch specifications for 2015 are as follows; OFL=15,993 mt, ABC= 13,334 mt, TAC= 13,334 mt.

Abundance estimates for Greenland Turbot and Deep-Sea Sole are highly uncertain. Dover sole survey biomass estimates have ranged from approximately 71,624 to 107,286 mt since 1990. Survey biomass estimates in the 1980s were low, but considered less reliable because survey methodology was different in those years.

Fishery: Deep-water flatfish are harvested with trawl gear. Dover Sole is the predominant target species in the complex.

Rex Sole
AFSC, NOAA Fisheries

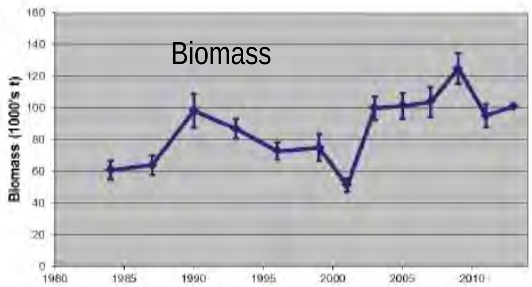
Stock assessment:

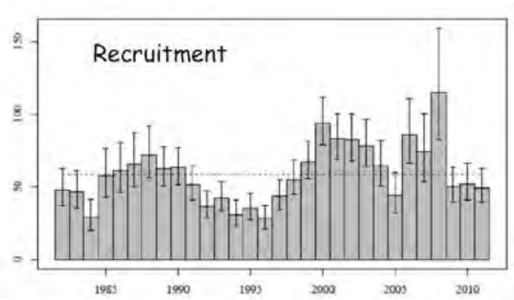
C. McGilliard 2014. Assessment of the Rex Sole stock in the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Biology: Rex Sole *Glyptocephalus zachirus* are distributed from Baja California to the BS, with concentrations in the GOA. Rex Sole closely associate with soft bottom benthic communities and are generally found at depths from less than 100 m to 800 m. Adult Rex Sole overwinter near the shelf margins and migrate onto the mid and outer continental shelf each year in April/May. Rex Sole exhibit latitudinal changes in growth rates and size at sexual maturity. Size at sexual maturity was greater for Rex Sole in the GOA than for those in Oregon. Rex Sole feed on polychaetes, euphausiids, amphipods and shrimp and are prey for skates, Spiny Dogfish, and Arrowtooth Flounder.

Recruitment to the fishery is estimated to occur at ages 8-10. Age at 50% maturity for females was estimated at 5.6 years (35.2 cm) in Alaska. Natural mortality is thought to be around M=0.17, and the oldest observed GOA Rex Sole was 27 years old. Rex Sole are batch spawners with a protracted spawning period in the GOA (peak spawning period occurs April/May).





Total catches, pre-season catch specifications, and exploitable biomass of Rex Sole* in the GOA, 1994-2015 (in mt).

*Separated from Deep Water Flatfish category 1994
[1]Catch data through November 2014.
[2]Biomass data corresponds to the annual SAFE report projections issued the preceding year.

Catch History: Prior to 1981, Rex Sole was caught incidentally in foreign fisheries targeting higher value species. Catches of Rex Sole have remained fairly stable since 1994, ranging from 1,464 mt in 2004 to a peak of 5,874 mt in 1996.

Stock Assessment: Rex Sole limits are set by a Tier 5 control rule. The 2015 projected biomass is 82,972 mt. Catch specifications for 2015 are as follows; OFL=11,957 mt, ABC= 9,150 mt, TAC= 9,150 mt. The ABC and TAC specifications are further subdivided among GOA subareas.

Fishery: GOA Rex Sole are caught using trawl gear in a directed fishery and fisheries targeting other species such as POP, Pacific Cod and Pollock. Fishing seasons are dictated by seasonal halibut PSC apportionments, with approximately 7 months of fishing occurring between January and November. Catches of Rex Sole occur primarily in the Central management area in the GOA.

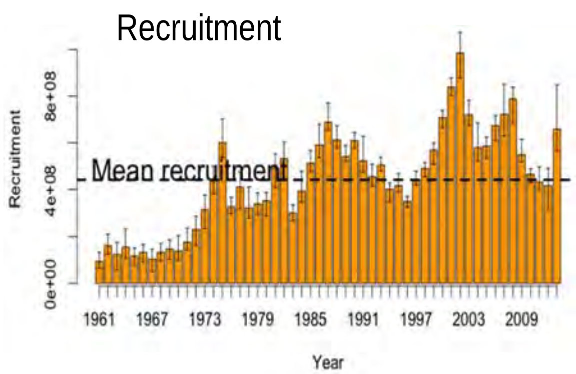
Arrowtooth Flounder
AFSC, NOAA Fisheries

Stock assessment:

I. Spies and B. Turnock. 2014. Assessment of Arrowtooth Flounder stock in the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Biology: Arrowtooth Flounder *Astheresthes stomias* are distributed from the Kamchatka Peninsula, through the BSAI down to central California. Arrowtooth Flounder are most abundant at depths from 100-500 m. Adults migrate seasonally from shelf margins in the winter to the inner and middle shelf in April/May with the onset of warmer waters temperatures. Smaller GOA Arrowtooth Flounder predate on euphausiids, capelin and herring while fish over 40 cm rely primarily on pollock. Predators of Arrowtooth Flounder include Pacific Cod, Pollock and skates



Arrowtooth Flounder recruitment to the fishery begins at about 3 years, and females are fully recruited by age 10. The estimated length at 50% maturity is 28 cm for males (4 years) and 37 cm for females (5 years) based on samples collected from Washington, and longevity extends to 21 years. Female natural mortality is estimated at M=0.2. Male natural mortality has a range estimate (M=0.27-0.36). Adult males range in size from 30-50 cm, and females range in size from 30-70 cm. The spawning period for Arrowtooth Flounder occurs from December to February at depths of 100-360 m. Spawning in the GOA occurs from Kodiak to Yakutat Bay.

Total catches, pre-season catch specifications, and exploitable biomass of Arrowtooth Flounder* in the GOA, 1990-2015 (in mt).

2015		103,300	192,921	226,390	1,957,970

*Separated from "Flounders" category 1990.
[1] Catch data through November 2014.
[2]Biomass from SAFE report projections.

Catch History: Prior to 1981, Arrowtooth Flounder was caught incidentally in foreign fisheries targeting higher value species. From 1991-2000, Arrowtooth Flounder catches ranged from 10,034 mt-22,583 mt, and have since increased with a 2014 catch of 35,026 mt.

Stock Assessment: The Arrowtooth Flounder assessment uses an automatic differentiation software developed as a set of libraries under C++ (AD Model Builder). This model incorporates fishery data and fishery independent data from NMFS and IPHC trawl surveys. Arrowtooth Flounder catch limits are set by a Tier 3a control rule. The 2015 projected biomass is 1,978,340 mt.

Arrowtooth Flounder biomass has increased steadily since the early 1990s. Estimated biomass averaged 1.7 million mt annually from 2000-2004 and about 2 million mt from 2004-2014.

Fishery: A directed fishery has recently developed in the GOA. In addition, Arrowtooth Flounder are an important byproduct of more valuable target trawl and longline fisheries, such as Pacific Cod and Pollock.

Flathead Sole
AFSC, NOAA Fisheries

Flathead Sole

Stock assessment:

C. McGilliard 2014. Assessment of Flathead Sole stock in the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Biology: Flathead Sole *Hippoglossoides elassodon* are distributed in the Kuril Islands, BS, GOA and south to California. Adult Flathead Sole exhibit a benthic lifestyle and overwinter near the shelf margins before migrating to the mid and outer continental shelf in April or May each year for feeding. They occur primarily on mixed mud and sand bottoms in depths less than 300 m. Pandalid shrimp and brittle stars are the most important prey for adult Flathead Sole in the GOA, while euphausiids and mysids constitute the most important prey items for juvenile Flathead Sole. Pacific Cod and Pacific Halibut are major predators on adults, while Arrowtooth Flounder, sculpins, Walleye Pollock and Pacific Cod are major predators on juveniles. However, 65% of adult mortality and 20% of juvenile mortality is unexplained.

Flathead Sole recruitment to the fishery is estimated to occur between the ages of 5 and 10, and longevity extends to 32 years. Estimated length at 50% maturity is 33 cm (8.7 years). Natural mortality is thought to be around M=0.20. Flathead Sole spawn in March and April, in deeper waters near the margins of the continental shelf, and feed on the mid- and outer-continental shelf in the summertime. Females release from 70,000-600,000 eggs.

Catch History: Flathead Sole catches increased from 452 mt in 1978 to 2,068 mt in 1980, and subsequently declined to a low of about 150 mt in 1986. After 1986, catches increased and reached a peak catch of 3,842 mt in 2010.

Stock Assessment: The Flathead Sole assessment uses a split-sex, age-based model with estimated age-based fishery and survey selectivity. This model incorporates fishery data and fishery independent data from triennial (1984-1999) and biennial (2001-2009) surveys. Flathead Sole catch limits are set by a Tier 3a control rule. Estimated Flathead Sole biomass is thought to have increased slowly and steadily since 1990.

Fishery: GOA Flathead Sole are caught using trawl gear in a directed fishery and fisheries targeting other species such as POP, Pacific Cod and Pollock. The majority of Flathead Sole in the GOA is taken in the Shelikof Strait and on Albatross Bank. About 90% of the catch is retained.

Total catches, pre-season catch specifications, and exploitable biomass of Flathead Sole* in the GOA, 1991-2015 (in mt).

Pacific Ocean Perch

Pacific Ocean Perch
AFSC, NOAA Fisheries

Biology: Pacific Ocean Perch (POP) *Sebastes alutus* distribution extends from Japan around the Pacific Rim, the BS and south to California. POP are most abundant in AI, GOA and British Columbia and are found primarily offshore along the continental slope at depths from 150-420 m. POP are generally considered a demersal species and are found over sandy and cobble substrate. Seasonal changes in depth distribution occur, and adults migrate farther offshore to deeper waters during winter. During late spring and summer, POP migrate to shallower waters inshore for summer feeding. Adults perform diel migrations off the sea floor to feed. POP populations occur in patchy aggregations, and POP are generally planktivorous. Smaller POP feed on calanoid copepods, whereas larger POP rely on euphausiids, shrimp and squids. POP are prey for Pacific Halibut, Sablefish, Pacific Cod and Arrowtooth Flounder.

SeaAlliance/AGDB

POP is a slow-growing, long lived species. Recruitment to trawl fisheries begins at age 5, and full recruitment to the fishery occurs around age 8. Females reach 50% maturity at 10.5 years in the GOA, and longevity extends to 80 plus years (oldest recorded 84 years in the GOA). Natural mortality is estimated to be M=0.06. Females are viviparous, retaining fertilized eggs within the ovary until larval extrusion. Mating takes place in late fall, and larval extrusion occurs in early spring. Females release from 10,000-300,000 larvae each year, depending on size.

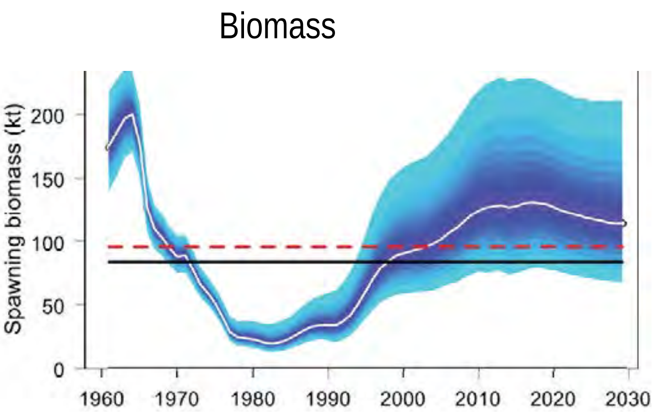
Stock assessment:

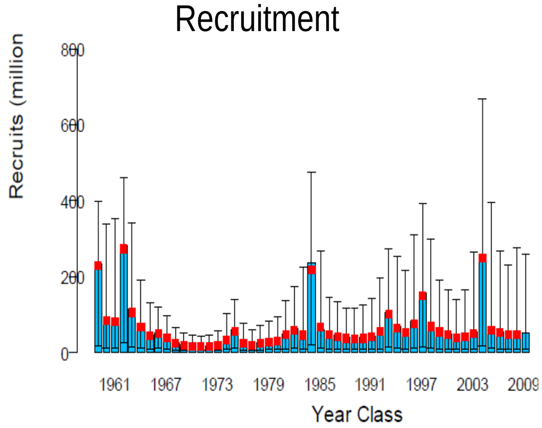
P-J. Hulson, D. Hanselman, S. K. Shotwell, C. Lunsford, and J. Ianelli 2014. Assessment of Pacific Ocean Perch stock in the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Catch History: POP was harvested in the GOA by the USSR and Japan beginning in the early 1960s. The fishery developed rapidly, and catches peaked in 1965 at 350,000 mt. High fishing effort by the foreign fleet caused a major decline in POP abundance/catches through the late 1960s. Catches continued to decline, and in 1985 foreign trawling in the GOA was prohibited.

The domestic fishery for POP in the GOA began in the early 1980s and expanded each year until 1991. POP catches remained relatively low through the 1990s, averaging 7,072 mt annually from 1991-2000. Catches have increased since 2000. The largest U.S. catch in the time series was in 2014 at 17,368 mt.





Fishery Management: In 1991, POP and the Shortraker/Rougheye complex were separated from the "Slope Rockfish" complex to prevent overfishing. A reduction in TACs after 1991 to promote POP stock rebuilding was also implemented. In 2004, Shortraker and Rougheye Rockfish were separated into their own management units due to disproportionally high harvests of Shortraker Rockfish. GOA rockfish stocks and complexes are managed with area-specific ABC and TAC apportionments to avoid the potential for localized depletions. Amendment 41, effective in 2000, prohibited trawling in the Eastern area east of 140°W longitude, an area previously fished for POP.

The Central GOA Rockfish Pilot Program, effective for 2007 through 2011, rationalized the rockfish and related trawl fisheries. The program provides cooperatives with exclusive catch shares (95% of the CGOA TAC) for target species of POP, Northern Rockfish, and pelagic shelf rockfish, as well as a allocated a portion of the TAC for suite of secondary species (Sablefish, cod, and thornyhead, Shortraker and Rougheye Rockfish), and a halibut prohibited species catch limit allocation. Cooperatives receive allocations based on catch history of cooperative member vessels. Sideboard limits for the target rockfish species are established in the Western GOA. A slightly revised program was adopted by the Council in 2010 for implementation in 2012.

Mark Fina, NPFMC

Total catches, pre-season catch specifications, and exploitable biomass of Pacific Ocean Perch* in the GOA, 1990-2015 (in mt).

2015		21,012	21,012	24,360	416,140

* Separated from Slope Rockfish in 1991.
1 Catch data through November 2014.
2 Biomass from annual SAFE report projections.

Stock Assessment: The POP assessment uses an age-structured model using AD Model Builder software. POP catch limits are set under Tier 3a OFL and ABC control rules. This model incorporates fishery data and fishery independent data from biennial trawl surveys. The 2015 projected biomass is 416,140 mt.

Estimated total biomass of POP was relatively low during the early 1990s, averaging 158,577 mt from 1991-1995. Since then, biomass has steadily increased from 211,160 mt in 2000 to 416,140 mt in 2015.

Fishery: POP are caught primarily in directed bottom trawl fisheries. The percentage of POP in the GOA taken in pelagic trawls increased from 2% in 1990 to 31% in 2008. The majority of POP are caught in the Central regulatory area, and TACs allocated for each area are generally met (except Southeastern area due to prohibited trawling).

Economics: In 2013, production was 12,300 mt for GOA rockfish products. Ex-vessel value of the rockfish catch in the GOA was $11.2 million.

Northern Rockfish

Northern Rockfish
AFSC, NOAA Fisheries

<u>Biology</u>: Northern Rockfish *Sebastes polyspinus* distribution extends from the Kamchatka Peninsula, through the BSAI, GOA and British Columbia. The species is most abundant in the central GOA to the western end of the AI. Adults concentrate at discrete sites along the outer continental shelf from 75-150 m. Northern Rockfish are demersal and are generally found in aggregations with patchy distributions. Northern Rockfish prey on calanoid copepods, euphausiids and chaetognaths. Based on stomach content data, Pacific Halibut and Sablefish likely prey on Northern Rockfish.

Northern Rockfish is a slow-growing, long-lived species. Age at 50% maturity is 12.8 years in the GOA, and longevity extends to 50 years (oldest recorded 67 in the GOA). GOA Northern Rockfish grow faster and reach a larger maximum length than the AI Northern Rockfish. Natural mortality is estimated to be M=0.06. Females are viviparous, retaining their fertilized eggs within the ovary until larval extrusion.

Stock assessment:

P-J. Hulson, C. Lunsford, J. Heifitz, D. Hanselman, K. Shotwell, and J. Ianelli. 2014. Assessment of Northern Rockfish stock in the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

<u>Catch History</u>: Northern Rockfish were initially harvested by Soviet and Japanese trawlers in the early 1960s. Foreign fishing effort increased quickly in the 1960s, and catches of rockfish in the GOA peaked in 1965 at 350,000 mt. It is likely that GOA Northern Rockfish comprised some portion of the early foreign catch (exact Northern Rockfish catch unknown for this period). Northern Rockfish was separated from the slope rockfish assemblage in 1993, and catches have remained fairly stable since 1994, ranging from a low of 2,947 mt in 1997 to a high of 5,968 in 1994 (average annual catch equals 4,262 mt from 1994-2009).

<u>Stock Assessment</u>: The Northern Rockfish assessment uses a separable, age-structured model using AD Model Builder software. This model incorporates fishery data and fishery independent data from biennial trawl surveys. Northern Rockfish catch limits are set under Tier 3a of the ABC/OFL control rules. The 2014 projected biomass is 102,893 mt.

Total catches, pre-season catch specifications, and exploitable biomass of Northern Rockfish* in the GOA, 1993-2015 (in mt).

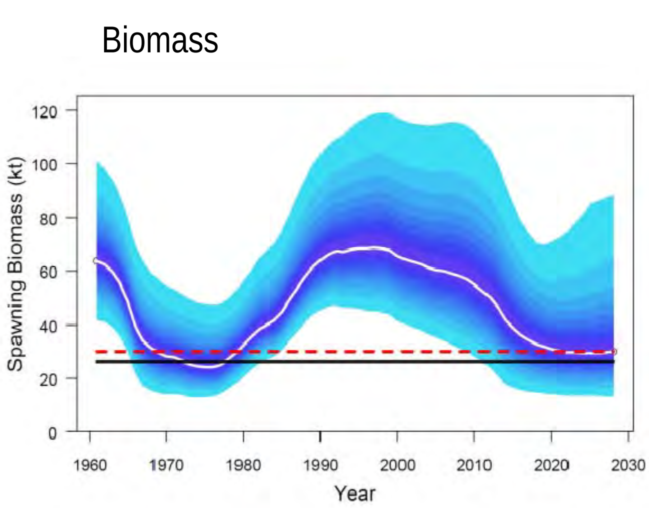
Separated from Other Slope Rockfish category 1993.
[1]Catch data through November 2014.
[2]Biomass from annual SAFE report projections.

<u>Fishery</u>: Northern Rockfish are fully allocated as a target species in the CGOA trawl rockfish program, with 95-98% of the CGOA TAC and sideboarded at 74.3% of the WGOA TAC.



Shortraker Rockfish

Shortraker Rockfish
AFSC, NOAA Fisheries

Stock assessment:

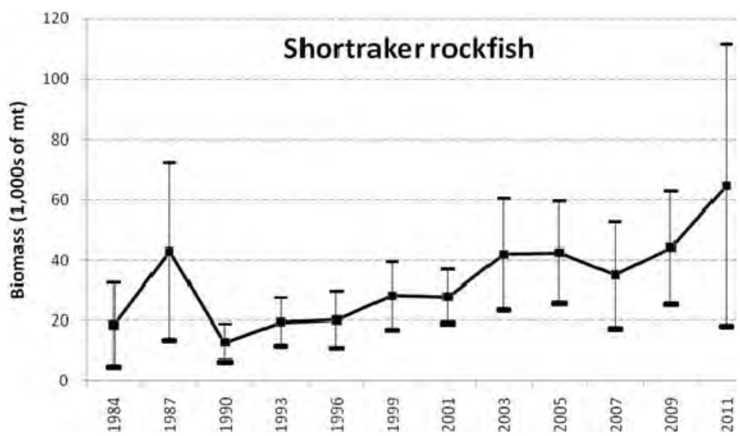
K. Echave and S. K. Shotwell 2014. Assessment of Shortraker Rockfish and "Other Slope Rockfish" stocks in the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Biology: Shortraker Rockfish *Sebastes borealis* are distributed from Japan around the Pacific Rim to Southern California, including the BSAI and the GOA. In Alaska, adults are especially concentrated along the continental slope in the 300-500 m depth interval. Shortraker Rockfish prey on shrimps, squids, and myctophids. Shortrakers attain the largest size of all *Sebastes*, with a maximum reported length of 120 cm. Shortraker Rockfish is one of the most long-lived species in the northeast Pacific, and longevity may exceed 120 years. Natural mortality is estimated to be M=0.03. Information on early life history stages of Shortraker Rockfish is limited.

Catch History: From 1991 to 2004, the NPFMC managed Shortraker Rockfish in the GOA together with Rougheye Rockfish as an assemblage. Combined catches for the two species ranged from 702 to 2,250 mt, averaging 1,617 mt annually. Shortraker was separated into a single species management unit in 2005, and catches of Shortraker Rockfish averaged 584 mt annually from 2005-2009.

Biomass



Stock Assessment: Due to limited biological data, the Shortraker Rockfish assessment uses a biomass-based approach for calculating ABCs, incorporating fishery independent data from trawl surveys. Shortraker Rockfish catch limits are set under Tier 5 ABC/OFL control rules. The 2015 projected biomass is 58,797 mt.

Total catches, pre-season catch specifications, and exploitable biomass of Shortraker Rockfish* in the GOA, 2005-2015 (in mt).

Year	Catch[1]	TAC	ABC	OFL	Biomass[2]
2005	498	753	753	982	32,723
2006	664	843	843	1,124	37,461
2007	608	843	843	1,124	37,461
2008	598	898	898	1,197	39,905
2009	550	898	898	1,197	39,905
2010	457	914	914	1,219	40,626
2011	546	914	914	1,219	40,626
2012	728	1,081	1,081	1,441	48,048
2013	730	1,081	1,081	1,441	48,048
2014	649	1,323	1,323	1,764	58,797
2015		1,323	1,323	1,764	58,797

Separated from Slope Rockfish in 1991 and Shortraker/Rougheye in 2004.
[1]Catch data through November 2014.
[2]Biomass from annual SAFE report projections.

Fishery: Shortraker Rockfish in the GOA are taken in both longline and trawl fisheries; each gear comprises about 50% of the annual catch. Shortrakers in the CGOA are allocated as a secondary species in the CGOA rockfish program. A total of 40% of the CGOA Shortraker TAC is allocated to the catcher processor sector.

Other Rockfish

Sharpchin Rockfish
AFSC, NOAA Fisheries

Stock assessment:

C. Tribuzio and K. Echave 2014. Assessment of "Other Rockfish" stock complex in the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Biology: The Other Rockfish complex consists of 25 rockfish species, although Sharpchin, Harlequin, Silvergray, Redstripe, and Redbanded Rockfish comprise the majority of the biomass in the GOA. The center of abundance for most of these species is farther south off British Columbia or the U.S. west coast. However, Harlequin Rockfish are most common in Alaskan waters, and Silvergray Rockfish appear to be most abundant in southeast Alaska and British Columbia. Within the GOA, Other Rockfish are most abundant in the eastern GOA and become increasingly scarce in areas farther west.

Blackgill Rockfish	*Sebastes melanostomus*
Bocaccio	*Sebastes paucispinis*
Canary Rockfish	*Sebastes pinniger*
Chilipepper	*Sebastes goodei*
China Rockfish	*Sebastes nebulosus*
Copper Rockfish	*Sebastes caurinus*
Darkblotched Rockfish	*Sebastes crameri*
Greenstriped Rockfish	*Sebastes elongatus*
Harlequin Rockfish	*Sebastes variegatus*
Northern Rockfish	*Sebastes polyspinis*
Pygmy Rockfish	*Sebastes wilsoni*
Quillback Rockfish	*Sebastes maliger*
Redbanded Rockfish	*Sebastes babcocki*
Redstripe Rockfish	*Sebastes proriger*
Rosethorn Rockfish	*S. helvomaculatus*
Sharpchin Rockfish	*Sebastes zacentrus*
Silvergray Rockfish	*Sebastes brevispinis*
Splitnose Rockfish	*Sebastes diploproa*
Stripetail Rockfish	*Sebastes saxicola*
Tiger Rockfish	*Sebastes nigrocinctus*
Vermilion Rockfish	*Sebastes miniatus*
Widow Rockfish	*Sebastes entomelas*
Yelloweye Rockfish	*Sebastes ruberrimus*
Yellowmouth Rockfish	*Sebastes reedi*
Yellowtail Rockfish	*Sebastes flavidus*

Life history data is limited for most Other Rockfish species. For Sharpchin Rockfish, size at 50% maturity is 26.5 cm (10 years). Natural mortality is estimated to be M=0.05 for Sharpchin and Silvergray Rockfish, M=0.10 for Redstripe Rockfish, and M=0.06 for harlequin and Redbanded Rockfish and all the minor species in the group.

Catch History: In 2012, additional species were added to the Other Rockfish complex including the former pelagic shelf rockfish species (not Dusky Rockfish), and the demersal shelf rockfish complex not in the Eastern Gulf. The current catch is a combination of former Other Slope and Pelagic Shelf Rockfish catches, and catch estimates of non-eastern GOA Demersal Shelf Rockfish. Since the mid-1990s, catches for Other Rockfish in the GOA have generally been less than 1,000 mt. The EGOA trawl closure that has been in effect since 1998 has limited the catch of Other Rockfish in the GOA.

Total catches, pre-season catch specifications, and exploitable biomass of Other Rockfish in the GOA, 1993-2015 (in mt).

Year	Catch[1]	TAC	ABC	OFL	Biomass[2]

2015		1,811	4,080	5,347	83,383

[1] Catch data through November 2014.
[2] Biomass from annual SAFE report projections.

Stock Assessment: Other Rockfish are managed under Tier 5 (Sharpchin Rockfish are managed under Tier 4). The 2015 projected biomass is 83,383 mt.

Fishery: There is no directed fishery for Other Rockfish in the GOA. Other Rockfish in the GOA are taken in trawl fisheries targeting higher value species.

Dusky Rockfish
AFSC, NOAA Fisheries

Dusky Rockfish

Biology: Dusky Rockfish *Sebastes variabilis* is an abundant species in the GOA. Adult Dusky Rockfish are concentrated around offshore banks and near gullies on the outer continental shelf at depths of 100 to 200 m. It is likely that Dusky Rockfish benthic distribution is associated with hard, rocky bottoms and epibenthic habitats. Dusky Rockfish prey on Pacific Sandlance and euphausiids. Dusky Rockfish age at 50% maturity is approximately 11.3 years. Mortality is estimated to be M=0.07, and longevity extends to 60 years. Dusky Rockfish are ovoviviparous with fertilization, embryonic development, and larval hatching occurring inside the mother. Parturition is believed to occur in the spring in the GOA.

Stock assessment:

C. Lunsford, S. K. Shotwell, P-J. Hulson, and D. Hanselman. 2014. Assessment of Dusky Rockfish in the Gulf of Alaska.

Catch History: Dusky Rockfish catch in the GOA generally increased after the rockfish management groups were first separated in 1988. Catches have remained fairly stable since 1994 and peaked in 1999 at 4,826 mt.

Stock Assessment: In 2012, Dusky Rockfish became a separate management category. Dusky Rockfish were formally grouped with Yellowtail Rockfish *S. flavidus* and Widow Rockfish *S. entomelas* in the Pelagic Shelf Rockfish stock complex. Since 2012, Yellowtail and Widow Rockfish have been managed in the Other Rockfish category. Dusky Rockfish are managed under Tier 3 of the ABC/OFL control rules. The 2015 projected biomass is 66,629 mt.

Fishery: In the CGOA, 95% of the Dusky Rockfish TAC is allocated to the CGOA Rockfish program. Catches of Dusky Rockfish are concentrated at a number of offshore banks of the outer continental shelf, west of Yakutat and around Kodiak in areas such as Portlock Bank and Albatross Bank.

Total catches, pre-season catch specifications, and exploitable biomass of Dusky Rockfish* in the GOA, 1988-2015 (in mt).

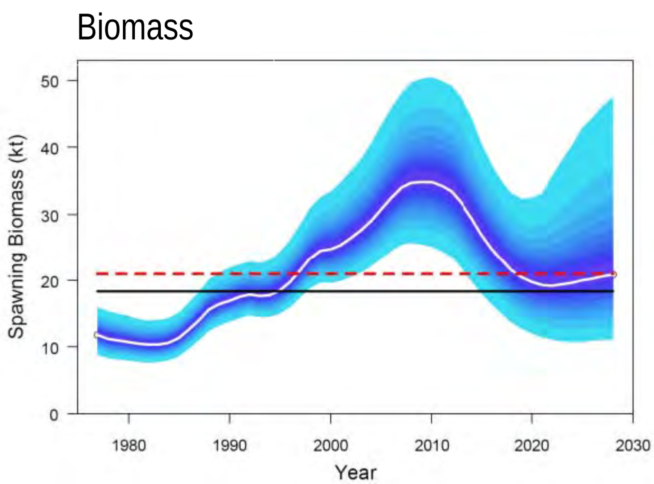
*Separated from Other Rockfish 1988. Dusky only since 2012.
[1]Catch data through November 2014.
[2]Biomass from annual SAFE report projections.



Rougheye and Blackspotted Rockfish

Blackspotted Rockfish
AFSC, NOAA Fisheries

Biology: The Rougheye and Blackspotted Rockfish (RE/BS) complex consists of 2 species; Rougheye Rockfish *Sebastes aleutianus* and Blackspotted Rockfish *Sebastes melanostictus*, recently identified by genetic research as distinct from Rougheye. The species are often difficult to differentiate from each other at sea. RE/BS distribution extends from Japan, through the BSAI, GOA to southern California. Adults primarily inhabit a narrow band along the upper continental slope at depths from 300-500 m. Although the two species distributions overlap, Blackspotted Rockfish are predominant in the AI, while Rougheye Rockfish are more common in the GOA and southeastern BS.

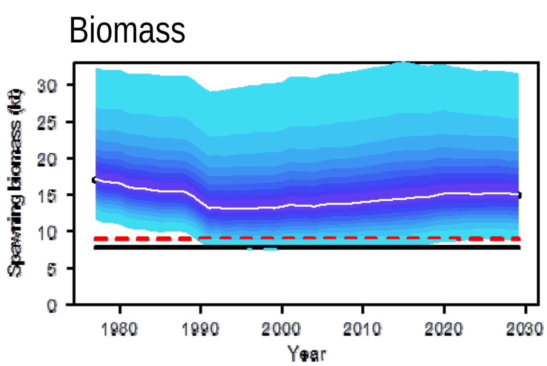
Rougheye Rockfish length at 50% maturity is 44 cm, and longevity may extend to 200 years. Natural mortality for RE/BS is estimated to be M=0.03. As with other rockfish, RE/BS are presumed to be viviparous. RE/BS Rockfish prey on pandalid shrimps, euphausiids, lanternfishes, and crabs. Predators of RE/BS include Pacific Halibut, Pacific Cod and Sablefish.

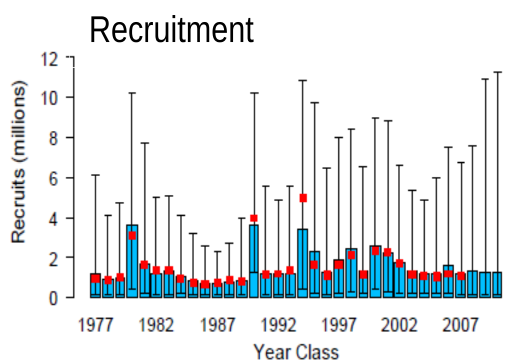
Stock assessment:

S. K. Shotwell, D. Hanselman, P. Hulson, and J. Heifetz. 2014. Assessment of Rougheye and Blockspotted Rockfish stock in the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Catch History: Gulf- wide catches of the Rougheye Rockfish and Blackspotted Rockfish ranged from 130-2,418 mt. from 1977-1990. RE/BS Rockfish are generally caught with either bottom trawls or longline gear. RE/BS Rockfish have been managed as a "bycatch" only species since the creation of the Shortraker/Rougheye Rockfish management subgroup in the Gulf of Alaska in 1991. RE/BS Rockfish were separated into their own management unit in 2004, and catches of RE/BS Rockfish averaged 345 mt annually from 2005- 2009.





Total catches, pre-season catch specifications, and exploitable biomass of Rougheye and Blackspotted Rockfish* in the GOA, 2005-2015 (in mt).

Year	Catch[1]	TAC	ABC	OFL	Biomass[2]

2015		1,122	1,122	1,345	36,584

*Separated from Slope Rockfish in 1991 and Shortraker/Rougheye Rockfish in 2004.
[1]Catch data through November 2014.
[2]Biomass from annual SAFE report projections.

Stock Assessment: The RE/BS Rockfish assessment uses a separable age-structured model that incorporates fishery data and fishery independent data from biennial trawl and annual longline surveys. RE/BS Rockfish limits are set by a Tier 3a control rule.

Fishery: RE/BS Rockfish in the GOA are primarily taken in rockfish bottom trawl fisheries and longline fisheries targeting Sablefish and Pacific Halibut.

Rougheye Rockfish
AFSC, NOAA Fisheries

Yelloweye Rockfish
ADF&G

Demersal Shelf Rockfish

<u>ology</u>: The Demersal Shelf Rockfish (DSR) complex consists of 7 species and are a management unit in the Southeast Outside area only (east of 140 W longitude). Elsewhere in the Gulf of Alaska, these species are managed as part of the "Other rockfish" complex.

Canary Rockfish	*Sebastes pinniger*
China Rockfish	*Sebastes nebulosus*
Copper Rockfish	*Sebastes caurimus*
Quillback Rockfish	*Sebastes maliger*
Rosethorn Rockfish	*Sebastes helvomaculatus*
Tiger Rockfish	*Sebastes nigrocinctus*
Yelloweye Rockfish	*Sebastes ruberrimus*

DSR are generally nearshore, bottom-dwelling species, located on the continental shelf and associated with rugged, rocky habitat. DSR species exhibit K-selected life history traits including slow growth and extreme longevity. DSR are viviparous, and parturition occurs from February through September with the majority of the species extruding larvae in spring.

Stock assessment:

K. Green and K. Van Kirk. 2014. Assessment of the Demersal Shelf Rockfish stock in the SEO District of the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

The primary species of the fishery is Yelloweye Rockfish. The oldest recorded Yelloweye Rockfish is 118 years, and natural mortality is estimated at M=0.02. Yelloweye reach a maximum length of about 91 cm with the length at 50% maturity at 45 cm (18 years). Yelloweye feed on shrimp, small crabs and a variety of fishes including small rockfish, herring and sandlance. Yelloweye are in turn prey for larger rockfish, lingcod, salmon and Pacific Halibut.

<u>Catch History</u>: The directed fishery for DSR began in 1979 as a small, shore-based, hook and line in Southeast Alaska, which targeted the entire DSR complex. Total DSR catch increased from 120 mt in 1982 to a peak of 778 mt in 1987.

Exploitable biomass, pre-season catch specifications, and total catches (including discards) of Demersal Shelf Rockfish* in the Southeast Outside sub-district of the GOA, 1992-2015 (in mt).

Year	Catch[1]	TAC	ABC	OFL	Biomass[2]

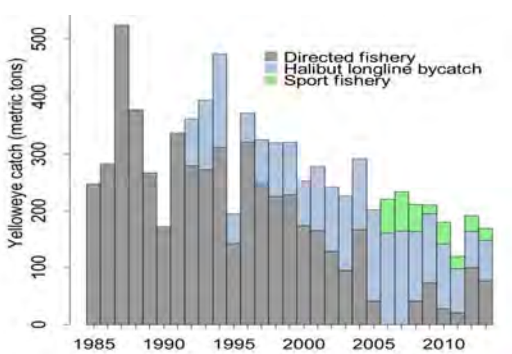
2014	104	274	274	438	13,274
2015		225	225	361	10,933

*Separated from Rockfish in 1991.
[1] Catch data through November 2014.
[2]Biomass from annual SAFE report projections.

<u>Fishery Management:</u> DSR are managed jointly by ADF&G and NMFS. Directed fishery quotas are set by management area and are based on the remaining ABC after subtracting the estimated DSR incidental catch (landed and at sea discard) in other fisheries. If there is sufficient directed quota available for DSR to hold a fishery, then this will be opened in late January and will be closed prior to the start of the halibut season in March.

<u>Stock Assessment</u>: Yelloweye Rockfish biomass is estimated from submersible transect density and area estimates of DSR habitat. DSR catch limits managed as a Tier 4 species, but the catch limits are set below maximum permissible by setting F=M.

<u>Fishery:</u> The directed fishery for DSR is almost entirely prosecuted by longline gear.



Thornyhead Rockfish

Shortspine Thornyhead
AFSC, NOAA Fisheries

Stock assessment:

S. K. Shotwell, J. Ianelli, and J. Heifetz. 2014. Assessment of the Thornyhead Stock Complex in the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Biology: The Thornyhead Rockfish Complex consists of 3 species; Shortspine *Sebastolobus alascanus*, Longspine *Sebastolobus altivelis,* and Broadfin *Sebastolobus macrochir* Thornyheads. Thornyheads are distinguished from "true" rockfish (*Sebastes*) due to their reproductive biology. Whereas *Sebastes spp*. rockfish are viviparous, thornyheads are oviparous, releasing fertilized eggs in floating gelatinous masses. Thornyheads are also differentiated from *Sebastes spp.* in lacking a swim bladder.

NOAA Fisheries Service

Shortspine Thornyheads are distributed in deep-water habitats throughout the North Pacific, and are concentrated between 150-450 m in the cooler, northern part of their range and are generally found in deeper habitats up to 1000 m in the warmer waters of their southern range. Females reach 50% maturity at about 22 cm, and longevity extends to 100 years or more. Natural mortality is estimated to be M=0.03. Shortspine Thornyheads feed on shrimps, crabs, zooplankton and amphipods and are in turn prey for Arrowtooth Flounder, Sablefish, sperm whales and sharks. Longspine Thornyheads are found only in the eastern North Pacific, around the Shumagin Islands, GOA and south to California. Longspines are generally found in deeper habitats from 200-1,750 m.

Catch History: The greatest reported harvest of Thornyheads in the GOA occurred from 1979-1983. Catches declined in 1984 and 1985 due to U.S. management restrictions and a transition to domestic fisheries. U.S. catches continued to increase through 1989, peaking at 3,055 mt.

Total catches, pre-season catch specifications, and exploitable biomass of age 5+ Thornyhead Rockfish* in GOA, 1992-2015 (mt).

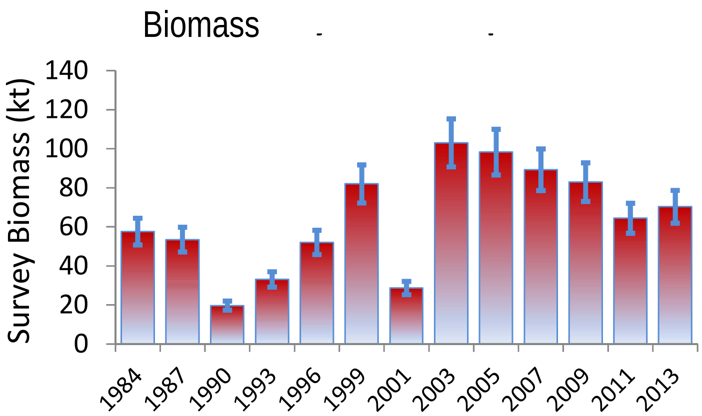
2015		1,841	1,841	2,454	81,816

* includes Longspine and Shortspine Thornyheads.
[1]Catch data through November 2014.
[2]TAC, ABC and OFL from annual Federal Register.

Stock Assessment: Thornyhead rockfish catch limits are set using a Tier 5 control rule. The 2015 projected biomass is 81,816 mt. Catch specifications for 2015 are as follows; OFL=2,454 mt, ABC= 1,841 mt, TAC= 1,841 mt.

Fishery: Thornyheads are caught by bottom trawl as a secondary target species in the CGOA Rockfish program and are also taken incidentally in the Sablefish longline fishery. Thornyheads are a valuable rockfish species, and most of the domestic harvest is exported to Japan.



Atka Mackerel

Atka Mackerel
AFSC, NOAA Fisheries

Biology: Atka Mackerel *Pleurogrammus monopterygius* are distributed along the continental shelf. Atka Mackerel is a schooling, semi-demersal species most commonly found in the AI, but also in the Western and Central GOA. Adult Atka Mackerel occur in large localized aggregations at depths less than 200 m over rough, uneven bottom areas with high tidal currents. Atka Mackerel feed on euphausiids and copepods and are prey for Pacific Cod, Arrowtooth Flounder, Stellar sea lions, and seabirds.

Atka Mackerel begin to recruit to the fishery at age 3 and longevity can extend to 15 years. Females reach 50% maturity at 38.2 cm (3.6 years). Natural mortality is estimated at M=0.30. Atka Mackerel is a substrate-spawning fish with male parental care. Behavioral studies have shown that the Atka Mackerel mating system is very complex. A significant characteristic is the bright and distinct coloration developed by territorial males during the spawning season. Spawning occurs from July to October, peaking in early September. Atka Mackerel have relative low fecundity, with females releasing around 30,000 eggs each year. Eggs are adhesive and deposited in rock crevices in nests guarded by males until hatching, which occurs about 40-45 days later.

Jackie Patt, UAF

Stock assessment:

S. Lowe. 2014. Assessment of Atka Mackerel stock in the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Catch History: Atka Mackerel supported a targeted foreign fishery (primarily Soviet vessels) in the Central GOA during the 1970s and 1980s. Catches peaked in 1975 at about 27,000 mt then declined dramatically to less than 5 mt in 1986. Joint venture operations participated in the Atka Mackerel fishery from 1983-1985, and the fishery was fully domestic by 1986.

Total catches, and pre-season catch specifications of Atka Mackerel* in the GOA, 1994-2015 (in mt).

2013	1,277	2,000	4,700	6,200
2014	981	2,000	4,700	6,200
2015		2,000	4,700	6,200

*Added to Other Species category in 1988 and separated from Other Species in 1994.
[1]Catch data through November 2014.

Fishery Management:. In 1988, Atka Mackerel were combined with the Other Species category due to low abundance. In 1994, Atka Mackerel were removed from the Other Species category and treated once again as a single species target stock. There has not been a directed Atka Mackerel fishery in the GOA since 1996.

Stock Assessment: The existing GOA bottom trawl survey data has limited utility for either absolute abundance estimates or indices for Atka Mackerel. Atka Mackerel fall under the Tier 6 control rule. The 2015 catch specifications for Atka Mackerel are as follows; OFL=6,200 mt, ABC=4,700 mt, TAC=2,000 mt.

Fishery: Atka Mackerel has been a “bycatch” only fishery in the GOA since 1996.

Ecosystem Components: Because Atka Mackerel is a common prey item for Steller sea lions, all directed fishing for Atka Mackerel is prohibited in the GOA.

Jackie Patt, UAF

Big Skates, Longnose Skates, Other Skates

Stock assessment:

O. Ormseth. 2014. Assessment of the skate stock complex in the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Biology: The GOA Skate complex is comprised of at least 15 skate species. Big Skate and Longnose Skate dominate the skate biomass in the GOA. *Bathyraja sp*. compose about a third of total GOA skate biomass, with the majority of these being the Aleutian Skate and Bering Skate. Skate biomass is concentrated in the Central GOA. Skates feed on bottom invertebrates, such as crustaceans, mollusks and polychaetes and fish. Skates are prey for sharks, Steller sea lions and sperm whales.

The highest biomass of skates in the GOA is found in continental shelf waters less than 100 m deep, and is dominated by the Big Skate. In continental shelf waters from 100-200 m depth, Longnose Skate dominates skate biomass, and *Bathyraja* skate species are dominant in the deeper waters extending from 200 to 1000 m or more in depth. Big and Longnose Skate are generally found in shallower waters in the GOA, and their distribution extends from the Bering Sea to southern Baja California. The Aleutian Skate ranges throughout the north Pacific from northern Japan to northern California and has been found at depths between 16-1602 m. The Alaska Skate is restricted to higher latitudes from the Sea of Okhotsk to the eastern GOA at depths from 17-392 m.

Big Skate	*Beringraja binoculata*
Longnose Skate	*Raja rhina*
Other skates	
Aleutian Skate	*Bathyraja aleutica*
Bering Skate	*Bathyraja interrrupta*
Alaska Skate	*Bathyraja parmifera*
Deepsea Skate	*Bathyraja abyssicola*
Commander Skate	*Bathyraja lindbergi*
Whiteblotched Skate	*Bathyraja maculata*
Butterfly Skate	*Bathyraja mariposa*
Whitebrow Skate	*Bathyraja minispinosa*
Leopard Skate	*Bathyraja pamifera sp.*
Mud Skate	*Bathyraja taranetzi*
Roughtail Skate	*Bathyraja trachura*
Okhotsk Skate	*Bathyraja violacea*
Roughshoulder Skate	*Bathyraja badia*

Big Skate
Megan Peterson, UAF

Skates are generally K-selected, with slow-growth, low fecundity and relatively large body size. Skates are oviparous; fertilization is internal, and eggs are deposited in horny cases for incubation. There are 1-7 embryos per egg case in locally occurring *Raja sp*., but little is known about the frequency of breeding or egg deposition for any of the local species. It is estimated that annual fecundity per females may be less than 50 eggs per year. The Big Skate is the largest skate in the GOA, with maximum sizes observed over 200 cm in the directed fishery in 2003. Observed sizes for the Longnose Skate range from 165-170 cm. The maximum observed lengths for *Bathyraja* species from bottom trawl surveys of the GOA range from 86-154 cm. Life history parameter data are limited for GOA skates. The AFSC Age and Growth Program has recently reported a maximum observed age of 25 years for the Longnose Skate in the GOA and a maximum observed age for GOA Big Skate of 15 years.

Catch History: Skates were caught as a bycatch only species in the GOA at about 1,000-2,000 mt per year from 1992-1995, principally by the longline Pacific Cod and bottom trawl pollock and flatfish fisheries. Most skates during this time period were not retained. A directed skate fishery developed in the GOA in 2003 due to an increase in the ex-vessel value of skates. The skate fishery was prosecuted generally by longline vessels less than 60 feet around Kodiak Island. Lower ex-vessel prices and a possible reduction in skate catch-per-unit effort resulted in a sharp decline in skate catches in 2004-2005.

Directed fishing for skates in the GOA has been prohibited since 2005. Annual average catches of Big Skate, Longnose Skate and other skates from 2005- 2014 have averaged 1,811 mt, 1,150 mt, and 1,280 mt respectively. Catches are highest in the central GOA regulatory area.

Fishery Management: Since the beginning of domestic fishing in the late 1980s through 2003, all species of skates in the GOA were managed under the Other Species FMP category (skates, sharks, squids, sculpins, and octopuses). Catch limits were determined for all Other Species as 5% of the sum of the TACs for GOA target species. Under Amendment 63 in 2003, GOA skates were removed from the Other Species category in 2004 for separate management in response to a developing fishery. Big and Longnose Skate were managed together under a single TAC in the Central GOA. The remaining skates were managed as an “Other Skates” species complex in the Central GOA, and all skates were managed as an “Other Skates” species complex in the Western and Eastern GOA.

In 2005, Big Skate and Longnose Skate were separated into single species management groups due to concerns about disproportionate harvests. The remaining skates (genus *Bathyraja*) continue to be managed as a gulf-wide species complex because they were not the targets of the fishery and are more difficult to identify. There has been no directed fishing for skates in the GOA since 2005.

Stock Assessment: The Skates stock assessment used estimated biomass data from NMFS summer bottom trawl surveys from 2003-fwd. Skates are managed under Tier 5 of the ABC/OFL control rule, based on an overall natural mortality rate of 0.10 applied to survey biomass estimates for each species group. Gulf wide catch specifications (mt) for 2015 are as follows.

	2015 Biomass	OFL	ABC	TAC	2014 Catch
Big Skate	43,398	4,340	3,225	3,225	1,379
Longnose Skate	42,911	4,291	3,218	3,218	1,148
Other skates	29,797	2,980	2,235	2,235	1,559

Note that the ABC and TAC are further broken out into Western, Central, and Eastern Gulf of Alaska for Big Skate and Longnose skate.

Fishery: GOA Skates have been a bycatch only fishery since 2005. Skates are generally caught as bycatch in Pacific Halibut and Pacific Cod longline fisheries and flatfish trawl fisheries, especially in the GOA Central regulatory area. The incidental catch of Big Skate in the Central area has the potential to constrain fisheries.

Ecosystem Components: Skates have few natural predators. In the GOA, skate predators include marine mammals such as Steller sea lions and sperm whales (which may consume adult or juvenile skates), and Spiny Dogfish (which likely consume juvenile skates).

Spiny Dogfish
AFSC, NOAA Fisheries

Sharks

Stock assessment:

C. Tribuzio, P. Hulson, K. Echave, and C. Rodgeveller. 2014. Assessment of the shark stock complex in the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Biology: The GOA Shark complex is composed of 8 shark species. The most abundant species in the GOA are the Spiny Dogfish, the Salmon Shark and the Pacific Sleeper Shark. GOA sharks exhibit K-selected life history traits including slow growth to maturity, low fecundity and large size. Spiny dogfish, Pacific sleeper shark and Salmon Sharks reproduce through aplacental vivipary. Shark diets vary with species and in general sharks are opportunistic feeders, but forage fish, crustaceans, squid and salmon are among the most common prey items.

Spiny dogfish	*Squalus acanthias*
Salmon shark	*Lamna ditropis*
Pacific sleeper shark	*Somniosus pacificus*
Brown cat shark	*Apristurus brunneus*
White shark	*Carcharodon carcharias*
Basking shark	*Cetorhinus maximus*
Sixgill shark	*Hexanchus griseus*
Blue shark	*Prionace glauca*

Spiny Dogfish are distributed from California to Alaska, through the Aleutian chain to the Asian coast and south to Japan. Spiny Dogfish are found at depths ranging from the intertidal to 900 m. Spiny Dogfish growth rates are among the slowest of all shark species. Estimates of Spiny Dogfish age-at-50%-maturity are 20 years for males to 34 years for females. Longevity is estimated to reach between 80 and 100 years. Natural mortality is estimated at M=0.097. Spiny Dogfish have one of the longest known gestation periods, approximately 18-24 months.

Spiny Dogfish, Mark Fina, NPFMC

Pacific Sleeper Sharks are found along the North Pacific continental shelf and slope, ranging from Japan to the Bering Sea. Distribution extends as far north as the Chukchi Sea and as far south as Baja California. At higher latitudes, Pacific Sleeper Sharks are found shallower from littoral zones to surface waters. At lower latitudes, they reside much deeper and down to 2000 m. Pacific Sleeper Sharks make extensive, nearly continuous vertical movements. The maximum lengths of captured Pacific Sleeper Sharks are 440 cm for females and 400 cm for males. Pacific Sleeper Sharks 150-250 cm in length are most common in Alaska. Pacific Sleeper Shark age and reproduction data are limited.

Salmon Shark, Ken Goldman, ADF&G

Salmon Shark distribution in the northern Pacific extends from Japan into the Sea of Okhotsk to the Bering Sea and possibly south as far as Baja California Mexico. Salmon Sharks live in areas with sea-surface temperatures between 5˚C and 18˚C and in depths up to 150 m. However, Salmon Sharks are primarily found in waters less than 50 m deep. While some Salmon Sharks migrate south during the winter months, others remain in the GOA throughout the year. Longevity estimates for Salmon Sharks are between 20-30 years with maturity occurring at 3-5 years for males and 6-9 years for females. Natural mortality is estimated at M=0.18.

Catch History: There are currently no directed commercial fisheries for shark species in federal or state managed waters of the GOA, and most incidentally caught sharks are not retained. A small number of Spiny Dogfish landings in Kodiak were reported in 2004, 2005 and 2007 (approximately 1 mt each year). Spiny Dogfish and Salmon Sharks are also caught in recreational fisheries in the GOA. Estimates of historic catches of sharks range from 308 mt in 1995 to a peak of 2,390 mt in 1998. Catches annually averaged 895 mt from 1992-1999 and 982 mt from 2000-2014.

Spiny dogfish, Cindy Tribuzio, AFSC, NOAA Fisheries

Total catches, and pre-season catch specifications of Sharks* in the GOA, 1994-2015 (in mt).

2015		5,989	5,989	7,986

*Split from Other Species in 2011.
[1]Catch data through November 2014.

Fishery Management: Until 2011, sharks were managed under the Other Species FMP category (sharks, squids, sculpins, and octopuses). Beginning in 2011, sharks have been managed in a separate complex.

Stock Assessment: Catch specifications for sharks are based on Tier 6. A Tier 5-like method is used for dogfish sharks, with natural mortality (M=0.097) applied to biomass estimate (79,257 mt). Standard tier 6 methodology is used for other sharks based on average historical catch from 1997-2007. Catch specifications for sharks in 2015 are as follows; OFL=7,986 mt, ABC=5,989 mt, and TAC=5,989 mt.

Fishery: GOA sharks are managed as a bycatch only fishery. On average, over 90% of the sharks are discarded. Spiny Dogfish were caught primarily in the longline Pacific Cod and bottom trawl flatfish fisheries. Over 90% of Pacific Sleeper Sharks and Salmon Sharks were caught in the Pollock fishery.

AFSC, NOAA Fisheries

Squid

Biology: There are at least 15 species of squid in the Gulf of Alaska and these are managed as a squid complex. The most common squid near the continental shelf are in the genus *Berryteuthis*. Further offshore, Boreopacific Armhook Squid and *Gonatus* squids appear to be the most common. Much more research is needed to adequately characterize squid distribution in the Gulf of Alaska.

Squids are active predators that swim by jet propulsion, reaching swimming speeds of up to 40 km/hr, the fastest of any aquatic invertebrate. Squids are short-lived (<4 years), maturing just prior to spawning and dying afterwards. Squid populations consist of multiple cohorts that school with similar sized individuals, and may occupy different areas of the shelf and slope.

Chiroteuthid sp.	*Chiroteuthis calyx*
Glass squid sp.	*Belonella borealis*
Glass squid sp.	*Galiteuthis phyllura*
Minimal Armhook Squid	*Berryteuthis anonychus*
Magistrate Armhook Squid	*Berryteuthis magister*
Armhook Squid	*Eogonatus tinro*
Boreopacific Armhook Squid	*Gonatopsis borealis*
Berry Armhook Squid	*Gonatus berryi*
Armhook squid sp.	*Gonatus madokai*
Armhook squid sp.	*Gonatus middendorffi*
Clawed Armhook Squid	*Gonatus onyx*
Robust Clubhook Squid	*Moroteuthis robusta*
Boreal Clubhook Squid	*Onychoteuthis borealijaponicus*
Red Flying Squid	*Ommastrephes bartramii*
North Pacific Bobtail Squid	*Rossia pacifica*

Fishery Management: Squid were defined as an "other species" in the GOA until 2011 when the "other species" complex was separated out into distinct species groupings.

Stock assessment:

O. Ormseth. 2014. Assessment of the squid stock complex in the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Stock Assessment: Catch specifications for Squid are set using a modified Tier 6 control rule, with catch specifications are based on the highest catch during 1997-2008. Squid estimated biomass in unknown. Catch specifications for squid in 2015 were as follows; OFL=1,530 mt, ABC=1,148 mt, TAC=1,148 mt.

Total catches, and pre-season catch specifications of Squid* in the GOA, 1997-2015 (in mt).

Year	Catch[1]	TAC	ABC	OFL
1997	97	-	-	-
1998	59	-	-	-
1999	41	-	-	-
2000	19	-	-	-
2001	91	-	-	-
2002	43	-	-	-

2009	345	-	-	-
2010	139	-	-	-
2011	238	1,148	1,148	1,530
2012	22	1,148	1,148	1,530
2013	321	1,148	1,148	1,530
2014	92	1,148	1,148	1,530
2015		1,148	1,148	1,530

*Split from Other Species in 2011.
[1]Catch data through November 2014.

Fishery: There is currently no target fishery for squid in the GOA. GOA squid are primarily (> 90%) taken as incidental catch in the pelagic trawl pollock fishery. They are also taken in smaller numbers in bottom trawl fisheries. About 90% of the squid catch has been retained in recent years.

Tim Evers

Ecosystem Components: Squid are not currently a commercially valuable species in the North Pacific. However they play a critical prey role in ecosystems, as squid are important components in the diets of many seabirds, fish and marine mammals. Overall fishing removals of squid are low (especially relative to natural predation).

Giant Pacific Octopus
Linda Kozak

Octopus

Stock assessment:

M.E. Conners and C. Conrath. 2014. Assessment of the Octopus Stock Complex in the Gulf of Alaska.

http://www.afsc.noaa.gov/refm/stocks/assessments.htm

Biology: There are at least 7 species of octopus present in federal waters of the GOA, and the species composition both of natural communities and commercial harvest is unknown. At depths less than 200 meters, the giant Pacific octopus *E. dofleini* appears to be the most abundant species. Octopus life spans are either 1-2 years or 3-5 years depending on the species. *E. dofleini* are estimated to mature at 1.5 – 3 years. male *E. dofleini* were found to mature at around 12.5 kg with females thought to mature at larger sizes. *E. dofleini* is a terminal spawner, females die after the eggs hatch while males die shortly after mating. The fecundity of this species in Japanese waters has been estimated at 30,000 to 100,000 eggs per female. There are two other common species of octopus in the GOA: the smoothskin octopus and the flapjack devilfish. The smoothskin octopus occurs from 250-1400 m. and produces few eggs that remain benthic after hatching. The flapjack devilfish is found from 300-1000m deep and spawn up to 2,400 eggs in multiple batches.

Giant Pacific octopus	*Enteroctopus dofleini*
Smoothskin octopus	*Benthoctopus leioderma*
Flapjack devilfish	*Opisthoteuthis californiana*
Pelagic octopus	*Japatella diaphana*
Red octopus	*Octopus californicus*
Black octopus	*Vampyroteuthis infernalis*
a small octopus	*Octopus sp. A*

Fishery Management: Until 2011, octopus were managed as part of the "Other species" management category within the GOA FMP. Beginning in 2011, octopuses have been managed as a single complex with its own ABC and OFL.

Stock Assessment: Octopus catch limits are specified using a modified Tier 6 control rule, with an estimate of natural mortality (M=0.53) applied to the biomass of the three most recent NMFS bottom trawl surveys. While the biomass is deemed unreliable for purposes of Tier 5, it does provide a minimum estimate of biomass. Catch specifications for octopus in 2015 are as follows; OFL=2,009 mt, ABC=1,507 mt, TAC=1,507 mt.

Megan Peterson, UAF

Total catches, and pre-season catch specifications of Octopus* in the GOA, 1997-2015 (in mt).

2015		1,507	1,507	2,009

*Split from Other Species in 2011.
[1]Catch data through November 2014.

Fishery: There is currently no target fishery for octopus in federal waters of the GOA. About 90% of the octopus catch is taken as incidental catch in the Pacific Cod pot fisheries in the western and central GOA. In 2014, approximately 529 mt of octopus were retained for human consumption or for bait for the halibut fishery. The species composition of the octopus catch is unknown, but based on research trawl data, the giant Pacific octopus is most abundant in shelf waters and predominates in commercial catch. Preliminary research suggests high survival for octopus released from pot gear.

Sculpins

Great Sculpin
AFSC, NOAA Fisheries

Biology: There are 39 species of sculpins identified in the Gulf of Alaska and managed as a sculpin complex. The most common sculpin species taken incidentally in GOA fisheries are the Yellow Irish Lord *Hemilepidotus jordani* making up over 60% of the catch, followed by Great Sculpin *Myoxocephalus polyacanthocephalus* , Bigmouth Sculpin *Hemitripterus bolini* and Plain Sculpin *M. joak*. Sculpins lay adhesive eggs in nests, and many exhibit parental care for eggs. Irish lords and great sculpins have an age at 50% maturity of about 7 years.

Catch history: There is no directed fishing for any sculpin species in the GOA at this time. Catch of sculpins in the last 15 years has been averaged about 900 mt per year, reaching a peak in 2008 of 1,943 mt.

Fishery Management: Prior to 2011, sculpins were managed as part of the GOA Other Species complex that included sculpins, skates, sharks, squid and octopus, with an aggregate OFL, ABC, and TAC. Beginning in 2011 sculpins were removed from Other Species and managed as a separate group, as were the remaining species groups. Sculpins are currently taken only as incidental catch in fisheries directed at other target species, and it is likely that catch of sculpins in the near future will continue to be dependent on the distribution and limitations placed on target fisheries, rather than on any harvest level established for this category.

Summary

Why is the Council considering action?

The South Atlantic Fishery Management Council (Council) is considering action to allow fishermen to harvest red snapper while preventing overfishing and allowing the stock to rebuild. Harvest of red snapper from federal waters has not been allowed since 2014 due to the total removals of red snapper (landings plus dead discards) exceeding the acceptable biological catch established in Amendment 28 to the Fishery Management Plan for the Snapper Grouper Fishery of the South Atlantic Region (Amendment 28) (SAFMC 2013). Amendment 28 amendment established a process that would set the annual catch limit to zero (no mini-season) if total removals (landings plus dead discards) exceeded the acceptable biological catch in the previous year. Dead discards were included in the process to determine the annual catch limit because a portion of red snapper released die as a result of hooking injuries, barotrauma, and/or predation. The estimated number of red snapper that die due to injuries when released exceeded the acceptable biological catch in 2014, 2015, and 2016 and the annual catch limit was set to zero in 2015, 2016, or 2017.

The health of the stock was investigated using a benchmark stock assessment completed 2016 and revised in 2017 with data through 2014 (SEDAR 41 2017). SEDAR 41was presented in April 2016 to the Council's Scientific and Statistical Committee, an advisory body to the Council that recommends acceptable biological catch levels, and was deemed best scientific information. SEDAR 41 indicated that the stock was overfished and overfishing was occurring over the last 20 years of the assessment (1994-2014). In April 2017, the Scientific and Statistical Committee was presented a revised SEDAR 41 due to changes made in the headboat at-sea discard index (SEDAR 2017). The changes in the index did not result in changes to the stock status, but they result in changes to spawning stock biomass, minimum stock size threshold, and maximum sustainable yield. The Scientific and Statistical Committee tabled discussions of revising the acceptable biological catch due to data uncertainties.

The acceptable biological catch recommendation based on the SEDAR 41 (2017) included both landings and dead discards. The National Marine Fisheries Service has stated that the use of an ABC based primarily on recreational discard estimates is likely ineffective for monitoring red snapper removals due to uncertainty in the estimate of discards and there upcoming changes to the effort estimation for calculating recreational effort (see **Appendix J**). Until the changes to the recreational survey are complete, the Council's Scientific and Statistical Committee recommended that Marine Recreational Information Program (MRIP) discard estimates from private recreational and charter vessels should not be used for managing red snapper (SAFMC 2017).

While the acceptable biological catch estimate is revised and the estimates from the Marine Recreational Information Program for private recreational and charter vessel are calibrated, the Council is considering conservative measures beginning in 2018 to allow a mini-season. Such measures would remain in place until modified. The alternatives the Council is considering are based on red snapper landings that occurred in 2012, 2013, and 2014 with some of the alternatives adjusted based on increases in red snapper abundance observed through a scientific survey. The landings used in the analysis included commercial logbook data, headboat logbook data, South Carolina charter boat logbook data, a Georgia charter boat survey, a survey of vessels using methods in Sauls et al. (2017), and other sources (see **Appendix N** and **O**). The scientific survey of the population is done with fish traps and has been conducted with similar methods since 1991 (see **Appendix L**)[1]. In 2015, the survey (using the time series recommended in SEDAR 41 (2017)) indicated that the red snapper stock increased by 35% compared to 2014. The population increased by another 12% in 2016 and is at the highest point since 1991. This increase in the population is an encouraging sign that management has been effective in addressing overfishing and continued to rebuild the stock (see **Appendix J**). The Scientific and Statistical Committee stated at their April 2017 meeting that "Although estimates of discards may be highly uncertain, a continuing upward trend in the fishery independent index has a high probability of reflecting increases in population size." (SAFMC 2017) Additionally, since the population size appears to be larger based on the fishery independent index (**Appendix L**), the risk of overfishing is likely reduced if annual catch limits are limited to recent catch levels. Overfishing is essentially a ratio of landings compared to population size. If landings are limited to recent levels and the population has grown, then the resulting fishing mortality and risk of overfishing is decreased.

Allowing a limited amount of harvest would likely reduce the social and economic impacts of a year-round closure. Allowing some harvest will enable additional scientific information on red snapper and the fishery. Fishery regulations for red snapper changed substantially in 2010 and fishery-dependent information, data collected from fishermen, has been limited during closed years. During the open seasons, scientists can collect information on the size of fish harvested, age of fish harvested, fishery selectivity, and fishermen's behavior on private recreational vessels. A recent publication from the Southeast Fishery Science Center has stated that collecting more age information for the snapper grouper fishery has the greatest influence on the accuracy of assessments (Siegfried et al. 2016).

What action being proposed in this amendment?

Amendment 43 to the Fishery Management Plan for the Snapper Grouper Fishery of the South Atlantic Region (Amendment 43) proposes the following action for red snapper:

1. Revise the Process to Determine the Annual Catch Limits (ACL) for Red Snapper.

Alternative 1 (No Action). The commercial and recreational ACLs for red snapper are zero. The process and formula established in Snapper Grouper Amendment 28 specifies current fishing year annual catch limits if the National Marine Fisheries

[1] Video data were not available through 2016 when developing this amendment.

Service determines that the previous year's estimated red snapper landings and dead discards are less than the acceptable biological catch.

Alternative 2. Remove the process and equation used to determine the red snapper ACL as specified in Snapper Grouper Amendment 28. Specify a total annual catch limit equal to 23,623 fish. Commercial annual catch limit equals 69,360 pounds (whole weight) and recreational annual catch limit equals 16,480 fish.

Alternative 3. Remove the process and equation used to determine the red snapper ACL as specified in Snapper Grouper Amendment 28. Specify a total annual catch limit equal to 44,411 fish. Commercial annual catch limit equals 130,396 pounds (whole weight) and recreational annual catch limit equals 30,982 fish.

Alternative 4. Remove the process and equation used to determine the red snapper ACL as specified in Snapper Grouper Amendment 28. Specify a total annual catch limit equal to 42,510 fish. Commercial annual catch limit equals 124,815 pounds (whole weight) and recreational annual catch limit equals 29,656 fish.

Alternative 5. Remove the process and equation used to determine the red snapper ACL as specified in Snapper Grouper Amendment 28. Specify a total annual catch limit equal to 79,919 fish. Commercial annual catch limit equals 234,652 pounds (whole weight) and recreational annual catch limit equals 55,753 fish.

Note: In Alternatives 2 through 5, the sector annual catch limits were calculated using the established allocation in the Comp ACL Amendment (2011). The allocation is 28.07% commercial and 71.93% recreational based on weight.

The current red snapper annual catch limit is set in numbers of fish in order to account for discards (SAFMC 17A 2010). The sector annual catch limits are apportioned based on allocation percentages determined by the Council established in the Comprehensive Annual Catch Limit Amendment (SAFMC 2011). The methods used to develop the commercial and recreational sector allocation are included in **Appendix K**. Annual catch limits for the recreational sector are specified in numbers of fish because it is a more reliable estimate for the sector than weight of fish. Surveys that estimate recreational landings collect information on the number of fish and convert those numbers to weights using biological samples. The commercial sector's annual catch limit is set in pounds of fish because that is how the commercial sector reports landings and thus weight is a more accurate representation of commercial landings.

Proposed ACLs in **Alternative 2** through **Alternative 5** are based on landings from 2012 to 2014, when mini-seasons were open for red snapper. **Alternative 2** is based on the average landings from 2012 to 2014. **Alternative 3** is based on the average of landings from 2012 to 2014, multiplied by an adjustment factor intended to account for the observed population growth since 2012-2014. The adjustment factor is based on the observed increase in numbers of red snapper from a long-term scientific survey (MARMAP and SEFIS). The scientific survey indicated the average population of red snapper increased by 1.88 when comparing the time period 2012 to 2014 to the time period 2015 to 2016 (**Figure S-1** and **Appendices K** and **L**).

Alternative 4 is based on the highest observed landings that occurred in a single year from 2012 to 2014. The highest landings occurred in 2014 with 42,510 red snapper being landed. **Alternative 5** is the highest landings that occurred in a single year from 2012 to 2014, multiplied by the adjustment factor (described above).

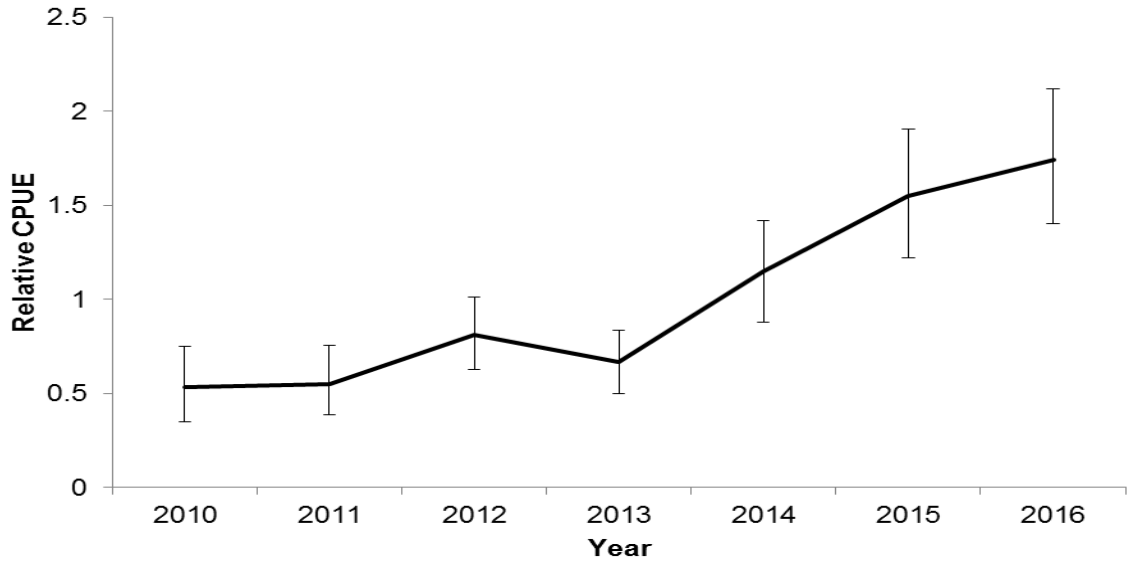

Figure S.1. Relative catch per unit effort (CPUE) with error bars from a scientific study of red snapper abundance in the South Atlantic region, 2010 to 2016.

Purpose for Action

The *purpose* of Snapper Grouper Amendment 43 is to revise annual catch limits for red snapper to provide fishing access.

Need for Action

The *need* for Snapper Grouper Amendment 43 is to prevent overfishing, continue to rebuild the stock, and, to the extent practicable, reduce adverse social and economic effects as per the Magnuson Stevens Fishery Conservation and Management Act.

Chapter 1. Introduction

1.1 What action is being proposed in this amendment?

Amendment 43 to the Fishery Management Plan for the Snapper Grouper Fishery of the South Atlantic Region (Amendment 43) proposes to revise the annual catch limit (ACL) for red snapper in the South Atlantic region. The ACL has been set to zero since 2014 based on the process established in Amendment 28 (SAFMC 2013). According to that process, if the National Marine Fisheries Service (NMFS) determined that the estimated red snapper landings and dead discards that occurred in the previous year were equal to or greater than the projected acceptable biological catch (ABC) for that year, no harvest would be allowed in upcoming fishing season. If NMFS determined that the estimated landings and dead discards that occurred in the previous year were less than the ABC, harvest would be allowed if the projected commercial and recreational fishing seasons were over three days long. The ABC was exceeded in 2014, 2015, and 2016 and no red snapper landings were allowed in those years. The South Atlantic Fishery Management Council (Council) is considering revising the ACLs for red snapper to enable a season beginning in 2018.

1.2 Who is proposing the amendment?

The Council develops the amendment and submits it to the NMFS which, on behalf of the Secretary of Commerce, ultimately approves, disapproves, or partially approves the amendment. NMFS implements the actions in the amendment through the development of regulations through rulemaking. NMFS is an office of the National Oceanic and Atmospheric Administration. The Council and NMFS are also responsible for making this document available for public comment.

The South Atlantic Fishery Management Council

- Responsible for conservation and management of fish stocks in the South Atlantic Region
- Consists of 13 voting members who are appointed by the Secretary of Commerce, 1 representative from each of the 4 South Atlantic states, the Southeast Regional Administrator of NMFS, and 4 non-voting members
- Responsible for developing fishery management plans and amendments under the Magnuson-Stevens Act; recommends actions to NMFS for implementation
- Management area is from 3 to 200 nautical miles off the coasts of North Carolina, South Carolina, Georgia, and east Florida through Key West, with the exception of Mackerel which is from New York to Florida, and Dolphin-Wahoo, which is from Maine to Florida

1.3 Where is the Project Located?

Management of the federal snapper grouper fishery located off the southeastern United States (South Atlantic) in the 3-200 nautical miles U.S. Exclusive Economic Zone (EEZ) is conducted under the Fishery Management Plan for the Snapper Grouper Fishery of the South Atlantic Region (Snapper Grouper FMP) (SAFMC 1983) (**Figure 1.3.1**). Red snapper is among the 55 species managed by the Council under the Snapper Grouper

FMP

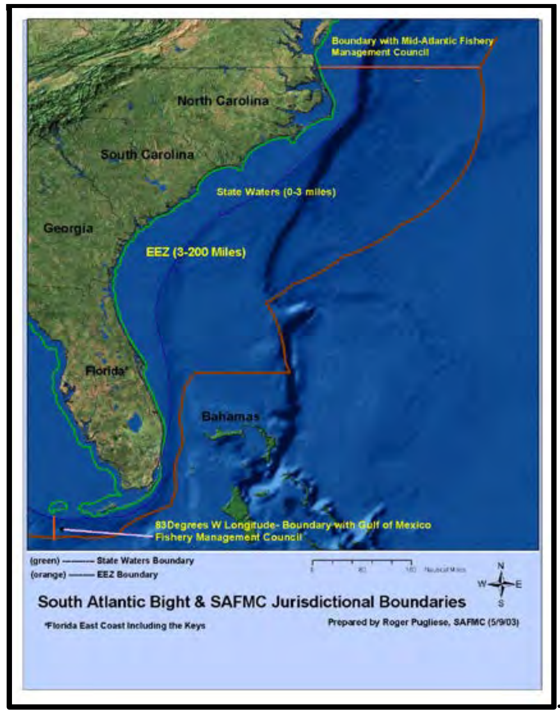

Figure 1.3.1. Jurisdictional boundaries of the Council.

1.4 Why is this action being considered (Purpose and Need)?

The Council intends to specify recreational and commercial ACLs for red snapper beginning in 2018, while the NMFS Southeast Fisheries Science Center (SEFSC) develops a method to specify a an acceptable biological catch for red snapper. The Council's goal is to minimize adverse socio-economic effects to fishermen and fishing communities that utilize red snapper as part of the snapper grouper fishery. Allowing limited harvest beginning in 2018 will promote beneficial economic and social effects to fishermen and fishing communities (see **Section 3.3**) while preventing overfishing from occurring and continuing to rebuild the stock (see **Section 1.7**).

Although there may be some concern that opening the red snapper fishery to limited harvest could cause overfishing because SEDAR 41 (2017) indicated that overfishing was occurring during 2012-2014, the available fishery independent index of abundance suggests the population has increased substantially since 2014. The Scientific and Statistical Committee (SSC) commented in April 2017 that "...a continuing upward trend in the fishery independent index has a high probability of reflecting increases in population size." Survey catch per unit effort (CPUE) values, which increased 35% in 2015 compared to 2014 and increased an additional 12% in 2016 compared to 2015, are currently highest in the entire time series (1990-2016). Additional supporting evidence of an increasing population is the increase in the number of discards reported in the recreational sector based on the MRIP survey, which in the past has corresponded to increasing population abundance and strong year classes moving through the fishery. The estimates of red snapper discards from 2015 and 2016, although uncertain and not recommended for use in management, are the two highest estimates since 1990, and even though the current preliminary estimate for 2017 only includes four months it would rank as the 6th highest since 1990. The increase in the population size is important to evaluating whether a given harvest level carries unacceptable risk of overfishing because fishing mortality levels are essentially based on the ratio of landings or removals to the population abundance.

Purpose for Action

The *purpose* of Snapper Grouper Amendment 43 is to revise annual catch limits for red snapper to allow fishing access.

Need for Action

The *need* for Snapper Grouper Amendment 43 is to prevent overfishing, continue to rebuild the red snapper stock, and, to the extent practicable, reduce adverse social and economic effects as per the Magnuson Stevens Fishery Conservation and Management Act.

1.5 What are annual catch limits and accountability measures and why are they required?

The reauthorization of the Magnuson-Stevens Fishery Conservation and Management Act (Magnuson-Stevens Act) in 2007 required implementation of ACLs and accountability measures (AM) to end and/or prevent overfishing to achieve the optimum yield (OY) from a fishery. An ACL is the level of annual catch of a stock that, if met or exceeded, triggers some corrective action. The AMs are the corrective actions, and they are management controls to prevent ACLs from being exceeded and to correct overages of ACLs if they occur. For example, a common AM is implementation of an in-season closure if catch is projected to reach the ACL. Amendment 43 includes alternatives that would revise the current ACLs for red snapper.

1.6 What are the current red snapper ACLs and how are fishing seasons determined?

Amendment 28 to the Snapper Grouper FMP (SAFMC 2013) set the commercial and recreational red snapper ACLs at zero and established a process for setting fishing seasons to allow limited harvest of red snapper in the South Atlantic EEZ. The current red snapper ABC was recommended by the SSC in November 2010 (SAFMC 2010) and is based on rebuilding projections in the Southeast Data Assessment and Review (SEDAR 24 2010) red snapper stock assessment.

Limited red snapper landings were allowed in 2012, 2013, and 2014. However, combined landings and estimated dead discards in 2014, 2015, and 2016 have exceeded the total ABCs for those years and no harvest has been allowed since 2014 (**Table 1.6.1**).

Table 1.6.1. Red snapper ABCs recommended by the SSC from projections included in SEDAR 24 (2010). Landings and estimates of dead discards of red snapper from the South Atlantic region since 2012, including during mini-seasons from 2012 to 2014. Bold values indicate landings plus dead discards exceeded the ABC.

Year	Total ABC (Numbers of Fish)	Landings (Numbers of Fish)	Landings + Dead Discards* (Numbers of Fish)
2012	86,000	16,591	80,516
2013	96,000	11,767	72,881
2014	106,000	42,510	**205,859**
2015	114,000	2,850	**276,729**
2016	121,000	830	**407,025**
2017	128,000		

*Values were reported in the SEFSC annual report on red snapper landings. Reports were presented at June Council meetings from 2013-2016.

Process implemented by Snapper Grouper Amendment 28

The annual ABCs for red snapper were recommended by the SSC in numbers of fish based on projections in SEDAR 24 (2010). If NMFS determines that the estimated landings and dead discards that occurred in the previous year were equal to or greater than the projected ABC, no harvest would be allowed in upcoming fishing season. If NMFS determined that the estimated landings and dead discards that occurred in the previous year were less than the ABC, harvest *might* be allowed. (Note: The commercial and recreational fishing seasons would not open if the projected season length is three days or less.)

NMFS calculates the total ACL following the formula implemented through the amendment and the sector ACLs based on the South Atlantic Council's approved allocations. NMFS projects the length of the commercial and recreational fishing seasons.

If harvest is allowed, NMFS announces the pre-determined commercial and recreational fishing year start dates. The commercial red snapper season closes when the commercial sector ACL was met or projected to be met. The recreational red snapper season is projected and announced before the start of the season. The NMFS Regional Administrator has the authority to delay the opening of red snapper fishing seasons in the event of a tropical storm or hurricane affecting the South Atlantic Council's area of authority.

The process would be repeated each year unless modified.

1.7 Will the Action Prevent Overfishing and Continue to Rebuild the Stock?

The most recent stock assessment for South Atlantic red snapper, completed through SEDAR 41, reviewed by the Council's SSC in May 2016 (SAFMC 2016), and revised in April 2017 (SEDAR 2017) suggested overfishing was occurring from 2012 to 2014 because the terminal exploitation status (fishing mortality based on the average over the last three years represented in the model) exceeded the maximum fishing mortality threshold.

The SSC reviewed the assessment in May 2016 and accepted the assessment as providing information useful for management and adequate to support fishing level recommendations. The SSC also noted there was considerable uncertainty in the exploitation status and thus estimates of the degree of overfishing are highly uncertain. The SSC indicated that the "most significant sources of uncertainty include: the stock-recruitment relationship, natural mortality at age, the age structure of the unfished population, the composition and magnitude of recreational discards, potential changes in CPUE catchability, and the selectivities for the different fishery fleets" (SAFMC 2016). The SSC commented further in April 2017 after receiving the revised SEDAR 41 that they could not provide an ABC for red snapper based on SEDAR 41 (SAFMC 2017).

The SEFSC also reported to the Council in February 2017 that the uncertainty with the assessment is large (**Appendix J**). The SEFSC further elaborated that the fishing mortality rates in the last few years of the assessment are very sensitive to 2014 data, and retrospective analyses indicate the fishing mortality rates are considerably lower if these data are excluded. The SEFSC also noted that the overfishing determination was ascertained using fishing mortality when there were mini-seasons (2012-2014) and that there were no fishing seasons for red snapper in 2015 and 2016.

Rebuilding an overfished stock:

In 2009, the NMFS notified the Council that the red snapper stock was overfished and overfishing was occurring based on the results of SEDAR 15 benchmark stock assessment, which suggested that the stock was overfished (SEDAR 2009). In response, the South Atlantic Council approved, and NMFS implemented, a 35-year rebuilding plan in 2010. The stock was reassessed in 2010 (SEDAR 24 2010). The results of SEDAR 24 suggested that red snapper were overfished and undergoing overfishing; however, the rate of overfishing found in SEDAR 24 was less than the rate of overfishing found in the previous assessment (SEDAR 15). The results of SEDAR 24 were used as the basis for Snapper Grouper Regulatory 10 (SAFMC 2011a) and for Amendment 28 (SAFMC 2013).

In 2017, NMFS notified the Council that the red snapper stock was still overfished and overfishing was occurring but the stock was rebuilding based on the results of the SEDAR 41 benchmark stock assessment including information through 2014 (SEDAR 2017, **Appendix J**). SEDAR 41 results suggest an increase in stock biomass since 2010 and increasing abundance of older age classes (ages greater than 6). At the June 2016 Council meeting, the SSC chair stated that when taking all of the available information into account, particularly the fishery-independent data, the progress in rebuilding of red snapper was unquestionable. NMFS informed the Council in a letter (dated 03/03/2017; **Appendix J**) that sufficient steps had been taken to address overfishing of red snapper and continue to rebuild the stock through harvest prohibitions in 2015 and 2016.

Abundance of snapper grouper species, including red snapper, has been monitored by the Marine Resources Monitoring Assessment and Prediction (MARMAP) Program since 1978. MARMAP is the only existing long-term program off the Atlantic coast of the southeastern U.S. that monitors reef fish length frequency, abundance, and life history based on fishery-independent data. These data provide critical input for the assessments of stock status conducted through the SEDAR process. The NMFS SEFSC SouthEast Fishery-Independent Survey (SEFIS) was established in 2010 to complement MARMAP with identical gear types and sampling methodology, and to expand the sample size and spatial distribution of the ongoing MARMAP trap survey.

The latest results of the chevron trap index from MARMAP and SEFIS were presented at the June 2017 South Atlantic Council meeting. The presentation included updated information on the relative abundance for red snapper from 1990 to present. After the meeting, a revised analysis was conducted and the shown in (**Figure 1.7.1)**.

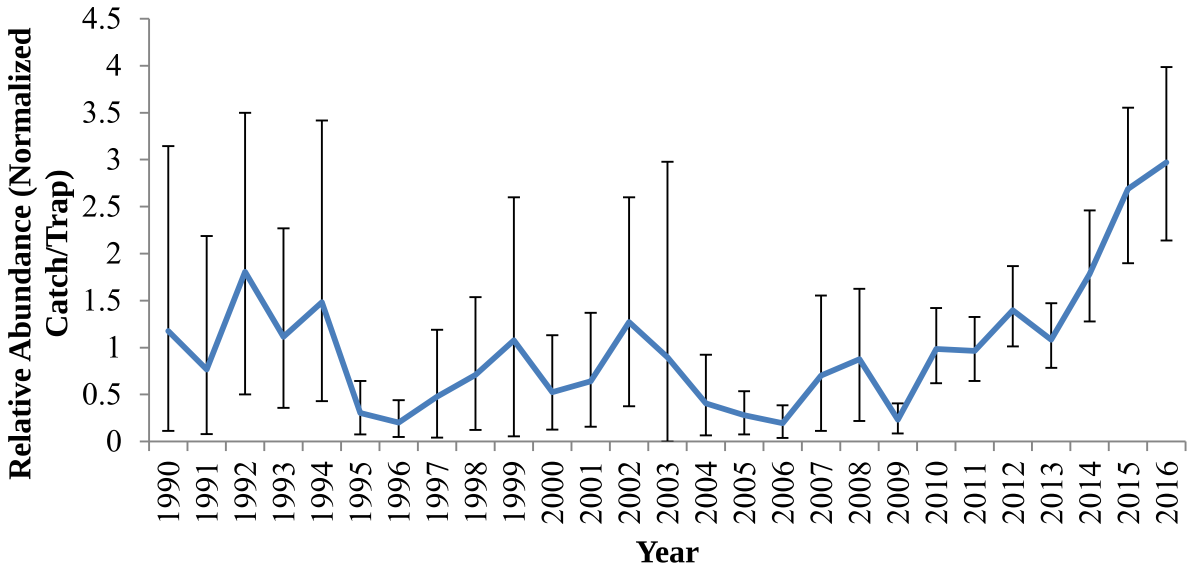

Figure 1.7.1. Relative abundance of red snapper collected in chevron traps in the South Atlantic Region calculated using methods developed in SEDAR 41 (2017). See **Appendix L** for more details.

Southeast Reef Fish Survey (SERFS)

- Includes 3 fishery independent sampling surveys.
  - MARMAP – since 1978
  - SEAMAP-SA – since 1986
  - SEFIS – since 2010
- Continuous sampling since 1972.
- Gear Used:
  - Fish traps (chevron)
  - Longlines
  - Rod and reel
  - Video
- Surveys conducted from April to October

The long-term fishery independent survey shows a very steep upward trend in relative abundance, reaching the highest levels to date in 2016 (**Figure 1.7.1**). The increase has occurred despite landings during the 2012-2014 mini-seasons and the large number of estimated dead discards since the moratorium on red snapper fishing was put in place in 2010. The SSC stated at their April 2017 meeting that "Although estimates of discards may be highly uncertain, a continuing upward trend in the fishery independent index has a high probability of reflecting increases in population size." (SAFMC 2017). This is important because the determination of overfishing is based on the level of removals and the population size. If the population increases, as the survey has indicated, then the fishing mortality estimate associated with a level of removals is decreased. Overfishing is defined in the Magnuson-Stevens Act as "a rate or level of fishing mortality that jeopardizes the capacity of a fishery to produce the maximum sustainable yield on a continuing basis" (16 U.S. C. 1802(10)). The removal levels in 2014 (highest since 2010) did not appear to jeopardize the stock because the population increased substantially despite 2014 landings. Thus, based on the SSC reports and fishery independent abundance index trends, allowing limited harvest of red snapper is expected not to result in overfishing nor prevent continued stock rebuilding.

ABC and Future Work:

Amendment 28 (SAFMC 2013) included an ABC for red snapper, which was recommended by the SSC based on projections from SEDAR 24 (2010). The SSC reviewed the SEDAR 41 assessment of red snapper in May 2016, concluding that the assessment provided adequate information for management and supporting fishing level recommendations. However, the SSC noted that "…many of the assessment limitations and uncertainties were caused by data issues and limitations." These are detailed more fully in their report (SAFMC 2016). The Council began work on Amendment 43 to address red snapper management and the ABC recommendations provided by the SSC.

However, in response to the South Atlantic Council's January 18, 2017, request for additional red snapper projections under a discards-only scenario, the SEFSC (02/15/2017; Appendix J) stated that providing an ABC based on discard-only projections was not possible due to the length of time since the terminal year of data for the stock assessment (SEDAR 2017), uncertainty in the recreational landings and discards associated with MRIP, and future changes likely in 2018 to MRIP due to methodology revisions. The South Atlantic Council discussed this response at their March 2017 meeting and requested that the SSC and SEFSC work together to recommend an appropriate ABC for red snapper.

In April 2017 the SSC considered a request from the Council to consider approaches for deriving ABC recommendations for red snapper in light of the recent the guidance from the agency regarding red snapper projections and uncertainties as detailed above (SAFMC 2017). The following statements were provided by the SSC:

- *Clarification was provided by NMFS to the SSC that the assessment is still considered BSIA (Best Scientific Information Available). However, the data available to monitor the landings and discards are too uncertain to track any projected ABC. Therefore, an index-based approach is being proposed to track and monitor the condition of Red Snapper.*
- *The current projected yield streams are still considered BSIA, but are not useful for management and monitoring because of the uncertainty in the catch data (as most of the catch is discarded).*
- *The SSC acknowledged that at this point it is unable to provide an ABC recommendation for Red Snapper.*
- *Although estimates of discards may be highly uncertain, a continuing upward trend in the fishery independent index has a high probability of reflecting increases in population size.*

Based on these recommendations from the SSC, the ABC for red snapper is currently unknown, a continuing upward trend in the fishery-independent index has a high probability of reflecting increases in population size, and a departure from traditional techniques and further investigation of an index based approach to provide fishing level recommendations is advised.

The Council has moved additional actions related to red snapper management contained in previous drafts of Amendment 43 to a separate amendment (Amendment 46). Amendment 46 will revisit red snapper management reference points, recreational reporting, and best fishing practices. Additionally, the SEFSC is exploring alternative methods to develop future ABCs for red snapper.

1.8 What is the history of management for red snapper?

The snapper grouper fishery is highly regulated; red snapper has been regulated since the development of the snapper grouper fishery management plan in 1983. A detailed history of management for all species in the snapper grouper fishery management unit may be found in **Appendix C**. Below is an annotated list of fishery management plan/amendments that contained actions specifically related to red snapper.

Fishery Management Plan for the Snapper Grouper Fishery of the South Atlantic Region (1983)

The original Fishery Management Plan (FMP) included provisions to prevent growth overfishing in thirteen species in the snapper grouper complex and established a procedure for preventing overfishing in other species; established minimum size limits for red snapper, yellowtail snapper, red grouper, Nassau grouper, and black sea bass; established a 4-inch trawl mesh size to achieve a 12-inch total length minimum size limit for vermilion snapper; and included additional harvest and gear limitations.

Amendment 4 (1991)

Amendment 4 prohibited the use of various gear, including fish traps, the use of bottom longlines for wreckfish, and powerheads in special management zones off South Carolina; established bag limits and minimum size limits for several species (20 inch total length minimum size limit and two fish bag limit for red snapper); required permits (commercial and for-hire) and specified data collection regulations; and required that all snapper grouper species possessed in the South Atlantic EEZ must have heads and fins intact through landing.

Amendment 11 (1998)

Amendment 11 amended the FMP to make definitions of maximum sustainable yield (MSY), optimum yield (OY), overfishing, and overfished consistent with National Standard Guidelines. Amendment 11 also identified and defined fishing communities, addressed bycatch management measures, and defined the red snapper F_{MSY} proxy as $F_{30\%SPR}$.

Interim Rule for Red Snapper (2009)

In 2008 the Council received notification (letter dated July 8) that the South Atlantic red snapper stock was undergoing overfishing and was overfished. In March 2009 the Council requested that the NMFS establish interim measures to reduce overfishing and fishing pressure on the red snapper stock. Interim measures became effective on January 4, 2010. The interim rule was effective until June 2, 2010, but was extended for an additional 186 days since the Council was developing long-term management measures in Snapper Grouper Amendment 17A to end overfishing of red snapper and rebuild the stock.

Amendment 17A (2010)

Actions in Amendment 17A (SAFMC 2010) included a harvest prohibition for red snapper and an area closure for all snapper grouper species. The area closure was 4,827 square miles and extended from southern Georgia to northern Florida where harvest and possession of all snapper grouper species would be prohibited (except when fishing with black sea bass pots or spearfishing gear for species other than red snapper). The red snapper prohibition was effective on January 3, 2011; however, NMFS delayed the effective date of the area closure until June 1, 2011, via an emergency rule, to allow time to review the results of a new red snapper stock assessment (SEDAR 24 2010).

The results of SEDAR 24 showed red snapper to be overfished and undergoing overfishing; however, the rate of overfishing found in SEDAR 24 was less than the rate of overfishing found in the previous stock assessment (SEDAR 15 2008). Based on the results from SEDAR 24, evidence of decreased effort in the recreational sector, and recommendations from their Scientific and Statistical Committee (SSC), the Council determined that the snapper grouper area closure approved in Amendment 17A, in addition to the harvest prohibition, was more conservative than what was necessary to end overfishing of red snapper.

Amendment 17A also required the use of non-stainless steel circle hooks when fishing for snapper grouper species with hook-and-line gear and natural baits in the South Atlantic EEZ north of 28 degrees North latitude and specified a fishery-independent monitoring program for red snapper.

Comprehensive Annual Catch Limits (ACL) Amendment (Snapper Grouper Amendment 25) (2011b)

Established sector allocations for many snapper grouper species, including red snapper, using an allocation formula based on historic and recent average landings. The commercial allocation for red snapper was set at 28.07% and the recreational allocation was set at 71.93%.

Regulatory Amendment 10 (2011a)

In December 2010, the Council

Definitions

Annual Catch Limits (ACL)
The level of annual catch (pounds or numbers) that triggers accountability measures to ensure that overfishing is not occurring.

Annual Catch Targets (ACT)
The level of annual catch (pounds or numbers) that is the management target of the fishery, and accounts for management uncertainty in controlling the actual catch at or below the ACL.

Accountability Measures (AM)
Management controls to prevent ACLs, including sector ACLs, from being exceeded, and to correct or mitigate overages of the ACL if they occur.

Allocations
A division of the overall ACL among sectors (e.g., recreational and commercial) to create sector ACLs.

Maximum Sustainable Yield (MSY)
Largest long-term average catch or yield that can be taken from a stock or stock complex under prevailing ecological and environmental conditions.

Optimum Yield (OY)
The amount of catch that will provide the greatest overall benefit to the nation, particularly with respect to food production and recreational opportunities and taking into account the protection of marine ecosystems.

Minimum Stock Size Threshold (MSST)
A status determination criterion. If current stock size is below MSST, the stock is overfished.

approved Regulatory Amendment 10 for review by the Secretary of Commerce by a unanimous vote. The action in Regulatory Amendment 10 eliminated the snapper grouper area closure approved in Amendment 17A. Regulatory Amendment 10 was implemented and became effective on May 31, 2011.

Emergency Rule (2012)

The rule established red snapper seasons for the commercial and recreational sectors in the South Atlantic EEZ in 2012.

Amendment 28 (2013)

The amendment set the commercial and recreational ACLs and seasons to allow limited harvest of red snapper in 2013. In addition, the amendment established a process to determine whether limited commercial and recreational fishing seasons in the South Atlantic EEZ could occur during a given fishing year, and specified management measures should limited harvest be allowed.

Regulatory Amendment 21 (2014a)

The amendment changed the Minimum Stock Size Threshold (MSST) definition for eight snapper grouper species including red snapper from MSST = [(1-M) or 0.5 whichever is greater]* B_{MSY} to 0.75* B_{MSY}.

Chapter 2. Proposed Actions and Alternatives

2.1 Action 1. Revise the Process to Determine the Annual Catch Limits (ACL) for Red Snapper

Alternative 1 (No Action). The commercial and recreational ACLs for red snapper are zero. The process and formula established in Snapper Grouper Amendment 28 specifies current fishing year annual catch limits if the National Marine Fisheries Service determines that the previous year's estimated red snapper landings and dead discards are less than the acceptable biological catch.

Alternative 2. Remove the process and equation used to determine the red snapper ACL as specified in Snapper Grouper Amendment 28. Specify a total annual catch limit equal to 23,623 fish. Commercial annual catch limit equals 69,360 pounds (whole weight) and recreational annual catch limit equals 16,480 fish.

Alternative 3. Remove the process and equation used to determine the red snapper ACL as specified in Snapper Grouper Amendment 28. Specify a total annual catch limit equal to 44,411 fish. Commercial annual catch limit equals 130,396 pounds (whole weight) and recreational annual catch limit equals 30,982 fish.

Alternative 4. Remove the process and equation used to determine the red snapper ACL as specified in Snapper Grouper Amendment 28. Specify a total annual catch limit equal to 42,510 fish. Commercial annual catch limit equals 124,815 pounds (whole weight) and recreational annual catch limit equals 29,656 fish.

Alternative 5. Remove the process and equation used to determine the red snapper ACL as specified in Snapper Grouper Amendment 28. Specify a total annual catch limit equal to 79,919 fish. Commercial annual catch limit equals 234,652 pounds (whole weight) and recreational annual catch limit equals 55,753 fish.

Note: In Alternatives 2 through 5, the sector annual catch limits were calculated using the Council's established allocation from the Comprehensive ACL Amendment (2011). The allocation is 28.07% commercial and 71.93% recreational.

2.1.1 Comparison of Alternatives

The overall red snapper annual catch limit (ACL) in **Alternative 1 (No Action)** is set in numbers of fish in order to account for discards. The sector annual catch limits are apportioned to each sector based on allocation percentages determined by the Council (see **Appendix K** for calculation of annual catch limits). ACL for the recreational sector are specified in numbers of fish because it is a more reliable estimate for that sector than specifying the ACL in weight of fish. Surveys that estimate recreational landings collect information on numbers of fish and convert those numbers to weights using biological samples. The commercial sector's ACL is set in pounds of fish because that is how the commercial sector reports landings and thus weight is a more accurate representation of commercial landings.

Alternative 2 through **Alternative 5** are based on landings from 2012 to 2014, when mini-seasons were open for red snapper. **Alternative 2** is the average of landings from 2012 to 2014. **Alternative 3** is the average of landings from 2012 to 2014, multiplied by an adjustment factor intended to account for the observed population growth since 2012-2014. The adjustment factor is based on the observed increase in numbers of red snapper from a long-term scientific survey (MARMAP and SEFIS combined). The scientific survey indicated the average population of red snapper increased by 1.88 when comparing the time period 2012 to 2014 to the time period 2015 to 2016 (**Figure 2.1.1**, see **Appendices K** and **L**).

Alternative 4 is based on the highest observed landings that occurred in a single year from 2012 to 2014. The highest landings occurred in 2014 with 42,510 red snapper being landed. **Alternative 5** is the highest landings that occurred in a single year from 2012 to 2014, multiplied by the adjustment factor (described above). Proposed ACLs under each alternative are shown in **Table 2.1.2**.

Process proposed in Amendment 43

NMFS would announce the pre-determined commercial and recreational fishing season start dates. The commercial red snapper season would close when the commercial ACL is met or projected to be met. The recreational red snapper season would be projected and announced before the start of the recreational season based on catch rates from previous years. The NMFS Regional Administrator would have the authority to delay the opening of red snapper fishing seasons in the event of a tropical storm or hurricane affecting the Council's area of authority.

The commercial fishing season would begin at 12:01 am on the second Monday in July. The recreational fishing season (weekends) would begin 12:01 am on the first Friday in July.

There would be no minimum size limit for either the commercial or recreational sector.

The commercial trip limit would be 75 pounds gutted weight (lbs gw).

The recreational bag limit would be 1 fish per person per day.

Table 2.1.1. Red snapper ABCs recommended by the SSC from projections included in SEDAR 24 (2010). Landings and estimates of dead discards of red snapper from the South Atlantic region since 2012, including during mini-seasons from 2012 to 2014.

Year	Landings ABC (Numbers of Fish)	Dead Discards ABC (Number of Fish)	Total ABC (Numbers of Fish)	ACL for Landings only (Numbers of Fish)	Landings (Numbers of Fish)	Landings + Dead Discards* (Numbers of Fish)
2012	45,000	41,000	86,000	13,067	16,591	80,516
2013	52,000	44,000	96,000	13,325	11,767	72,881
2014	59,000	47,000	106,000	31,387	42,510	205,859
2015	64,000	50,000	114,000	0	2,850	276,729
2016	69,000	52,000	121,000	0	830	407,025
2017	74,000	54,000	128,000	0**		
				Average 2012 to 2014	23,623	
				Max observed 2012 to 2014	42,510	

*Values were reported in the SEFSC annual report on red snapper landings. Reports were presented at June Council meetings from 2013-2016.
**NMFS announced the ACL for red snapper was zero for 2017 at the June 2017 Council meeting.

Table 2.1.2. Proposed total, commercial, and recreational red snapper ACLs for 2018 calculated in numbers of fish and whole weight.

Alternative	ACL Number	ACL Weight (ww)	Commercial ACL Weight (ww)	Commercial ACL Number	Recreational ACL Weight (ww)	Recreational ACL Number
Alt 1	TBD					
Alt 2	23,623	247,097	75,537	7,143	177,737	16,480
Alt 3	44,411	464,539	130,396	13,429	334,143	30,982
Alt 4	42,510	444,655	124,815	12,854	319,840	29,656
Alt 5	79,919	835,953	234,652	24,166	601,301	55,753

The conversion factor used to derive number of fish from weight is 9.71 pounds and is based on the average weight of commercially caught red snapper from 2012 to 2014 (SEDAR 41 2017). The recreational ACL, expressed in weight and number of fish, is the difference between total ACL weight/number and commercial weight/number.

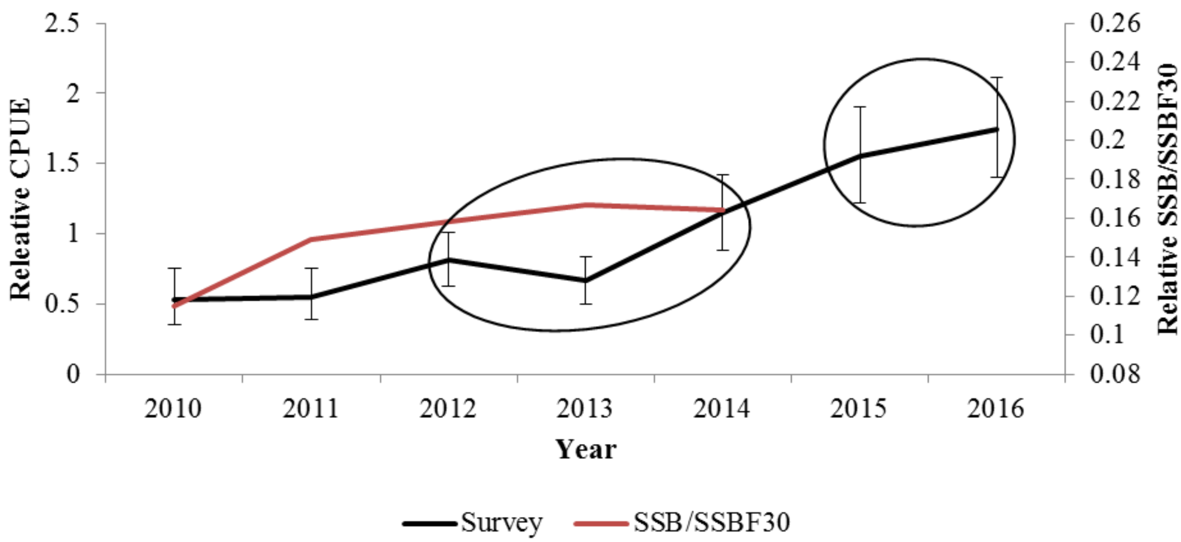

Figure 2.1.1. Relative catch per unit effort (CPUE) from the MARMAP and SEFIS chevron trap survey standardized with the ratio of annual spawning stock biomass compared to spawning stock biomass at F30% from SEDAR 41 (2017). Circles represent the two time periods that were compared to develop the adjustment factor. See **Appendix L** for more information on the index.

Alternative 1 (No Action), would result in no commercial or recreational harvest of red snapper allowed in 2018 due to exceeding the ABC in 2017. While allowing no harvest might be biologically beneficial to a stock, it is expected that the resulting level of dead discards would continue to increase. The long-term biological effects of continued high bycatch and resulting mortality on the red snapper stock are unknown because the red snapper stock has continued to increase after high levels of bycatch based on survey data. **Alternative 1 (No Action)** has the least economic and social benefits and a continued administrative burden to calculate the ACL each year. **Alternatives 3** and **5** propose ACLs above recent catch levels since they are adjusted to account for perceived recent population growth by a factor of 1.88. Therefore, these alternatives might result in negative biological effects over the status quo since it is not known how the stock might be impacted and whether such levels of harvest could result in overfishing. **Alternative 5** has the largest economic benefit and most social benefits followed by **Alternative 3**. **Alternatives 2** and **4** would be less likely to result in negative biological effects than **Alternatives 3** and **5** since **Alternatives 2** and **4** propose ACLs based on 2012-2014 catch levels and data suggest red snapper abundance increased from 2014 levels by 35% in 2015 and an additional 12% in 2016. **Alternative 4** has greater economic and social benefits than **Alternative 2** but less than **Alternatives 3** and **5**.

Table 2.1.3. A summary and comparison of the effects of the alternatives.

Alternatives		Effects			
		Biological	**Economic**	**Social**	**Administrative**
1	No Action ACL would be 0 in 2018	+ lowest risk of overfishing -Bycatch of red snapper continued	Commercial Ex-Vessel Revenue: $0 Recreational Consumer surplus=$0	-No allowable harvest	No change. -Continued process to calculate ACL each year.
2	Revise and set ACL =23,623 fish	-2nd lowest risk of overfishing + Some red snapper bycatch would be converted to landings.	Commercial Ex-Vessel Revenue: $318,362 Recreational Consumer surplus=$1,334,880	+ Allows red snapper harvest	-Rule-making, data monitoring, outreach, and enforcement
3	Revise and set ACL =44,411 fish	-2nd Highest risk of overfishing + Some red snapper bycatch would be converted to landings.	Commercial Ex-Vessel Revenue: $545,981 to $598,518 Recreational Consumer surplus=$2,509,542	+ Allows red snapper harvest	-Rule-making, data monitoring, outreach, and enforcement
4	Revise and set ACL =42,510 fish	-3rd lowest risk of overfishing + Some red snapper bycatch would be converted to landings.	Commercial Ex-Vessel Revenue: $545,981 to $572,901 Recreational Consumer surplus=$2,402,136	+ Allows red snapper harvest	-Rule-making, data monitoring, outreach, and enforcement
5	Revise and set ACL =79,919 fish	-Highest risk of overfishing + Some red snapper bycatch would be converted to landings.	Commercial Ex-Vessel Revenue: $545,981 to $731,614 Recreational Consumer surplus=$4,515,993	+Allows red snapper harvest	-Rule-making, data monitoring, outreach, and enforcement

Chapter 3. Affected Environment

This section describes the affected environment in the proposed project area. The affected environment is divided into four major components:

- **Habitat environment** (Section 3.1)
- **Biological and Ecological environment** (Section 3.2)
- **Economic and Social environment** (Sections 3.3)
- **Administrative environment** (Section 3.4)

3.1 Habitat Environment

3.1.1 Inshore/Estuarine Habitat

Many snapper grouper species utilize both pelagic and benthic habitats during several stages of their life histories; larval stages of these species live in the water column and feed on plankton. Most juveniles and adults are demersal (bottom dwellers) and associate with hard structures on the continental shelf that have moderate to high relief (e.g., coral reef systems and artificial reef structures, rocky hard-bottom substrates, ledges and caves, sloping soft-bottom areas, and limestone outcroppings). Juvenile stages of some snapper grouper species also utilize inshore seagrass beds, mangrove estuaries, lagoons, oyster reefs, and embayment systems. In many species, various combinations of these habitats may be utilized during daytime feeding migrations or seasonal shifts in cross-shelf distributions. Additional information on the habitat utilized by species in the Snapper Grouper Complex is included in Volume II of the Fishery Ecosystem Plan[2] (FEP; SAFMC 2009) and incorporated here by reference. The life history of red snapper is summarized in **Section 3.2.1**.

3.1.2 Offshore Habitat

Predominant snapper grouper offshore fishing areas are located in live bottom and shelf-edge habitats where water temperatures range from 11º to 27º C (52º to 81º F) due to the proximity of the Gulf Stream, with lower shelf habitat temperatures varying from 11º to 14º C (52º to 57º F). Water depths range from 16 to 55 meters (54 to 180 ft) or greater for live-bottom habitats, 55 to

[2] http://safmc.net/ecosystem-management/fishery-ecosystem-plan/

110 meters (180 to 360 ft) for the shelf-edge habitat, and from 110 to 183 meters (360 to 600 ft) for lower-shelf habitat areas.

The exact extent and distribution of productive snapper grouper habitat in South Atlantic continental shelf habitats is unknown. Current data suggest from 3% to 30% of the shelf is suitable habitat for these species. These live-bottom habitats may include low relief areas, supporting sparse to moderate growth of sessile (permanently attached) invertebrates, moderate relief reefs from 0.5 to 2 meters (1.6 to 6.6 ft), or high relief ridges at or near the shelf break consisting of outcrops of rock that are heavily encrusted with sessile invertebrates such as sponges and sea fan species. Live-bottom habitat is scattered irregularly over most of the shelf north of Cape Canaveral but is most abundant offshore from northeastern Florida. South of Cape Canaveral the continental shelf narrows from 56 to 16 kilometers (35 to 10 mi) wide off the southeast coast of Florida and the Florida Keys. The lack of a large shelf area, presence of extensive, rugged living fossil coral reefs, and dominance of a tropical Caribbean fauna are distinctive benthic characteristics of this area.

Rock outcroppings occur throughout the continental shelf from Cape Hatteras, North Carolina to Key West, Florida (MacIntyre and Milliman 1970; Miller and Richards 1979; Parker et al. 1983), which are principally composed of limestone and carbonate sandstone (Newton et al. 1971), and exhibit vertical relief ranging from less than 0.5 to over 10 meters (33 ft). Ledge systems formed by rock outcrops and piles of irregularly sized boulders are also common. Parker et al. (1983) estimated that 24% (9,443 km^2) of the area between the 27 and 101 meter (89 and 331 ft) depth contours from Cape Hatteras, North Carolina to Cape Canaveral, Florida is reef habitat. Although the bottom communities found in water depths between 100 and 300 meters (328 and 984 ft) from Cape Hatteras, North Carolina to Key West, Florida is relatively small compared to the whole shelf, this area, based upon landing information of fishers, constitutes prime reef fish habitat and probably significantly contributes to the total amount of reef habitat in this region.

Artificial reef structures are also utilized to attract fish and increase fish harvests; however, research on artificial reefs is limited and opinions differ as to whether or not these structures promote an increase of ecological biomass or merely concentrate fishes by attracting them from nearby, natural un-vegetated areas of little or no relief. There are several notable shipwrecks along the southeast coast in state and federal waters including *Lofthus* (eastern Florida), *SS Copenhagen* (southeast Florida), *Half Moon* (southeast Florida), *Hebe* (Myrtle Beach, South Carolina), *Georgiana* (Charleston, South Carolina), *U.S.S. Monitor* (Cape Hatteras, North Carolina), *Huron* (Nags Head, North Carolina), and *Metropolis* (Corolla, North Carolina).

The distribution of coral and live hard bottom habitat as presented in the Southeast Marine Assessment and Prediction Program (SEAMAP) bottom mapping project is a proxy for the distribution of the species within the snapper grouper complex. Maps are available on the South Atlantic Council's Habitat and Ecosystem Atlas[3].

[3] http://ocean.floridamarine.org/safmc_atlas/

Plots of the spatial distribution of offshore species were generated from the Marine Resources Monitoring, Assessment, and Prediction Program (MARMAP) data. The plots serve as point confirmation of the presence of each species within the scope of the sampling program. These plots, in combination with the hard bottom habitat distributions previously mentioned, can be employed as proxies for offshore snapper grouper complex distributions in the South Atlantic region. Maps of the distribution of snapper grouper species by gear type based on MARMAP data can also be generated through the Council's Internet Mapping System at the above address.

Additional information on the habitat utilized by snapper grouper species is included in Volume II of the Fishery Ecosystem Plan (FEP; SAFMC 2009).

3.1.3 Essential Fish Habitat

Essential Fish Habitat (EFH) is defined in the Magnuson-Stevens Fishery Conservation and Management Act (Magnuson-Stevens Act as "those waters and substrates necessary to fish for spawning, breeding, feeding, or growth to maturity" (16 U.S. C. 1802(10)). Specific categories of EFH identified in the South Atlantic Bight, which are utilized by federally managed fish and invertebrate species, include both estuarine/inshore and marine/offshore areas. Specifically, estuarine/inshore EFH includes: estuarine emergent and mangrove wetlands, submerged aquatic vegetation, oyster reefs and shell banks, intertidal flats, palustrine emergent and forested systems, aquatic beds, and estuarine water column. Additionally, marine/offshore EFH includes: live/hard bottom habitats, coral and coral reefs, artificial and manmade reefs, *Sargassum* species, and marine water column.

EFH utilized by snapper grouper species in this region includes coral reefs, live/hard bottom, submerged aquatic vegetation, artificial reefs, and medium to high profile outcroppings on and around the shelf break zone from shore to at least 183 meters [600 ft (but to at least 2,000 ft for wreckfish)] where the annual water temperature range is sufficiently warm to maintain adult populations of members of this largely tropical fish complex. EFH includes the spawning area in the water column above the adult habitat and the additional pelagic environment, including *Sargassum*, required for survival of larvae and growth up to and including settlement. In addition, the Gulf Stream is also EFH because it provides a mechanism to disperse snapper grouper larvae.

For specific life stages of estuarine-dependent and near shore snapper grouper species, EFH includes areas inshore of the 30 meter (100-ft) contour, such as attached macroalgae; submerged rooted vascular plants (seagrasses); estuarine emergent vegetated wetlands (saltmarshes, brackish marsh); tidal creeks; estuarine scrub/shrub (mangrove fringe); oyster reefs and shell banks; unconsolidated bottom (soft sediments); artificial reefs; and coral reefs and live/hard bottom habitats.

3.1.4 Habitat Areas of Particular Concern

Areas which meet the criteria for Essential Fish Habitat-Habitat Areas of Particular Concern (EFH-HAPC) for species in the snapper grouper management unit include medium to high profile offshore hard bottoms where spawning normally occurs; localities of known or likely periodic spawning aggregations; near shore hard bottom areas; The Point, The Ten Fathom Ledge, and Big Rock (North Carolina); The Charleston Bump (South Carolina); mangrove habitat; seagrass habitat; oyster/shell habitat; all coastal inlets; all state-designated nursery habitats of particular importance to snapper grouper (e.g., Primary and Secondary Nursery Areas designated in North Carolina); pelagic and benthic *Sargassum*; Hoyt Hills for wreckfish; the Oculina Bank Habitat Area of Particular Concern; all hermatypic coral habitats and reefs; manganese outcroppings on the Blake Plateau; Council-designated Artificial Reef Special Management Zones (SMZs); and deep-water Marine Protected Areas (MPAs). Areas that meet the criteria for EFH-HAPC include habitats required during each life stage (including egg, larval, postlarval, juvenile, and adult stages).

In addition to protecting habitat from fishing related degradation though fishery management plan regulations, the Council, in cooperation with NMFS, actively comments on non-fishing projects or policies that may impact EFH. With guidance from the Habitat Advisory Panel, the Council has developed and approved policies on: energy exploration, development, transportation and hydropower re-licensing; beach dredging and filling and large-scale coastal engineering; protection and enhancement of submerged aquatic vegetation; alterations to riverine, estuarine and near shore flows; offshore aquaculture; and marine and estuarine invasive species.

The potential impacts the action in this amendment may have on EFH and EFH-HAPC, are discussed in **Chapter 4** of this document.

3.2 Biological and Ecological Environment

3.2.1 Fish Populations Affected by this Amendment

The reef environment in the South Atlantic management area affected by actions in this environmental assessment is defined by two components (**Figure 3.2.1**). Each component will be described in detail in the following sections.

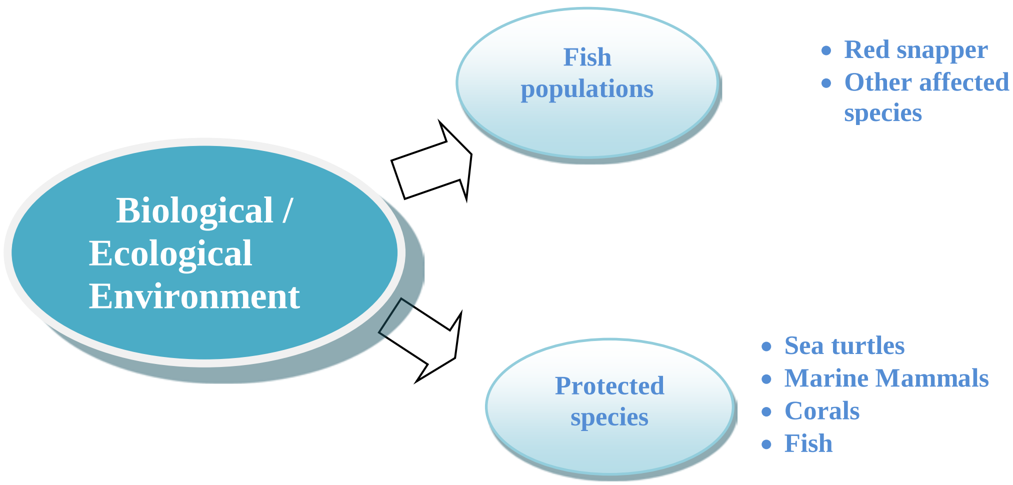

Figure 3.2.1. Two components of the biological environment described in this document.

The waters off the South Atlantic coast are home to a diverse population of fish. The snapper grouper fishery management unit contains 55 species of fish, many of them neither "snappers" nor "groupers." These species live in depths from a few feet (typically as juveniles) to hundreds of feet. As far as north/south distribution, the more temperate species tend to live in the upper reaches of the South Atlantic management area (e.g., black sea bass, red porgy) while the tropical species' core residence are in the waters off south Florida, Caribbean Islands, and northern South America (e.g., black grouper, mutton snapper). These are reef-dwelling species that live amongst each other. These species rely on the reef environment for protection and food. There are several reef tracts that follow the southeastern coast. The fact that these fish populations congregate dictates the nature of the fishery (multi-species) and further forms the type of management regulations proposed in this document.

Red Snapper

The red snapper is found from North Carolina to the Florida Keys and throughout the Gulf of Mexico to the Yucatan Peninsula (Robins and Ray 1986). It can be found at depths from 10 to 190 m (33-623 ft). Adults usually occur over rocky bottoms. Juveniles inhabit shallow waters and are common over sandy or muddy bottom habitat (Allen 1985).

Juvenile red snapper are rarely encountered in the U.S. South Atlantic. SEAMAPs fishery-independent trawling survey collected three in 1999, two in 2000, seven in 2013, and four in 2014 in nearshore (<30 ft deep) habitat. A headboat fisherman landed one age-0 red snapper during the 2012 mini-season. One age-0 fish was landed in the commercial fishery in 1980. Fishermen have reported observing juvenile red snapper on artificial reefs in shallow water. Estimates of juvenile red snapper mortality have been developed in the Gulf of Mexico; however, little information is available for the U.S. South Atlantic (SEDAR 41 2017).

The maximum size reported for this species is 100 cm (40 in) total length (TL) (Allen 1985; Robins and Ray 1986) and 22.8 kg (50 lbs) (Allen 1985). For samples collected from North Carolina to eastern Florida, maximum reported age is 45 years (White and Palmer 2004). The most recent maximum observed age for red snapper is 51 years. This fish was a 904 mm (36 in) TL female, and was caught in 2003 at 67 meters depth off Florida by a charter boat fisherman (SEDAR 41 2017).

Red snapper Life History
An Overview

- Extend from North Carolina to the Florida Keys, and throughout the Gulf of Mexico to the Yucatan Peninsula
- Waters ranging from 33-623 feet
- Red snapper do not migrate but can move long distances
- The spawning season extends from May to October, peaking in July through September.
- Can live for at least 51 years

In the U.S. South Atlantic, recent analyses (SEDAR 41 2017) estimate that 50% of female red snapper are mature at 1.3 years old and 325 mm (12.8 in) TL. Fifty percent of male red snapper are mature at 166 mm (6.5 in) TL (SEDAR 41 2017). Grimes (1987) found that the spawning season of this species varies with location, but in most cases occurs nearly year round. Farmer et al. (2017 and references therein) report spawning activity in the South Atlantic occurring from May through October peaking in June through September. According to SEDAR 41 (2017) spawning along the Atlantic coast of the southeastern U.S. generally occurs from April through October and peaks during June through August based on the presence of females with spawning indicators (i.e., the occurrence of hydrated oocytes and/or postovulatory follicles).

Red snapper eat fishes, shrimps, crabs, worms, cephalopods, and some planktonic items (Szedlemayer and Lee 2004).

3.2.2 Bycatch

The snapper grouper fishery is a multi-species fishery, which uses mostly hook and line gear although some trips use other gears such as pots/traps and spears. While the red snapper component of the snapper grouper fishery has been closed, red snapper have been bycatch in the fishery. Bycatch of red snapper is commonly associated with catches of black sea bass, red grouper, gag, scamp, greater amberjack, vermilion snapper, and gray triggerfish. The action in this amendment is not expected to result in significant changes in bycatch of red snapper and may reduce bycatch of red snapper during limited open seasons (**Appendix D**). In addition, the

Council, the NMFS, and the SEFSC have implemented and plan to implement numerous management measures and reporting requirements that have improved, or are likely to improve monitoring efforts of discards and discard mortality in the snapper grouper fishery. Therefore, no additional action is needed to minimize bycatch or bycatch mortality within the snapper grouper fishery. See **Appendix D** for detailed descriptions of bycatch when fishing for red snapper.

3.2.3 Other Species Affected

For details on the life histories and ecology of co-occurring species, the reader is referred to Volume II of the Fishery Ecosystem Plan (SAFMC 2009)[4].

3.2.4 The Stock Assessment Process

The Southeast Data, Assessment, and Review (SEDAR) process is a cooperative Fishery Management Council initiative to improve the quality and reliability of fishery stock assessments in the South Atlantic, Gulf of Mexico, and U.S. Caribbean. The Caribbean, Gulf of Mexico, and South Atlantic Fishery Management Councils manage SEDAR in coordination with the NMFS and the Atlantic and Gulf States Marine Fisheries Commissions. SEDAR seeks improvements in the scientific quality of stock assessments, constituent and stakeholder participation in assessment development, transparency in the assessment process, and a rigorous and independent scientific review of completed stock assessments.

SEDAR is organized around three workshops. First is the Data Workshop, during which fisheries monitoring and life history data are reviewed and compiled. Second is the Assessment Workshop, which may be conducted via a workshop and several webinars, during which assessment models are developed and population parameters are estimated using the information provided from the Data Workshop. Third and final is the Review Workshop, during which independent experts review the input data, assessment methods, and assessment products. The completed assessment, including the reports of all three workshops and all supporting documentation, are then forwarded to the Council's Scientific and Statistical Committee (SSC). The SSC considers whether the assessment represents the best available science and develops fishing level recommendations for Council consideration.

SEDAR workshops are public meetings organized by SEDAR. Workshop participants appointed by the lead Council are drawn from state and federal agencies, non-government organizations, Council members, Council advisors, and the fishing industry with a goal of including a broad range of disciplines and perspectives. All participants are expected to contribute to this scientific process by preparing working papers, contributing data, providing

[4] http://safmc.net/ecosystem-management/fishery-ecosystem-plan/

assessment analyses, evaluating and discussing information presented, and completing the workshop report.

3.2.5 Red snapper Stock Status

Manooch et al. (1998) conducted the first formal assessment of red snapper in the South Atlantic. The authors concluded that the status of the stock was not ideal but seemed to be responding to management action. Potts and Brennan (2001) revisited the results of that assessment and suggested a broader range of reduction in fishing mortality (F), from 30% to 80%.

The red snapper stock in the South Atlantic was assessed through the SEDAR process in 2007-2008. That assessment applied a statistical catch-age model using data through 2006 (SEDAR 15 2008). The assessment found that overfishing had been occurring since the 1960s and the red snapper stock was overfished. Although quantitative results varied, the qualitative results of overfishing a depleted stock were consistent across all catch-age model configurations examined during and after the assessment process (approximately 40 sensitivity runs), as well as with an alternative model formulation (surplus-production model).

In 2010, a benchmark assessment using the Beaufort Assessment Model (BAM) with data through 2009 was completed (SEDAR 24 2010). BAM is a statistical catch-age model developed by the analysts at the Beaufort, NC NMFS SEFSC laboratory, and is customizable to the data available. A surplus production model called ASPIC (Prager 1994; Prager 2004) was used as a complement for comparison purposes. Based on the assessment provided from the BAM, the SEDAR Review Panel concluded that the red snapper stock was overfished and overfishing was occurring. Similar to SEDAR 15 (2008), more than 40 sensitivities were run, all of which resulted in the same status determinations.

A benchmark assessment was completed in 2016 (SEDAR 41 2017) with data through 2014. Although the SEDAR Review Panel concluded that assessment results represent the best available science, the Panel identified several areas of uncertainty including the composition and magnitude of recreational discards, the stock-recruitment relationship, potential changes in CPUE catchability, and the selectivities for the different fishery fleets. The SSC reviewed the assessment and provided fishing level recommendations at their May 2016 meeting based on $F_{30\%SPR}$ as a proxy for F_{MSY}. The base assessment run suggested that in the terminal year of 2014 the stock remained overfished. The SSC did not have confidence in the terminal fishing mortality estimates; however, they recommended that the assessment results suggested overfishing was likely occurring in the terminal years of the assessment (2012-2014) although the degree to which overfishing was occurring at that time could not be reliably quantified from the assessment results (see May 2016 Final SSC report).

SEDAR 41 (2017) estimated the long-term maximum sustainable yield (MSY) to be about 25% of what it was estimated to be in SEDAR 24 (2010), and projected catch levels from SEDAR 41 at the fishing mortality level predicted to rebuild the stock in the specified timeframe ($F_{Rebuild}$) were approximately 21% of the catch levels projected for 2017 based on SEDAR 24

(2010). Given this, and the various sources of uncertainty in the SEDAR 41 (2017) assessment, the Council sought the SSC's recommendations on additional projection runs and reference point criteria, reliability of MRIP estimates for red snapper (landings and discards), and the risk associated with using different values of MSY (see October 2016 Final SSC Report, **Appendix M**). In addition, the Council requested that projections under a discards-only scenario be provided for discussion at their March 2017 meeting. However, the SEFSC indicated (via letter dated February 15, 2017 and included in **Appendix J**) the projections could not be completed due to the length of time since the completion of the assessment, uncertainty in the landings since most landings are coming from discards, and the change in MRIP methodology for estimating landings and discards. Moreover, the Council received a letter from the NMFS (dated March 3, 2017 and included in **Appendix J**) stating the Council has likely taken sufficient action to address overfishing of red snapper in the South Atlantic and should focus efforts on a methodology to obtain an ABC for red snapper. SEDAR 41 was updated due to revisions in the headboat index and presented to the SSC in April 2017. The SSC indicated they could not provide an ABC that was useful in management (SAFMC 2017). Hence, and due to the issues laid out by the SEFSC, the Council requested that the SEFSC and the SSC collaborate to explore approaches to arrive at an ABC for red snapper that can be applied to a long-term management approach.

3.2.6 Protected Species

There are at least 51 species, or distinct population segments (DPSs) of species, protected by federal law that may occur in the exclusive economic zone (EEZ) of the South Atlantic Region. Thirty-one of these species are marine mammals protected under the Marine Mammal Protection Act (MMPA) (Wynne and Schwartz 1999, Waring et al. 2013). The MMPA requires that each commercial fishery be classified by the number of marine mammals they seriously injure or kill. NMFS's List of Fisheries (LOF) classifies U.S. commercial fisheries into three categories based on the number of incidental mortality or serious injury they cause to marine mammals. More information about the LOF can be found online[5].

Four of the marine mammal species (sperm, sei, fin, blue, and North Atlantic right whales (NARW)) protected by the MMPA, are also listed as endangered under the Endangered Species Act (ESA). In addition to those five marine mammals, six species or DPSs of sea turtles (green North Atlantic and South Atlantic DPSs, hawksbill, Kemp's ridley, leatherback, and the loggerhead NWA DPS); the smalltooth sawfish; five DPSs of Atlantic sturgeon; Nassau grouper, and seven species of coral [elkhorn coral (*Acropora palmata*), staghorn coral (*A. cervicornis*) ("*Acropora*" collectively); lobed star coral (*Orbicella annularis*), mountainous star coral (*O. faveolata*), boulder star (*O. franksi*); rough cactus coral (*Mycetophylia ferox*), and pillar coral (*Dendrogyra cylindrus*)] are also protected under the ESA and occur within the action area of the snapper grouper fishery. Portions of designated critical habitat for NARW, the Northwest Atlantic (NWA) DPS of loggerhead sea turtles, and *Acropora* corals occur within the South Atlantic Council's jurisdiction.

[5] http://www.nmfs.noaa.gov/pr/interactions/fisheries/2017_list_of_fisheries_lof.html

NMFS has conducted specific analyses ("Section 7 consultations") to evaluate the potential adverse effects from the South Atlantic snapper grouper fishery on species and critical habitat protected under the ESA. On December 1, 2016, NMFS completed its most recent biological opinion on the snapper grouper fishery of the South Atlantic Region (NMFS 2016). In this biological opinion, NMFS concluded that the snapper grouper fishery's continued authorization is likely to adversely affect but is not likely to jeopardize the continued existence of the NARW, loggerhead sea turtle Northwest Atlantic DPS, leatherback sea turtle, Kemp's ridley sea turtle, green sea turtle North Atlantic DPS, green sea turtle South Atlantic DPS, hawksbill sea turtle, smalltooth sawfish U.S. DPS, or Nassau grouper. NMFS also concluded that designated critical habitat and other ESA-listed species in the South Atlantic Region were not likely to be adversely affected. Summary information on the species that may be adversely affected by the snapper-grouper fishery and how they are affected is presented below. The 2016 biological opinion provides additional information on these species, how they are affected by the snapper grouper fishery, and the authorized incidental take levels of these species in the snapper-grouper fishery.

3.2.6.1 North Atlantic Right Whales

The NARW, *Eubalaena glacialis* (Rosenbaum et al. 2000), is a large baleen whale. NARWs feed on larger species of zooplankton and almost exclusively on copepods. Feeding takes place subsurface (subsurface feeding) or at the water's surface (surface skim feeding), depending on the vertical distribution of their food species. NARW dive as deep as 306 m (1,003 ft) (Mate et al. 1992).

The coastal waters of the southeastern United States are a wintering and sole known calving area for NARW. NARW generally occur off South and North Carolina from November 1 through April 30 (NMFS 2008d) and have been sighted as far as about 30 nm offshore (Knowlton et al. 2002; Pabst et al. 2009). Sighting records of NARW spotted in the core calving area off Georgia and Florida consist of mostly mother-calf pairs and juveniles but also some adult males and females without calves (Cole et al. 2013; Kraus and Rolland 2007; Parks et al. 2007a). Based on preliminary photo-identification analysis of right whale photographs collected in the southeastern U.S., the median number of NARWs (including calves, but excluding reported or assumed calf mortalities) documented in the southeastern U.S. from the 2009-2013 calving seasons is 165 (Right Whale Consortium 2014; K. Jackson, personal communication, July 21, 2016; Waring et al. 2016). Right whale concentrations are highest in the core calving area from November 15 through April 15 (71 FR 36299, June 26, 2006); on rare occasions, right whales have been spotted as early as September and as late as July (Taylor et al. 2010). Most calves are likely born early in the calving season. NARW distribution off Georgia and Florida is restricted to the south and east by the warm waters of the Gulf Stream, which serves as a thermal limit for NARW (Keller et al. 2006). Water temperature, bathymetry, and surface chop are factors in the distribution of calving NARW in the southeastern U.S. (Good 2008; Keller et al. 2012). Systematic surveys conducted off the coast of North Carolina during the winters of 2001 and 2002 sighted 8 calves, suggest the calving grounds may extend as far north as Cape Fear. Four of the calves were not sighted by surveys conducted further south. One of the cows photographed was new to researchers, having effectively eluded identification over the period of its maturation (McLellan et al. 2003).

Commercial and recreational fishers in the South Atlantic snapper-grouper fishery use hook-and-line gear, spear/powerheads, and pot/traps to target black sea bass). The black seas bass pot component of the snapper-grouper fishery is the only component of the fishery that NMFS determined may adversely affect NARWs; NMFS discounted effects from all the other gear types in the biological opinion. NMFS estimated that the number of annual lethal takes for NARWs from black sea bass trap/pot gear ranged from an estimated minimum of 0.005 to a maximum of 0.08. This equates to 1 estimated lethal entanglement approximately every 25 to 42 years.

3.2.6.2 ESA-Listed Sea Turtles

Green, hawksbill, Kemp's ridley, leatherback, and loggerhead sea turtles are all highly migratory and travel widely throughout the South Atlantic. This section includes a brief overview of the general life history characteristics of the sea turtles found in the South Atlantic region. Several volumes exist that cover the biology and ecology of these species more thoroughly (i.e., Lutz and Musick (eds.) 1997, Lutz et al. (eds.) 2002).

Green sea turtle hatchlings are thought to occupy pelagic areas of the open ocean and are often associated with *Sargassum* rafts (Carr 1987, Walker 1994). Pelagic stage green sea turtles are thought to be carnivorous. Stomach samples of these animals found ctenophores and pelagic snails (Frick 1976, Hughes 1974). At approximately 20 to 25 cm carapace length, juveniles migrate from pelagic habitats to benthic foraging areas (Bjorndal 1997). As juveniles move into benthic foraging areas a diet shift towards herbivory occurs. They consume primarily seagrasses and algae, but are also know to consume jellyfish, salps, and sponges (Bjorndal 1980, 1997; Paredes 1969; Mortimer 1981, 1982). The diving abilities of all sea turtles species vary by their life stages. The maximum diving range of green sea turtles is estimated at 110 m (360 ft) (Frick 1976), but they are most frequently making dives of less than 20 m (65 ft.) (Walker 1994). The time of these dives also varies by life stage. The maximum dive length is estimated at 66 minutes with most dives lasting from 9 to 23 minutes (Walker 1994).

The **hawksbill's** pelagic stage lasts from the time they leave the nesting beach as hatchlings until they are approximately 22-25 cm in straight carapace length (Meylan 1988, Meylan and Donnelly 1999). The pelagic stage is followed by residency in developmental habitats (foraging areas where juveniles reside and grow) in coastal waters. Little is known about the diet of pelagic stage hawksbills. Adult foraging typically occurs over coral reefs, although other hard-bottom communities and mangrove-fringed areas are occupied occasionally. Hawksbills show fidelity to their foraging areas over several years (Van Dam and Diéz 1998). The hawksbill's diet is highly specialized and consists primarily of sponges (Meylan 1988). Gravid females have been noted ingesting coralline substrate (Meylan 1984) and calcareous algae (Anderes Alvarez and Uchida 1994), which are believed to be possible sources of calcium to aid in eggshell production. The maximum diving depths of these animals are not known, but the maximum length of dives is estimated at 73.5 minutes. More routinely, dives last about 56 minutes (Hughes 1974).

Kemp's ridley hatchlings are also pelagic during the early stages of life and feed in surface waters (Carr 1987, Ogren 1989). Once the juveniles reach approximately 20 cm carapace length they move to relatively shallow (less than 50 m) benthic foraging habitat over unconsolidated substrates (Márquez-M. 1994). They have also been observed transiting long distances between foraging habitats (Ogren 1989). Kemp's ridleys feeding in these nearshore areas primarily prey on crabs, though they are also known to ingest mollusks, fish, marine vegetation, and shrimp (Shaver 1991). The fish and shrimp Kemp's ridleys ingest are not thought to be a primary prey item but instead may be scavenged opportunistically from bycatch discards or from discarded bait (Shaver 1991). Given their predilection for shallower water, Kemp's ridleys most routinely make dives of 50 m or less (Soma 1985, Byles 1988). Their maximum diving range is unknown. Depending on the life stage, Kemp's ridleys may be able to stay submerged anywhere from 167 minutes to 300 minutes, though dives of 12.7 minutes to 16.7 minutes are much more common (Soma 1985, Mendonca and Pritchard 1986, Byles 1988). Kemp's ridleys may also spend as much as 96% of their time underwater (Soma 1985, Byles 1988).

Leatherbacks are the most pelagic of all ESA-listed sea turtles and spend most of their time in the open ocean. Although they will enter coastal waters and are seen over the continental shelf on a seasonal basis to feed in areas where jellyfish are concentrated. Leatherbacks feed primarily on cnidarians (medusae, siphonophores) and tunicates. Unlike other sea turtles, leatherbacks' diets do not shift during their life cycles. Because leatherbacks' ability to capture and eat jellyfish is not constrained by size or age, they continue to feed on these species regardless of life stage (Bjorndal 1997). Leatherbacks are the deepest diving of all sea turtles. It is estimated that these species can dive in excess of 1,000 m (Eckert et al. 1989) but more frequently dive to depths of 50 m to 84 m (Eckert et al. 1986). Dive times range from a maximum of 37 minutes to more routines dives of 4 to 14.5 minutes (Standora et al. 1984, Eckert et al. 1986, Eckert et al. 1989, Keinath and Musick 1993). Leatherbacks may spend 74% to 91% of their time submerged (Standora et al. 1984).

Loggerhead hatchlings forage in the open ocean and are often associated with *Sargassum* rafts (Hughes 1974, Carr 1987, Walker 1994, Bolten and Balazs 1995). The pelagic stage of these sea turtles eat a wide range of organisms including salps, jellyfish, amphipods, crabs, syngnathid fish, squid, and pelagic snails (Brongersma 1972). Stranding records indicate that when pelagic immature loggerheads reach 40-60 cm straight-line carapace length they begin to live in coastal inshore and nearshore waters of the continental shelf throughout the U.S. Atlantic (Witzell 2002). Here they forage over hard- and soft-bottom habitats (Carr 1986). Benthic foraging loggerheads eat a variety of invertebrates with crabs and mollusks being an important prey source (Burke et al. 1993). Estimates of the maximum diving depths of loggerheads range from 211 m to 233 m (692-764ft.) (Thayer et al. 1984, Limpus and Nichols 1988). The lengths of loggerhead dives are frequently between 17 and 30 minutes (Thayer et al. 1984, Limpus and Nichols 1988, Limpus and Nichols 1994, Lanyan et al. 1989) and they may spend anywhere from 80 to 94% of their time submerged (Limpus and Nichols 1994, Lanyan et al. 1989).

Sea turtles are vulnerable to capture by bottom longline and vertical hook-and-line gear. Hook-and-line gear used in the fishery includes commercial bottom longline gear and commercial and recreational vertical line gear (e.g., handline, bandit gear, and rod-and-reel). The magnitude of the interactions between sea turtles and the South Atlantic snapper grouper fishery was most recently evaluated in the 2016 biological opinion (i.e., NMFS (2016). In **Table 3.2.1** the 3-year estimated captures and mortalities authorized for the fishery in the 2016 biological opinion are specified. Section 5.2 of the 2016 biological opinion presents a summary of the data sources considered for the sea turtle analyses, estimation methods, and data limitations and assumptions associated with the estimates for each fishery component. Loggerhead sea turtles are the species most affected by the proposed action. The majority of estimated sea turtle captures appear to occur in the recreational vertical lines targeting snapper grouper species due to the large amount of recreation fishing effort. However, it is also important to recognize that the sea turtle capture estimates for the recreational vertical line are also likely the most uncertain.

Table 3.2.1. Estimated 3-year sea turtle (T) and mortalities (M) estimates in the South Atlantic Snapper-Grouper Fishery by fishery component and overall.

Fishery Component	Loggerhead		Kemp's ridley		Green		Hawksbill		Leatherback	
	T	M	T	M	T	M	T	M	T	M
Commercial Bottom Longline*	9	5	1	1	1	1	1	1	3	2
Commercial Vertical Line**	62	26	18	8	11	5	1	1	1	1
Recreational Vertical Line ***	546	165	159	48	96	30	2	1	1	1
All Components Combined	617	196	178	57	108	36	5	3	5	4

*Only 10 hardshell sea turtles combined are estimated to be captured every 3 years; only 1 hawksbill, Kemp's ridley or green sea turtle is expected to be captured and killed every 3 years in this component. **No more than 90 hardshell sea turtles combined are estimated for this component. ***No more than 801 hardshell sea turtle combined are estimated for this component.

Regulations implemented through Amendment 15B to the Snapper Grouper FMP (74 FR 31225; June 30, 2009; SAFMC 2008) require all commercial or charter/headboat vessels with a South Atlantic snapper grouper permit, carrying hook-and-line gear on board, to possess required literature and release gear to aid in the safe release of incidentally caught sea turtles. Comprehensive Ecosystem-Based Amendment 2 modified these requirements (76 FR 82183; December 30, 2011; SAFMC 2011e) by requiring different gear for vessels with different freeboard heights, mirroring the requirements in the Gulf of Mexico. These regulations are thought to decrease the mortality associated with accidental interactions with sea turtles.

Snapper-grouper vessels transiting to and from fishing areas and moving during fishing activity also pose a potential threat to sea turtles (NMFS 2016). As explained in the 2016 biological opinion, it is very difficult to definitively or even approximately evaluate the potential risk to sea turtles stemming from specific vessel traffic from any action because of the numerous variables (e.g., vessel type, speed, traffic, environmental conditions, sea turtle abundance in area transited) that may impact vessel strike rates. This difficulty is compounded by a general lack of information on vessel use trends, particularly in regard to offshore vessel traffic.

3.2.6.3 ESA-Listed Marine Fish

Historically the **smalltooth sawfish** in the U.S. ranged from New York to the Mexico border. Their current range is poorly understood but believed to have contracted from these historical areas. In the South Atlantic region, they are most commonly found in Florida, primarily off the Florida Keys (Simpfendorfer and Wiley 2004). Only two smalltooth sawfish have been recorded north of Florida since 1963 [the first was captured off North Carolina in 1963 and the other off Georgia in 2002 (National Smalltooth Sawfish Database, Florida Museum of Natural History)]. Historical accounts and recent encounter data suggest that immature individuals are most common in shallow coastal waters less than 25 meters (Bigelow and Schroeder 1953, Adams and Wilson 1995), while mature animals occur in waters in excess of 100 meters (Simpfendorfer pers. comm. 2006). Smalltooth sawfish feed primarily on fish. Mullet, jacks, and ladyfish are believed to be their primary food sources (Simpfendorfer 2001). Smalltooth sawfish also prey on crustaceans (mostly shrimp and crabs) by disturbing bottom sediment with their saw (Norman and Fraser 1938, Bigelow and Schroeder 1953).

On June 29, 2016, NMFS published a final rule in the *Federal Register* listing Nassau grouper as threatened under the Endangered Species Act due to a decline in its population (81 FR 42268). The final rule became effective on July 29, 2016. The Nassau grouper's confirmed distribution currently includes “Bermuda and Florida (USA), throughout the Bahamas and Caribbean Sea” (e.g., Heemstra and Randall 1993, Hill and Sadovy de Mitcheson, 2013). The Nassau grouper is primarily a shallow-water, insular fish species that has long been valued as a major fishery resource throughout the wider Caribbean, South Florida, Bermuda, and the Bahamas (Carter et al. 1994). As larvae, Nassau grouper are planktonic. After an average of 35-40 days and at an average size of 32 millimeters total length (TL), larvae recruit from an oceanic environment into demersal habitats (Colin 1992, Eggleston 1995). Juvenile Nassau grouper (12-15 centimeters TL) are relatively solitary and remain in specific areas (associated with macroalgae, and both natural and artificial reef structure) for months (Bardach 1958). As juveniles grow, they move progressively to deeper areas and offshore reefs (Tucker et al. 1993, Colin et al. 1997). Smaller juveniles occur in shallower inshore waters (3.7-16.5 meters [m]) and larger juveniles are more common near deeper (18.3-54.9 m) offshore banks (Bardach et al. 1958, Cervigón 1966, Silva Lee 1974, Radakov et al. 1975, Thompson and Munro 1978). Adult Nassau grouper also tend to be relatively sedentary and are commonly associated with high-relief coral reefs or rocky substrate in clear waters to depths of 130 m. Generally, adults are most common at depths less than 100 m (Hill and Sadovy de Mitcheson 2013) except when at spawning aggregations where they are known to descend to depths of 255 m (Starr et al. 2007). Nassau grouper form spawning aggregations at predictable locations around the winter full moons, or between full and new moons (Smith 1971, Colin 1992, Tucker et al. 1993, Aguilar-Perera 1994, Carter et al. 1994, Tucker and Woodward 1994). The most serious threats to the status of Nassau grouper today are fishing at spawning aggregations and inadequate law enforcement protecting spawning aggregations in many foreign nations. are no known spawning aggregations within the South Atlantic Region.

Of the 3 basic types of gear used in the South Atlantic snapper-grouper fishery by commercial and/or recreational fishers (i.e., hook-and-line gear, spear/powerheads, and black sea bass pots), we believe only snapper-grouper hook-and-line gear may adversely affect smalltooth sawfish and Nassau grouper. Interactions with smalltooth sawfish are limited to off of Florida;

and are quite rare. In the 2016 biological opinion, NMFS anticipates only 8 smalltooth sawfish interactions every three years in all snapper-grouper hook-and-line-gear components combined and they are anticipated to all be non-lethal. Nassau grouper incidental captures appear to be more frequent. Farmer (2016) estimated that over the last 10 years, a total of approximately 1,387 Nassau grouper have been captured annually in the fishery. Based on an estimated 20% mortality rate, Farmer (2016) estimated an annual average expected mortality of approximately 282 fish. Future anticipated captures and mortalities are expected to remain at these same levels.

3.3 Economic and Social Environment

3.3.1 Economic Environment

Details on red snapper, and the South Atlantic snapper grouper fishery in general, can be found in Snapper Grouper Amendment 17A (SAFMC 2010) and the Comprehensive ACL Amendment for the South Atlantic Region (SAFMC 2011b), respectively.

3.3.1.1 Economic Description of the Commercial Sector

The major sources of data summarized in this description are the NMFS SERO Permits Information Management System (PIMS) and the SEFSC Social Science Research Group (SSRG) Socioeconomic Panel[6] data set. Inflation adjusted revenues and prices are reported in 2016 dollars.

Permits

Any fishing vessel that harvests and sells any of the snapper grouper species from the South Atlantic EEZ must have a valid South Atlantic commercial snapper grouper permit, which is a limited access permit. As of July 10, 2017, there were 544 valid or renewable South Atlantic Snapper Grouper Unlimited Permits and 114 valid or renewable 225-lb Trip-limited Permits. After a permit expires, it can be renewed or transferred up to one year after the date of expiration. The number of valid or renewable snapper grouper permits declined steadily from 2012 through 2016 (**Table 3.3.1**).

Table 3.3.1. Number of valid or renewable South Atlantic commercial snapper grouper permits.

	Unlimited	225-lb Trip-limited
2012	604	132
2013	592	129
2014	584	125
2015	571	121

[6] This data set is compiled by the SEFSC SSRG from Federal Logbook System (FLS) data, supplemented by average prices calculated from the Accumulated Landings System (ALS). Because these landings are self-reported, they may diverge slightly from dealer-reported landings presented elsewhere.

2016	565	116
Average	583	125

Source: NMFS SERO Permits Dataset, 2017.

Landings, Value, and Effort

The number of federally permitted commercial vessels that landed South Atlantic red snapper increased from 2012 through 2014 and then dropped sharply in 2015 and 2016, during which time there was no federal commercial red snapper season (**Table 3.3.2**). Landings of red snapper followed a similar pattern. The landings reported in 2015 and 2016 are either from state water catches or misreported/out-of-season harvests. On average (2012 through 2016), vessels that landed red snapper did so on approximately 9% of their South Atlantic trips and red snapper accounted for only 2% of their annual all species revenue, including revenue from Gulf trips (**Table 3.3.2** and **Table 3.3.3**). Average all species vessel-level revenue for these vessels rose steadily from 2012 through 2016, increasing by approximately 45% overall. During this time period, the average annual price per pound gutted weight (gw) of red snapper ranged from $4.21 to $5.28 (2016 dollars) (**Table 3.3.3**).

Imports

Imports of seafood products compete in the domestic seafood market and have in fact dominated many segments of the seafood market. Imports aid in determining the price for domestic seafood products and tend to set the price in the market segments in which they dominate. Seafood imports have downstream effects on the local fish market. At the harvest level for snapper species, including red snapper, imports affect the returns to fishermen through the ex-vessel prices they receive for their landings. As substitutes to domestic production of snappers, imports tend to cushion the adverse economic effects on consumers resulting from a reduction in domestic landings. The following describes the imports of fish products that directly compete with domestic harvest of snappers, including red snapper.

Imports[7] of fresh snapper were 22.7 million lbs product weight (pw) in 2012. They increased steadily to 30.5 million lbs pw in 2016. Total revenue from fresh snapper imports increased from $69.4 million (2016 dollars[8]) in 2012 to a five-year high of $90.2 million in 2016. Imports of fresh snappers primarily originated in Mexico or Central America, and entered the U.S. through the port of Miami. Imports of fresh snapper were highest on average (2012 through 2016) during the months of March through July.

[7] NOAA Fisheries Service purchases fisheries trade data from the Foreign Trade Division of the U.S. Census Bureau. Data are available for download at http://www.st.nmfs.noaa.gov/st1/trade/index.html.
[8] Converted to 2016 dollars using the annual, not seasonally adjusted GDP implicit price deflator provided by the U.S. Bureau of Economic Analysis.

Imports of frozen snapper were substantially less than imports of fresh snapper from 2012 through 2016. The annual value of frozen snapper imports ranged from $25 million (2016 dollars) to $38 million during the time period, with a peak in 2016. Imports of frozen snapper primarily originated in South America (especially Brazil), Indonesia, Mexico, and Central America. The majority of frozen snapper imports entered the U.S. through the ports of Miami, New York, and San Juan. Imports of frozen snappers tended to be lowest during March through May when fresh snapper imports were high.

Business Activity

The commercial harvest and subsequent sales and consumption of fish generates business activity as fishermen expend funds to harvest the fish and consumers spend money on goods and services, such as red snapper purchased at a local fish market and served during restaurant visits. These expenditures spur additional business activity in the region(s) where the harvest and purchases are made, such as jobs in local fish markets, grocers, restaurants, and fishing supply establishments. In the absence of the availability of a given species for purchase, consumers would likely spend their money on substitute goods, such as other finfish or seafood products, and services, such as visits to different food service establishments. As a result, the analysis presented below represents a distributional analysis only; that is, it only shows how economic effects may be distributed through regional markets and should not be interpreted to represent the impacts if these species are not available for harvest or purchase.

Estimates of the U.S. average annual business activity associated with the commercial harvest of red snapper, and all species harvested by the vessels that harvested these red snapper, were derived using the model[9] developed for and applied in NMFS (2017) and are provided in **Table 3.3.4**. This business activity is characterized as jobs (full- and part-time), income impacts (wages, salaries, and self-employed income), output (sales) impacts (gross business sales), and value-added impacts, which represent the contribution made to the U.S. Gross Domestic Product (GDP). These impacts should not be added together because this would result in double counting. It should be noted that the results provided should be interpreted with caution and demonstrate the limitations of these types of assessments. These results are based on average relationships developed through the analysis of many fishing operations that harvest many different species. Separate models to address individual species are not available. For example, the results provided here apply to a general reef fish category rather than just red snapper, and a harvester job is "generated" for approximately every $32,000 (2016 dollars) in ex-vessel revenue. These results contrast with the number of harvesters (vessels) with recorded landings of red snapper presented in **Table 3.3.2**.

Table 3.3.4. Average annual business activity (2012 - 2016) associated with the commercial harvest of red snapper and the harvest of all species by vessels that landed red snapper. All monetary estimates are in 2016 dollars.*

[9] A detailed description of the input/output model is provided in NMFS (2011).

Species	Average Ex-vessel Value ($ thousands)	Total Jobs	Harvester Jobs	Output (Sales) Impacts ($ thousands)	Income Impacts ($ thousands)	Value Added ($ thousands)
Red snapper	$122	16	4	$1,207	$443	$626
All species harvested by vessels that landed red snapper.	$6,896	921	219	$68,390	$25,115	$35,485

*Converted to 2016 dollars using the annual, not seasonally adjusted GDP implicit price deflator provided by the U.S. Bureau of Economic Analysis.

3.3.1.2 Economic Description of the Recreational Sector

The South Atlantic recreational sector is comprised of the private and for-hire modes. The private mode includes anglers fishing from shore (all land-based structures) and private/rental boats. The for-hire mode is composed of charter boats and headboats (also called partyboats). Charter boats generally carry fewer passengers and charge a fee on an entire vessel basis, whereas headboats carry more passengers and payment is per person. The type of service, from a vessel- or passenger-size perspective, affects the flexibility to search different fishing locations during the course of a trip and target different species since larger concentrations of fish are required to satisfy larger groups of anglers.

Angler Effort

Recreational effort derived from the Marine Recreational Information Program (MRIP) database can be characterized in terms of the number of trips as follows:

- Target effort - The number of individual angler trips, regardless of duration, where the intercepted angler indicated that the species or a species in the species group was targeted as either the first or the second primary target for the trip. The species did not have to be caught.
- Catch effort - The number of individual angler trips, regardless of duration and target intent, where the individual species or a species in the species group was caught. The fish did not have to be kept.
- Total recreational trips - The total estimated number of recreational trips in the South Atlantic, regardless of target intent or catch success.

A target trip may reveal an angler’s preference for a certain species, and thus may carry more relevant information when assessing the economic effects of regulations on the subject species than the other two measures of recreational effort. The majority of red snapper target trips in the South Atlantic, as estimated by MRIP, were recorded in Florida on private vessels from 2012 through 2016 (**Table 3.3.5**). Estimates of red snapper target effort for additional years, and other measures of directed effort, are available online[10].

During the short red snapper seasons that occurred in 2012, 2013, and 2014, both Florida and Georgia also collected some recreational effort data as part of their state-run survey programs.[11] Florida estimated the total number of private recreational boat trips that targeted red snapper and these estimates are incorporated herein by reference (Sauls et al. 2017). Direct comparison of these estimates to the MRIP estimates is not possible because MRIP data are recorded at the angler level rather than the vessel level. Georgia conducted telephone surveys of for-hire (charter vessel and headboat) captains to collect catch and effort data during the 2012-2014 recreational red snapper seasons and also administered a voluntary, private angler electronic catch survey during that time. These estimates are also incorporated herein by reference (Knowlton 2015). The number of for-hire red snapper target trips recorded by Georgia was greater than what was estimated by MRIP, but the number of voluntarily reported private angler trips was significantly lower than the MRIP estimate (**Table 3.3.6**). North Carolina and South Carolina did not collect target red snapper effort data in 2012-2014.

[10] http://www.st.nmfs.noaa.gov/recreational-fisheries/access-data/run-a-data-query/queries/index.
[11] These survey programs were designed to maximize sampling opportunities during the mini-seasons.

Table 3.3.6. Georgia estimates of angler trips that targeted red snapper, 2012-2014.

Year	For-hire (charter and headboat) angler trips*	Private angler trips
2012	100	31
2013	70	53
2014	312	120

Source: Knowlton (2015).
*There were 76, 47, and 180 charter angler trips targeting red snapper in 2012, 2013, and 2014, respectively.

Similar analysis of recreational angler trips (with the exception of the Georgia-based telephone survey) is not possible for the headboat mode because headboat data are not collected at the angler level. Estimates of effort by the headboat mode are provided in terms of angler days, or the total number of standardized full-day angler trips.[12] Headboat effort in the South Atlantic, in terms of angler days, increased substantially in Florida through Georgia from 2012 through 2014, and then leveled off through 2016. In North Carolina and South Carolina, it was mostly stable during this time period (**Table 3.3.7**). Headboat effort was the highest, on average, during the summer months of June through August (**Table 3.3.8**).

[12] Headboat trip categories include half-, three-quarter-, full-, and 2-day trips. A full-day trip equals one angler day, a half-day trip equals .5 angler days, etc. Angler days are not standardized to an hourly measure of effort and actual trip durations may vary within each category.

Permits

For-hire vessels are required to have a for-hire snapper grouper permit to fish for or possess snapper grouper species in the South Atlantic EEZ. As of July 10, 2017, there were 1,649 valid for-hire snapper grouper permits. This sector operates as an open access fishery and not all permitted vessels are necessarily active in the fishery. Some vessel owners may have obtained open access permits as insurance for uncertainties in the fisheries in which they currently operate. The number of for-hire vessel permits issued for the South Atlantic snapper grouper fishery reached a five-year high of 1,867 permits in 2016 (**Table 3.3.9**). The majority of snapper grouper for-hire permitted vessels were home-ported in Florida; a relatively high proportion of these permitted vessels were also home-ported in North Carolina and South Carolina. Many vessels with South Atlantic for-hire snapper grouper permits were home-ported in states outside of the SAFMC's area of jurisdiction. On average (2012 through 2016), these vessels accounted for approximately 11% of the total number of for-hire snapper grouper permits issued.

Table 3.3.9. Number of South Atlantic for-hire snapper grouper permits, by homeport state, 2012-2016.

Home Port	2012	2013	2014	2015	2016	Average
North Carolina	313	308	294	308	331	311

Florida	1,121	1,120	1,062	1,071	1,100	1,095
Gulf (AL-TX)	93	91	81	73	69	81
Others	106	100	96	94	102	100
Total	1,797	1,799	1,727	1,779	1,867	1,794

Source: NMFS SERO Permits Dataset, 2017.

Although the for-hire permit application collects information on the primary method of operation, the permit itself does not identify the permitted vessel as either a headboat or a charter vessel and vessels may operate in both capacities. However, only federally permitted headboats are required to submit harvest and effort information to the NMFS Southeast Region Headboat Survey (SRHS). Participation in the SRHS is based on determination by the Southeast Fishery Science Center (SEFSC) that the vessel primarily operates as a headboat. As of February 17, 2017, 63 South Atlantic headboats were registered in the SRHS (K. Fitzpatrick, NMFS SEFSC, pers. comm.). The majority of these headboats were located in Florida/Georgia (36), followed by North Carolina (16) and South Carolina (11).

There are no specific permitting requirements for recreational anglers to harvest snapper grouper species. Instead, anglers are required to possess either a state recreational fishing permit that authorizes saltwater fishing in general, or be registered in the federal National Saltwater Angler Registry system, subject to appropriate exemptions. As a result, it is not possible to identify with available data how many individual anglers would be expected to be affected by this proposed amendment.

Economic Value

Participation, effort, and harvest are indicators of the value of saltwater recreational fishing. However, a more specific indicator of value is the satisfaction that anglers experience over and above their costs of fishing. The monetary value of this satisfaction is referred to as consumer surplus (CS). The value or benefit derived from the recreational experience is dependent on several quality determinants, which include fish size, catch success rate, and the number of fish kept. These variables help determine the value of a fishing trip and influence total demand for recreational fishing trips. The estimated value of the CS for catching and keeping a second red snapper on an angler trip is approximately $81 (values updated to 2016 dollars[13]), and decreases thereafter (approximately $54 for a third red snapper, $40 for a fourth red snapper, and $31 for a fifth red snapper in 2016 dollars) (Carter and Liese 2012).

The foregoing estimates of economic value should not be confused with economic impacts associated with recreational fishing expenditures. Although expenditures for a specific good or service may represent a proxy or lower bound of value (a person would not logically pay more for something than it was worth to them), they do not represent the net value (benefits minus cost), nor the change in value associated with a change in the fishing experience.

With regards to for-hire businesses, economic value can be measured by producer surplus (PS) per passenger trip (the amount of money that a vessel owner earns in excess of the cost of providing the trip). Estimates of the PS per for-hire passenger trip are not available. Instead, net operating revenue (NOR), which is the return used to pay all labor wages, returns to capital, and owner profits, is used as a proxy for PS. The estimated NOR value for an average South Atlantic charter angler trip is $165 (2016 dollars) and the estimated NOR value for a South Atlantic headboat angler trip is $45 (2016 dollars) (C. Liese, NMFS SEFSC, pers. comm.). Estimates of NOR per red snapper target trip are not available.

Business Activity

The desire for recreational fishing generates economic activity as consumers spend their income on various goods and services needed for recreational fishing. This spurs economic activity in the region where recreational fishing occurs. It should be clearly noted that, in the absence of the opportunity to fish, the income would presumably be spent on other goods and services and these expenditures would similarly generate economic activity in the region where the expenditure occurs. As such, the analysis below represents a distributional analysis only.

Estimates of the business activity (economic impacts) associated with recreational angling for South Atlantic red snapper were calculated using average trip-level impact coefficients derived from the 2015 Fisheries Economics of the U.S. report (NMFS 2017) and underlying data provided by the National Oceanic and Atmospheric Administration (NOAA) Office of Science and Technology. Economic impact estimates in 2015 dollars were adjusted to 2016 dollars using

[13] Converted to 2016 dollars using the annual, not seasonally adjusted GDP implicit price deflator provided by the U.S. Bureau of Economic Analysis.

the annual, not seasonally adjusted GDP implicit price deflator provided by the U.S. Bureau of Economic Analysis.

Business activity (economic impacts) for the recreational sector is characterized in the form of jobs (full- and part-time), income impacts (wages, salaries, and self-employed income), output (sales) impacts (gross business sales), and value-added impacts (contribution to the GDP in a state or region). Estimates of the average annual economic impacts (2012-2016) resulting from South Atlantic red snapper target trips are provided in **Table 3.3.10**. These estimates are low due to the small number of estimated red snapper target trips that occurred during the mini-seasons in 2012-2014 and during the subsequent closed seasons in 2015 and 2016. The average impact coefficients, or multipliers, used in the model are invariant to the "type" of effort and can therefore be directly used to measure the impact of other effort measures such as red snapper catch trips. To calculate the multipliers from **Table 3.3.10**, simply divide the desired impact measure (sales impact, value-added impact, income impact or employment) associated with a given state by the number of target trips for that state.

The estimates provided in **Table 3.3.10** only apply at the state-level. Addition of the state-level estimates to produce a regional (or national) total may underestimate the actual amount of total business activity, because state-level impact multipliers do not account for interstate and interregional trading. It is also important to note, that these economic impacts estimates are based on trip expenditures only and do not account for durable expenditures. Durable expenditures cannot be reasonably apportioned to individual species. As such, the estimates provided in **Table 3.3.10** may be considered a lower bound on the economic activity associated with those trips that targeted red snapper.

Estimates of the business activity associated with headboat effort are not available. Headboat vessels are not covered in MRIP, so, in addition to the absence of estimates of target effort, estimation of the appropriate business activity coefficients for headboat effort has not been conducted.

Table 3.3.10. Estimated annual average economic impacts (2012-2016) from South Atlantic recreational red snapper target trips, by state and mode, using state-level multipliers. All monetary estimates are in 2016 dollars.

	NC	SC	GA*	FL

Source: effort data from MRIP; economic impact results calculated by NMFS SERO using NMFS (2017) and underlying data provided by the NOAA Office of Science and Technology.
*Georgia estimates of charter angler trips for 2012-2014 from Knowlton (2015) were used in place of the MRIP estimates.

3.3.2 Social Environment

This amendment affects commercial and recreational management of red snapper. This section provides the background for the proposed actions, which will be evaluated in **Chapter 4**. Commercial and recreational landings by state are included to provide information on the geographic distribution of fishing involvement. Descriptions of the top communities involved in commercial red snapper are included along with the top recreational fishing communities based on recreational engagement. Community level data are presented in order to meet the requirements of National Standard 8 of the Magnuson-Stevens Act, which requires the consideration of the importance of fishery resources to human communities when changes to fishing regulations are considered. Lastly, social vulnerability data are presented to assess the potential for environmental justice concerns. Additional information on the South Atlantic recreational and commercial red snapper fishery is provided in the Economic Environment in **Section 3.3**.

3.3.2.1 Landings by State

The South Atlantic red snapper season was closed in 2010, 2011, 2015, and 2016 and was open for a short season during 2012, 2013, and 2014. Landings by state for the years of 2012 through 2014 are described below because these data represent the most recent years that red snapper was open in federal waters. Red snapper were landed during 2015 and 2016; however because fishing was closed in federal waters and in all state waters except for Florida, the majority of landings were from waters adjacent to Florida with some reported landings from North Carolina and South Carolina (MRIP and SRHS Datasets).

Commercial

The majority of commercial red snapper landings came from waters adjacent to Florida (82.7% on average for years 2012-2014, SERO and SEFSC ACL Files), followed by South Carolina (9%) and North Carolina and Georgia (approximately 8.1%). Data for North Carolina are combined with Georgia in order to maintain confidentiality, but the majority of the landings reported for the combined category occurred in North Carolina. From 2012 to 2014, commercial landings ranged from 7,627 lbs ww to 65,807 lbs ww (SERO and SEFSC ACL Files).

Recreational

The majority of recreational red snapper landings come from waters adjacent to Florida (88.3% on average for years 2012-2014), followed by North Carolina (6.3%), Georgia (4.8%), and South Carolina (0.5%). From 2012 to 2014, recreational landings have ranged from 6,629 fish to 31,069 fish. Recreational landings were a combination of both MRIP and red snapper state surveys done by the individual states of the South Atlantic region. An ad-hoc group reviewed the MRIP and state survey results, and determined the better estimate of recreational red snapper landings for each state and year.

3.3.2.2 Fishing Communities

The descriptions of South Atlantic communities include information about the top communities based on a "regional quotient" (RQ) of commercial landings and value for red snapper. The RQ is the proportion of landings and value out of the total landings and value of that species for that region, and is a relative measure. These communities would be most likely to experience the effects of the proposed actions that could change the red snapper fishery and impact participants, associated businesses, and communities within the region. If a community is identified as a red snapper community based on the RQ, this does not necessarily mean that the community would experience significant impacts due to changes in the fishery if a different species or number of species was also important to the local community and economy. Additional detailed information about communities with the highest RQs can be found for South Atlantic communities at the Southeast Regional Office's Community Snapshots website[14].

In addition to examining the RQs to understand how communities are engaged and reliant on fishing, indices were created using secondary data from permit and landings information for the commercial sector (Jepson and Colburn 2013, Jacob et al. 2013). Fishing engagement is primarily the absolute numbers of permits, landings, and value for all species. For commercial fishing, the analysis used the number of vessels designated commercial by homeport and owner address, value of landings, and total number of commercial permits for each community for all species. Fishing reliance includes the same variables as fishing engagement divided by population to give an indication of the per capita influence of this activity. Fishing engagement

[14] http://sero.nmfs.noaa.gov/sustainable_fisheries/social/community_snapshot/

and reliance data rely on fishing data up to the year 2014 and population data from the U.S. Census American Community Survey (ACS) 2010 through 2014 five-year estimates.

Using a principal component and single solution factor analysis, each community receives a factor score for each index to compare to other communities. Factor scores of both engagement and reliance were plotted for the communities with the highest RQs. Two thresholds of one and one-half standard deviation above the mean are plotted to help determine a threshold for significance. The factor scores are standardized; therefore, a score above a value of 1.0 is also above one standard deviation. A score above one-half standard deviation is considered engaged or reliant with anything above one standard deviation to be very engaged or reliant.
The reliance index uses factor scores that are normalized. The factor score is similar to a z-score in that the mean is always zero, positive scores are above the mean, and negative scores are below the mean. Comparisons between scores are relative; however, like a z-score, the factor score puts the community on a point in the distribution. Objectively, that community will have a score related to the percent of communities with similar attributes. For example, a score of 2.0 means the community is two standard deviations above the mean and is among the 2.27% most vulnerable places in the study (normal distribution curve). Reliance score comparisons between communities are relative; however, if the community scores greater than two standard deviations above the mean, this indicates that the community is dependent on fishing. Examining the component variables on the reliance index and how they are weighted by factor score provides a measurement of commercial reliance. The reliance index provides a way to gauge change over time in these communities and also provides a comparison of one community with another.

Landings for the recreational sector are not available by species at the community level; therefore, it is not possible with available information to identify communities as dependent on recreational fishing for red snapper. Because limited data are available concerning how recreational fishing communities are engaged and reliant on specific species, indices were created using secondary data from permit and infrastructure information for the southeast recreational fishing sector at the community level (Jepson and Colburn 2013, Jacob et al. 2013). Recreational fishing engagement is represented by the number of recreational permits and vessels designated as “recreational” by homeport and owners address. Fishing reliance includes the same variables as fishing engagement, divided by population. Factor scores of both engagement and reliance were plotted. **Figure 3.4.3** identifies the top communities that are engaged and reliant upon recreational fishing in general.

A description of the social environment, including analysis of communities engaged in red snapper fishing, was provided in Amendment 28 for snapper grouper (SAFMC 2013b) and is incorporated herein by reference. The referenced description focuses on available geographic and demographic data to identify top commercial red snapper communities using 2009 Accumulated Landings System (ALS) data and engagement, reliance, and social vulnerability indicators from 2009. This section has been updated using 2014 ALS data and 2014 community social vulnerability indicators data, the most recent year available.

Commercial Fishing Communities

Figure 3.4.1 includes the top red snapper communities by regional quotient landings and value during 2014, the most recent year with a federal season for red snapper. The majority of the top red snapper communities are located in Florida; however, a few of top communities are located in South Carolina and North Carolina. About 53% of red snapper is landed in the top four communities (Cocoa, Mayport, Port Orange, and Cape Coral, Florida), representing about 52% of the South Atlantic-wide ex-vessel value for the species. The remaining top communities collectively represent about 32% of South Atlantic red snapper landings and 33% of ex-vessel value (including approximately 24% of landings and 24% of value for the Florida communities of Saint Augustine, Titusville, Melbourne, Ormond Beach, Key West, Winter Springs, Sebastian, and Merritt Island and approximatively 8% of landings and 9% of value for the South Carolina and North Carolina communities of Murrells Inlet, South Carolina and Morehead City and Beaufort, North Carolina).

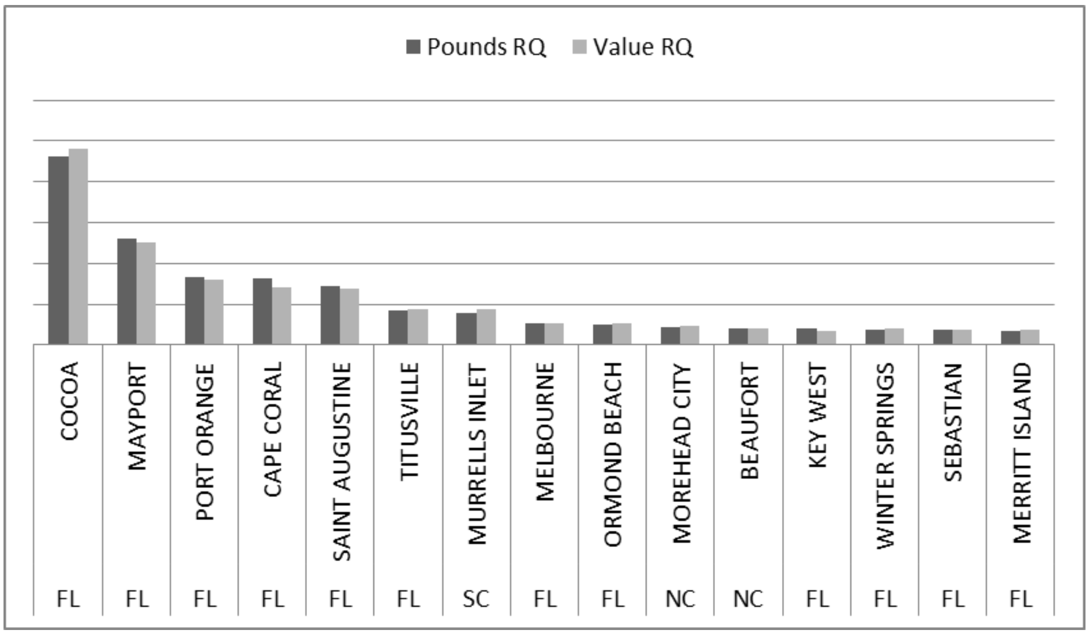

Figure 3.4.1. Top South Atlantic communities ranked by pounds and value regional of quotient (RQ) of red snapper.
The actual RQ values (y-axis) are omitted from the figure to maintain confidentiality.
Source: SERO, Community ALS 2014.

The commercial engagement and reliance indices of the top commercial red snapper communities are included in **Figure 3.4.2**. The details of how these indices are generated are explained at the beginning of the Fishing Communities section. Two thresholds of one and one-half standard deviation above the mean were plotted to help determine a threshold for significance. The primary communities that demonstrate high levels of commercial fishing engagement include Mayport, Cape Coral, Saint Augustine, Key West, Sebastian, and Merritt Island, Florida and Morehead City and Beaufort, North Carolina. The community with substantial commercial reliance is Mayport, Florida.

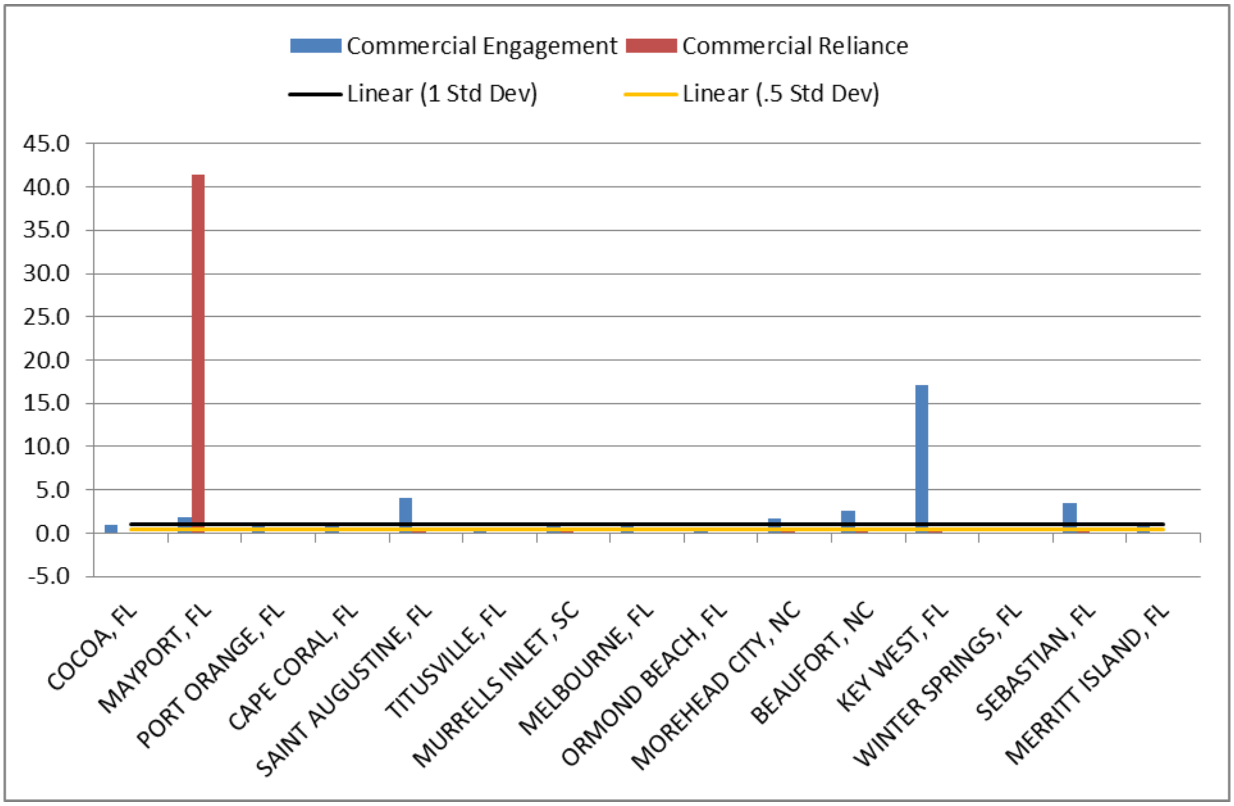

Figure 3.4.2. Commercial engagement and reliance for South Atlantic red snapper fishing communities. Source: SERO, Community Social Vulnerability Indicators Database 2014 (ACS 2010-2014).

Recreational Fishing Communities

Figure 3.4.3 identifies the top 20 recreational communities located in the South Atlantic that are the most engaged and reliant on recreational fishing, in general. All included communities demonstrate high levels of recreational engagement. Six communities (Key West, Florida; Marathon, Florida; Islamorada, Florida; Hatteras, North Carolina; Manteo, North Carolina; and Atlantic Beach, North Carolina) demonstrate high levels of recreational reliance.

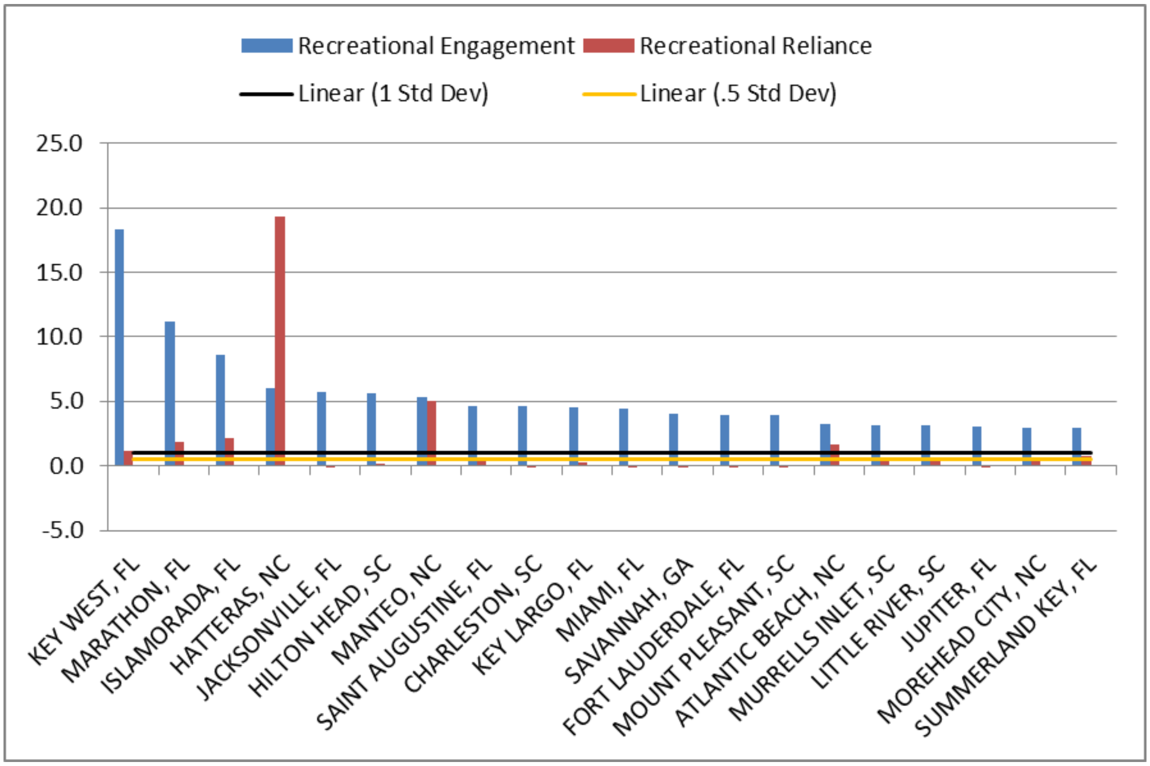

Figure 3.4.3. Top recreational fishing communities' engagement and reliance.
Source: SERO, Community Social Vulnerability Indicators Database 2014 (ACS 2010-2014).

3.3.2.3 Environmental Justice Considerations

Executive Order 12898 requires federal agencies conduct their programs, policies, and activities in a manner to ensure individuals or populations are not excluded from participation in, or denied the benefits of, or subjected to discrimination because of their race, color, or national origin. In addition, and specifically with respect to subsistence consumption of fish and wildlife, federal agencies are required to collect, maintain, and analyze information on the consumption patterns of populations who principally rely on fish and/or wildlife for subsistence. The main focus of Executive Order 12898 is to consider "the disproportionately high and adverse human health or environmental effects of its programs, policies, and activities on minority populations and low-income populations in the United States and its territories…" This executive order is generally referred to as environmental justice (EJ).

Commercial and recreational fishermen and associated industries could be impacted by the proposed actions. However, information on the race and income status for groups at the different participation levels (individual fishermen and crew) is not available. Although information is available concerning communities overall status with regard to minorities and poverty (e.g., census data), such information is not available specific to fishermen and those involved in the industries and activities, themselves. To help assess whether any environmental justice concerns arise from the actions in this amendment, a suite of indices were created to examine the social vulnerability of coastal communities. These indices rely on data from the U.S. Census ACS 2010 through 2014 five-year estimates. The three indices are poverty, population composition, and personal disruptions. The variables included in each of these indices have been identified through the literature as being important components that contribute to a community's vulnerability. Indicators such as increased poverty rates for different groups, more single female-headed households and households with children under the age of five, disruptions such as higher separation rates, higher crime rates, and unemployment all are signs of populations experiencing vulnerabilities. Again, for those communities that exceed the threshold it would be expected that they would exhibit vulnerabilities to sudden changes or social disruption that might accrue from regulatory change.

Figure 3.4.4 and **Figure 3.4.5** provide the social vulnerability of the top commercial and recreational communities. Several South Atlantic communities exceed the threshold of one-half standard deviation for at least one of the social vulnerability indices: Cocoa, Marathon, Miami, and St. Augustine, Florida; Savannah, Georgia; and Beaufort, Manteo, and Morehead City, North Carolina. The communities of Cocoa, Florida; Miami, Florida; and Savannah, Georgia exceed the threshold for all three social vulnerability indices. These communities have substantial vulnerabilities and may be susceptible to further effects from any regulatory changes depending upon the direction and extent of that change.

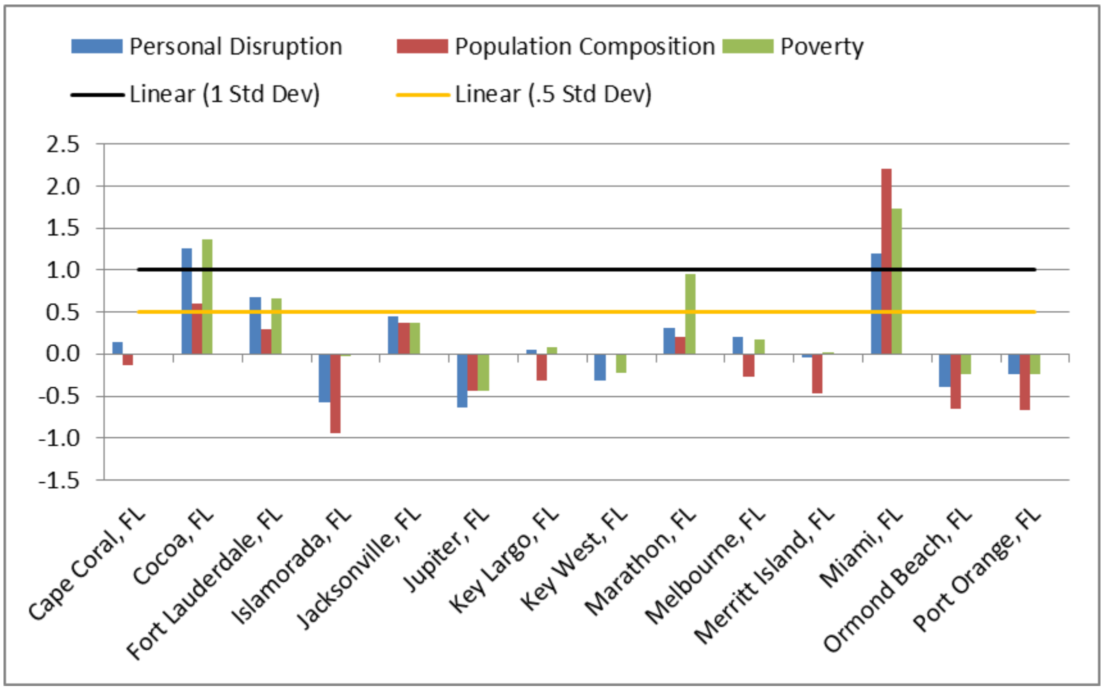

Figure 3.4.4. Social vulnerability indices for top commercial and recreational communities.
Source: SERO, Community Social Vulnerability Indicators Database 2014 (ACS 2010-2014).

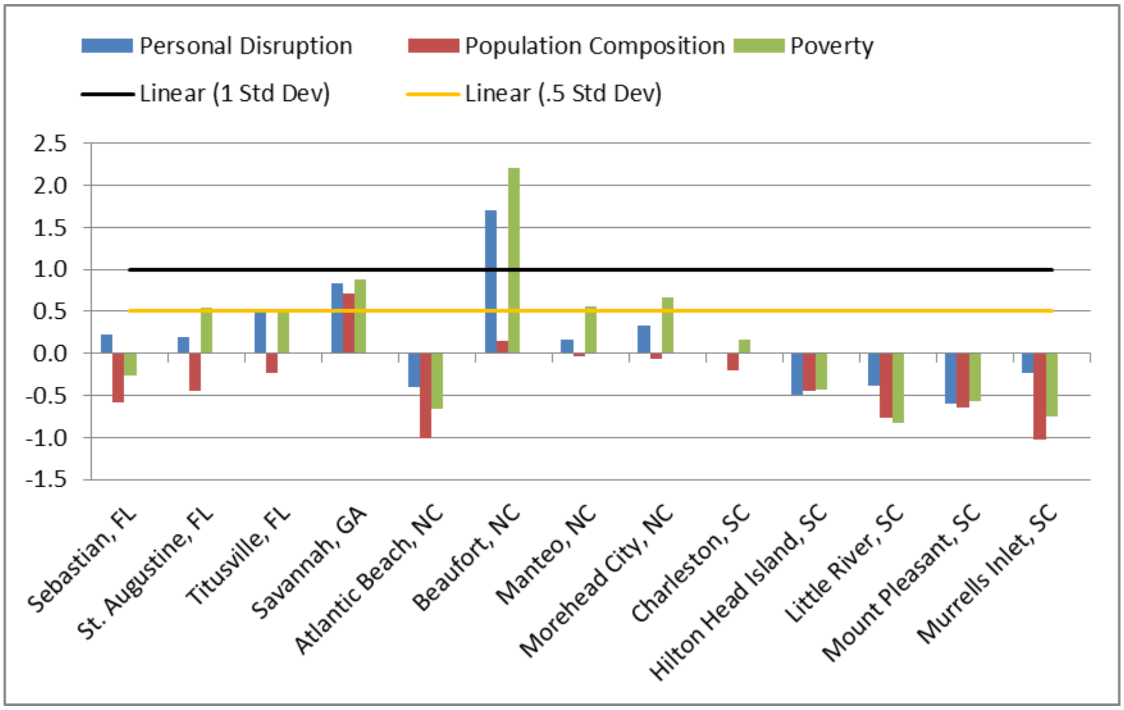

Figure 3.4.4. Social vulnerability indices for top commercial and recreational communities continued. Source: SERO, Community Social Vulnerability Indicators Database 2014 (ACS 2010-2014).

People in these communities may be affected by fishing regulations in two ways: participation and employment. Although these communities may have the greatest potential for EJ concerns, no data are available on the race and income status for those involved in the local fishing industry (employment), or for their dependence on red snapper specifically (participation). Although no EJ issues have been identified, the absence of potential EJ concerns cannot be assumed.

3.4 Administrative Environment

3.4.1 The Fishery Management Process and Applicable Laws

3.4.1.1 Federal Fishery Management

Federal fishery management is conducted under the authority of the Magnuson-Stevens Fishery Conservation and Management Act (Magnuson-Stevens Act) (16 U.S.C. 1801 et seq.), originally enacted in 1976 as the Fishery Conservation and Management Act. The Magnuson-Stevens Act claims sovereign rights and exclusive fishery management authority over most fishery resources within the EEZ, an area extending 200 nm from the seaward boundary of each of the coastal states, and authority over U.S. anadromous species and continental shelf resources that occur beyond the U.S. EEZ.

Responsibility for federal fishery management decision-making is divided between the U.S. Secretary of Commerce (Secretary) and eight regional fishery management councils that represent the expertise and interests of constituent states. Regional councils are responsible for preparing, monitoring, and revising management plans for fisheries needing management within their jurisdiction. The Secretary is responsible for collecting and providing the data necessary for the councils to prepare fishery management plans and for promulgating regulations to implement proposed plans and amendments after ensuring that management measures are consistent with the Magnuson-Stevens Act and with other applicable laws. In most cases, the Secretary has delegated this authority to NMFS.

The Council is responsible for conservation and management of fishery resources in federal waters of the U.S. South Atlantic. These waters extend from 3 to 200 miles offshore from the seaward boundary of North Carolina, South Carolina, Georgia, and east Florida to Key West. The Council has thirteen voting members: one from NMFS; one each from the state fishery agencies of North Carolina, South Carolina, Georgia, and Florida; and eight public members appointed by the Secretary. On the Council, there are two public members from each of the four South Atlantic States. Non-voting members include representatives of the U.S. Fish and Wildlife Service, U.S. Coast Guard, State Department, and Atlantic States Marine Fisheries Commission (ASMFC). The Council has adopted procedures whereby the non-voting members serving on the Council Committees have full voting rights at the Committee level but not at the full Council level. The Council also established two voting seats for the Mid-Atlantic Council on the South Atlantic Mackerel Committee. Council members serve three-year terms and are recommended by state governors and appointed by the Secretary from lists of nominees submitted by state governors. Appointed members may serve a maximum of three consecutive terms.

Public interests also are involved in the fishery management process through participation on Advisory Panels and through council meetings, which, with few exceptions for discussing personnel and legal matters, are open to the public. The Council uses its Scientific and Statistical Committee (SSC) to review the data and science being used in assessments and fishery management plans/amendments. In addition, the regulatory process is in accordance with the Administrative Procedure Act, in the form of "notice and comment" rulemaking.

3.4.1.2 State Fishery Management

The state governments of North Carolina, South Carolina, Georgia, and Florida have the authority to manage fisheries that occur in waters extending three nautical miles from their respective shorelines. North Carolina's marine fisheries are managed by the Marine Fisheries Division of the North Carolina Department of Environmental Quality. The Marine Resources Division of the South Carolina Department of Natural Resources regulates South Carolina's marine fisheries. Georgia's marine fisheries are managed by the Coastal Resources Division of the Department of Natural Resources. The Marine Fisheries Division of the Florida Fish and Wildlife Conservation Commission is responsible for managing Florida's marine fisheries. Each state fishery management agency has a designated seat on the Council. The purpose of state representation at the Council level is to ensure state participation in federal fishery management decision-making and to promote the development of compatible regulations in state and federal waters.

The South Atlantic States are also involved through the Atlantic States Marine Fisheries Commission (ASMFC) in management of marine fisheries. This commission was created to coordinate state regulations and develop management plans for interstate fisheries. It has significant authority, through the Atlantic Striped Bass Conservation Act and the Atlantic Coastal Fisheries Cooperative Management Act, to compel adoption of consistent state regulations to conserve coastal species. The ASFMC is also represented at the Council level, but does not have voting authority at the Council level.

NMFS's State-Federal Fisheries Division is responsible for building cooperative partnerships to strengthen marine fisheries management and conservation at the state, inter-regional, and national levels. This division implements and oversees the distribution of grants for two national (Inter-jurisdictional Fisheries Act and Anadromous Fish Conservation Act) and two regional (Atlantic Coastal Fisheries Cooperative Management Act and Atlantic Striped Bass Conservation Act) programs. Additionally, it works with the ASMFC to develop and implement cooperative State-Federal fisheries regulations.

3.4.1.3 Enforcement

Both the NMFS Office for Law Enforcement (NOAA/OLE) and the United States Coast Guard (USCG) have the authority and the responsibility to enforce Council regulations. NOAA/OLE agents, who specialize in living marine resource violations, provide fisheries expertise and investigative support for the overall fisheries mission. The USCG is a multi-mission agency, which provides at sea patrol services for the fisheries mission.

Neither NOAA/OLE nor the USCG can provide a continuous law enforcement presence in all areas due to the limited resources of NOAA/OLE and the priority tasking of the USCG. To supplement at sea and dockside inspections of fishing vessels, NOAA entered into Cooperative Enforcement Agreements with all but one of the states in the Southeast Region (North Carolina), which granted authority to state officers to enforce the laws for which NOAA/OLE has jurisdiction. In recent years, the level of involvement by the states has increased through Joint Enforcement Agreements, whereby states conduct patrols that focus on federal priorities and, in some circumstances, prosecute resultant violators through the state when a state violation has occurred.

The NOAA Office of General Counsel Penalty Policy and Penalty Schedule is available online[15].

[15] http://www.gc.noaa.gov/enforce-office3.html.

Chapter 4. Environmental Effects and Comparison of Alternatives

4.1 Action 1. Revise the Process to Determine the Annual Catch Limits (ACL) for Red Snapper

4.1.1 Biological Effects

The following documents outline the biological effects of the current red snapper management regime and provide the background for the biological effects of **Alternative 1 (No Action)**:

- Emergency rule to establish a limited 2012 fishing season (NMFS 2012a,b)
- Amendment 28 to the Fishery Management Plan for the Snapper Grouper Fishery of the South Atlantic Region (Snapper Grouper Amendment 28) (SAFMC 2013)

The reader is directed to these documents for details on the effects of the current management of red snapper. Amendment 28 is available at www.safmc.net, and hereby incorporated by reference.

> ***Alternatives****
>
> **Alternative 1 (No Action):** The commercial and recreational annual catch limits for red snapper are zero. Process in place to allow limited harvest based on ABC.
>
> **Alternative 2**. Remove the process and equation used to determine the red snapper ACL as specified in Snapper Grouper Amendment 28. Specify Total ACL = 23,623 fish. Commercial ACL = 69,360 lbs (whole weight). Recreational ACL = 16,480 fish.
>
> **Alternative 3**. Remove the process and equation used to determine the red snapper ACL as specified in Snapper Grouper Amendment 28. Specify Total ACL = 44,411 fish. Commercial ACL = 130,396 lbs (whole weight). Recreational ACL = 30,982 fish.
>
> **Alternative 4**. Remove the process and equation used to determine the red snapper ACL as specified in Snapper Grouper Amendment 28. Specify Total ACL = 42,510 fish. Commercial ACL = 124,815 lbs (whole weight). Recreational ACL = 29,656 fish.
>
> **Alternative 5**. Remove the process and equation used to determine the red snapper ACL as specified in Snapper Grouper Amendment 28. Specify Total ACL = 79,919 fish. Commercial ACL = 234,652 lbs (whole weight). Recreational ACL = 55,753 fish.
>
> * Refer to Chapter 2 for detailed language of alternatives

In summary, the South Atlantic Fishery Management Council (Council) and National Marine Fisheries Service (NMFS) determined that retention of a limited number of red snapper in 2012, along with appropriate management controls, would not jeopardize the rebuilding of the red snapper stock and established a limited season through emergency action in 2012. In 2013, Amendment 28 implemented a process to determine if a red snapper fishing season would occur each year, including specification of the allowable harvest and season lengths for the commercial and recreational sectors (78 FR 44461, July 24, 2013). Amendment 28 also included a formula to determine the annual catch limit (ACL) for each sector; as well as management measures (limited fishing seasons, no minimum size limit, one fish per person per day recreational bag limit, and 75 pounds (lbs) commercial trip limit), if fishing were allowed. Following the management measures of Amendment 28, the total removals exceeded the accepted biological catch (ABC) in 2014, 2015, and 2016, and the harvest of red snapper has been prohibited since 2015 (**Table 4.1.1**).

Table 4.1.1. Total removals (landings and dead discards) of red snapper during the limited fishing seasons for the commercial and recreational sectors in 2012, 2013, and 2014.

Year	Allowable Removals (numbers of fish)	Total Removals (numbers of fish)	Commercial Fishing Season	Recreational Fishing Season
2012	86,000	Commercial= 13,317 HB= 4,606 Charter= 9,264 Private= 53,329 Total= 80,516	Sept 17-24; Reopened Nov 13-21 and Dec 12-19 (22 days)	Sept 14-17, and Sept 21-24 (6 days)
2013	96,000	Commercial=16,779 HB=20,683 Charter (FL study)=5,395 Private (FL study)=29,919 Total (FL study)=72,776	Aug 26-Oct 8 (43 days)	Aug 23-Aug 26 (3 days)
2014	106,000	Commercial=24,827 HB=22,063 Charter=20,619 Private=138,350 Total=205,859	Jul 14-Sept 9 (57 days)	Jul 11-14, Jul 18-21, Jul 26-27(8 days)

Under **Alternative 1 (No Action)**, the commercial and recreational ACLs for red snapper would be zero in 2018. **Alternative 2** through **5** would allow limited harvest of red snapper beginning in 2018 (**Table 4.1.2**). The existing management measures such as season start dates, commercial trip limit, and recreational bag limit would remain unchanged from those implemented by the final rule for Amendment 28 (78 FR 44461, July 24, 2013). When possible, the South Atlantic Council prefers specifying the recreational ACL in numbers of fish and the commercial ACL in pounds whole weight. The rationale is that recreational landings are already tracked in numbers of fish while commercial landings are tracked in pounds. However, the total ACL is specified in numbers of fish. To ensure that allocation is derived using the formula established in the Comprehensive ACL Amendment (SAFMC 2011b), the numbers of fish were converted to weight of red snapper (see **Appendix K** for more details). Based on the allocation formula implemented by the Comprehensive ACL Amendment (SAFMC 2011b), the commercial allocation is 28.07% of the total landings in pounds and recreational allocation is

71.93%. The commercial and recreational ACLs for each sector under each of the proposed alternatives are provided in **Table 4.1.2.**

Table 4.1.2. Proposed total, commercial, and recreational red snapper ACLs for 2018 in numbers of fish and pounds whole weight.

Alternative	Total ACL Number	Total ACL Weight (lbs ww)	Commercial ACL Weight (lbs ww)	Commercial ACL Number	Recreational ACL Weight (lbs ww)	Recreational ACL Number
Alt 1	0	0	0	0	0	0
Alt 2	23,623	247,097	75,537	7,143	177,737	16,480
Alt 3	44,411	464,539	130,396	13,429	334,143	30,982
Alt 4	42,510	444,655	124,815	12,854	319,840	29,656
Alt 5	79,919	835,953	234,652	24,166	601,301	55,753

Commercial conversion factor is 9.71 lbs based on average weight of commercially caught red snapper from 2012 to 2014 in SEDAR 41 (2017). Recreational weight and number is the difference between total ACL weight/number and commercial weight/number.

ACLs proposed under **Alternatives 2** and **3** use the average landings from 2012 to 2014 (**Table 4.1.2**). **Alternative 2** is based on the average landing from 2012 to 2014. **Alternative 3** is based on the average landings from 2012 to 2014 multiplied by an adjustment factor based on the increase in the average catch rate of red snapper observed in the scientific survey in 2015 and 2016 compared to average catch rate from 2012, 2013, and 2014 (1.88 times, **Figure 4.1.1**).

Alternatives 4 and **5** propose using maximum recorded landings to establish the ACL (**Table 4.1.2**). **Alternative 4** is set equal to the maximum landings from 2012 to 2014. **Alternative 5** is the maximum landings multiplied by the adjustment factor discussed above (**Table 4.1.2**). **Alternative 5** is higher than landings from 2012 to 2014.

Alternative 3 and **Alternative 5** are different that values that were in a draft Amendment 43 presented at the June Council meeting. The revised values reflect NMFS SEFSC's guidance to use a calculation more similar to the approach used in SEDAR 41 (2017). Revised values were provided using the improved methodology and further described in **Appendix K**.

Recreational landings of red snapper in the South Atlantic EEZ was not allowed in 2010, 2011, 2015 and 2016, and was only open for short periods of time in 2012 (6 days), 2013 (3 days), and 2014 (8 days). Recreational landings ranged from 6,629 fish to 31,069 during 2012-2014 (**Table 4.1.3**). The total number of red snapper landed in 2014 value in **Table 4.1.3** is different than the **Alternative 4** recreational sector ACL (**Table 4.1.2**) because the ACL had to be divided among the recreational and commercial sectors using the allocation established in the Comprehensive ACL Amendment (2011b). The total ACL in number of fish had to be converted to weight to use the allocation. These conversions led to differences in the reported recreational landings (**Table 4.1.3**) and the recreational sector ACL (**Table 4.1.2**).

Table 4.1.3. Recreational landings (numbers of fish) for red snapper by wave, 2012-2016.

	Jan/Feb	Mar/Apr	May/June	Jul/Aug	Sep/Oct	Nov/Dec	Total
2012	1	478	353	79	14,080	0	14,991
2013	0	2	403	2,050	4,160	14	6,629
2014	1,151	45	722	28,798	19	334	31,069
2015	0	847	467	486	56	14	1,870
2016	0	1	188	205	3	6	403

Note: Landings in Florida state waters is allowed for red snapper.

NMFS completed the red snapper season analysis for 2018 based on the process in Amendment 28. At the present time commercial landings are available from January 1st to July 11, 2017, and recreational landings and discards are available from January 1st to April 30, 2017. **Table 4.1.4** summarizes the available 2017 landings and discards in numbers of fish. The total removals in 2017 (152,459 fish) already exceed the ABC for 2017 (128,000 fish). Since the ABC has already been exceeded in 2017, the ACL for 2018 would be set to zero according the process in Amendment 28 (**Alternative 1 (No Action))**.

Table 4.1.4. Estimated landings and dead discards by sector equaling total removals for South Atlantic red snapper in 2017.

Variable	Number of Fish 2017
Commercial Landings	93
Recreational Headboat Landings	3
Recreational Charter Dead Discards	12,806
Recreational Private Dead Discards	139,557
Total Removals	152,459

The short recreational openings in 2012, 2013, and 2014, occurred over different months; therefore, landings from different months and years were combined to predict future landings (see **Appendix O** for more details on the data analysis and projections for the recreational sector). **Table 4.1.5** shows the predicted landings and closure dates in 2018, assuming the recreational sector opens to harvest on Jul 13, 2018. The “Predicted Landings” scenario is a prediction of future landings, and the “High Landings” scenario is an adjusted prediction using a 1.88 adjustment factor following the assumption of a larger stock size. Under the “Predicted Landings” scenario, the recreational fishery would be open for as short as 4 days (**Alternative 2**) and as long as 28 days (**Alternative 5**); and would be open for 7 days under **Alternative 4 (Table 4.1.5)**. Under the “High Landings” scenario, the recreational fishery would be open for as short as 2 days (**Alternative 2**) and as long as 8 days (**Alternative 5**); and would be open for 4 days under **Alternatives 3** and **4 (Table 4.1.5)**.

Table 4.1.5. Predicted closure dates (number of open days) for the recreational sector under the different proposed ACL alternatives for 2018.

	Alternative 1	Alternative 2	Alternative 3	Alternative 4	Alternative 5
ACL	**TBD**	**16,480 Fish**	**30,982 Fish**	**29,656 Fish**	**55,753 Fish**
Predicted Landings	TBD	21-Jul (4)	28-Jul (7)	28-Jul (7)	15-Sep (28)
High Landings	TBD	15-Jul (2)	21-Jul (4)	21-Jul (4)	29-Jul (8)

Note: These closure dates assume the recreational sector starts on Friday, July 13, 2018. Under **Alternative 1 (No Action),** according to preliminary estimates, the fishery has exceeded the ABC in 2017 and the ACL would be set to zero in 2018. See **Appendix O** for more details.

The South Atlantic red snapper commercial fishery was closed in 2010, 2011, 2015 and 2016, and was only open for short periods of time in 2012 (22 days, harvesting 6,872 lbs), 2013 (43 days, 27,309 lbs), and 2014 (57 days, 54,887 lbs)[16]. **Figure 4.1.1** shows the pounds per commercial trip harvested for the two most recent years (2013 and 2014) under the 75 pounds gutted weight (lbs gw) trip limit.

The short commercial openings in 2012, 2013, and 2014 occurred over different months; therefore, landings from different months and years were combined to predict future landings (**Table 4.1.6**, see Appendix N for more details). **Table 4.1.6** shows the predicted landings and closure dates in 2018, assuming the commercial sector opens to harvest on July 9, 2018. The "Predicted Landings" scenario is a prediction of future landings, and the "High Landings" is the prediction of future landings with a 34% increase in landings following the assumption that more fishermen will meet the trip limit of 75 lbs gw due to an increased stock size. Under **Alternatives 3** through **5** and using the "Predicted Landings" scenario, the commercial fishery would not close **(Table 4.1.6)**. Under **Alternative 2** and using the "Predicted Landings", the commercial fishery would close September 17, 2018. If the "High Landings" scenario is used, the commercial fishery would close for all alternatives except **Alternative 5**. Closing dates range from August 23 to October 21.

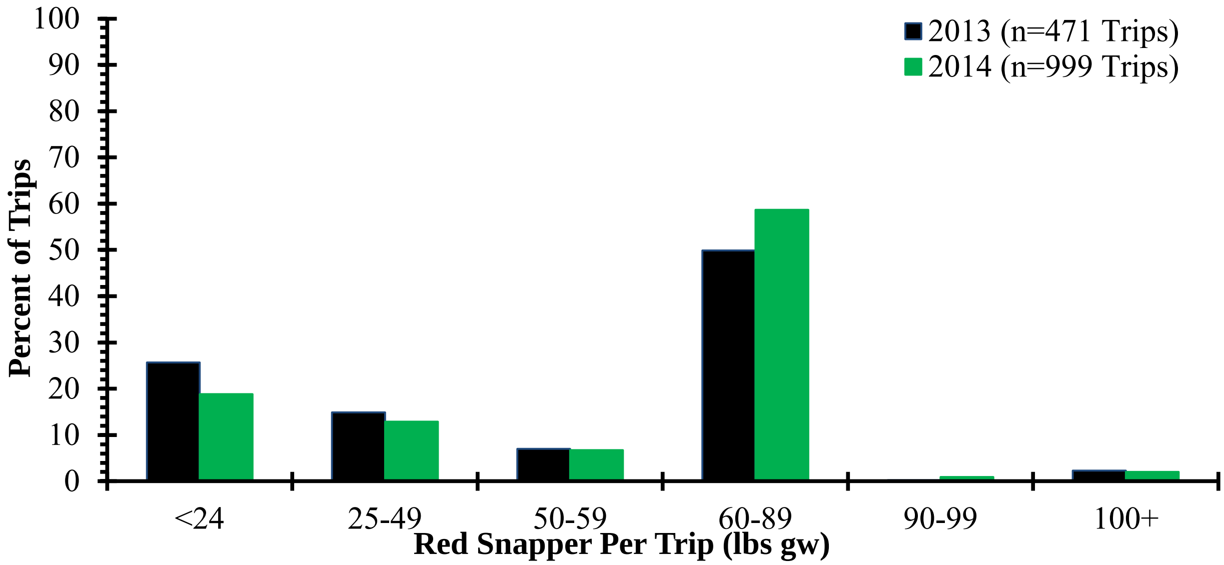

Figure 4.1.1. Distribution of commercial red snapper harvested per trip (lbs gw) in 2013 and 2014. Source: Commercial logbook dataset.

Table 4.1.6. Predicted closure dates for the commercial sector under the different proposed ACL alternatives for 2018.

	Alternative 1	**Alternative 2**	**Alternative 3**	**Alternative 4**	**Alternative 5**
ACL		**69,360 lbs ww**	**130,396 lbs ww**	**124,815 lbs ww**	**234,652 lbs ww**
Predicted Landings	TBD	17-Sep	No Closure	No Closure	No Closure
High Landings	TBD	23-Aug	26-Nov	21-Oct	No Closure

Note: These closure dates assume the recreational sector starts on Monday, July 9, 2018. Under **Alternative 1 (No Action),** according to preliminary estimates, the fishery has exceeded the ABC in 2017 and the ACL would be set to zero in 2018. See **Appendix O** for more details.

Alternative 1 (No Action), would result in no commercial or recreational harvest of red snapper allowed in 2018 due to exceeding the ABC in 2017. While allowing no harvest might be biologically beneficial to a stock, it is expected that the resulting level of dead discards would continue to increase, possibly resulting in negative biological effects. Estimated removals from 2012 to 2016 ranged from 72,881 fish in 2013 to 407,025 fish in 2016 (**Table 2.1.1**). These estimates of removals were not recommended for use in management due to uncertainty in Marine Recreational Information Program estimates (**Appendix J**), and ACL alternatives were developed using a combination of estimates from other monitoring programs (see **Appendix O**). Meanwhile, fishery-independent data suggest that the red snapper population in the South Atlantic is steadily increasing, indicating that the recent level of removals has not negatively affected recent population growth since 2014. Therefore, the long-term biological effects of continued high bycatch and resulting mortality on the red snapper stock are unknown. **Alternatives 3** and **5** propose ACLs above recent catch levels since they are adjusted to account for perceived recent population growth by a factor of 1.88. Therefore, these alternatives might result in negative biological effects over the status quo since it is not known how the stock might be impacted and whether such levels of harvest could result in overfishing. **Alternatives 2** and **4** would be less likely to result in negative biological effects since they propose ACLs based on 2012-2014 catch levels and data suggest red snapper abundance increased from 2014 levels by 35% in 2015 and an additional 12% in 2016. SEDAR 41 (2017) suggested that overfishing could occur due to the level of landings that occurred in 2014, the terminal year of the assessment; however, this remains uncertain since such a determination is based on the ratio of landings compared to population size and, according to fishery-independent data, red snapper abundance has increased since 2014. Hence, the greatest beneficial effects to the biological environment are expected under **Alternative 1 (No Action)**, followed by **Alternatives 2**, **4**, **3** and **5**.

Alternative 2 through **5** have the potential benefit of providing data for future stock assessments. Red snapper are a long-lived fish reaching ages up to 50 years old. Because they are a long-lived fish, age-based stock assessment models, which have been used to assess red snapper in SEDARs 15 (2008), 24 (2010), and 41 (2016), are likely the best type to determine the status of the stock. Ages are an important component to determine status of the stock and may be more important than other pieces of information because the decline in abundance at age is critical information for determining mortality rates (Yin and Sampson 2004, Siegfried et al. 2016). These age data are informative even when the level of removals is uncertain, as is the case with red snapper. Fishery-dependent age composition data from recreational and commercial catches are unavailable for years after 2014 because there have been no landings to sample for ages. The only available data for ages is from the fishery-independent SERFS index. While this survey is a great source of information, the survey alone may not be sufficient to produce adequate data for an age-based stock assessment. A primary concern is that ages collected from a single survey or fishery have been shown to result in biased age and growth curves (Huse et al. 1999, Binion et al. 2009). Bias in age composition data can lead to issues with estimating fishery selectivity, fishing levels, and biomass (Bertignac and Pontual 2007, Hulson and Hanselman 2014). While information on the selectivity of the survey can be used to reduce bias, the lack of information on the ages or sizes of fish not represented in the survey can greatly increase assessment uncertainty. Allowing some level of landings through **Alternative 2** through **5** that facilitate collecting representative age data would be extremely beneficial to future stock assessments needed to track the recovery of red snapper. Ensuring that representative age data are available for future assessments can potentially reduce the chance of inaccurately characterizing the status of the stock.

Observers are collecting red snapper length data on headboats from Florida to North Carolina and on charter boats from Florida. These data need to be combined with age data to determine the age structure of the caught fish because it can be difficult to estimate the age of a red snapper based on its length. For example, a red snapper that is 20 inches (508 mm TL; the former size limit) can be anywhere from 2 to 10 years old based on observed data in SEDAR 41 (2017).

Therefore, age distributions based on past length distributions alone may not accurately describe the current age distribution of the stock.

The Bycatch Practicability Analysis (**Appendix D**) evaluates the practicability of taking additional action to minimize bycatch and bycatch mortality using the ten factors provided at 50 CFR section 600.350(d)(3)(i). The action proposed in Amendment 43 has the potential to reduce bycatch of red snapper during a limited opening of the recreational and commercial sectors as some bycatch is turned into retained catch. The action is not expected to result in significant changes in bycatch of red snapper. In addition, the Council, NMFS, and the SEFSC have developed and plan to implement numerous management measures and reporting requirements that have improved, or are likely to improve monitoring efforts of discards and discard mortality.

In the 2016 biological opinion, NMFS analyzed the effects of commercial and recreational hook-and line hook-and-line gear in the snapper-grouper fishery on sea turtles, smalltooth sawfish, and Nassau grouper assuming 2012-2015 average hook-and-line effort levels are representative of future effort levels in the snapper-grouper fishery (NMFS 2016). Thus, for three of the four years (i.e., 2012-2014) used to project average effort levels, the recreational and commercial red snapper fishery was open for short periods of time, as now being considered again in this Amendment

Thus continued fishing effort levels under the status quo would potentially reduce overall effort in the fishery from 2012-2015 average hook-and-line effort levels and thus decrease potential bycatch in the fishery. Overall fishing effort could increase in the commercial and recreational sectors slightly in response to the limited reopening(s) of red snapper under Alternatives 2 through 5, and therefore, increase the potential for bycatch, relative to the status quo. However, as stated in Chapter 2 and analyzed in detail in Chapter 4, the reopening(s) would be of short duration in the recreational sector and limited to an incidental catch limit (75 lbs) in the commercial sector (see Chapter 6 for details), therefore potential increases in overall fishing effects would be very small and potential increases in incidental captures given their rarity unlikely.

4.1.2 Economic Effects

As described in **Section 4.1.1**, it is expected that the red snapper stock will continue to rebuild under **Alternatives 1, 2**, and **4**, despite allowing for a limited harvest of red snapper, and it is unknown how the stock will respond under **Alternatives 3** and **5**. It is also expected that no harvest will be allowed for either sector under **Alternative 1 (No Action)**, as the high level of discards of red snapper that have kept the fishery closed to harvest over the past two years are unlikely to improve as the stock continues to rebuild. **Alternative 1 (No Action)** would be expected to have no impact on the rebuilding rate of the red snapper stock; however, because no fishing would be allowed to occur in the foreseeable future, it would result in foregone direct, short-term economic benefits to the commercial and recreational sectors.

The expected changes in commercial ex-vessel revenue and recreational consumer surplus (CS) relative to the status quo (**Alternative 1 (No Action)**) under **Alternative 2**, **Alternative 3**, **Alternative 4**, and **Alternative 5** are provided in **Table 4.1.7**. For the commercial sector, the ex-vessel revenue is presented as a range, using two sets of projected landings. The lower bound is based on predicted landings under the current stock size and the upper bound is based on higher predicted landings that are adjusted for an increased stock size (see **Appendix N** and **Appendix O**). Although some small level of state landings have occurred in recent years during the federal closures, it is not expected that the current action would affect state landings and so they are excluded from this analysis.

Under **Alternative 2**, **Alternative 3**, **Alternative 4**, and **Alternative 5**, it is estimated that ex-vessel revenue would increase, relative to the status quo (**Alternative 1 (No Action)**), by a range of approximately $318,000 to $732,000 (2016 dollars; **Table 4.1.7**)[17]. Under these alternatives the commercial season would be open for 45 to 175 days in 2018. Estimates vary depending on the alternative being examined and the landings assumption used. With regard to economic effects on the recreational sector, it is estimated that recreational CS and season length would scale up proportionally to the ACL that is implemented and range from approximately $1.34 million to $4.52 million[18]. The recreational season would be open for 2 to 28 days in 2018.

Table 4.1.2.1. Estimated change in commercial ex-vessel revenue, recreational consumer surplus (CS), and season length relative to the status quo.

	Commercial ex-vessel revenue (2016 dollars)	Commercial season length (days)*		Recreational consumer surplus (2016 dollars)	Recreational season length (days)**
Alternative 1 (No Action)	0	0		0	0
Alternative 2	$318,362	45 to 70		$1,334,880	2 to 4
Alternative 3	$545,981 to $598,518	140 to 175		$2,509,542	4 to 7
Alternative 4	$545,981 to $572,901	104 to 175		$2,402,136	4 to 7
Alternative 5	$545,981 to $731,614	175		$4,515,993	8 to 28

Source: SERO LAPP/DM (Appendix N and O) for landings and season length projections; WTP per red snapper from Carter and Liese (2012) (see **Section 3.3.2**); Ex-vessel average annual price (2012-2014 only) of $4.59 (2016 dollars) from SERO ACL dataset (May 2017).
*The commercial red snapper season would open on July 9, 2018 until which time the ACL is projected to be met.
*The recreational red snapper season would open on July 13, 2018 for Fridays, Saturdays, and Sundays only, until which time the ACL is projected to be met.

[17] Only 2012-2014 (the years when commercial harvest of red snapper in federal waters of the South Atlantic was open) were used for average price calculations. This is to minimize potential bias from misreported landings or variations in the size and quality of state- versus federally-caught fish during fully-closed years.
[18] The estimates of CS are based on a willingness to pay of $81 for a second fish harvested on a trip (Carter and Liese 2012; 2016 dollars) (**Section 3.3.2**). An estimate for the first red snapper harvested on an angler trip is not available. Given the current one fish per person bag limit and the assumption of diminishing marginal utility per fish harvested, the CS estimate provided may potentially underestimate the value of allowing for red snapper harvest beginning in 2018.

By allowing for recreational red snapper harvest, there is the potential that angler demand for for-hire (charter and headboat) trips would increase as well, resulting in increased booking rates and for-hire business net operating revenue (NOR). Due to the complex nature of angler behavior and the for-hire industry, it is not possible to quantify these potential economic effects with available data.[19] As such, no estimates of the change in for-hire NOR are provided, although they may exist. The estimates of NOR per charter and headboat trip in the South Atlantic are provided in **Section 3.3.2**. It is expected that as the ACL increases, so would the potential for increases in for-hire NOR. This is because a larger ACL would result in a longer red snapper fishing season, affording for-hire businesses greater opportunity to market and sell their services.

As discussed in **Section 3.3.1** and **Section 3.3.2**, commercial and recreational fishing for red snapper spurs business activity (economic impacts) in the region in which it occurs. This action may be reasonably expected to increase such business activity relative to the status quo, by increasing recreational and commercial expenditures on goods and services necessary for fishing and by increasing the supply of red snapper into the seafood value chain. Although retail prices for red snapper would likely be tempered by substitute finfish species and snapper imports, fresh locally-caught red snapper may fetch a price premium in seafood markets and restaurants, resulting in an increase in producer surplus. In addition, because seafood consumers may have strong preferences for locally-caught red snapper over other seafood options, it could result in an increase in consumer surplus as well. These potential economic benefits cannot be quantified with available data.

In addition to the short-term economic effects described above, medium to long-term indirect negative economic effects could ensue from this action as a result of its effects on the red snapper stock, future management decisions, and future catch rates. It is not known if any of the alternatives would be likely to jeopardize the sustainability of the stock but the negative economic effects would be more likely with **Alternatives 3** and **5** as these two alternatives set ACLs above recently observed levels of harvest for the species.

Given the increasing economic benefits associated with higher ACLs for red snapper, **Alternative 5** will provide the largest positive economic effects, at least in the short-term, followed by **Alternative 3**, **Alternative 4**, **Alternative 2**, and **Alternative 1 (No Action)**.

4.1.3 Social Effects

The communities with the largest levels of red snapper landings, in addition to communities with highest engagement and reliance on commercial and recreational fishing are described in **Section 3.3.2**. Red snapper is an extremely popular species, especially for participants in the

[19] Anglers have heterogeneous preferences and may target and/or harvest a diverse mix of snapper grouper and other species on a trip. The absence of the opportunity to fish for any single species may or may not affect their overall desire to take/pay for trips.

recreational fishery. The absence of a fishing season for red snapper in recent years has been highly controversial with negative effects on recreational anglers, for-hire businesses and commercial vessels, especially when compared to the benefits to fishermen during the allowed seasons in 2012, 2013, and 2014. The social effects of the proposed alternatives are expected to be associated with restricted access to the red snapper resource for several years, combined with distrust in science and management due to inconsistency in what fishermen see on the water versus the scientific models. Additionally, there will be social effects associated with transforming discards into landings if there is a fishing season, along with social effects of improved data collection during a fishing season.

Alternative 1 (No action) would keep the current system that determines if red snapper harvest will be allowed each year, based on removals from the previous year. In the most recent two years (2015, 2016, and 2017), there has been no red snapper season, even for a few days. The rebuilding plan for red snapper implemented through Amendment 17A (SAFMC 2010) is considered to be working successfully, and this should lead to expected benefits to the fishermen. However, the outcome of the successful rebuilding plan is that interactions with red snapper have become more difficult to avoid, which leads to the discard rate that calculates to high levels of removals each year. Under current conditions, it is likely that there will be no open fishing seasons for red snapper in the foreseeable future under **Alternative 1 (No action)**.

Input from fishermen indicate that they are more and more frustrated with the perceived waste of the resource due to discards of red snapper. Additionally, under **Alternative 1 (No action)**, there is distrust in the science because harvest is prohibited, but fishermen report that there are plenty of red snapper. The current system sends a conflicting message to fishermen in that regulations are intended to protect stocks and rebuild overfished stocks, but there will be no benefit to the fishermen because the Council and NMFS cannot allow any harvest of red snapper.

By allowing an ACL for red snapper in **Alternative 2** through **5**, there should be positive social effects as it would allow fishermen to harvest this popular species, in addition to revenue generated for charter/headboat and commercial businesses when compared to **Alternative 1 (No action)**. It is assumed that with available ACL, there would be increased fishing opportunities for private, for-hire and commercial fishermen, and that there would be fewer discards as these fish are landed. Therefore, with the expected ACLs under the proposed alternatives, the most social benefits would be expected under **Alternative 5**, followed by **Alternative 3**, **Alternative 4**, **Alternative 2,** and then **Alternative 1 (No Action).**

4.1.4 Administrative Effects

Chapter 5. Council's Choice for the Preferred Alternatives

5.1 Action 1. Revise the Process to Determine the Annual Catch Limits (ACLs) for Red Snapper

5.1.1 Snapper Grouper Advisory Panel (AP) Comments and Recommendations

The Snapper Grouper AP discussed actions in Amendment 43 during their April 17-19, 2017 meeting. At that time, however, Amendment 43 contained different actions than the one currently proposed. Hence the Snapper Grouper AP did not have recommendations for setting the ACL for red snapper. Regarding possible management measures, AP members offered the following comments:

- Regarding a possible commercial trip limit, the AP stated that specifying it in numbers of fish might lead to high grading. If the allowable harvest results in a low trip limit, then don't consider a size limit.
- Because of the depths where commercial harvest takes place, there shouldn't be a minimum size limit requirement. Consider full retention for the commercial sector.
- Red snapper should continue to be managed as a bycatch fishery in the commercial sector.
- Consider initially allowing a recreational harvest two days per week to make it easier for fishermen to plan trips and for enforcement.

Alternatives*

Alternative 1 (No Action): The commercial and recreational annual catch limits for red snapper are zero. Process in place to allow limited harvest based on ABC.

Alternative 2. Remove the process and equation used to determine the red snapper ACL as specified in Snapper Grouper Amendment 28. Specify Total ACL = 23,623 fish. Commercial ACL = 69,360 lbs (whole weight). Recreational ACL = 16,480 fish.

Alternative 3. Remove the process and equation used to determine the red snapper ACL as specified in Snapper Grouper Amendment 28. Specify Total ACL = 44,411 fish. Commercial ACL = 130,396 lbs (whole weight). Recreational ACL = 30,982 fish.

Alternative 4. Remove the process and equation used to determine the red snapper ACL as specified in Snapper Grouper Amendment 28. Specify Total ACL = 42,510 fish. Commercial ACL = 124,815 lbs (whole weight). Recreational ACL = 29,656 fish.

Alternative 5. Remove the process and equation used to determine the red snapper ACL as specified in Snapper Grouper Amendment 28. Specify Total ACL = 79,919 fish. Commercial ACL = 234,652 lbs (whole weight). Recreational ACL = 55,753 fish.

* Refer to Chapter 2 for detailed language of alternatives

5.1.2 Law Enforcement AP Comments and Recommendations

The Law Enforcement AP discussed Amendment 43 during their May 18-19, 2017 meeting. At that time, however, Amendment 43 contained different actions than the one currently proposed. Hence the Law Enforcement AP did not have recommendations for setting the ACL for red snapper. Regarding possible management measures, Law Enforcement AP members offered the following comments:

- For small trip limit amounts (i.e., 25 pounds) it would be easier to specify trip limit in numbers of fish
- Highgrading is a concern and not easy to prevent; using numbers instead of weight would be useful for enforcement.

5.1.3 Scientific and Statistical Committee (SSC) Comments and Recommendations

The SSC discussed Amendment 43 during their April 25-27, 2017 meeting. At that time Amendment 43 included options for red snapper bag, trip, and size limits and seasons for recreational and commercial sectors as well as potential area and season combinations. Also included were options to establish a permit and reporting requirements for private recreational fishermen and best fishing practices. Below are summarized comments/recommendations from the meeting report on the red snapper stock assessment:

- The SSC received a presentation from Southeast Fisheries Science Center (SEFSC) staff on revisions to the red snapper assessment (SEDAR 41). The revisions addressed the headboat discard index SEFSC staff indicated that the differences between the original and corrected assessment were minimal but the new likelihood estimator was not investigated in the corrected assessment. However, the SSC noted that the corrected Maximum Sustainable Yield is 7% lower than in the original assessment, and a side by side comparison was not included in the report. The results of the corrected assessment were not further discussed as the SSC was unable to provide an acceptable biological catch (ABC) recommendation for red snapper.
- SEFSC staff clarified that the red snapper assessment is still considered Best Scientific Information Available (BSIA). However, the data available to monitor the landings and discards are too uncertain to track any projected ABC. Therefore, an index-based approach is being proposed to track and monitor the condition of red snapper.
- The projected yield streams from SEDAR 41 are still considered BSIA, but are not useful for management and monitoring because of the uncertainty in the catch data (as most of the catch is discarded).

The SSC provided further commetns and recommendations on red snapper management that are not directly relevant to the action proposed in Amendment 43. Refer to the April 2017 SSC report for additional details.

5.1.4 Public Comments and Recommendations

The Council held public scoping meetings from January 23 to February 8, 2017 at various locations in the four South Atlantic states. The actions included for scoping at that time differ from what is being considered currently in Amendment 43. A summary of public comments received during those meetings was provided to the Snapper Grouper Committee at the March 2017 Council meeting in Jekyll Island, GA. The summary also included written comments received via the online comment form on the Council's website or other means such as by mail, fax, or email. In total, there were 144 comments provided during the public comment period that ended on February 10, 2017. Of these, 69 were submitted verbally and 77 were submitted in writing. The summary of comments can be found on the March 2017 meeting brefing book available on the Council's website.

The Council will hold public hearings on Amendment 43 via webinar on August 3-10, 2017 and during the September 11-15, 2017, Council meeting.

5.1.5 Council's Rationale

Annual catch limits are established with accountability measures to prevent overfishing. Typically the annual catch limit is established below the acceptable biological catch; however, the Scientific and Statistical Committee was unable to provide an acceptable biological catch recommendation for red snapper based on the revised SEDAR 41 assessment (SSC 2017). The landings and discard data were too uncertain to track any projected acceptable biological catch. The Scientific and Statistical Committee also indicated that the stock status was still valid, the increasing number of discards had a high probability of reflecting increases in population size, and a short season to obtain representative age samples would require a scientific design. While the Scientific and Statistical Committee and National Marine Fisheries Serive continue to work on developing methods to develop an acceptable biological catch that can be tracked, the Council is proposing to establish a conservative annual catch limit based on past red snapper landings.

Alternative 4 proposes a higher annual catch limit than **Alternative 2** and therefore would have a greater social and economic benefit, which meets the purpose of the action. **Alternative 4** relies on an observed landings level and does not assume an increase in red snapper abundance thereby reducing the chances that allowing that level of harvest would lead to overfishing. However, **Alternative 4** proposes a lower annual catch limit than **Alternatives 3** and **5** and therefore is expected to result in lower social and economic benefit. However, **Alternatives 3** and **5** propose scaling the landings based on fishery-independent survey observations and may cause overfishing since the correlation between survey data and the true population abundance is unknown.

In-seasons closures will be used to prevent landings from exceeding the ACL. For the recreational sector, season length would be calculated based on past fishing rates and the Natinal Marine Fisheries Service would issue a notification specifying a season. For the commercial sector, landings would be tracked using the weekly reporting system and harvest would close when the commercial annual catch limit is met or is projected to be met. These accountability measures combined with the ACL proposed in **Alternative X**, would best meet the purpose of revising the ACL for the red snapper component of the snapper grouper fishery to increase socio economic benefits to fishermen while preventing overfishing.

5.1.6 How is this Action Addressing the Vision Blueprint for the Snapper Grouper Fishery?

The Vision Blueprint for the Snapper Grouper Fishery (Vision Blueprint) was approved in December 2015 and is intended to inform management of the snapper grouper fishery through 2020. As such, the Vision Blueprint serves as a "living document" to help guide future management, builds on stakeholder input and how the Council envisions future management of the fishery, guides the development of new amendments that address priority objectives and strategies, and illustrates actions that could be developed through the regular amendment process. The Vision Blueprint is organized into four strategic goal areas: (1) Science, (2) Management, (3) Communication, and (4) Governance. Each goal area has a set of objectives, strategies, and actions.

Action 1 to revise the annual catch limit for red snapper in the South Atlantic would address Objective 3: "Ensure that management decisions help maximize social and economic opportunity for all sectors" under the Management Goal. Specifically, the action would respond to Strategy 3.2: "Consider development of management approaches that support recreational fishing and allow increased opportunity for trip satisfaction". Allowing limited recreational harvest of red snapper in the South Atlantis is expected to increase fishing opportunities and trip satisfaction for fishermen who have very limited access to red snapper in recent years. In addition, Action B under Strategy 3.2 to "Consider mechanisms based on abundance and availability of easily accessible species" is also being addressed through the action in Amendment 43 since allowing a limited harvest of red snapper is being considered based partly on recent increases in abundance as indicated by a scientific survey. As the red snapper stock in the South Atlantic region continues to rebuild, fishermen are interacting with red snapper more frequently as evidenced by the estimates of discarded fish and fishermen's testimony. Further, the action being considered in Amendment 43 to specify the timeframe during which retention of red snapper would be allowed responds to a "hot topic" under Objective 3 to "Set a fishing season at the beginning of the fishing year with known open and close dates."

Chapter 6. Cumulative Effects

6.1 Affected Area

The immediate impact area would be the federal 200-mile limit of the Atlantic off the coasts of North Carolina, South Carolina, Georgia, and east Florida to Key West, which is also the South Atlantic Fishery Management Council's (Council) area of jurisdiction. In light of the available information, the extent of the boundaries would depend upon the degree of fish immigration/emigration and larval transport, whichever has the greatest geographical range. The ranges of affected species are described in **Section 3.2**. For the actions found in Amendment 43, the cumulative effects analysis (CEA) includes an analysis of data from ….

6.2 Past, Present, and Reasonably Foreseeable Actions Impacting the Affected Area

Fishery managers implemented the first significant regulations pertaining to red snapper in 1983 through the Snapper Grouper FMP (SAFMC 1983). The regulations included a 12-inch total length minimum size limit for red snapper. Listed below are other past, present, and reasonably foreseeable actions occurring in the South Atlantic region. These actions, when added to the proposed management measures, may result in cumulative effects on the biophysical and socio-economic environment. The complete history of management of the snapper grouper fishery can be found in **Appendix C (History of Management)**.

Past Actions

The South Atlantic Headboat Reporting Amendment was implemented on January 27, 2014, and requires that all federally-permitted headboats on the South Atlantic report their landings information electronically, and on a weekly basis in order to improve the timeliness and accuracy of harvest data.

The Generic Dealer Reporting Amendment, which became effective on August 7, 2014, established one dealer permit for the Gulf of Mexico and South Atlantic regions and increased the reporting frequency requirements for species managed by the Gulf of Mexico and Councils. This amendment is expected to improve fisheries data collection, through more timely and accurate dealer reporting, and streamline the dealer permit system.

Amendment 29 to the Snapper Grouper FMP, which became effective on July 1, 2015, updated the Council's acceptable biological catch (ABC) control rule to incorporate methodology for determining the ABC of "Only Reliable Catch Stocks"; (2) adjusted ABCs for the affected unassessed species; (3) specified annual catch limits (ACLs) for 7 species based on the updated ABCs; and (4) modified management measures for gray triggerfish in federal waters of the South Atlantic region (SAFMC 2014b).

The Generic Accountability Measures (AM) and Dolphin Allocation Amendment, in part, modified AMs for snapper grouper species (including mutton snapper) to make them more consistent with AMs already implemented for other species and other fishery management plans. The regulations became effective on February 22, 2016.

Present Actions

Amendment 36 to the Snapper Grouper FMP would establish new Spawning Special Management Zones to protect spawning areas for snapper grouper species. The regulations became effective on July 31, 2017.

Amendment 37 to the Snapper Grouper FMP would modify the hogfish fishery management unit, specify fishing levels for the two South Atlantic hogfish stocks, establish a rebuilding plan for the Florida Keys/East Florida stock, and establish/revise management measures for both hogfish stocks in the South Atlantic Region, such as size limits, recreational bag limits, and commercial trip limits. The regulations will become effective on August 24, 3017.

Amendment 41 to the Snapper Grouper FMP updates the MSY, ABC, ACL, OY, minimum stock size threshold, designate spawning months for regulatory purposes, and revise management measures for mutton snapper.

The South Atantic For-Hire Electronic Reporting Amendment would require charter vessels to regularly report their landings information electronically. Including charter boats in the recreational harvest reporting system would further improve the agency's ability to monitor recreational catch rates in-season.

Reasonably Foreseeable Future Actions

The Vision Blueprint Recreational Amendment (Amendment 26) for the Snapper Grouper Fishery of the South Atlantic considers actions to evaluate and modify the composition of the recreational aggregate snapper bag limit, recreational aggregate grouper bag limit, and the recreational aggregate for species without a bag limit. The amendment would also consider modifying the current recreational prohibition on harvest and possession of shallow water groupers, remove the recreational minimum size limit for deep-water species, and modify the recreational minimum size limit for black sea bass.

The Vision Blueprint Commercial Amendment (Amendment 27) for the Snapper Grouper Fishery of the South Atlantic is currently under development.

The Bycatch Reporting Amendment contains an action to improve bycatch reporting for the snapper grouper fishery.

A Joint Commercial Logbook Reporting Amendment would require electronic reporting of logbook information by federally-permitted vessels.

Expected Impacts from Past, Present, and Future Actions

6.3 Consideration of Climate Change and Other Non-Fishery Related Issues

Climate Change

Global climate changes could have significant effects on South Atlantic fisheries, though the extent of these effects on the snapper grouper fishery is not known at this time. The Environmental Protection Agency's climate change webpage (https://www.epa.gov/climate-indicators/marine-species-distribution), and NOAA's Office of Science and Technology climate webpage (https://www.st.nmfs.noaa.gov/ecosystems/climate/index), provides background information on climate change, including indicators which measure or anticipate effects on oceans, weather and climate, ecosystems, health and society, and greenhouse gases. The United Nations Intergovernmental Panel on Climate Change's Fifth Assessment Report also provides a compilation of scientific information on climate change (November 2, 2014). Those findings are summarized below.

Ocean acidification, or a decrease in surface ocean pH due to absorption of anthropogenic carbon dioxide emissions, affects the chemistry and temperature of the water. Increased thermal stratification alters ocean circulation patterns, and causes a loss of sea ice, sea level rise, increased wave height and frequency, reduced upwelling, and changes in precipitation and wind patterns. Changes in coastal and marine ecosystems can influence organism metabolism and alter ecological processes such as productivity, species interactions, migration, range and distribution, larval and juvenile survival, prey availability, and susceptibility to predators. The "center of biomass," a geographical representation of each species' weight distribution, is being used to identify the shifting of fish populations. Warming sea temperature trends in the southeast have been documented, and animals must migrate to cooler waters, if possible, if water temperatures exceed survivable ranges (Needham et al. 2012). Harvesting and habitat changes also cause geographic population shifts. Changes in water temperatures may also affect the distribution of native and exotic species, allowing invasive species to establish communities in areas they may not have been able to survive previously. The combination of warmer water and expansion of salt marshes inland with sea-level rise may increase productivity of estuarine-dependent species in the short term. However, in the long term, this increased productivity may be temporary because of loss of fishery habitats due to wetland loss (Kennedy et al. 2002). The numerous changes to the marine ecosystem may cause an increased risk of disease in marina biota. An increase in the occurrence and intensity of toxic algae blooms will negatively influence the productivity of keystone animals, such as corals, and critical coastal ecosystems such as wetlands, estuaries, and coral reefs (IPCC 2014; Kennedy et al. 2002).

Climate change may impact snapper grouper species in the future, but the level of impacts cannot be quantified at this time, nor is the time frame known in which these impacts will occur.

In the near term, it is unlikely that the management measures contained in Amendment 43 would compound or exacerbate the ongoing effects of climate change on snapper grouper species.

Weather Variables

Hurricane season is from June 1 to November 30, and accounts for 97% of all tropical activity affecting the Atlantic basin. These storms, although unpredictable in their annual occurrence, can devastate areas when they occur. Although these effects may be temporary, those fishing-related businesses whose profitability is marginal may go out of business if a hurricane strikes.

Deepwater-Horizon Oil Spill

On April 20, 2010, an explosion occurred on the Deepwater Horizon MC252 oil rig, resulting in the release of an estimated 4.9 million barrels of oil into the Gulf of Mexico (Gulf). In addition, 1.84 million gallons of Corexit 9500A dispersant were applied as part of the effort to constrain the spill. The cumulative effects from the oil spill and response may not be known for several years. The oil spill affected more than one-third of the Gulf area from western Louisiana east to the panhandle of Florida and south to the Campeche Bank in Mexico. The impacts of the Deepwater Horizon MC252 oil spill on the physical environment are expected to be significant and may be long-term. Oil is dispersed on the surface, and because of the heavy use of dispersants, oil is also documented as being suspended within the water column, some even deeper than the location of the broken well head. Floating and suspended oil washed onto shore in several areas of the Gulf, as well as non-floating tar balls. Whereas suspended and floating oil degrades over time, tar balls are more persistent in the environment and can be transported hundreds of miles. Oil on the surface of the water could restrict the normal process of atmospheric oxygen mixing into and replenishing oxygen concentrations in the water column. In addition, microbes in the water that break down oil and dispersant also consume oxygen; this could lead to further oxygen depletion. Zooplankton that feed on algae could also be negatively impacted, thus allowing more of the hypoxia-fueling algae to grow. The highest concern is that the oil spill may have impacted spawning success of species that spawn in the summer months, either by reducing spawning activity or by reducing survival of the eggs and larvae. Effects on the physical environment, such as low oxygen, could lead to impacts on the ability of larvae and post-larvae to survive, even if they never encounter oil. In addition, effects of oil exposure may create sub-lethal effects on the eggs, larva, and early life stages. The stressors could potentially be additive, and each stressor may increase the susceptibility to the harmful effects of the other. The oil from the spill site was not detected in the South Atlantic region, and does not likely pose a threat to the South Atlantic species addressed in this amendment. However, the effects of the oil spill on fish species would be taken into consideration in future Southeast Data Assessment and Review assessments. Indirect and inter-related effects on the biological and ecological environment of the fisheries in concert with the Deepwater Horizon MC252 oil spill are not well understood. Changes in the population size structure could result from shifting fishing effort to specific geographic segments of populations, combined with any anthropogenically induced natural mortality that may occur from the impacts of the oil spill. The impacts on the food web from phytoplankton, to zooplankton, to mollusks, to top predators may be significant in the future.

6.4 Overall Impacts Expected from Past, Present, and Future Actions

6.5 Monitoring and Mitigation

Chapter 7. List of Interdisciplinary Plan Team (IPT) Members

Name	Agency/Division	Title
Manny Antonaras	SERO/OLE	Deputy Special Agent in Charge
Myra Brouwer	SAFMC	Fishery Biologist
David Carter	SEFSC	Economist
Brian Cheuvront	SAFMC	Deputy Executive Director
Chip Collier	SAFMC	Interdisciplinary plan team (IPT) Lead/ Biologist
Scott Crosson	SEFSC	Economist
David Dale	SERO/HC	EFH Specialist
Rick Devictor	SERO/SF	Assistant Regional Adminstrator
Tracy Dunn	SERO/OLE	Assistant Director
Mike Errigo	SAFMC	Data Analyst
Nick Farmer	SERO/SF	Data Analyst
John Hadley	SAFMC	Economist
Frank Helies	SERO/SF	IPT Lead/Fishery Biologist
David Records	SERO/SF	Economist
Mike Larkin	SERO/SF	Biologist
Jennifer Lee	SERO/PR	Fishery Biologist
Jack McGovern	SERO/SF	Assistant Regional Administrator
Kari McLauchlin	SAFMC	Social Scientist
Nikhil Mehta	SERO/SF	IPT Lead/Fishery Biologist
Christina Package-Ward	SERO/SF	Social Scientist
David Records	SERO/SF	Economist
Scott Sandorf	SERO/SF	Technical Writer and Editor
Kate Siegfried	SEFSC	Research Fishery Biologist
Noah Silverman	NMFS/SER	Regional NEPA Coordinator
Monica Smit-Brunello	NOAA GC	General Counsel

NMFS = National Marine Fisheries Service, SAFMC = South Atlantic Fishery Management Council, SF = Sustainable Fisheries Division, PR = Protected Resources Division, SERO = Southeast Regional Office, HC = Habitat Conservation Division, GC = General Counsel

Appendix A. Considered But Rejected Alternatives

No actions or alternatives were removed from further analysis. Several actions considered in an early version of Amendment 43 were moved into Amendment 46.

Appendix B. Glossary

Allowable Biological Catch (ABC): Maximum amount of fish stock than can be harvested without adversely affecting recruitment of other components of the stock. The ABC level is typically higher than the total allowable catch, leaving a buffer between the two.

ALS: Accumulative Landings System. NMFS database which contains commercial landings reported by dealers.

Biomass: Amount or mass of some organism, such as fish.

B_{MSY}: Biomass of population achieved in long-term by fishing at F_{MSY}.

Bycatch: Fish harvested in a fishery, but not sold or kept for personal use. Bycatch includes economic discards and regulatory discards, but not fish released alive under a recreational catch and release fishery management program.

Caribbean Fishery Management Council (CFMC): One of eight regional councils mandated in the Magnuson-Stevens Fishery Conservation and Management Act to develop management plans for fisheries in federal waters. The CFMC develops fishery management plans for fisheries off the coast of the U.S. Virgin Islands and the Commonwealth of Puerto Rico.

Catch Per Unit Effort (CPUE): The amount of fish captured with an amount of effort. CPUE can be expressed as weight of fish captured per fishing trip, per hour spent at sea, or through other standardized measures.

Charter Boat: A fishing boat available for hire by recreational anglers, normally by a group of anglers for a short time period.

Cohort: Fish born in a given year. (See year class.)

Control Date: Date established for defining the pool of potential participants in a given management program. Control dates can establish a range of years during which a potential participant must have been active in a fishery to qualify for a quota share.

Constant Catch Rebuilding Strategy: A rebuilding strategy where the allowable biological catch of an overfished species is held constant until stock biomass reaches B_{MSY} at the end of the rebuilding period.

Constant F Rebuilding Strategy: A rebuilding strategy where the fishing mortality of an overfished species is held constant until stock biomass reached BMSY at the end of the rebuilding period.

Directed Fishery: Fishing directed at a certain species or species group.
Discards: Fish captured, but released at sea.

Discard Mortality Rate: The % of total fish discarded that do not survive being captured and released at sea.

Derby: Fishery in which the TAC is fixed and participants in the fishery do not have individual quotas. The fishery is closed once the TAC is reached, and participants attempt to maximize their harvests as quickly as possible. Derby fisheries can result in capital stuffing and a race for fish.

Effort: The amount of time and fishing power (i.e., gear size, boat size, horsepower) used to harvest fish.

Exclusive Economic Zone (EEZ): Zone extending from the shoreline out to 200 nautical miles in which the country owning the shoreline has the exclusive right to conduct certain activities such as fishing. In the United States, the EEZ is split into state waters (typically from the shoreline out to 3 nautical miles) and federal waters (typically from 3 to 200 nautical miles).

Exploitation Rate: Amount of fish harvested from a stock relative to the size of the stock, often expressed as a percentage.

F: Fishing mortality.

Fecundity: A measurement of the egg-producing ability of fish at certain sizes and ages.

Fishery Dependent Data: Fishery data collected and reported by fishermen and dealers.

Fishery Independent Data: Fishery data collected and reported by scientists who catch the fish themselves.

Fishery Management Plan: Management plan for fisheries operating in the federal produced by regional fishery management councils and submitted to the Secretary of Commerce for approval.

Fishing Effort: Usually refers to the amount of fishing. May refer to the number of fishing vessels, amount of fishing gear (nets, traps, hooks), or total amount of time vessels and gear are actively engaged in fishing.

Fishing Mortality: A measurement of the rate at which fish are removed from a population by fishing. Fishing mortality can be reported as either annual or instantaneous. Annual mortality is the percentage of fish dying in one year. Instantaneous is that percentage of fish dying at any one time.

Fishing Power: Measure of the relative ability of a fishing vessel, its gear, and its crew to catch fishes, in reference to some standard vessel, given both vessels are under identical conditions.

$F_{30\%SPR}$: Fishing mortality that will produce a static SPR = 30%.

$F_{45\%SPR}$: Fishing mortality that will produce a static SPR = 45%.

F_{OY}: Fishing mortality that will produce OY under equilibrium conditions and a corresponding biomass of B_{OY}. Usually expressed as the yield at 85% of F_{MSY}, yield at 75% of F_{MSY}, or yield at 65% of F_{MSY}.

F_{MSY}: Fishing mortality that if applied constantly, would achieve MSY under equilibrium conditions and a corresponding biomass of B_{MSY}.

Fork Length (FL): The length of a fish as measured from the tip of its snout to the fork in its tail.

Framework: An established procedure within a fishery management plan that has been approved and implemented by NMFS, which allows specific management measures to be modified via regulatory amendment.

Gear restrictions: Limits placed on the type, amount, number, or techniques allowed for a given type of fishing gear.

Growth Overfishing: When fishing pressure on small fish prevents the fishery from producing the maximum poundage. Condition in which the total weight of the harvest from a fishery is improved when fishing effort is reduced, due to an increase in the average weight of fishes.

Gulf of Mexico Fishery Management Council (GFMC): One of eight regional councils mandated in the Magnuson-Stevens Fishery Conservation and Management Act to develop management plans for fisheries in federal waters. The GFMC develops fishery management plans for fisheries off the coast of Texas, Louisiana, Mississippi, Alabama, and the west coast of Florida.

Headboat: A fishing boat that charges individual fees per recreational angler onboard.

Highgrading: Form of selective sorting of fishes in which higher value, more marketable fishes are retained, and less marketable fishes, which could legally be retained are discarded.

Individual Fishing Quota (IFQ): Fishery management tool that allocates a certain portion of the TAC to individual vessels, fishermen, or other eligible recipients.

Longline: Fishing method using a horizontal mainline to which weights and baited hooks are attached at regular intervals. Gear is either fished on the bottom or in the water column.

Magnuson-Stevens Fishery Conservation and Management Act: Federal legislation responsible for establishing the fishery management councils and the mandatory and discretionary guidelines for federal fishery management plans.

Marine Recreational Information Program (MRIP): Survey operated by NMFS in cooperation with states that collects marine recreational data.

Maximum Fishing Mortality Threshold (MFMT): The rate of fishing mortality above which a stock's capacity to produce MSY would be jeopardized.

Maximum Sustainable Yield (MSY): The largest long-term average catch that can be taken continuously (sustained) from a stock or stock complex under average environmental conditions.

Minimum Stock Size Threshold (MSST): The biomass level below which a stock would be considered overfished.

Modified F Rebuilding Strategy: A rebuilding strategy where fishing mortality is changed as stock biomass increases during the rebuilding period.

Multispecies fishery: Fishery in which more than one species is caught at the same time and location with a particular gear type.

National Marine Fisheries Service (NMFS): Federal agency within NOAA responsible for overseeing fisheries science and regulation.

National Oceanic and Atmospheric Administration: Agency within the Department of Commerce responsible for ocean and coastal management.

Natural Mortality (M): A measurement of the rate at which fish are removed from a population by natural causes. Natural mortality can be reported as either annual or instantaneous. Annual mortality is the percentage of fish dying in one year. Instantaneous is that percentage of fish dying at any one time.

Optimum Yield (OY): The amount of catch that will provide the greatest overall benefit to the nation, particularly with respect to food production and recreational opportunities and taking into account the protection of marine ecosystems.

Overfished: A stock or stock complex is considered overfished when stock biomass falls below the minimum stock size threshold (MSST) (e.g., current biomass < MSST = overfished).

Overfishing: Overfishing occurs when a stock or stock complex is subjected to a rate of fishing mortality that exceeds the maximum fishing mortality threshold (e.g., current fishing mortality rate > MFMT = overfishing).
Quota: % or annual amount of fish that can be harvested.

Recruitment (R): Number or percentage of fish that survives from hatching to a specific size or age.

Recruitment Overfishing: The rate of fishing above which the recruitment to the exploitable stock becomes significantly reduced. This is characterized by a greatly reduced spawning stock, a decreasing proportion of older fish in the catch, and generally very low recruitment year after year.

Scientific and Statistical Committee (SSC): Fishery management advisory body composed of federal, state, and academic scientists, which provides scientific advice to a fishery management council.

Selectivity: The ability of a type of gear to catch a certain size or species of fish.

South Atlantic Fisheries Management Council (SAFMC): One of eight regional councils mandated in the Magnuson-Stevens Fishery Conservation and Management Act to develop management plans for fisheries in federal waters. The SAFMC develops fishery management plans for fisheries off North Carolina, South Carolina, Georgia, and the east coast of Florida.

Spawning Potential Ratio (Transitional SPR): Formerly used in overfished definition. The number of eggs that could be produced by an average recruit in a fished stock divided by the number of eggs that could be produced by an average recruit in an unfished stock. SPR can also be expressed as the spawning stock biomass per recruit (SSBR) of a fished stock divided by the SSBR of the stock before it was fished.

% Spawning Per Recruit (Static SPR): Formerly used in overfishing determination. The maximum spawning per recruit produced in a fished stock divided by the maximum spawning per recruit, which occurs under the conditions of no fishing. Commonly abbreviated as %SPR.

Spawning Stock Biomass (SSB): The total weight of those fish in a stock which are old enough to spawn.

Spawning Stock Biomass Per Recruit (SSBR): The spawning stock biomass divided by the number of recruits to the stock or how much spawning biomass an average recruit would be expected to produce.

Total Allowable Catch (TAC): The total amount of fish to be taken annually from a stock or stock complex. This may be a portion of the Allowable Biological Catch (ABC) that takes into consideration factors such as bycatch.

Total Length (TL): The length of a fish as measured from the tip of the snout to the tip of the tail.

Appendix C. History of Management

South Atlantic Snapper Grouper History of Management
Last Updated: 6/23/17

The snapper grouper fishery is highly regulated; some of the species included in this amendment have been regulated since 1983. The following table summarizes actions in each of the amendments to the original Snapper Grouper Fishery Management Plan (FMP), as well as some events not covered in amendment actions.

*Shaded rows indicate FMP Amendments

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
FMP (1983)	08/31/83	PR: 48 FR 26843 FR: 48 FR 39463	-12" total length (TL) limit – red snapper, yellowtail snapper, red grouper, Nassau grouper; -8" limit – black sea bass; -4" trawl mesh size; -Gear limitations – poisons, explosives, fish traps, trawls; -Designated modified habitats or artificial reefs as Special Management Zones (SMZs).
Regulatory Amendment #1 (1987)	03/27/87	PR: 51 FR 43937 FR: 52 FR 9864	-Prohibited fishing in SMZs except with hand-held hook-and-line and spearfishing gear; -Prohibited harvest of goliath grouper in SMZs.
Amendment #1 (1988a)	01/12/89	PR: 53 FR 42985 FR: 54 FR 1720	-Prohibited trawl gear to harvest fish south of Cape Hatteras, NC and north of Cape Canaveral, FL; -Directed fishery defined as vessel with trawl gear and ≥200 lb s-g on board; -Established rebuttable assumption that vessel with s-g on board had harvested such fish in the exclusive economic zone (EEZ).
Regulatory Amendment #2 (1988b)	03/30/89	PR: 53 FR 32412 FR: 54 FR 8342	-Established 2 artificial reefs off Ft. Pierce, FL as SMZs.
Emergency Rule	8/3/90	55 FR 32257	-Added wreckfish to the fishery management unit (FMU); -Fishing year beginning 4/16/90; -Commercial quota of 2 million pounds; -Commercial trip limit of 10,000 pounds per trip.
Fishery Closure Notice	8/8/90	55 FR 32635	- Fishery closed because the commercial quota of 2 million pounds was reached.
Notice of Control Date	09/24/90	55 FR 39039	-Anyone entering federal wreckfish fishery in the EEZ off S. Atlantic states after 09/24/90 was not assured of future access if limited entry program developed.
Regulatory Amendment #3	11/02/90	PR: 55 FR 28066 FR: 55 FR 40394	-Established artificial reef at Key Biscayne, FL as SMZ;

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
(1989)			-Fish trapping, bottom longlining, spear fishing, and harvesting of Goliath grouper prohibited in SMZ.
Amendment #2 (1990a)	10/30/90	PR: 55 FR 31406 FR: 55 FR 46213	-Prohibited harvest/possession of goliath grouper in or from the EEZ; -Defined overfishing for goliath grouper and other species.
Emergency Rule Extension	11/1/90	55 FR 40181	-Extended the measures implemented via emergency rule on 8/3/90.
Amendment #3 (1990b)	01/31/91	PR: 55 FR 39023 FR: 56 FR 2443	-Added wreckfish to the FMU; -Defined optimum yield (OY) and overfishing; -Required permit to fish for, land or sell wreckfish; -Required catch and effort reports from selected, permitted vessel; -Established control date of 03/28/90; -Established a fishing year for wreckfish starting April 16; -Established a process to set annual quota, with initial quota of 2 million pounds; provisions for closure; -Established 10,000 pound trip limit; -Established a spawning season closure for wreckfish from January 15 to April 15; -Provided for annual adjustments of wreckfish management measures.
Notice of Control Date	07/30/91	56 FR 36052	-Anyone entering federal snapper grouper fishery (other than for wreckfish) in the EEZ off S. Atlantic states after 07/30/91 was not assured of future access if limited entry program developed.
Amendment #4 (1991)	01/01/92	PR: 56 FR 29922 FR: 56 FR 56016	-Prohibited gear: fish traps except black sea bass traps north of Cape Canaveral, FL; entanglement nets; longline gear inside 50 fathoms; bottom longlines to harvest wreckfish; powerheads and bangsticks in designated SMZs off S. Carolina. -Defined overfishing/overfished and established rebuilding timeframe: red snapper and groupers ≤ 15 years (year 1 = 1991); other snappers, greater amberjack, black sea bass, red porgy ≤ 10 years (year 1 = 1991); -Required permits (commercial & for-hire) and specified data collection regulations; -Established an assessment group and annual adjustment procedure (framework); -Permit, gear, and vessel id requirements specified for black sea bass traps; -No retention of snapper grouper spp. caught in other fisheries with gear prohibited in snapper grouper fishery if captured snapper grouper had no bag limit or harvest was prohibited. If had a bag limit, could retain only the bag limit; -8" TL limit – lane snapper;

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
			-10" TL limit – vermilion snapper (recreational only); -12" TL limit – red porgy, vermilion snapper (commercial only), gray, yellowtail, mutton, schoolmaster, queen, blackfin, cubera, dog, mahogany, and silk snappers; -20" TL limit – red snapper, gag, and red, black, scamp, yellowfin, and yellowmouth groupers; -28" fork length (FL) limit – greater amberjack (recreational only); -36" FL or 28" core length – greater amberjack (commercial only); -Bag limits – 10 vermilion snapper, 3 greater amberjack -Aggregate snapper bag limit – 10/person/day, excluding vermilion snapper and allowing no more than 2 red snappers; -Aggregate grouper bag limit – 5/person/day, excluding Nassau and goliath grouper, for which no retention (recreational & commercial) is allowed; -Spawning season closure – commercial harvest greater amberjack > 3 fish bag prohibited in April; -Spawning season closure – commercial harvest mutton snapper >snapper aggregate prohibited during May and June; -Charter/headboats and excursion boat possession limits extended.
Amendment #5 (1992a)	04/06/92	PR: 56 FR 57302 FR: 57 FR 7886	For wreckfish: -Established limited entry system with individual transferable quotas (ITQs); -Required dealer to have permit; -Rescinded 10,000 lb. trip limit; -Required off-loading between 8 am and 5 pm; -Reduced occasions when 24-hour advance notice of offloading required for off-loading; -Established procedure for initial distribution of percentage shares of total allowable catch (TAC).
Emergency Rule	8/31/92	57 FR 39365	For Black Sea Bass (bsb): -Modified definition of bsb pot; -Allowed multi-gear trips for bsb; -Allowed retention of incidentally-caught fish on bsb trips.
Emergency Rule Extension	11/30/92	57 FR 56522	For Black Sea Bass: -Modified definition of bsb pot; -Allowed multi-gear trips for bsb; -Allowed retention of incidentally-caught fish on bsb trips.

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
Regulatory Amendment #4 (1992b)	07/06/93	FR: 58 FR 36155	-For Black Sea Bass: -Modified definition of bsb pot; -Allowed multi-gear trips for bsb; -Allowed retention of incidentally-caught fish on bsb trips.
Regulatory Amendment #5 (1992c)	07/31/93	PR: 58 FR 13732 FR: 58 FR 35895	-Established 8 SMZs off South Carolina, where only hand-held, hook-and-line gear and spearfishing (excluding powerheads) was allowed.
Amendment #6 (1993)	07/27/94	PR: 59 FR 9721 FR: 59 FR 27242	-Set up separate commercial TAC levels for golden tilefish and snowy grouper; -Established commercial trip limits for snowy grouper, golden tilefish, speckled hind, and warsaw grouper; -Included golden tilefish in grouper recreational aggregate bag limits; -Prohibited sale of warsaw grouper and speckled hind; -100% logbook coverage upon renewal of permit; -Creation of the *Oculina* Experimental Closed Area; -Data collection needs specified for evaluation of possible future individual fishing quota system.
Amendment #7 (1994a)	01/23/95	PR: 59 FR 47833 FR: 59 FR 66270	-12” FL – hogfish; -16” TL – mutton snapper; -Required dealer, charter and headboat federal permits; -Allowed sale under specified conditions; -Specified allowable gear and made allowance for experimental gear; -Allowed multi-gear trips in NC; -Added localized overfishing to list of problems and objectives; -Adjusted bag limit and crew specs. for charter and head boats; -Modified management unit for scup to apply south of Cape Hatteras, NC; -Modified framework procedure.
Regulatory Amendment #6 (1994b)	05/22/95	PR: 60 FR 8620 FR: 60 FR 19683	-Established actions which applied only to EEZ off Atlantic coast of FL: Bag limits – 5 hogfish/person/day (recreational only), 2 cubera snapper/person/day > 30” TL; 12” TL – gray triggerfish.
Notice of Control Date	04/23/97	62 FR 22995	-Anyone entering federal black sea bass pot fishery off South Atlantic states after 04/23/97 was not assured of future access if limited entry program developed.
Interim Rule Request	1/16/98		-The South Atlantic Fishery Management Council (Council) requested all Amendment 9 measures except black sea bass pot construction changes be implemented as an interim request under the

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
			Magnuson-Stevens Act.
Action Suspended	5/14/98		-NMFS informed the Council that action on the interim rule request was suspended.
Emergency Rule Request	9/24/98		-Council requested Amendment 9 be implemented via emergency rule.
Amendment #8 (1997)	12/14/98	PR: 63 FR 1813 FR: 63 FR 38298	-Established program to limit initial eligibility for snapper grouper fishery: -Must have demonstrated landings of any species in the snapper grouper FMU in 1993, 1994, 1995 or 1996; and have held valid snapper grouper permit between 02/11/96 and 02/11/97; -Granted transferable permit with unlimited landings if vessel landed ≥ 1,000 pounds (lb) of snapper grouper species in any of the years; -Granted non-transferable permit with 225 lb trip limit to all other vessels; -Modified problems, objectives, OY, and overfishing definitions; -Expanded the Council's habitat responsibility; -Allowed retention of snapper grouper species in excess of bag limit on permitted vessel with a single bait net or cast nets on board; -Allowed permitted vessels to possess filleted fish harvested in the Bahamas under certain conditions.
Request not Implemented	1/22/99		-NMFS informed the Council that the final rule for Amendment 9 would be effective 2/24/99; therefore they did not implement the emergency rule.
Regulatory Amendment #7 (1998a)	01/29/99	PR: 63 FR 43656 FR: 63 FR 71793	-Established 10 SMZs at artificial reefs off South Carolina.

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
Amendment #9 (1998b)	2/24/99	PR: 63 FR 63276 FR: 64 FR 3624	-Red porgy: 14" TL (recreational and commercial); 5 fish rec. bag limit; no harvest or possession > bag limit, and no purchase or sale, in March and April; -Black sea bass: 10" TL (recreational and commercial); 20 fish rec. bag limit; required escape vents and escape panels with degradable fasteners in bsb pots; -Greater amberjack: 1 fish rec. bag limit; no harvest or possession > bag limit, and no purchase or sale, during April; quota = 1,169,931 lb; began fishing year May 1; prohibited coring; -Specified size limits for several snapper grouper species (indicated in parentheses in inches TL): including yellowtail snapper (12), mutton snapper (16), red snapper (20); red grouper, yellowfin grouper, yellowmouth grouper, and scamp (20) ; -Vermilion snapper: 11" TL (recreational), 12" TL commercial; -Gag: 24" TL (recreational); no commercial harvest or possession > bag limit, and no purchase or sale, during March and April; -Black grouper: 24" TL (recreational and commercial); no harvest or possession > bag limit, and no purchase or sale, during March and April; -Gag and Black grouper: within 5 fish aggregate grouper bag limit, no more than 2 fish may be gag or black grouper (individually or in combination); -All snapper grouper without a bag limit: aggregate recreational bag limit 20 fish/person/day, excluding tomtate and blue runner; -Vessels with longline gear aboard may only possess snowy, warsaw, yellowedge, and misty grouper, and golden, blueline and sand tilefish.
Emergency Action	9/3/99	64 FR 48326	-Reopened the Amendment 8 permit application process.
Emergency Interim Rule	09/08/99, expired 08/28/00	64 FR 48324 and 65 FR 10040	-Prohibited harvest or possession of red porgy.
Amendment #10 Comprehensive Essential Fish Habitat Amendment (1998c)	07/14/00	PR: 64 FR 37082 and 64 FR 59152 FR: 65 FR 37292	-Identified essential fish habitat (EFH) and established habitat areas of particular concern (HAPC) for species in the snapper grouper FMU.

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
Amendment #11 Comprehensive Sustainable Fisheries Act Amendment (1998d)	12/02/99	PR: 64 FR 27952 FR: 64 FR 59126	-Maximum sustainable yield (MSY) proxy: goliath and Nassau grouper = 40% static spawning potential ratio (SPR); all other species = 30% static SPR; -OY: hermaphroditic groupers = 45% static SPR; goliath and Nassau grouper = 50% static SPR; all other species = 40% static SPR -Overfished/overfishing evaluations: BSB: overfished (minimum stock size threshold (MSST)=3.72 mp, 1995 biomass=1.33 mp); undergoing overfishing (maximum fishing mortality threshold (MFMT)=0.72, F1991-1995=0.95) Vermilion snapper: overfished (static SPR = 21-27%) Red porgy: overfished (static SPR = 14-19%). Red snapper: overfished (static SPR = 24-32%) Gag: overfished (static SPR = 27%) Scamp: no longer overfished (static SPR = 35%) Speckled hind: overfished (static SPR = 8-13%) Warsaw grouper: overfished (static SPR = 6-14%) Snowy grouper: overfished (static SPR = 5-15%) White grunt: no longer overfished (static SPR = 29-39%) Golden tilefish: overfished (couldn't estimate static SPR) Nassau grouper: overfished (couldn't estimate static SPR) Goliath grouper: overfished (couldn't estimate static SPR) -overfishing level: goliath and Nassau grouper = F>F40% static SPR; all other species: = F>F30% static SPR Approved definitions for overfished and overfishing. MSST = [(1-M) or 0.5 whichever is greater]*B_{MSY}. MFMT = $F_{MSY.}$
Amendment #12 (2000a)	09/22/00	PR: 65 FR 35877 FR: 65 FR 51248	For Red porgy: -MSY=4.38 mp; OY=45% static SPR; MFMT=0.43; MSST=7.34 mp; rebuilding timeframe=18 years (1999=year 1); -no sale of red porgy during Jan-April; -1 fish bag limit; -50 lb. bycatch commercial trip limit May-December; -Modified management options and list of possible framework actions.
Regulatory Amendment #8 (2000b)	11/15/00	PR: 65 FR 41041 FR: 65 FR 61114	-Established 12 SMZs at artificial reefs off Georgia; revised boundaries of 7 existing SMZs off Georgia to meet CG permit specs; restricted fishing in new and revised SMZs.

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
Amendment #9 (1998b) resubmitted	10/13/00	PR: 63 FR 63276 FR: 65 FR 55203	-Commercial trip limit for greater amberjack.
Amendment #13A (2003)	04/26/04	PR: 68 FR 66069 FR: 69 FR 15731	-Extended for an indefinite period the regulation prohibiting fishing for and possessing snapper grouper species within the *Oculina* Experimental Closed Area.
Notice of Control Date	10/14/05	70 FR 60058	-Considered management measures to further limit participation or effort in the commercial fishery for snapper grouper species (excluding wreckfish).
Amendment #13C (2006)	10/23/06	PR: 71 FR 28841 FR: 71 FR 55096	-End overfishing of snowy grouper, vermilion snapper, black sea bass, and golden tilefish. Increase allowable catch of red porgy. Year 1 = 2006; 1. <u>Snowy Grouper</u> Commercial: -Quota = 151,000 lb gutted weight (gw) in year 1, 118,000 lb gw in year 2, and 84,000 lb gw in year 3 onwards. -Trip limit = 275 lb gw in year 1, 175 lb gw in year 2, and 100 lb gw in year 3 onwards; Recreational: -Limit possession to one snowy grouper in 5 grouper per person/day aggregate bag limit; 2. <u>Golden Tilefish</u> Commercial: Quota of 295,000 lb gw, 4,000 lb gw trip limit until 75% of the quota is taken when the trip limit is reduced to 300 lb gw. Do not adjust the trip limit downwards unless 75% is captured on or before September 1; Recreational: Limited possession to 1 golden tilefish in 5 grouper per person/day aggregate bag limit; 3. <u>Vermilion Snapper</u> Commercial: Quota of 1,100,000 lb gw; Recreational: 12" TL size limit. 4. <u>Black Sea Bass</u> Commercial: Quota of 477,000 lb gw in year 1, 423,000 lb gw in year 2, and 309,000 lb gw in year 3 onwards; -Required use of at least 2" mesh for the entire back panel of black sea bass pots effective 6 months after publication of the final rule; -Required black sea bass pots be removed from the water when the quota is met; -Changed fishing year from calendar year to June 1 – May 31; Recreational: Recreational allocation of 633,000 lb

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
			gw in year 1, 560,000 lb gw in year 2, and 409,000 lb gw in year 3 onwards. Increase minimum size limit from 10" to 11" in year 1 and to 12" in year 2; -Reduced recreational bag limit from 20 to 15 per person per day; -Changed fishing year from the calendar year to June 1 through May 31. 5. Red Porgy Commercial and recreational: -Retained 14" TL size limit and seasonal closure (retention limited to the bag limit); -Specified a commercial quota of 127,000 lb gw and prohibit sale/purchase and prohibit harvest and/or possession beyond the bag limit when quota is taken and/or during January through April; -Increased commercial trip limit from 50 lb ww to 120 red porgy (210 lb gw) during May through December;--Increased recreational bag limit from one to three red porgy per person per day.
Notice of Control Date	3/8/07	72 FR 60794	-Considered measures to limit participation in the snapper grouper for-hire sector.
Amendment #14 (2007)	2/12/09	PR: 73 FR 32281 FR: 74 FR 1621	-Established eight deepwater Type II marine protected areas (MPAs) to protect a portion of the population and habitat of long-lived deepwater snapper grouper species.
Amendment #15A (2008a)	3/14/08	73 FR 14942	- Established rebuilding plans and status determination criteria for snowy grouper, black sea bass, and red porgy.
Notice of Control Date	12/4/08	74 FR 7849	-Established a control date for the golden tilefish portion of the snapper grouper fishery in the South Atlantic.
Notice of Control Date	12/4/08	74 FR 7849	-Established control date for black sea bass pot sector in the South Atlantic.
Amendment #15B (2008b)	2/15/10	PR: 74 FR 30569 FR: 74 FR 58902	-Prohibited the sale of snapper grouper harvested or possessed in the EEZ under the bag limits and prohibited the sale of snapper grouper harvested or possessed under the bag limits by vessels with a Federal charter vessel/headboat permit for South Atlantic snapper grouper were harvested; -Reduced the effects of incidental hooking on sea turtles and smalltooth sawfish; -Adjusted commercial permit renewal periods and transferability requirements; -Revised the management reference points for golden tilefish; -Implemented plan to monitor and assess bycatch; -Required a vessel that fished in the EEZ, if selected by NMFS, to carry an observer and install electronic logbook and/or video monitoring equipment provided by NMFS;

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
			-Established reference points for golden tilefish; -Established allocations for snowy grouper (95% commercial & 5% recreational); -Established allocations for red porgy (50% commercial & 50% recreational).
Amendment #16 (2009a)	7/29/09	PR: 74 FR 6297 FR: 74 FR 30964	-Specified status determination criteria for gag and vermilion snapper; For gag: -Specified interim allocations 51% commercial & 49% recreational; -Recreational and commercial shallow water grouper spawning closure January through April; -Directed commercial quota= 352,940 lb gw; -Reduced 5-fish aggregate grouper bag limit, including tilefish species, to a 3-fish aggregate; -Captain and crew on for-hire trips cannot retain the bag limit of vermilion snapper and species within the 3-fish grouper aggregate; For vermilion snapper: -Specified interim allocations 68% commercial & 32% recreational; -Directed commercial quota split Jan-June=315,523 lb gw and 302,523 lb gw July-Dec; -Reduced bag limit from 10 to 4 and a recreational closed season November through March; -Required venting and dehooking tools when catching snapper grouper species to reduce recreational and commercial bycatch mortality.
Amendment #19 Comprehensive Ecosystem-Based Amendment 1 (CE-BA1) (2009b)	7/22/10	PR: 75 FR 14548 FR: 75 FR 35330	-Amended coral, coral reefs, and live/hardbottom habitat FMP to establish deepwater coral HAPCs; -Created a "shrimp fishery access area" (SFAA) within the Stetson-Miami Terrace CHAPC boundaries; -Created allowable "golden crab fishing areas" with the Stetson-Miami Terrace CHAPC and Pourtales Terrace CHAPC boundaries; -Amended the golden crab FMP to require vessel monitoring.
Amendment #17A (2010a)	12/3/10 red snapper closure; circle	PR: 75 FR 49447 FR: 75 FR 76874	-Required use of non-stainless steel circle hooks when fishing for snapper grouper species with hook-and-line gear north of 28 deg. N latitude in the South

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
	hooks 3/3/2011		Atlantic EEZ; -Specified an annual catch limit (ACL) and an accountability measure (AM) for red snapper with management measures to reduce the probability that catches will exceed the stocks' ACL; -Specified a rebuilding plan for red snapper; -Specified status determination criteria for red snapper; -Specified a fishery-independent monitoring program for red snapper. -Implemented an area closure for snapper grouper species.
Emergency Rule	12/3/10	75 FR 76890	-Delayed the effective date of the area closure for snapper grouper species implemented through Amendment 17A.
Amendment #17B (2010b)	1/30/11	PR: 75 FR 62488 FR: 75 FR 82280	-Specify ACL of 0 and prohibit fishing for speckled hind and warsaw grouper; -Prohibited harvest of 6 deepwater species seaward of 240 feet to curb bycatch of speckled hind and warsaw grouper (snowy grouper, blueline tilefish, yellowedge grouper, misty grouper, queen snapper, silk snapper). -Specify allocations, ACLs and AMs for golden tilefish; -Modified management measures as needed to limit harvest to the ACL or ACT; -Updated the framework procedure for specification of total allowable catch; -Specified ACLs, ACTs, and AMs, where necessary, for 9 species undergoing overfishing (snowy grouper, black grouper, black sea bass, red grouper, vermilion snapper, gag, speckled hind, warsaw grouper, golden tilefish);
Regulatory Amendment #9 (2010a)	Bag limit: 6/22/11 Trip limits: 7/15/11	PR: 76 FR 23930 FR: 76 FR 34892	-Established trip limits for vermilion snapper and gag; -Increased trip limit for greater amberjack; -Harvest management measures for black sea bass (trip limit, split season quotas, carry-over of unused ACL, gear restrictions, bag limit modification, and a spawning season closure).
Regulatory Amendment #10 (2010b)	5/31/11	PR: 76 FR 9530 FR: 76 FR 23728	-Eliminated closed area for snapper grouper species approved in Amendment 17A.
Regulatory Amendment #11 (2011c)	5/10/12	PR: 76 FR 78879 FR: 77 FR 27374	-Eliminated 240 ft harvest prohibition for six deepwater species (snowy grouper, blueline tilefish, yellowedge grouper, queen snapper, silk snapper, misty grouper);

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
Amendment # 25 Comprehensive Annual Catch Limit Amendment (2011d)	4/16/12	PR: 76 FR 74757 Amended PR: 76 FR 82264 FR: 77 FR 15916	-Reorganize FMUs to 6 complexes (deepwater, jacks, snappers, grunts, shallow-water groupers, porgies) (see final rule for species list); -Established acceptable biological catch (ABC) control rules and established ABCs, ACLs, and AMs for species not undergoing overfishing; -Removed some species from South Atlantic FMU (Tiger grouper, black margate, blue-striped grunt, French grunt, porkfish, smallmouth grunt, queen triggerfish, crevalle, yellow jack, grass porgy, sheepshead, puddingwife); -Designated species as ecosystem component species (schoolmaster, ocean triggerfish, bank triggerfish, rock triggerfish, longspine porgy); -Specified allocations between the commercial and, recreational sectors for species not undergoing overfishing; -Limited the total mortality for federally managed species in the South Atlantic to the ACLs.
Amendment #24 (2011e)	7/11/12	PR: 77 FR 19169 FR: 77 FR 34254	-Rebuilding plan (including MSY, ACLs, AMs, and OY, and allocations) for red grouper.
Amendment #23 Comprehensive Ecosystem-based Amendment 2 (CE-BA2) (2011f)	1/30/12	PR: 76 FR 69230 FR: 76 FR 82183	-Designated the Deepwater MPAs as EFH-HAPCs; -Modify management measures for Octocoral; -Limit harvest of snapper grouper species in SC SMZs to the bag limit; -Modify sea turtle release gear; -Designated new EFP for pelagic Sargassum habitat.
Amendment #18A (2012a)	7/1/12	PR: 77 FR 16991 FR: 77FR3 2408	-Limited participation and effort in the black sea bass sector; -Modifications to management of the black sea bass pot sector; -Improved data reporting (accuracy, timing, and quantity of fisheries statistics).
Amendment #20A (2012b)	10/26/12	PR: 77 FR 19165 FR: 77 FR 59129	- Individual transfer quota (ITQ) program for wreckfish: -Defined and reverted inactive shares; -Redistributed reverted shares; -Established a share cap; -Established an appeals process.
Regulatory Amendment #12 (2012c)	10/9/12	PR: 77 FR 42688 FR: 77 FR 61295	-Revised the ACL and OY for golden tilefish; -Revised recreational AMs for golden tilefish;

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
Amendment #18B (2013a)	5/23/13	PR: 77 FR 75093 FR: 77 FR 23858	For Golden Tilefish: -Limited participation and effort in the commercial sector through establishment of a longline endorsement; -Established eligibility requirements and allowed transferability of longline endorsement; -Established an appeals process; -Modified trip limits; -Specified allocations ACLs for gear groups (longline and hook and line); -Adjusted the fishing year.
Amendment #28 (2013b)	8/23/13	PR: 78 FR 25047 FR: 78 FR 44461	-Established regulations to allow harvest of red snapper in the South Atlantic (formula used to compute ACLs, AMs, fishing seasons).
Regulatory Amendment #13 (2013c)	7/17/13	PR: 78 FR 17336 FR: 78 FR 36113	-Revised the ABCs, ACLs (including sector ACLs), and ACTs for 37 species implemented by the Comprehensive ACL Amendment (see final rule for list of species). The revisions may prevent a disjunction between the established ACLs and the landings used to determine if AMs are triggered.
Regulatory Amendment #15 (2013d)	9/12/13	PR: 78 FR 31511 FR: 78 FR 49183	-Modified ACLs and OY for yellowtail snapper; -Modified the commercial and recreational yellowtail snapper fishing years and commercial spawning season closure; -Modified the gag commercial ACL and AM to remove the requirement that all other shallow water groupers (black grouper, red grouper, scamp, red hind, rock hind, graysby, coney, yellowmouth grouper, and yellowfin grouper) are prohibited from harvest in the South Atlantic when the gag commercial ACL is met or projected to be met.
Regulatory Amendment #18 (2013e)	9/5/13	PR: 78 FR 26740 FR: 78 FR 47574	-Revised ACLs and OY for vermilion snapper; -Modified commercial trip limit for vermilion snapper; -Modified commercial fishing season and recreational closed season for vermilion snapper; -Revised ACLs and OY for red porgy.
Regulatory Amendment #19 (2013f)	ACL: 9/23/13 Pot closure: 10/23/13	PR: 78 FR 39700 FR: 78 FR 58249	-Specified ABC, and adjusted the ACL, recreational ACT and OY for black sea bass; -Implemented an annual closure on the use of black sea bass pots from November 1 to April 30.
Amendment #27 (2013g)	1/27/2014	PR:78 FR 78770 FR: 78 FR 57337	-Established the Council as the responsible entity for managing Nassau grouper throughout its range including federal waters of the Gulf of Mexico; -Modified the crew member limit on dual-permitted snapper grouper vessels; -Modified the restriction on retention of bag limit

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
			quantities of some snapper grouper species by captain and crew of for-hire vessels; -Minimized regulatory delay when adjustments to snapper grouper species' ABC, ACLs, and ACTs are needed as a result of new stock assessments; -Removed blue runner from snapper grouper FMP; -Addressed harvest of blue runner by commercial fishermen who do not possess a South Atlantic Snapper Grouper Permit.
Amendment #31 Joint South Atlantic and Gulf of Mexico Generic Headboat Reporting Amendment (2013h)	1/27/2014	PR: 78 FR 59641 FR: 78 FR 78779	-Included under the Generic charter/headboat reporting amendment, that modified required logbook reporting for headboat vessels to require electronic reporting, regarding snapper grouper landings.
Amendment #?? (Revisions to Dealer Permitting and Reporting Requirements) (2013i)	8/7/2014	PR: 79 FR 81 FR: 79 FR 19490	- Modified permitting and reporting requirements for seafood dealers who first receive fish managed by the SA and Gulf through eight FMPs.
Regulatory Amendment #14 (2014a)	12/8/2014	PR: 79 FR 22936 FR: 79 FR 66316	-Modified the commercial and recreational fishing year for greater amberjack; -Modified the commercial and recreational sector fishing years for black sea bass; -Modified the recreational AM for black sea bass; -Modified the recreational AM for vermilion snapper; -Modify the commercial trip limit for gag.
Regulatory Amendment # 21 (2014b)	11/6/2014	PR: 79 FR 44735 FR: 79 FR 60379	-Modified the definition of the overfished threshold (MSST) for red snapper, blueline tilefish, gag, black grouper, yellowtail snapper, vermilion snapper, red porgy, and greater amberjack.
Amendment #29 (2014c)	7/1/2015	NOA: 79 FR 69819 PR: 79 FR 72567 FR: 80 FR 30947	-Updated the ABC control rule to incorporate methodology for determining the ABC of unassessed species; -Adjusted the ABCs for fourteen unassessed snapper grouper species (see final rule); -Adjusted the ACLs and ACTs for three species complexes and four snapper grouper species based on revised ABCs; -Established ACLs for unassessed species; -Modified gray triggerfish minimum size limits; -Established a commercial split season and commercial trip limits for gray triggerfish.

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
Blueline Tilefish Emergency Rule	4/17/2014 through 10/10/2014 or 4/18/2015	PR: 79 FR 21636 FR:79 FR 61262	-Removed the blueline tilefish portion from the deep-water complex ACL; -Established separate commercial and recreational ACLs and AMs for blueline tilefish.
Regulatory Amendment #20 (2014d)	8/20/2015	PR: 80 FR 18797 FR: 80 FR 43033	-Adjusted the recreational and commercial ACLs for snowy grouper; -Adjusted the rebuilding strategy; -Modified the commercial trip limit; -Modified recreational bag limit; -Modified the recreational fishing season.
Amendment #32 (2014e)	3/30/2015	PR: 80 FR 3207 FR: 80 FR 16583	-End overfishing of blueline tilefish; -Removed blueline tilefish from the deepwater complex; -Specified AMs, ACLs, recreational ACLs, commercial trip limit, adjust recreational bag limit for blueline tilefish; -Specified ACLs and revised the AMs for the recreational section of the deepwater complex (yellowedge grouper, silk snapper, misty grouper, queen snapper, sand tilefish, black snapper, and blackfin snapper);
Regulatory Amendment #22 (2015a)	9/11/2015, except for the amendments to §§ 622.190(b) and 622.193(r)(1) which were effective 8/12/2015	PR: 80 FR 31880 FR: 80 FR 48277	-Adjusted ACLs and OY for gag and wreckfish;
Amendment # 33 Dolphin Wahoo Amendment 7 and Snapper Grouper Amendment 33 (2015b)	12/28/2015	NOA:80 FR 55819 PR:80 FR 60601 FR:80 FR 80686	-Allowed dolphin and wahoo fillets to enter the U.S. EEZ after lawful harvest in The Bahamas; -Specified the condition of any dolphin, wahoo, and snapper grouper fillets; -Described how the recreational bag limit is determined for any fillets; -Prohibited the sale or purchase of any dolphin, wahoo, or snapper grouper recreationally harvested in The Bahamas; -Specified the required documentation to be onboard any vessels that have these fillets; -Specified transit and stowage provisions for any vessels with fillets.
Amendment #34 Generic Accountability Measures and Dolphin	2/22/2016	NOA:80 FR 41472 PR:80 FR 58448 FR:81 FR 3731	-Modified AMs for snapper grouper species (golden tilefish, snowy grouper, gag, red grouper, black grouper, scamp, the shallow-water grouper complex (SASWG: red hind, rock hind, yellowmouth grouper, yellowfin grouper, coney, and graysby), greater amberjack, the jacks complex (lesser amberjack, almaco jack, and banded rudderfish), bar jack,

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
Allocation Amendment (2015c)			yellowtail snapper, mutton snapper, the snappers complex (cubera snapper, gray snapper, lane snapper, dog snapper, and mahogany snapper), gray triggerfish, wreckfish (recreational sector), Atlantic spadefish, hogfish, red porgy, the porgies complex (jolthead porgy, knobbed porgy, whitebone porgy, scup, and saucereye porgy); -Modified the AM for commercial golden crab fishery; -Adjusted sector allocations for dolphin.
Amendment #35 (2015d)	6/22/2016	NOA:81 FR 6222 PR:81 FR 11502 FR:81 FR 32249	-Removed black snapper, dog snapper, mahogany snapper, and schoolmaster from the Snapper Grouper FMP; -Clarified regulations governing the use of Golden Tilefish Longline Endorsements.
Regulatory Amendment #16 (2016a)	12/29/2016 (closure) 1/30/2017 (gear markings)	NOI: 78 FR 72868 PR: 81 FR 53109 FR: 81 FR 95893	-Revise the area where fishing with black sea bass pots is prohibited from Nov.1-April 30. -Add additional gear marking requirements for black sea bass pot gear.
Regulatory Amendment #25 (2016b)	8/12/2016 except changes to blueline tilefish, effective 7/13/2016.	PR: 81 FR 34944 FR: 81 FR 45245	-Revised commercial and recreational ACL for blueline tilefish; -Revised the recreational bag limit for black sea bass; -Revised the commercial and recreational fishing year for yellowtail snapper.
Amendment #37 (2016c)	TBD	NOI: 80 FR 45641 NOA: 81 FR 69774 PR: 81 FR 91104	-Modify the hogfish fishery management unit; -Specify fishing levels for the two South Atlantic hogfish stocks; -Establish a rebuilding plan for the Florida Keys/East Florida stock; -Establish/revised management measures for both hogfish stocks in the South Atlantic Region, such as size limits, recreational bag limits, and commercial trip limits.
Amendment #26 (Bycatch Reporting Amendment)	TBD	TBD	-Modifies bycatch and discard reporting for commercial and for-hire vessels.
Amendment #36 (2016d)	TBD	NOI: 82 FR 810 PR: 82 FR 5512	-Establish SMZs to enhance protection for snapper grouper species in spawning condition including speckled hind and warsaw grouper.
Amendment #39 (Generic For-Hire Reporting Amendment) (2017b)	TBD		-Weekly electronic reporting for charter vessel operators with a federal for-hire permit; reduce the time allowed for headboat operators to complete electronic reports; and requires location reporting by charter vessels with the same detail currently

Document	All Actions Effective By:	Proposed Rule Final Rule	Major Actions. Note that not all details are provided here. Please refer to Proposed and Final Rules for all impacts of listed documents.
			required for headboat vessels.
Amendment #41 (2017a)	TBD	TBD	-Update the MSY, ABC, ACL, OY, minimum stock size threshold, designate spawning months for regulatory purposes, and revise management measures for mutton snapper.

Appendix D. Bycatch Practicability Analysis

1.1 Population Effects for the Bycatch Species

Background
In 2008, a stock assessment for red snapper indicated the red snapper stock was overfished and undergoing overfishing (Southeast Data, Assessment, and Review (SEDAR 15; 2008a). Consequently, an interim rule was published on December 4, 2009 (NOAA's National Marine Fisheries Service (NMFS) 2010), which prohibited harvest and possession of red snapper beginning on January 4, 2010. That rule was extended for 186 days. A new benchmark assessment completed in 2010, further confirmed that red snapper is experiencing overfishing and is overfished (SEDAR 24 2010b). Amendment 17A to the Fishery Management Plan for the Snapper Grouper Fishery of the South Atlantic Region (Snapper Grouper FMP) (Amendment 17A; SAFMC 2010a), effective December 3, 2010, continued the harvest and possession prohibition of red snapper to end overfishing and also implemented a rebuilding plan. Appendix R of Amendment 17A contains the BPA conducted for that amendment, and is incorporated herein by reference. At their June 2012 meeting, the South Atlantic Fishery Management Council (South Atlantic Council) reviewed red snapper discard mortality estimates and compared them to the 2012 acceptable biological catch (ABC) from the rebuilding projection, which were recommended by the South Atlantic Council's Scientific and Statistical Committee based on the results of SEDAR 24 (2010b). The estimated mortalities for 2012 were less than the ABC for 2012 suggesting some minimal level of harvest of red snapper could occur without negatively affecting the stock (Appendix B of Measures to Allow Limited Harvest of Red Snapper (*Lutjanus campechanus*) in the South Atlantic in 2012 (Temporary Measures through Emergency Action) (NMFS 2012)). As a result, the South Atlantic Council recommended reopening red snapper to a small amount of harvest in 2012.

With the exception of limited openings in 2012, 2013, and 2014, harvest of red snapper in federal waters has been prohibited since January 4, 2010. There have been very limited landings of red snapper in Florida state waters since Florida has not adopted compatible regulations (as of July 2017). Since 2010, dead discards have accounted for most of the total removals (92%) and resulted from incidental catch of red snapper while fishermen targeted co-occurring species. Amendment 17A indicated the top co-occurring species with red snapper are black sea bass, red grouper, gag, scamp, greater amberjack, vermilion snapper, and gray triggerfish. The Southeast Fisheries Science Center (SEFSC) provided a report on the level of landings and dead discards of red snapper in 2010 and 2011, which is contained in Appendix B of Measures to Allow Limited Harvest of Red Snapper (*Lutjanus campechanus*) in the South Atlantic in 2012 (Temporary Measures through Emergency Action) (NMFS 2012).

In 2012 Amendment 28 put forth a process to determine if a red snapper fishing season would occur each year and would specify annual catch limits for landings. Based on the annual catch limits, season lengths for the commercial and recreational sectors would be projected. Following the management measures of Amendment 28, an annual catch limit was set greater than zero and red snapper landings were allowed in 2012, 2013, and 2014. Landings were not allowed in 2015 and 2016.

SEDAR 41, a 2016 benchmark stock assessment for red snapper, indicated the red snapper stock was overfished and undergoing overfishing was still occurring (SEDAR 2017). During the review of the assessment, the Scientific and Statistical Committee of the South Atlantic Fishery Management Council (SSC) outlined several sources of uncertainty including: the stock-recruitment relationship, natural mortality at age, the age structure of the unfished population, the composition and magnitude of recreational discards, potential changes in CPUE catchability, and the selectivities for the different fishery fleets. Due to these uncertainties the SSC stated the stock was experiencing but the level of overfishing could not be determined and the population was rebuilding (SAFMC 2016).

The directed commercial snapper grouper fishery for most of the top co-occurring species with red snapper (red grouper, gag, scamp, greater amberjack, and gray triggerfish) is executed primarily with hook and line gear (Table 1). Black sea bass, another species that co-occurs with red snapper, are predominantly taken with pots. Red snapper were taken primarily (84%) with hook and line gear during the limited commercial openings in 2012, 2013, and 2014. This percentage is similar to the Amendment 17A BPA, which described red snapper primary gear as hook and line prior to the closure.

Table 1. Mean percentage of commercial landings by gear (2012-2014).

Species	Diving	Hook and Line	Longline	Pot	Other
Black sea bass	0.56%	41.12%	0.00%	54.62%	3.69%
Red grouper	6.04%	85.98%	7.28%	0.34%	0.36%
Gag	12.61%	85.85%	0.39%	0.27%	0.88%
Scamp	9.40%	89.07%	0.44%	0.16%	0.94%
Greater amberjack	5.02%	93.97%	0.05%	0.38%	0.57%
Vermilion snapper	0.53%	98.22%	0.31%	0.15%	0.78%
Gray triggerfish	2.51%	95.24%	0.32%	1.27%	0.66%

Between 2012 and 2014, the recreational sector dominated the landings of red grouper (>60% of landings) while black sea bass, greater amberjack, and gray triggerfish landings were evenly divided between the commercial and recreational sectors (Table 2). The commercial sector dominated landings of gag, vermilion snapper that commonly occur with red snapper. Appendix R from Amendment 17A indicates the recreational sector took approximately 83% of the red snapper landings during 2005-2008.

Table 2. Mean commercial and recreational landings (pounds whole weight) during 2012-2014. Commercial landings include all of Monroe County, Florida; MRFSS landings do not include Monroe County, Florida; Headboat landings include Monroe County, Florida for Atlantic-based vessels.

Species	Headboat	MRIP	Total Recreational	Commercial	Percent	Percent
					Recreational	Commercial
Black sea bass	385,656	117,050	502,706	446,078	53%	47%
Red grouper	231,018	12,937	243,954	137,478	64%	36%
Gag	176,023	15,646	191,669	415,611	32%	68%
Scamp	36,528	14,639	51,167	167,390	23%	77%
Greater amberjack	802,835	66,939	869,774	908,878	49%	51%
Vermilion snapper	135,838	150,565	286,403	965,649	23%	77%
Gray triggerfish	268,536	116,971	385,507	303,214	56%	44%

Source: SEFSC commercial annual catch limit (ACL) data (May 2017); Recreational ACL data (June 2017).

Commercial Sector

Based on the commercial logbook, the average number of trips per year between 2012 and 2014 was 13,130; and fishermen spent an average of 1.64 days at sea per trip (Table 3). Only trips that landed species under the SAFMC's snapper grouper fisheries management plan were used to calculate effort.

Table 3. Snapper grouper commercial fishery effort for South Atlantic.

Year	Trips	Days	Days per Trip
2012	12,737	20,899	1.64
2013	12,088	20,674	1.71
2014	14,564	23,019	1.58
Mean	13,130	21,531	1.64

Source: NMFS SEFSC coastal logbook program that records landings.

Among red snapper and co-occurring species during 2012-2014, the average percentage of trips that reported discards was greatest for red snapper and black sea bass (26.46% and 25.22%, respectively), followed by vermilion snapper (21.48%), gray triggerfish (14.13%), and gag (12.04%) (Table 4). Species with the greatest number of individuals discarded during 2012-2014 were black sea bass (41,821), vermilion snapper (21,944), and red snapper (18,734) (Table 4).

Since the discard logbook database represents a sample, data were expanded to estimate the number of discarded fish caught on vertical line and long line (Table 4). The formula used for expansion was: "discard per unit effort from discard logbook database * total effort from commercial logbook." Release mortality estimates for the commercial sector compiled from the most recent stock assessments (as available) using the SEDAR process are: 38% red snapper (SEDAR 41; 2017); 40% gag (SEDAR 10; 2006b); 7% for hook and line and 1% for pot caught black sea bass (SEDAR 25; 2011); 41% vermilion snapper (SEDAR 17 Update; 2012); 20% red grouper and 20% black grouper (SEDAR 19; 2010a); 20% greater amberjack (SEDAR 15; 2008); and 12.5% gray triggerfish (SEDAR 41; 2017) (Table 4). Dead discards were estimated by applying the release mortality rates to the total discards. Discard mortality was highest for vermilion snapper (8,997), followed by red snapper (7,119) (Table 4). See the "Finfish Bycatch Mortality" and "Practicability of Management Measures in Directed Fisheries Relative to their Impact on Bycatch and Bycatch Mortality" sections of this BPA for more details.

Table 4. Percentage of commercial trips that discarded species and expanded commercial discards of red snapper and co-occurring species from 2012-2014.

Species	Percentage of trips that discarded species	Total discards	Release mortality	Dead Discards
Black sea bass	25.22%	41,821	7%	2,927
Red grouper	5.56%	2,105	20%	421
Gag	12.04%	9,697	40%	3,879
Scamp	10.55%	1,268	Unknown	Unknown
Greater Amberjack	6.64%	2,029	20%	406
Red snapper	26.46%	18,734	38%	7,119
Vermilion snapper	21.48%	21,944	41%	8,997
Gray triggerfish	14.13%	12,918	12.50%	1,615

Note: Computed using mean discard rates (2012-2014) of vertical line and longline from commercial discard logbook applied to overall commercial effort reported to commercial logbook. Discard logbook and commercial logbook data provided by SEFSC April 2017.

Table 5. Percentage of commercial trips that discarded species and expanded commercial discards of red snapper and co-occurring species from 2015-2016.

Species	Percentage of trips that discarded species	Total discards	Release mortality	Dead Discards
Black sea bass	14.97%	48,380	7%	3,387
Red grouper	1.70%	818	20%	164
Gag	8.54%	5,918	40%	2,367
Scamp	8.10%	1,132	Unknown	Unknown
Greater Amberjack	8.13%	4,300	20%	860
Red snapper	33.82%	24,131	38%	9,170
Vermilion snapper	20.85%	24,527	41%	10,056
Gray triggerfish	12.97%	15,236	12.50%	1,905

Note: Computed using mean discard rates (2015-2016) of vertical line and longline from commercial discard logbook applied to overall commercial effort reported to commercial logbook. Discard logbook and commercial logbook data provided by SEFSC April 2017.

Recreational Sector

For the recreational sector, estimates of the number of recreational discards are available from Marine Recreational Information Program (MRIP) and the NMFS headboat survey. The MRIP system classifies recreational catch into three categories:
Type A - Fishes that were caught, landed whole, and available for identification and enumeration by the interviewers.
Type B - Fishes that were caught but were either not kept or not available for identification:
Type B1 - Fishes that were caught and filleted, released dead, given away, kept but not observed by interviewer, or disposed of in some way other than Types A or B2.
Type B2 - Fishes that were caught and released alive.

Recreational harvest of red snapper co-occurring species was greatest for black sea bass followed by vermilion snapper, gray triggerfish, and gag (Table 6). There were differences in the amount and variety of species harvested by the private recreational sector and the "for-hire" sectors (charter boats/headboats). During 2010 and 2011, 90% of black sea bass, 89% of red grouper, and 84% of gag were discarded in the private recreational sector (Table 6). During the same period, 87% of red grouper and 67% of black sea bass were released by fishermen on charter boats, versus 88% of red grouper, and 68% of black sea bass by fishermen on headboats (Table 6).

Release mortality estimates for the recreational sector compiled from the most recent stock assessments using data from SEDAR stock assessments (as available) are: 25% gag (SEDAR 10; 2006b); 7% black sea bass (SEDAR 25; 2011); 38% vermilion snapper (SEDAR 17; 2008b); 20% red grouper (SEDAR 19; 2010a); 20% greater amberjack (SEDAR 15; 2008a); and 12.5% gray triggerfish (SEDAR 41; 2017) (Table 6). Dead discards were estimated by applying the release mortality rates to the total discards. In 2010 and 2011, discard mortality was highest for black sea bass (207,156), vermilion snapper (19,425), and gag (19,136) for the private recreational sector (Table 6). For the "for-hire" sector (charter boats/headboats), discard mortality was highest for black sea bass (13,051/35,426), followed by vermilion snapper (6,464/35,228) and red grouper (1,381/2,099) (Table 6). Discard mortality was zero for gray triggerfish in 2010 and 2011, for both the private recreational and "for-hire" sectors (Table 6).

The SEFSC's May 2012 report (Appendix B of NMFS 2012) shows red snapper discard mortalities in the private recreational sector decreasing from 31,561 fish in 2010, to 16,156 fish in 2011. Conversely, the same report reveals red snapper discard mortalities in the "for-hire" sector (charter boats/headboats) increasing from 20,569 fish in 2010, to 22,131 fish in 2011. These estimates used the release mortality rates used in SEDAR 24 (2010b). If the new estimate for discard mortality for the private sector was used (28.5%), the mortalities would have been lower. The number of mortalities in the recreational sector has increased dramatically in 2014 from an average of 36,531 from 2012 and 2013 to 107,822 in 2014.

Table 6. Mean number (expanded) of fish based on harvest (A + B1) and discards (B2) from MRIP for private and charter boat trips and SHBS for headboat trips for the South Atlantic from 2012-2014.

Finfish Bycatch Mortality

SEDAR 41 used estimates release mortality rates of red snapper for the commercial sector (38%) and the recreational sector (28.5%). This stock assessment used a revised release mortality estimates from SEDAR 24 (2010b) which were 48% for the commercial sector, 41% for recreational for-hire sector (charter boats and headboats), and 39% for the private recreational sector, in the South Atlantic. SEDAR 15 (2008a) used the release mortality estimate of 90% for the commercial sector as reported in SEDAR 15 (2008a). There was no significant difference between the two stock assessments regarding the release mortality of red snapper in the recreational sector, which was 40%, as per the findings in SEDAR 15 (2008a). The most recent release mortality estimate was based on Sauls et al. (2015), which was a working paper submitted to SEDAR 41 (2017). In this paper, the researchers calculated the release mortality rate through a mark recapture study and relative risk of injury due to several factors. The estimate was revised due to suggestions at the workshop and recommended for use for the recreational sector in the assessment. The commercial sector used information from Burns et al. (2002), but the discard mortality was decreased due to use of circle hooks. Diamond and Campbell (2009) reported a delayed mortality rate of 64% off Texas. A study by Burns et al. (2004) conducted on headboats off Florida in the Atlantic and Gulf of Mexico found a release mortality of 64% for red snapper. The majority of acute mortalities in this study (capture depth of 9-42 m) were attributed to hooking (49%), whereas barotrauma accounted for 13.5%. An earlier study by Burns et al. (2002), also conducted in the Atlantic and Gulf of Mexico, had similar results, as J-hook mortality accounted for 56% of the acute mortalities of red snapper on headboats. Using tagging data and cage studies, Burns et al. (2002) determined the depth at which 50% of the released red snapper would die is 43.7 m (143 feet). SEDAR 15 (2008a) indicated red snapper were most often caught at depths of 141-190 feet by the recreational sector and 141-234 feet by the commercial sector. Rummer and Bennett (2005) reported over 70 different overexpansion injuries related to barotrauma in red snapper, and Wilde (2009) observed reduced survival of this species when vented.

SEDAR 17 (2008b) recommended a release mortality rate for vermilion snapper of 41% for the commercial sector and 38% for the recreational sector. The commercial sector has slightly higher discard mortality rate because that sector typically fishes in deeper water than the recreational sector. Ruderhshausen et al. (2007) estimated release mortality rate to be15% for undersized vermilion snapper. Immediate mortality of vermilion snapper was estimated to be 10% at depths of 25-50 m and delayed mortality was estimated to be 45% at the same depths. Rudershausen et al. (2007) indicated minimum size limits are moderately effective in shallower water for vermilion snapper. Previously, SEDAR 2 (2003) estimated a release mortality rate of 40% and 25% for vermilion snapper taken by commercial and recreational fishermen, respectively. Release mortality rates for vermilion snapper from SEDAR 2 (2003) were based on cage studies conducted by Collins (1996) and Collins et al. (1999). Burns et al. (2002) suggested that release mortality rates of vermilion snapper could be higher than those estimated from cage studies because cages protect the fish from predators. A higher release mortality rate is supported by low recapture rates of vermilion snapper in tagging studies. Burns et al. (2002) estimated a 0.7% recapture rate for 825 tagged vermilion snapper; whereas, recapture rates for red grouper, gag, and red snapper ranged from 3.8% to 6.0% (Burns et al. 2002). McGovern and Meister (1999) estimated a 1.6% recapture rate for 3,827 tagged vermilion snapper. Alternatively, recapture rates could be low if population size was very high or tagged fish were unavailable to fishing gear. Harris and Stephen (2005) indicated approximately 50% of released vermilion snapper caught by one commercial fisherman were unable to return to the bottom. Lower recapture rates were estimated for black sea bass (10.2%), gray triggerfish (4.9%), gag (11%), and greater amberjack (15.1%) (McGovern and Meister 1999; McGovern et al. 2005). Burns et al. (2002) suggested released vermilion snapper did not survive as well as other species due to predation. Vermilion snapper that do not have air removed from swim bladders are subjected to predation at the surface of the water. Individuals with a ruptured swim bladder or those that have air removed from the swim bladder are subject to bottom predators, since fish would not be able to join schools of other vermilion snapper hovering above the bottom (Burns et al. 2002). However, Wilde (2009) reports that venting appears to be increasingly harmful for fish captured from deep water.

SEDAR 10 (2006b) estimated release mortality rates of 40% and 25% for gag taken by commercial and recreational fishermen, respectively. A tagging study conducted by McGovern et al. (2005) indicated recapture rates of gag decreased with increasing depth. The decline in recapture rate was attributed to depth-related mortality. Assuming there was no depth-related mortality at 0 m, McGovern et al. (2005) estimated depth related mortality ranged from 14% at 11-20 m (36-65 feet) to 85% at 71-80 m (233-262 feet). Similar trends in depth related mortality were provided by a gag tagging study conducted by Burns et al. (2002). Overton et al. (2008) reported post-release mortality for gag as 13.3%. Release mortality rates are not known for other shallow water grouper species, but could be similar to gag since they have a similar depth distribution. Rudershausen et al. (2007) estimated release mortality rates of 33% for undersized gag taken with J-hooks in depths of 25-50 m off North Carolina. For other gag caught at depths of 25-50 m, no immediate mortality was observed but delayed mortality was estimated to be 49%. McGovern et al. (2005) estimated a release mortality rate of 50% at 50 m, which is similar to the findings of Rudershausen et al. (2007). Rudershausen et al. (2007) concluded minimum size limits are effective for gag in the shallower portions of their depth range.

Release mortality rates were estimated as 20% for red grouper taken by recreational and commercial fishermen in SEDAR 19 (2010a). There was limited information to estimate discard mortality for red grouper. Wilson and Burns (1996) reported potential mortality rates for released red grouper to be low (0 - 14%) as long as the fish were caught from waters shallower than 44 m. It was recommended to use a discard mortality of 20% based on gag discard mortality since some studies did not account for post release mortality. The 20% release mortality for red snapper was used a proxy for Nassau Grouper in the 2016 biological opinion (NMFS 2016). SEDAR 15 (2008a) estimated a 20% release mortality rate for greater amberjack. Although SEDAR 41 (2017) assessment was not approved as best science for assessing the gray triggerfish stock, a literature review was conducted on the release mortality. The report recommended using a release mortality of 12.5% for gray triggerfish.

Release mortality of black sea bass is considered to be low (7% for the recreational sector and 7% for hook and line fishery and 1% for pot fishery in the commercial sector) (SEDAR 25; 2011) indicating minimum size limits are probably an effective management tool for black sea bass. McGovern and Meister (1999) report a recapture rate of 10.2% for 10,462 that were tagged during 1993-1998 suggesting that survival of released black sea bass is high. Rudershausen et al. (2007) reported a sub-legal discard rate of 12% for black sea bass. Collins et al. (1999) reported venting of the swim bladder yielded reductions in release mortality of black sea bass, and the benefits of venting increased with capture depth. The same study was analyzed by Wilde (2009) to suggest that venting increased the survival of black sea bass, although this was an exception to the general findings of Wilde's (2009) study.

Practicability of Management Measures in Directed Fisheries Relative to their Impact on Bycatch and Bycatch Mortality

The snapper grouper fishery represents many species occupying the same location at the same time. For example, the top co-occurring species with red snapper are black sea bass, red grouper, gag, scamp, greater amberjack, vermilion snapper, and gray triggerfish. Fishermen could harvest one of these species and return a co-occurring species to the water as "regulatory discards" (e.g., if the fish is under the size limit) or if undesirable. A portion of the population would not survive. Species with the greatest average annual number of individuals discarded by the commercial sector during 2012 to 2014 were black sea bass (32,548), vermilion snapper (21,944), red snapper (18,734), and) (Table 4). During 2012 to 2014, 94% of black sea bass,, 90% of gag, and 75% of red grouper were discarded in the private recreational sector (Table 5). During the same period, 88% of gag, 87% of black sea bass, and 81% of red grouper were released by fishermen on charter boats, versus 89% of black sea bass and 85% of red grouper by fishermen on headboats (Table 5).

Although fishery management actions can adversely impact non-target species, the proposed action is not anticipated to significantly increase bycatch of snapper-grouper species. The red snapper open seasons in 2012, 2013, and 2014 were short in duration (total days open since 2010: 17 recreational and 122 commercial) and future seasons based on landings during this time period would also be small. Rather, the proposed action is likely to allow fishermen to retain incidentally caught red snapper when targeting co-occurring species. A portion of these red snapper might otherwise die when returned to the water.

Alternative 1 (no action) would retain the current process to determine the annual catch limit for red snapper. Under the current process, the annual catch limit has been zero due to exceeding the acceptable biological catch based on landings and discards in the previous year. The SSC has indicated there is a great deal of uncertainty in the catch and discards in the recreational sector and the catch statistic should not be used in management. Under Alternative 1 (No Action), if the season were to reopen, the minimum size limit would be effective. Alternative 4 would establish an annual catch limit of 42,510 red snapper. The commercial annual catch limit would be 124,815 pounds (whole weight) and recreational annual catch limit would be 29,656 fish. Both alternatives could have adverse effects on the stock due to discarding fish to the water of which a portion would not survive. Release mortality rates for red snapper range from 28.5 to 38% depending on the fishing sector (SEDAR 41; 2017). Fishermen may produce "regulatory discards" under both alternatives; but Alternative 4 could have a lower amount of discards because a portion of the red snapper would be retained as landings. If the red snapper fishery remains closed as has happened since 2014, then the bycatch would be higher under Alternative 1 (No Action).

Adverse effects (additional mortality) could be produced from both Alternative 1 (No Action) and Alternative 4 through "high-grading" behavior. High-grading is a practice of selectively landing fish so that only the best quality (usually largest) fish are brought ashore. For example, recreational fishermen may discard smaller size fish in order to retain a larger, more desirable red snapper. High-grading can result in many dead discards. Both Alternative 1 (No Action) and Alternative 4 could have similar impacts from additional mortality since fishermen would be restricted to 1 red snapper per person (if a season fishermen opens for Alternative 1 (No Action)).

Amendment 14 to the Snapper Grouper FMP (Amendment 14; SAFMC 2009a) established eight marine protected areas (MPAs) from North Carolina to Florida where harvest of snapper grouper species is prohibited. One of the objectives of Amendment 14 was to protect some areas where spawning of snapper grouper species (e.g., snowy grouper, golden tilefish, speckled hind, red porgy, vermilion snapper, gray triggerfish, red snapper, scamp, gag, red grouper, gray triggerfish, and others) was known to occur. As all harvest of snapper grouper species is prohibited in the MPAs, no bycatch of snapper grouper species in occurring in these areas.

Seasonal closures of shallow water grouper species (commercial and recreational sectors) and vermilion snapper (recreational sector) implemented through Amendment 16 to the Snapper Grouper FMP (Amendment 16; SAFMC 2009b) has likely reduced bycatch mortality of red snapper. Expected harvest reductions for red snapper from Amendment 16 in total kill was estimated to be 16.5% (commercial sector), 1.1 to 7.7% (headboat sector), and 2.3% (private/charter sector) (SERO 2009a; SERO 2009b; SERO 2009c; SERO 2009d). A longer spawning seasonal closure could enhance the reproductive potential of grouper stocks. For example, Amendment 16 established a January-April spawning season closure for gag, red grouper, black grouper, and shallow water grouper species. Gag are in spawning condition from December through April each year. There is some evidence spawning aggregations may be in place before and after a spawning season (Gilmore and Jones 1992). When aggregated, gag are extremely susceptible to fishing pressure since the locations are often well known by fishermen. Gilmore and Jones (1992) showed that the largest and oldest gag in aggregations are the most aggressive and first to be removed by fishing gear. Since gag change sex, larger and older males can be selectively removed. As a result, a situation could occur where there are not enough males in an aggregation to spawn with the remaining females. Furthermore, the largest, most fecund females could also be selectively removed by fishing gear. Therefore, a spawning season closure for all shallow water grouper species is expected to protect grouper species when they are most vulnerable to capture, reduce bycatch of co-occurring grouper species, increase the percentage of males in grouper populations, enhance reproductive success, and increase the magnitude of recruitment. Other actions in Amendment 16 that could reduce bycatch of snapper grouper species include a reduction in the recreational bag limit to 1 gag or black grouper (combined) per day within a grouper aggregate bag limit of 3 fish and the establishment of a commercial quota for gag. When the commercial quota is met, all fishing for or possession of shallow water grouper species will be prohibited.

Unobserved mortality due to predation or trauma associated with capture could be substantial (Burns et al. 2002; Rummer and Bennett 2005; St. John and Syers 2005; Parker et al. 2006; Rudershausen et al. 2007; Hannah et al. 2008; Diamond and Campbell 2009). Amendment 16 also included actions that required the use of dehooking devices, which could help reduce bycatch mortality of vermilion snapper, black sea bass, gag, red grouper, black grouper, and red snapper. Dehooking devices can allow fishermen to remove hooks with greater ease and more quickly from snapper grouper species without removing the fish from the water. If a fish does need to be removed from the water, dehookers could still reduce handling time in removing hooks, thus increasing survival (Cooke et al. 2001).

In addition to prohibiting the harvest of red snapper, Amendment 17A implemented regulations requiring the use of non-stainless circle hooks north of 28 degrees N. latitude, effective March 2, 2011. Circle hooks are generally thought to reduce the discard mortality rate for red snapper (SEDAR 7 2005; Rummer 2007); however, Burns et al. (2004) did not observe decreased discard mortality rate when comparing recapture rates of red snapper caught on circle and J-hooks. Rummer (2007), and Diamond and Campbell (2009) found that a greater differential between the surface and bottom temperature caused a higher discard mortality rate for red snapper. Amendment 17B to the Snapper Grouper FMP (Amendment 17B; SAFMC 2010b) established ACLs and accountability measures (AMs) and addressed overfishing for eight species in the snapper grouper management complex listed at that time as undergoing overfishing: snowy grouper; speckled hind; warsaw grouper; black sea bass; gag; and red grouper; in addition to black grouper, golden tilefish, and vermilion snapper.

The Comprehensive ACL Amendment (SAFMC 2011a) implemented ACLs and accountability measures (AMs) for species not undergoing overfishing in four fishery management plans, in addition to other actions such as allocations and establishing annual catch targets for the recreational sector. The Comprehensive ACL Amendment also established additional measures to reduce bycatch in the snapper grouper fishery with the establishment of species complexes based on biological, geographic, economic, taxonomic, technical, social, and ecological factors. ACLs were assigned to these species complexes, and when the ACL for the complex is met or projected to be met, fishing for species included in the entire species complex is prohibited for the fishing year. ACLs and AMs will likely reduce bycatch of target species and species complexes as well as incidentally caught species (i.e., red snapper).

Amendment 18A to the Snapper Grouper FMP (Amendment 18A; SAFMC 2011b) contains measures to limit participation and effort for black sea bass, and does not directly affect red snapper. Amendment 18A established an endorsement program than enables snapper grouper fishermen with a certain catch history to harvest black sea bass with pots. In addition, Amendment 18A included measures to reduce bycatch in the black sea bass pot fishery, modify the rebuilding strategy, and other necessary changes to management of black sea bass as a result of a 2011 stock assessment (SEDAR 25). Amendment 24 to the Snapper Grouper FMP (Amendment 24; SAFMC 2011c) established a rebuilding plan for red grouper which is overfished and undergoing overfishing. Amendment 24 also established ACLs and AMs for red grouper that could help to reduce bycatch of red grouper and co-occurring species such as red snapper.

NMFS must examine ways to reduce mortality of Nassau grouper. This includes, but is not limited to, examining possible modifications to fishing practices that can be adopted through changes in fishery management plan related regulations, as well as recommended best fishing practices. NMFS must assess:

> (a) the potential effectiveness of non-stainless steel circle hooks on reducing injury and mortality to Nassau grouper. If deemed an effective measure, NMFS shall consider revision of regulations to expand their current use to include areas south of 28° N. lat. for fishing activities that could incidentally capture Nassau grouper.

(b) the potential effectiveness of fishing practices after fish are captured that could reduce and minimize the effects of fishing. This includes, but is not limited to 1) de-hooking and 2) treatment for barotrauma, e.g., the possible use of "descender" devices. If deemed effective, NMFS shall consider revision of regulations to implement their use for incidentally caught Nassau grouper.

Ecological Effects Due to Changes in the Bycatch

The ecological effects of bycatch mortality are the same as fishing mortality from directed fishing efforts. If not properly managed and accounted for, either form of mortality could potentially reduce stock biomass to an unsustainable level.

Overall fishing effort could increase in the commercial and recreational sectors in response to the limited reopening(s) of red snapper, and therefore, increase the potential for bycatch. However, as stated in Chapter 2 and analyzed in detail in Chapter 4, the reopening(s) would be of short duration in the recreational sector and limited to an incidental catch limit (75 lbs) in the commercial sector (see Chapter 6 for details), and therefore, the ecological effects due to changes in the bycatch would likely be small (see Appendix C (SERO 2012)) for detailed analysis.

Changes in the Bycatch of Other Fish Species and Resulting Population and Ecosystem Effects

The action in the amendment could allow a limited harvest of red snapper beginning in 2018, and subsequent years. Thus, ecological changes could occur in the community structure of reef ecosystems through the proposed action, due to increased fishing pressure on co-occurring species that could be caught as bycatch. These ecological changes could affect the nature and magnitude of bycatch over time. However, as stated in Chapters 2 and 4, the allowed harvest of red snapper beginning in 2018 would likely be relatively limited in scope, and changes in the bycatch of other fish species and resulting population and ecosystem effects could be minimal in nature.

The commercial red snapper season would close when the commercial sector ACL is met or projected to be met. The end of the recreational red snapper season would be projected and announced before the start of the recreational season. The NMFS Regional Administrator has the authority to delay the opening of red snapper fishing seasons in the event of a tropical storm or hurricane affecting the South Atlantic Council's area of authority. The process would be repeated each year until modified.

Effects on Marine Mammals and Birds

Under Section 118 of the Marine Mammal Protection Act (MMPA), NMFS must publish, at least annually, a List of Fisheries (LOF) that places all U.S. commercial fisheries into one of three categories based on the level of incidental serious injury and mortality of marine mammals that occurs in each fishery. The southeast U.S. Atlantic black sea bass pot fishery is included in the grouping of the Atlantic mixed species trap/pot fisheries, which the 2017 LOF classified as a Category II (82 FR 3655; January 12, 20177). Gear types used in these fisheries are determined to have occasional incidental mortality and serious injury of marine mammals. The SEFSC Supplementary Discard Data Program (SDDP) initiated in July of 2001. The SDDP sub-samples 20% of the vessels with an active permit. Since August 2001, only three interactions with marine mammals have been documented; each was taken by handline gear and each released alive (McCarthy SEFSC database). The longline and hook-and-line gear components of the snapper grouper fishery in the South Atlantic are classified as Category III fisheries ().

Although the black sea bass pot fishery can pose an entanglement risk to large whales due to their distribution and occurrence, sperm, fin, sei, and blue whales are unlikely to overlap with the black sea bass pot fishery operated within the snapper grouper fishery since it is executed primarily off North Carolina and South Carolina (with some effort off Florida) in waters ranging from 70-120 feet deep (21.3-36.6 meters). North Atlantic right overlap both spatially and temporally with the black sea bass pot fishery. In 2007, revisions to the Atlantic Large Whale Take Reduction Plan folded the Atlantic mixed species trap/pot fisheries into the plan (72 FR 57104; October 5, 2007). In the 2016 biologocal opinion, NMFS estimated that the number of annual lethal takes for NARWs from black sea bass trap/pot gear ranged from an estimated minimum of 0.005 to a maximum of 0.08. This equates to 1 estimated lethal entanglement approximately every 25 to 42 years. Bermuda petrels are occasionally seen in the waters of the Gulf Stream off the coasts of North and South Carolina during the summer. Sightings are considered rare and only occurring in low numbers (Alsop 2001). Roseate terns occur widely along the Atlantic coast during the summer but in the southeast region, they are found mainly off the Florida Keys (unpublished U.S. Fish and Wildlife Service data). Interaction with fisheries has not been reported as a concern for either of these species.

These species are not commonly found and neither has been described as associating with vessels or having had interactions with fisheries, including the snapper grouper fishery. Thus, it is believed that the snapper grouper fishery has no effectaffect the Bermuda petrel and the roseate tern

Changes in Fishing, Processing, Disposal, and Marketing Costs

With the exception of a limited opening in 2012, 2013, and 2014, landing red snapper has been prohibited since January 4, 2010 for both the commercial and recreational sectors. The action in the amendment may allow a limited harvest of red snapper beginning in 2018. Since red snapper is a desirable species, it is highly likely that all opportunities to harvest this species would be entertained. Therefore, there could be changes to costs associated with the fishing, processing, disposal, and marketing of red snapper. It is likely that all four states (North Carolina, South Carolina, Georgia, and Florida) would be affected by the regulations associated with this action, since fishermen from all the states would be interested in participating in any reopening that allows landings of red snapper. Additionally, factors such as waterfront property values, availability of less expensive imports, etc. may affect economic decisions made by recreational and commercial fishermen.

The South Atlantic Council has discussed options to enhance current data collection programs in future amendments. This might provide more insight in calculating the changes in fishing, processing, disposal, and marketing costs. The states and the SEFSC would work together to collect as much biological information as possible during the limited commercial and recreational openings for red snapper. The life history information obtained through data collection efforts may help in assessing the status of the stock in the future.

Changes in Fishing Practices and Behavior of Fishermen

Allowing harvest of red snapper could result in a modification of fishing practices by commercial and recreational fishermen, thereby affecting the magnitude of discards. However, as the increase in the red snapper ACL as proposed by proposed alternatives in this amendment is likely to be very small and the seasons would be relatively short, none of the proposed actions are expected to substantially increase overall fishing effort or the spatial and/or temporal distribution of current fishing effort. With the exception of limited openings in 2012, 2013, and 2014, harvest of red snapper has been prohibited since January 4, 2010 for both the commercial and recreational sectors. Since red snapper is a desirable species, it is highly likely that all opportunities to harvest this species would be entertained. Predicting changes in angler behavior in response to a reopening is difficult. Many factors can influence fishing activity (see Chapter 3 for more details) including: fuel costs and trip expenses; weather; changes in regulations; changes in fishing behavior; and conflicting activities (e.g., family activities, sporting events on weekends).

Landings of red snapper have only been allowed for 17 days for the recreational sector and 122 days for the commercial sector since 2010. Additionally, landings of red snapper from federal waters has not been allowed since 2014. The limited information available for red snapper make it difficult to determine how fishermen will respond to a similar opening in 2018.

NMFS would announce the pre-determined commercial and recreational fishing year start dates. The commercial red snapper season would close when the commercial sector ACL is met or projected to be met. The end of the recreational red snapper season would be projected and announced before the start of the recreational season. The NMFS Regional Administrator has the authority to delay the opening of red snapper fishing seasons in the event of a tropical storm or hurricane affecting the South Atlantic Council's area of authority. The process would be repeated each year unless modified.

Changes in Research, Administration, and Enforcement Costs and Management Effectiveness

Research and monitoring is ongoing to understand the effectiveness of proposed management measures and their effect on bycatch. Efforts are underway by the states and the SEFSC to enhance data collection activities if a limited opening for red snapper were to occur. In 1990, the SEFSC initiated a logbook program for vessels with federal permits in the snapper grouper fishery from the Gulf of Mexico and South Atlantic. Approximately 20% of commercial fishermen are asked to fill out discard information in logbooks; however, a greater percentage of fishermen could be selected with emphasis on individuals that dominate landings. Recreational discards are obtained from the Marine Recreational Information Program (MRIP) and logbooks from the NMFS headboat program.

Additional data collection activities for the recreational sector are being considered by the South Atlantic Council that could allow for a better monitoring of snapper grouper bycatch in the future. The SEFSC is developing electronic logbooks, which could be used to enable fishery managers to obtain information on species composition, size distribution, geographic range, disposition, and depth of fishes that are released. Some observer information has been provided by Marine Fisheries Initiative and Cooperative Research Programs, but more is desired for the snapper grouper fishery. Electronic logbook reporting is in place for headboats in the southeast, which is expected to improve the quality of data in that sector. Further, the South Atlantic Council is developing an amendment that could require vessel monitoring systems for snapper grouper vessels, which would be expected to improve data quality.

Cooperative research projects between science and industry are being used to a limited extent to collect bycatch information on the snapper grouper fishery in the South Atlantic. For example, Harris and Stephen (2005) characterized the entire (retained and discarded) catch of reef fishes from a selected commercial fisherman in the South Atlantic including total catch composition and disposition of fishes that were released. The Gulf and South Atlantic Fisheries Foundation, Inc. conducted a fishery observer program within the snapper grouper vertical hook-and-line (bandit rig) fishery of the South Atlantic United States. Through contractors they randomly placed observers on cooperating vessels to collect a variety of data quantifying the participation, gear, effort, catch, and discards within the fishery.

In the spring 2010, Archipelago Marine Research Ltd. worked with North Carolina Sea Grant and several South Atlantic Unlimited Snapper Grouper Permit holders to test the effectiveness of electronic video monitoring to measure catch and bycatch. A total of 93 trips were monitored with video monitoring, 34 by self-reported fishing logbooks, and 5 by observers. Comparisons between electronic video monitoring data and observer data showed that video monitoring was a reliable source of catch and bycatch data for most species.

Research funds for observer programs, gear testing and testing of electronic devices or both are also available each year in the form of grants from the Marine Fisheries Initiative, Saltonstall-Kennedy program, and the CRP. Efforts are made to emphasize the need for observer and logbook data in requests for proposals issued by granting agencies. A condition of funding for these projects is that data are made available to the Councils and NMFS upon completion of a study.

Stranding networks for sea turtles and marine mammals are established in the Southeast Region. The NMFS SEFSC is the base for the Southeast United States Marine Mammal Stranding Program (http://sero.nmfs.noaa.gov/protected_resources/marine_mammal_health_and_stranding_response_program/index.html). NMFS authorizes organizations and volunteers under the MMPA to respond to marine mammal strandings throughout the United States. These organizations form the stranding network whose participants are trained to respond to, and collect samples from live and dead marine mammals that strand along southeastern United State beaches. The SEFSC is responsible for: coordinating stranding events; monitoring stranding rates; monitoring human caused mortalities; maintaining a stranding database for the southeast region; and conducting investigations to determine the cause of unusual stranding events including mass strandings and mass mortalities (http://www.sefsc.noaa.gov/species/mammals/strandings.htm). The Southeast Regional Office and the SEFSC participate in a wide range of training and outreach activities to communicate bycatch related issues. The NMFS Southeast Regional Office issues public announcements, Southeast Fishery Bulletins, or News Releases on different topics, including use of turtle exclusion devices, bycatch reduction devices, use of methods and devices to minimize harm to turtles and sawfish, information intended to reduce harm and interactions with marine mammals, and other methods to reduce bycatch for the convenience of constituents in the southern United States. These are mailed out to various organizations, government entities, commercial interests and recreational groups. This information is also included in newsletters and publications that are produced by NMFS and the various regional fishery management councils. Announcements and news released are also available on the internet and broadcasted over NOAA weather radio.

NMFS established the South East Fishery-Independent Survey in 2010 to strengthen fishery independent sampling efforts in southeast U.S. waters, addressing both immediate and long-term fishery-independent data needs, with an overarching goal of improving fishery-independent data utility for stock assessments. Meeting these data needs is critical to improving scientific advice to the management process, ensuring overfishing does not occur, and successfully rebuilding overfished stocks on schedule.

Changes in the Economic, Social, or Cultural Value of Fishing Activities and Non-Consumptive Uses of Fishery Resources

Preferred alternatives, including those that are likely to increase or decrease discards could result in social and/or economic impacts as discussed in Chapter 4 of the EA.

Changes in the Distribution of Benefits and Costs

The ACL for the commercial and recreational sectors was established in the Comprehensive ACL Amendment (SAFMC 2011). Management measures proposed in the amendment have the potential to reduce bycatch of red snapper during a limited opening of the recreational and commercial sectors. See earlier section titled, “Practicability of Management Measures in Directed Fisheries Relative to their Impact on Bycatch and Bycatch Mortality”, in this BPA for a list of amendments and a summary of actions within them that could help reduce bycatch and discard mortality in the snapper grouper fishery. The extent to which these management measures would increase or decrease the magnitudes of discards is unknown. However, this depends on the degree to which fishermen shift effort to other species, seasons, or fisheries and whether effort decreases in response to more restrictive management measures as well as changes in community structure and age/size structures that could result from ending overfishing.

Social Effects

The social effects of all the alternatives, including those most likely to reduce bycatch, are described in Chapter 4 of the EA.

Conclusion

This section evaluates the practicability of taking additional action to minimize bycatch and bycatch mortality using the ten factors provided at 50 CFR section 600.350(d)(3)(i). In summary, revising the process to determine annual catch limits for red snapper proposed in the amendment has the potential to reduce bycatch of red snapper during a limited opening of the recreational and commercial sectors as some bycatch is turned into retained catch. As summarized in Section 1.3 of this BPA, the action in the amendment is not expected to result in significant changes in bycatch of red snapper. In addition, the Council, NMFS, and the SEFSC have implemented and plan to implement numerous management measures and reporting requirements that have improved, or are likely to improve monitoring efforts of discards and discard mortality in the snapper grouper fishery. Therefore, no additional action is needed to minimize bycatch or bycatch mortality within the snapper grouper fishery.

Appendix E. Regulatory Impact Review

Introduction

The National Marine Fisheries Service (NMFS) requires a Regulatory Impact Review (RIR) for all regulatory actions that are of public interest. The RIR does three things: 1) It provides a comprehensive review of the level and incidence of impacts associated with a regulatory action; 2) it provides a review of the problems and policy objectives prompting the regulatory proposals and an evaluation of the major alternatives which could be used to solve the problem; and 3) it ensures that the regulatory agency systematically and comprehensively considers all available alternatives so that the public welfare can be enhanced in the most efficient and cost effective way. The RIR also serves as the basis for determining whether any proposed regulations are a "significant regulatory action" under certain criteria provided in Executive Order 12866 (E.O. 12866) and whether the approved regulations will have a "significant economic impact on a substantial number of small business entities" in compliance with the Regulatory Flexibility Act of 1980.

Problems and Objectives

The purpose and need, issues, problems, and objectives of this action are presented in **Chapter 1** of this amendment and are incorporated herein by reference.

Description of Fisheries

A description of the red snapper portion of the snapper grouper fishery of the Atlantic region is provided in **Chapter 3** of this Amendment and is incorporated herein by reference.

Effects of Management Measures

A detailed analysis and discussion of the expected economic effects of each alternative for all proposed actions is included in **Chapter 4**. The following discussion summarizes the expected economic effects of the preferred alternatives for each action.

Action 1. Revise the process to determine the annual catch limits (ACLs) for red snapper

Cumulative Economic Effects Summary

Action 1

Public and Private Costs of Regulations

Determination of Significant Regulatory Action

Pursuant to E.O. 12866, a regulation is considered a "significant regulatory action" if it is likely to result in: 1) an annual effect of $100 million or more or adversely affect in a material way the economy, a sector of the economy, productivity, competition, jobs, the environment, public health or safety, or State, local, or tribal governments or communities; 2) create a serious inconsistency or otherwise interfere with an action taken or planned by another agency; 3) materially alter the budgetary impact of entitlements, grants, user fees, or loan programs or the rights or obligations of recipients thereof; or 4) raise novel legal or policy issues arising out of legal mandates, the President's priorities, or the principles set forth in this executive order.

Appendix F. Regulatory Flexibility Analysis

Introduction

The purpose of the Regulatory Flexibility Act (RFA) is to establish a principle of regulatory issuance that agencies shall endeavor, consistent with the objectives of the rule and applicable statutes, to fit regulatory and informational requirements to the scale of businesses, organizations, and governmental jurisdictions subject to regulation. To achieve this principle, agencies are required to solicit and consider flexible regulatory proposals and to explain the rationale for their actions to assure that such proposals are given serious consideration. The RFA does not contain any decision criteria; instead, the purpose of the RFA is to inform the agency, as well as the public, of the expected economic impacts of the alternatives contained in the FMP or amendment (including framework management measures and other regulatory actions) and to ensure that the agency considers alternatives that minimize the expected impacts while meeting the goals and objectives of the FMP and applicable statutes.

With certain exceptions, the RFA requires agencies to conduct a regulatory flexibility analysis for each proposed rule. The regulatory flexibility analysis is designed to assess the impacts various regulatory alternatives would have on small entities, including small businesses, and to determine ways to minimize those impacts. The following regulatory flexibility analysis was conducted to determine if the proposed rule would have a significant economic impact on a substantial number of small entities or not.

Statement of the need for, objective of, and legal basis for the proposed rule

The primary purpose and need, issues, problems, and objectives of the proposed action are presented in **Section 1.2** and are incorporated herein by reference.

Identification of federal rules which may duplicate, overlap or conflict with the proposed rule

No federal rules have been identified that duplicate, overlap or conflict with the proposed rule.

Description and estimate of the number of small entities to which the proposed action would apply

This rule concerns commercial and recreational fishing for red snapper in the South Atlantic EEZ. Anglers are not considered small entities as that term is defined in 5 U.S.C. 601(6), whether fishing from for-hire fishing, private or leased vessels. Therefore, an estimate of the number of anglers directly affected by the rule is not provided here.

The rule would directly apply to businesses that operate commercial fishing vessels that harvest red snapper in the South Atlantic EEZ. Any commercial fishing vessel that harvests red snapper or any other species or species group of the snapper grouper fishery in the South Atlantic EEZ must have a valid commercial snapper grouper permit that is specifically assigned to that vessel. The permit is a limited access permit for either an unlimited quantity of pounds (of most species within the fishery) per trip or no more than 225 pounds per trip.

As of September 12, 2016, there are 525 valid unlimited and 104 valid 225-lb permits. If all of the permits that are currently not valid but are renewable are included, there would be 551 unlimited and 114 225-lb permits representing a total of 665 commercial fishing vessels that may be directly affected by the rule. Approximately 71% of the permits (and vessels) are owned by Florida residents.

An estimated 557 businesses own the above snapper grouper permits and operate the 655 vessels. Approximately 91% (506) of these businesses operate only one of the 665 permitted vessels (**Table F-1**). Half of a percent of the businesses operate approximately 5% of the vessels. Of the businesses with one permitted vessel, 106 have 225-lb permits and 400 have unlimited pounds permits. Of the 51 businesses with multiple permitted vessels, 46 hold only unlimited pound permits. The other five businesses with multiple permitted vessels have at least one 225-lb permit.

Table F-1. Number of Businesses by Number of Vessels Owned/Operated with SA Snapper Grouper Permits.

Number			Percent of vessels	Percent of businesses
Permitted vessels	**Businesses**	**Combined vessels**		
1	506	506	76.1%	90.8%
2	31	62	9.3%	5.6%
3	8	24	3.6%	1.4%
4	6	24	3.6%	1.1%
5	3	15	2.3%	0.5%
6 and Over	3	34	5.1%	0.5%
Total	**557**	**665**	**100.0%**	**100.0%**

Appendix H. Essential Fish Habitat and Ecosystem-based Management

South Atlantic Fishery Management Council Habitat Conservation, Ecosystem Coordination and Collaboration

The South Atlantic Fishery Management Council (Council), using the Essential Fish Habitat Plan as the cornerstone, adopted a strategy to facilitate the move to an ecosystem-based approach to fisheries management in the region. This approach required a greater understanding of the South Atlantic ecosystem and the complex relationships among humans, marine life, and the environment including essential fish habitat. To accomplish this, a process was undertaken to facilitate the evolution of the Habitat Plan into a Fishery Ecosystem Plan (FEP), thereby providing a more comprehensive understanding of the biological, social, and economic impacts of management necessary to initiate the transition from single species management to ecosystem-based management in the region.

Moving to Ecosystem-Based Management

The Council adopted broad goals for Ecosystem-Based Management to include maintaining or improving ecosystem structure and function; maintaining or improving economic, social, and cultural benefits from resources; and maintaining or improving biological, economic, and cultural diversity. Development of a regional FEP (SAFMC 2009a) provided an opportunity to expand the scope of the original Council Habitat Plan and compile and review available habitat, biological, social, and economic fishery and resource information for fisheries in the South Atlantic ecosystem. The Council views habitat conservation as the core of the move to EBM in the region. Therefore, development of the FEP was a natural next step in the evolution and expands and significantly updates the SAFMC Habitat Plan (SAFMC 1998a) incorporating comprehensive details of all managed species (SAFMC, South Atlantic States, ASMFC, and NOAA Fisheries Highly Migratory Species and Protected Species) including their biology, food web dynamics, and economic and social characteristics of the fisheries and habitats essential to their survival. The FEP therefore serves as a source document and presents more complete and detailed information describing the South Atlantic ecosystem and the impact of fisheries on the environment. This FEP updated information on designated Essential Fish Habitat (EFH) and EFH-Habitat Areas of Particular Concern; expanded descriptions of biology and status of managed species; presented information that will support ecosystem considerations for managed species; and described the social and economic characteristics of the fisheries in the region. In addition, it expanded the discussion and description of existing research programs and needs to identify biological, social, and economic research needed to fully address ecosystem-based management in the region. It is anticipated that the FEP will provide a greater degree of guidance by fishery, habitat, or major ecosystem consideration of bycatch reduction, prey-predator interactions, maintaining biodiversity, and spatial management needs. This FEP serves as a living source document of biological, economic, and social information for all Fishery Management Plans (FMP). Future Environmental Assessments and Environmental Impact Statements associated with subsequent amendments to Council FMPs will draw from or cite by reference the FEP.

The Fishery Ecosystem Plan for the South Atlantic Region encompasses the following volume structure:
FEP Volume I - Introduction and Overview of FEP for the South Atlantic Region
FEP Volume II - South Atlantic Habitats and Species
FEP Volume III - South Atlantic Human and Institutional Environment
FEP Volume IV - Threats to South Atlantic Ecosystem and Recommendations
FEP Volume V - South Atlantic Research Programs and Data Needs
FEP Volume VI - References and Appendices

Comprehensive Ecosystem-Based Amendment (CE-BA) 1 (SAFMC 2009b) is supported by this FEP and updated EFH and EFH-HAPC information and addressed the Final EFH Rule (e.g., GIS presented for all EFH and EFH-HAPCs). Management actions implemented in CE-BA 1 established deepwater Coral HAPCs to protect what is thought to be the largest continuous distribution (>23,000 square miles) of pristine, deepwater coral ecosystems in the world.

The Fishery Ecosystem Plan, slated to be revised every 5 years, will again be the vehicle to update and refine information supporting designation and future review of EFH and EFH-HAPCs for managed species. Planning for the update is being conducted in cooperation with the Habitat Advisory Panel during the fall and winter of 2013 with initiation during 2014.

Ecosystem Approach to Deepwater Ecosystem Management

The Council manages coral, coral reefs and live/hard bottom habitat, including deepwater corals, through the Fishery Management Plan for Coral, Coral Reefs and Live/Hard Bottom Habitat of the South Atlantic Region (Coral FMP). Mechanisms exist in the FMP, as amended, to further protect deepwater coral and live/hard bottom habitats. The SAFMC's Habitat and Environmental Protection Advisory Panel and Coral Advisory Panel have supported proactive efforts to identify and protect deepwater coral ecosystems in the South Atlantic region. Management actions in Comprehensive Ecosystem-Based Amendment (CE-BA 1) (SAFMC 2009b) established deepwater coral HAPCs (C- HAPCs) to protect what is thought to be the largest continuous distribution (>23,000 square miles) of pristine deepwater coral ecosystems in the world. In addition, CE-BA 1 established areas within the CHAPC, which provide for traditional fishing in limited areas, which do not impact deepwater coral habitat. CE-BA 1, supported by the FEP, also addressed non-regulatory updates for existing EFH and EFH- HAPC information and addressed the spatial requirements of the Final EFH Rule (i.e., GIS presented for all EFH and EFH-HAPCs). Actions in this amendment included modifications in the management of the following: octocorals; special management zones (SMZs) off the coast of South Carolina; and sea turtle release gear requirements for snapper grouper fishermen. The amendment also designated essential fish habitat (EFH) and EFH-Habitat Areas of Particular Concern (EFH-HAPCs).

CE-BA 2 established annual catch limits (ACL) for octocorals in the South Atlantic as well as modifying the Fishery Management Unit (FMU) for octocorals to remove octocorals off the coast of Florida from the FMU (SAFMC 2011). The amendment also limited the possession of managed species in the SMZs off South Carolina to the recreational bag limit for snapper grouper and coastal migratory pelagic species; modified sea turtle release gear requirements for the snapper grouper fishery based upon freeboard height of vessels; amends Council fishery management plans (FMPs) to designate or modify EFH and EFH-HAPCs, including the FMP for Pelagic Sargassum Habitat; amended the Coral FMP to designate EFH for deepwater Coral HAPCs designated under CE-BA 1; and amended the Snapper Grouper FMP to designate EFH-HAPCs for golden and blueline tilefish and the deepwater Marine Protected Areas. The final rule was published in the federal register on December 30, 2011, and regulations became effective on January 30, 2012.

Building from a Habitat to an Ecosystem Network to Support the Evolution

Starting with our Habitat and Environmental Protection Advisory Panel, the Council expanded and fostered a comprehensive Habitat network in our region to develop the Habitat Plan of the South Atlantic Region completed in 1998 to support the EFH rule. Building on the core regional collaborations, the Council facilitated an expansion to a Habitat and Ecosystem network to support development of the FEP and CE-BA as well as coordinate with partners on other regional efforts.

Integrated Ocean Observing System (IOOS) and Southeast Coastal and Ocean Observing Regional Association (SECOORA)

The Integrated Ocean Observing System (IOOS®) is a partnership among federal, regional, academic, and private sector parties that works to provide new tools and forecasts to improve safety, enhance the economy, and protect our environment. IOOS supplies critical information about our Nation's oceans, coasts, and Great Lakes. Scientists working to understand climate change, governments adapting to changes in the Arctic, municipalities monitoring local water quality, and industries affected by coastal and marine spatial planning all have the same need: reliable, timely, and sustained access to data and information that inform decision making. Improving access to key marine data and information supports several purposes. IOOS data sustain national defense, marine commerce, and navigation safety. Scientists use these data to issue weather, climate, and marine forecasts. IOOS data are also used to make decisions for energy siting and production, economic development, and ecosystem-based resource management. Emergency managers and health officials need IOOS information to make decisions about public safety. Teachers and government officials rely on IOOS data for public outreach, training, and education.

SECOORA is one of 11 Regional Associations established nationwide through the US IOOS whose primary source of funding is through a 5-year cooperative agreement titled "Coordinated Monitoring, Prediction, and Assessment to Support Decision-Makers Needs for Coastal and Ocean Data and Tools". However, SECOORA was recently awarded funding via a NOAA Regional Ocean Partnership grant through the Governors' South Atlantic Alliance. SECOORA is the regional solution to integrating coastal and ocean observing data in the Southeast United States to inform decision makers and the general public. The SECOORA region encompasses 4 states, over 42 million people, and spans the coastal ocean from North Carolina to the west Coast of Florida and is creating customized products to address these thematic areas: Marine Operations; Coastal Hazards; Ecosystems, Water Quality, Living Marine Resources; and Climate Change. The Council is a voting member and Council staff was recently re-elected to serve on the

Board of Directors for the Southeast Coastal Regional Ocean Observing Association (SECOORA) to guide and direct priority needs for observation and modeling to support fisheries oceanography and integration into stock assessments through SEDAR. Cooperation through SECOORA is envisioned to facilitate the following:

- Refining current or water column designations of EFH and EFH-HAPCs (e.g., Gulf Stream and Florida Current).
- Providing oceanographic models linking benthic, pelagic habitats, and food webs.
- Providing oceanographic input parameters for ecosystem models.
- Integration of OOS information into Fish Stock Assessment process in the SA region.
- Facilitating OOS system collection of fish and fishery data and other research necessary to support the Council's use of area-based management tools in the SA Region including but not limited to EFH, EFH-HAPCs, Marine Protected Areas, Deepwater Coral Habitat Areas of Particular Concern, Special Management Zones, and Allowable Gear Areas.
- Integration of OOS program capabilities and research Needs into the South Atlantic Fishery Ecosystem Plan.
- Collaboration with SECOORA to integrate OOS products with information included in the Council's Habitat and Ecosystem Web Services and Atlas to facilitate model and tool development.
- Expanding Map Services and the Regional Habitat and Ecosystem Atlas in cooperation with SECOORAs Web Services that will provide researchers access to data or products including those collected/developed by SA OOS partners.

SECOORA researchers are developing a comprehensive data portal to provide discovery of, access to, and metadata about coastal ocean observations in the southeast US. Below are various ways to access the currently available data.

One project recently funded by SECOORA initiated development of species specific habitat models that integrate remotely sensed and in situ data to enhance stock assessments for species managed by the Council. The project during 2013/2014 was initiated to address red porgy, gray triggerfish, black seabass, and vermilion snapper. Gray triggerfish and red porgy are slated for assessment through SEDAR in 2014/15 and 2015/16 respectively.

National Fish Habitat Plan and Southeast Aquatic Resource Partnership (SARP)

In addition, the Council serves on the National Habitat Board and, as a member of the Southeast Aquatic Resource Partnership (SARP), has highlighted this collaboration by including the Southeast Aquatic Habitat Plan (SAHP) and associated watershed conservation restoration targets into the FEP. Many of the habitat, water quality, and water quantity conservation needs identified in the threats and recommendations Volume of the FEP are directly addressed by on-the-ground projects supported by SARP. This cooperation results in funding fish habitat restoration and conservation intended to increase the viability of fish populations and fishing opportunity, which also meets the needs to conserve and manage Essential Fish Habitat for Council managed species or habitat important to their prey. To date, SARP has funded 53 projects in the region through this program. This work supports conservation objectives identified in the SAHP to improve, establish, or maintain riparian zones, water quality, watershed connectivity, sediment flows, bottoms and shorelines, and fish passage, and addresses other key factors associated with the loss and degradation of fish habitats. SARP also developed the Southern Instream Flow Network (SIFN) to address the impacts of flow alterations in the Southeastern US aquatic ecosystems which leverages policy, technical experience, and scientific resources among partners based in 15 states. Maintaining appropriate flow into South Atlantic estuarine systems to support healthy inshore habitats essential to Council managed species is a major regional concern and efforts of SARP through SIFN are envisioned to enhance state and local partners ability to maintain appropriate flow rates.

Governor's South Atlantic Alliance (GSAA)

Initially discussed as a South Atlantic Eco-regional Compact, the Council has also cooperated with South Atlantic States in the formation of a Governor's South Atlantic Alliance (GSAA). This will also provide regional guidance and resources that will address State and Council broader habitat and ecosystem conservation goals. The GSAA was initiated in 2006. An Executive Planning Team (EPT), by the end of 2007, had created a framework for the Governors South Atlantic Alliance. The formal agreement between the four states (NC, SC, GA, and FL) was executed in May 2009. The Agreement specifies that the Alliance will prepare a "Governors South Atlantic Alliance Action Plan" which will be reviewed annually for progress and updated every five years for relevance of content. The Alliance's mission and purpose is to promote collaboration among the four states, and with the support and interaction of federal agencies, academe, regional organizations, non-governmental organizations, and the private sector, to sustain and enhance the region's coastal and marine resources. The Alliance proposes to regionally implement science-based actions and policies that balance coastal and marine ecosystems capacities to support both human and natural systems. The GSAA Action Plan was released in December 2010 and describes the four Priority Issue Areas that were identified by the Governors to be of mutual importance to the sustainability of the region's resources: Healthy Ecosystems; Working Waterfronts; Clean Coastal and Ocean Waters; and Disaster-Resilient Communities. The goals, objectives, actions, and implementation steps for each of these priorities were further described in the GSAA Implementation Plan released in July 2011. The final Action Plan was released on December 1, 2010 and marked the beginning of intensive work by the Alliance Issue Area Technical Teams (IATTs) to develop implementation steps for the actions and objectives. The GSAA Implementation Plan was published July 6, 2011, and the Alliance has been working to implement the Plan through the IATTs and two NOAA-funded Projects. The Alliance also partners with other federal agencies, academia, non-profits, private industry, regional organizations, and others. The Alliance supports both national and state-level ocean and coastal policy by coordinating federal, state, and local entities to ensure the sustainability of the region's economic, cultural, and natural resources. The Alliance has organized itself around the founding principles outlined in the GSAA Terms of Reference and detailed in the GSAA Business Plan. A team of natural resource managers, scientists, and information management system experts have partnered to develop a Regional Information Management System (RIMS) and recommend decision support tools that will support regional collaboration and decision-making. In addition to regional-level stakeholders, state and local coastal managers and decision makers will also be served by this project, which will enable ready access to new and existing data and information. The collection and synthesis of spatial data into a suite of visualization tools is a critical step for long-term collaborative planning in the South Atlantic region for a wide range of coastal uses. The Council's Atlas presents the spatial representations of Essential Fish Habitat, managed areas, regional fish and fish habitat distribution, and fishery operation information and it can be linked to or drawn on as a critical part of the collaboration with the RIMS.

South Atlantic Landscape Conservation Cooperative

One of the more recent collaborations is the Council's participation as Steering Committee member for the newly establish South Atlantic Landscape Conservation Cooperative (SALCC). Landscape Conservation Cooperatives (LCCs) are applied conservation science partnerships focused on a defined geographic area that informs on-the-ground strategic conservation efforts at landscape scales. LCC partners include DOI agencies, other federal agencies, states, tribes, non-governmental organizations, universities, and others. The newly formed Department of Interior Southeast Climate Services Center (CSC) has the LCCs in the region as their primary clients. One of the initial charges of the CSCs is to downscale climate models for use at finer scales.

The SALCC developed a Strategic Plan through an iterative process that began in December 2011. The plan provides a simple strategy for moving forward over the next few years. An operations plan was developed under direction from the SALCC Steering Committee to redouble efforts to develop version 1.0 of a shared conservation blueprint by spring-summer of 2014. The SALCC is developing the regional blueprint to address the rapid changes in the South Atlantic including but not limited to climate change, urban growth, and increasing human demands on resources which are reshaping the landscape. While these forces cut across political and jurisdictional boundaries, the conservation community does not have a consistent cross-boundary, cross-organization plan for how to respond. The South Atlantic Conservation Blueprint will be that plan. The blueprint is envisioned to be a spatially-explicit map depicting the places and actions need to sustain South Atlantic LCC objectives in the face of future change. The steps to creating the blueprint include development of: indicators and targets (shared metrics of success); the State of the South Atlantic (past, present, and future condition of indicators); and a Conservation Blueprint. Potential ways the blueprint could be used include: finding the best places for people and organizations to work together; raising new money to implement conservation actions; guiding infrastructure development (highways, wind, urban growth, etc.); creating incentives as an alternative to regulation; bringing a landscape perspective to local adaptation efforts; and locating places and actions to build resilience after major disasters (hurricanes, oil spills, etc.). Integration of connectivity, function, and threats to river, estuarine and marine systems supporting Council managed species is supported by the SALCC and enhanced by the Council being a voting member of its Steering Committee. In addition, the Council's Regional Atlas presents spatial representations of Essential Fish Habitat, managed areas, regional fish and fish habitat distribution, and fishery operation information and it be linked to or drawn on as a critical part of the collaboration with the recently developed SALCC Conservation Planning Atlas.

Building Tools to support EBM in the South Atlantic Region

The Council has developed a Habitat and Ecosystem Section of the website http://www.safmc.net/ecosystem/Home/EcosystemHome/tabid/435/Default.aspx and, in cooperation with the Florida Wildlife Research Institute (FWRI), developed a Habitat and Ecosystem Internet Map Server (IMS). The IMS was developed to support Council and regional partners' efforts in the transition to EBM. Other regional partners include NMFS Habitat Conservation, South Atlantic States, local management authorities, other Federal partners, universities, conservation organizations, and recreational and commercial fishermen. As technology and spatial information needs evolved, the distribution and use of GIS demands greater capabilities. The Council has continued its collaboration with FWRI in the now evolution to Web Services provided through the regional SAFMC Habitat and Ecosystem Atlas (http://ocean.floridamarine.org/safmc_atlas/) and the SAFMC Digital Dashboard (http://ocean.floridamarine.org/safmc_dashboard/). The Atlas integrates services for the following:

Species distribution and spatial presentation of regional fishery independent data from the SEAMAP-SA, MARMAP, and NOAA SEFIS systems; SAFMC Fisheries: (http://ocean.floridamarine.org/SA_Fisheries/)

Essential Fish Habitat and Essential Fish Habitat Areas of Particular Concern; SAFMC EFH: (http://ocean.floridamarine.org/sa_efh/)

Spatial presentation of managed areas in the region; SAFMC Managed Areas: (http://ocean.floridamarine.org/safmc_managedareas/)

An online life history and habitat information system supporting Council managed, State managed, and other regional species was developed in cooperation with FWRI. The Ecospecies system is considered dynamic and presents, as developed, detailed individual species life history reports and provides an interactive online query capability for all species included in the system: http://atoll.floridamarine.org/EcoSpecies

Web Services System Updates:
Essential Fish Habitat (EFH) – displays EFH and EFH-HAPCS for SAFMC managed species and NOAA Fisheries Highly Migratory Species.
Fisheries - displays Marine Resources Monitoring, Assessment, and Prediction (MARMAP) and Southeast Area Monitoring and Assessment Program South Atlantic (SEAMAP-SA) data.
Managed Areas - displays a variety of regulatory boundaries (SAFMC and Federal) or management boundaries within the SAFMC's jurisdiction.
Habitat – displays habitat data collected by SEADESC, Harbor Branch Oceanographic Institute (HBOI), and Ocean Exploration dives, as well as the SEAMAP shallow and ESDIM deepwater bottom mapping projects, multibeam imagery, and scientific cruise data.
Multibeam Bathymetry - displays a variety of multibeam data sources and scanned bathymetry charts.
Nautical Charts – displays coastal, general, and overview nautical charts for the SAFMC's jurisdictional area.

Ecosystem Based Action, Future Challenges and Needs

The Council has implemented ecosystem-based principles through several existing fishery management actions including establishment of deepwater Marine Protected Areas for the Snapper Grouper fishery, proactive harvest control rules on species (e.g., dolphin and wahoo) which are not overfished, implementing extensive gear area closures which in most cases eliminate the impact of fishing gear on Essential Fish Habitat, and use of other spatial management tools including Special Management Zones. Pursuant to development of the

Comprehensive Ecosystem-Based Amendment, the Council has taken an ecosystem approach to protect deepwater ecosystems while providing for traditional fisheries for the Golden Crab and Royal Red shrimp in areas where they do not impact deepwater coral habitat. The stakeholder based process taps in on an extensive regional Habitat and Ecosystem network. Support tools facilitate Council deliberations and with the help of regional partners, are being refined to address long-term ecosystem management needs.

One of the greatest challenges to the long-term move to EBM in the region is funding high priority research, including but not limited to, comprehensive benthic mapping and ecosystem model and management tool development. In addition, collecting detailed information on fishing fleet dynamics including defining fishing operation areas by species, species complex, and season, as well as catch relative to habitat is critical for assessment of fishery, community, and habitat impacts and for Council use in place based management measures. Additional resources need to be dedicated to expand regional coordination of modeling, mapping, characterization of species use of habitats, and full funding of regional fishery independent surveys (e.g., MARMAP, SEAMAP, and SEFIS) which are linking directly to addressing high priority management needs. Development of ecosystem information systems to support Council management should build on existing tools (e.g., Regional Habitat and Ecosystem GIS and Arc Services) and provide resources to regional cooperating partners for expansion to address long-term Council needs.

The FEP and CE-BA 1 complement, but do not replace, existing FMPs. In addition, the FEP serves as a source document to the CE-BAs. NOAA should support and build on the regional coordination efforts of the Council as it transitions to a broader management approach. Resources need to be provided to collect information necessary to update and refine our FEP and support future fishery actions including but not limited to completing one of the highest priority needs to support EBM, the completion of mapping of near-shore, mid-shelf, shelf edge, and deepwater habitats in the South Atlantic region. In developing future FEPs, the Council will draw on SAFEs (Stock Assessment and Fishery Evaluation reports) which NMFS is required to provide the Council for all FMPs implemented under the Magnuson-Stevens Act. The FEP, which has served as the source document for CE-BAs, could also meet some of the NMFS SAFE requirements if information is provided to the Council to update necessary sections.

EFH and EFH-HAPC Designations Translated to Cooperative Habitat Policy Development and Protection

The Council actively comments on non-fishing projects or policies that may impact fish habitat. Appendix A of the Comprehensive Amendment Addressing Essential Fish Habitat in Fishery Management Plans of the South Atlantic Region (SAFMC 1998b) outlines the Council's comment and policy development process and the establishment of a four-state Habitat Advisory Panel. Members of the Habitat Advisory Panel serve as the Council's habitat contacts and professionals in the field. AP members bring projects to the Council's attention, draft comment letters, and attend public meetings. With guidance from the Advisory Panel, the Council has developed and approved policies on:

1. Energy exploration, development, transportation, and hydropower re-licensing;
2. Beach dredging and filling and large-scale coastal engineering;
3. Protection and enhancement of submerged aquatic vegetation;

4. Alterations to riverine, estuarine, and nearshore flows;
5. Marine aquaculture;
6. Marine Ecosystems and Non-Native and Invasive Species: and
7. Estuarine Ecosystems and Non-Native and Invasive Species.

NOAA Fisheries, State and other Federal agencies apply EFH and EFH-HAPC designations and protection policies in the day-to-day permit review process. The revision and updating of existing habitat policies and the development of new policies is being coordinated with core agency representatives on the Habitat and Coral Advisory Panels. Existing policies are included at the end of this Appendix.

The Habitat and Environmental Protection Advisory Panel, as part of their role in providing continued policy guidance to the Council, is during 2013/14, reviewing and proposing revisions and updates to the existing policy statements and developing new ones for Council consideration. The effort is intended to enhance the value of the statements and support cooperation and collaboration with NOAA Fisheries Habitat Conservation Division and State and Federal partners in better addressing the Congressional mandates to the Council associated with designation and conservation of EFH in the region.

South Atlantic Bight Ecopath Model

The Council worked cooperatively with the University of British Columbia and the Sea Around Us project to develop a straw-man and preliminary food web models (Ecopath with Ecosim) to characterize the ecological relationships of South Atlantic species, including those managed by the Council. This effort was envisioned to help the Council and cooperators in identifying available information and data gaps while providing insight into ecosystem function. More importantly, the model development process provides a vehicle to identify research necessary to better define populations, fisheries, and their interrelationships. While individual efforts are still underway in the South Atlantic, only with significant investment of new resources through other programs will a comprehensive regional model be further developed.

The latest collaboration builds on the previous Ecopath model developed through the Sea Around Us project for the South Atlantic Bight with a focus on beginning a dialogue on the implications of potential changes in forage fish populations in the region that could be associated with environmental or climate change or changes in direct exploitation of those populations.

Essential Fish Habitat and Essential Fish Habitat Areas of Particular Concern

Following is a summary of the current Council's EFH and EFH-HAPCs. Information supporting their designation was updated (pursuant to the EFH Final Rule) in the Council's Fishery Ecosystem Plan and Comprehensive Ecosystem Amendment:

Snapper Grouper FMP

Essential fish habitat for snapper grouper species includes coral reefs, live/hard bottom, submerged aquatic vegetation, artificial reefs, and medium to high profile outcroppings on and around the shelf break zone from shore to at least 600 feet (but to at least 2,000 feet for wreckfish) where the annual water temperature range is sufficiently warm to maintain adult populations of members of this largely tropical complex. EFH includes the spawning area in the water column above the adult habitat and the additional pelagic environment, including *Sargassum*, required for larval survival and growth up to and including settlement. In addition the Gulf Stream is an essential fish habitat because it provides a mechanism to disperse snapper grouper larvae.

For specific life stages of estuarine dependent and nearshore snapper grouper species, essential fish habitat includes areas inshore of the 100-foot contour, such as attached macroalgae; submerged rooted vascular plants (seagrasses); estuarine emergent vegetated wetlands (saltmarshes, brackish marsh); tidal creeks; estuarine scrub/shrub (mangrove fringe); oyster reefs and shell banks; unconsolidated bottom (soft sediments); artificial reefs; and coral reefs and live/hard bottom.

Areas which meet the criteria for EFH-HAPCs for species in the snapper grouper management unit include medium to high profile offshore hard bottoms where spawning normally occurs; localities of known or likely periodic spawning aggregations; nearshore hard bottom areas; The Point, The Ten Fathom Ledge, and Big Rock (North Carolina); The Charleston Bump (South Carolina); mangrove habitat; seagrass habitat; oyster/shell habitat; all coastal inlets; all state-designated nursery habitats of particular importance to snapper grouper (e.g., Primary and Secondary Nursery Areas designated in North Carolina); pelagic and benthic *Sargassum*; Hoyt Hills for wreckfish; the *Oculina* Bank Habitat Area of Particular Concern; all hermatypic coral habitats and reefs; manganese outcroppings on the Blake Plateau; and Council-designated Artificial Reef Special Management Zones (SMZs). In addition, the Council through CEBA 2 (SAFMC 2011) designated the deepwater snapper grouper MPAs and golden tilefish and blueline tilefish habitat as EFH-HAPCs under the Snapper Grouper FMP as follows:

EFH-HAPCs for golden tilefish to include irregular bottom comprised of troughs and terraces inter-mingled with sand, mud, or shell hash bottom. Mud-clay bottoms in depths of 150-300 meters are HAPC. Golden tilefish are generally found in 80-540 meters, but most commonly found in 200-meter depths.

EFH-HAPC for blueline tilefish to include irregular bottom habitats along the shelf edge in 45-65 meters depth; shelf break or upper slope along the 100-fathom contour (150-225 meters); hardbottom habitats characterized as rock overhangs, rock outcrops, manganese-phosphorite rock slab formations, or rocky reefs in the South Atlantic Bight; and the Georgetown Hole (Charleston Lumps) off Georgetown, SC.

EFH-HAPCs for the snapper grouper complex to include the following deepwater Marine Protected Areas (MPAs) as designated in Snapper Grouper Amendment 14: Snowy Grouper Wreck MPA, Northern South Carolina MPA, Edisto MPA, Charleston Deep Artificial Reef MPA, Georgia MPA, North Florida MPA, St. Lucie Hump MPA, and East Hump MPA.

Deepwater Coral HAPCs designated in Comprehensive Ecosystem-Based Amendment 1 are designated as Snapper Grouper EFH-HAPCs: Cape Lookout Coral HAPC, Cape Fear Coral HAPC, Blake Ridge Diapir Coral HAPC, Stetson-Miami Terrace Coral HAPC, and Pourtalés Terrace Coral HAPC.

Shrimp FMP

For penaeid shrimp, Essential Fish Habitat includes inshore estuarine nursery areas, offshore marine habitats used for spawning and growth to maturity, and all interconnecting water bodies as described in the Habitat Plan. Inshore nursery areas include tidal freshwater (palustrine), estuarine, and marine emergent wetlands (e.g., intertidal marshes); tidal palustrine forested areas; mangroves; tidal freshwater, estuarine, and marine submerged aquatic vegetation (e.g., seagrass); and subtidal and intertidal non- vegetated flats. This applies from North Carolina through the Florida Keys.

For rock shrimp, essential fish habitat consists of offshore terrigenous and biogenic sand bottom habitats from 18 to 182 meters in depth with highest concentrations occurring between 34 and 55 meters. This applies for all areas from North Carolina through the Florida Keys. Essential fish habitat includes the shelf current systems near Cape Canaveral, Florida, which provide major transport mechanisms affecting planktonic larval rock shrimp. These currents keep larvae on the Florida Shelf and may transport them inshore in spring. In addition, the Gulf Stream is an essential fish habitat because it provides a mechanism to disperse rock shrimp larvae.

Essential fish habitat for royal red shrimp include the upper regions of the continental slope from 180 meters (590 feet) to about 730 meters (2,395 feet), with concentrations found at depths of between 250 meters (820 feet) and 475 meters (1,558 feet) over blue/black mud, sand, muddy sand, or white calcareous mud. In addition, the Gulf Stream is an essential fish habitat because it provides a mechanism to disperse royal red shrimp larvae.

Areas which meet the criteria for EFH-HAPCs for penaeid shrimp include all coastal inlets, all state-designated nursery habitats of particular importance to shrimp (for example, in North Carolina this would include all Primary Nursery Areas and all Secondary Nursery Areas), and state-identified overwintering areas.

Coastal Migratory Pelagics FMP

Essential fish habitat for coastal migratory pelagic species includes sandy shoals of capes and offshore bars, high profile rocky bottom, and barrier island ocean-side waters, from the surf to the shelf break zone, but from the Gulf Stream shoreward, including *Sargassum*. In addition, all coastal inlets and all state-designated nursery habitats of particular importance to coastal migratory pelagics (for example, in North Carolina this would include all Primary Nursery Areas and all Secondary Nursery Areas).

For Cobia essential fish habitat also includes high salinity bays, estuaries, and seagrass habitat. In addition, the Gulf Stream is an essential fish habitat because it provides a mechanism to disperse coastal migratory pelagic larvae.

For king and Spanish mackerel and cobia essential fish habitat occurs in the South Atlantic and Mid-Atlantic Bights.

Areas which meet the criteria for EFH-HAPCs include sandy shoals of Capes Lookout, Cape Fear, and Cape Hatteras from shore to the ends of the respective shoals, but shoreward of the Gulf stream; The Point, The Ten-Fathom Ledge, and Big Rock (North Carolina); The Charleston Bump and Hurl Rocks (South Carolina); The Point off Jupiter Inlet (Florida); *Phragmatopoma* (worm reefs) reefs off the central east coast of Florida; nearshore hard bottom south of Cape Canaveral; The Hump off Islamorada, Florida; The Marathon Hump off Marathon, Florida; The "Wall" off of the Florida Keys; Pelagic *Sargassum*; and Atlantic coast estuaries with high numbers of Spanish mackerel and cobia based on abundance data from the ELMR Program. Estuaries meeting these criteria for Spanish mackerel include Bogue Sound and New River, North Carolina; Bogue Sound, North Carolina (Adults May-September salinity >30 ppt); and New River, North Carolina (Adults May-October salinity >30 ppt). For Cobia they include Broad River, South Carolina; and Broad River, South Carolina (Adults & juveniles May-July salinity >25ppt).

Golden Crab FMP

Essential fish habitat for golden crab includes the U.S. Continental Shelf from Chesapeake Bay south through the Florida Straits (and into the Gulf of Mexico). In addition, the Gulf Stream is an essential fish habitat because it provides a mechanism to disperse golden crab larvae. The detailed description of seven essential fish habitat types (a flat foraminferan ooze habitat; distinct mounds, primarily of dead coral; ripple habitat; dunes; black pebble habitat; low outcrop; and soft-bioturbated habitat) for golden crab is provided in Wenner et al. (1987). There is insufficient knowledge of the biology of golden crabs to identify spawning and nursery areas and to identify HAPCs at this time. As information becomes available, the Council will evaluate such data and identify HAPCs as appropriate through the framework.

Spiny Lobster FMP

Essential fish habitat for spiny lobster includes nearshore shelf/oceanic waters; shallow subtidal bottom; seagrass habitat; unconsolidated bottom (soft sediments); coral and live/hard bottom habitat; sponges; algal communities (*Laurencia*); and mangrove habitat (prop roots). In addition, the Gulf Stream is an essential fish habitat because it provides a mechanism to disperse spiny lobster larvae.

Areas which meet the criteria for EFH-HAPCs for spiny lobster include Florida Bay, Biscayne Bay, Card Sound, and coral/hard bottom habitat from Jupiter Inlet, Florida through the Dry Tortugas, Florida.

Coral, Coral Reefs, and Live/Hard Bottom Habitats FMP

Essential fish habitat for corals (stony corals, octocorals, and black corals) incorporate habitat for over 200 species. EFH for corals include the following:

A. Essential fish habitat for hermatypic stony corals includes rough, hard, exposed, stable substrate from Palm Beach County south through the Florida reef tract in subtidal waters to 30 m depth; subtropical (15°-35° C), oligotrophic waters with high (30-35$^{o}/_{oo}$) salinity and turbidity levels sufficiently low enough to provide algal symbionts adequate sunlight penetration for photosynthesis. Ahermatypic stony corals are not light restricted and their essential fish habitat includes defined hard substrate in subtidal to outer shelf depths throughout the management area.

B. Essential fish habitat for *Antipatharia* (black corals) includes rough, hard, exposed, stable substrate, offshore in high (30-35$^{o}/_{oo}$) salinity waters in depths exceeding 18 meters (54 feet), not restricted by light penetration on the outer shelf throughout the management area.

C. Essential fish habitat for octocorals excepting the order Pennatulacea (sea pens and sea pansies) includes rough, hard, exposed, stable substrate in subtidal to outer shelf depths within a wide range of salinity and light penetration throughout the management area.

D. Essential fish habitat for Pennatulacea (sea pens and sea pansies) includes muddy, silty bottoms in subtidal to outer shelf depths within a wide range of salinity and light penetration.

Areas which meet the criteria for EFH-HAPCs for coral, coral reefs, and live/hard bottom include: The 10-Fathom Ledge, Big Rock, and The Point (North Carolina); Hurl Rocks and The Charleston Bump (South Carolina); Gray's Reef National Marine Sanctuary (Georgia); The *Phragmatopoma* (worm reefs) reefs off the central east coast of Florida; Oculina Banks off the east coast of Florida from Ft. Pierce to Cape Canaveral; nearshore (0-4 meters; 0-12 feet) hard bottom off the east coast of Florida from Cape Canaveral to Broward County); offshore (5-30 meter; 15-90 feet) hard bottom off the east coast of Florida from Palm Beach County to Fowey Rocks; Biscayne Bay, Florida; Biscayne National Park, Florida; and the Florida Keys National Marine Sanctuary. In addition, the Council through CEBA 2 (SAFMC 2011) designated the Deepwater Coral HAPCs as EFH-HAPCs under the Coral FMP as follows:

Deepwater Coral HAPCs designated in Comprehensive Ecosystem-Based Amendment 1 as Snapper Grouper EFH-HAPCs: Cape Lookout Coral HAPC, Cape Fear Coral HAPC, Blake Ridge Diapir Coral HAPC, Stetson-Miami Terrace Coral HAPC, and Pourtalés Terrace Coral HAPC.

Dolphin and Wahoo FMP

EFH for dolphin and wahoo is the Gulf Stream, Charleston Gyre, Florida Current, and pelagic *Sargassum*. This EFH definition for dolphin was approved by the Secretary of Commerce on June 3, 1999 as a part of the Council's Comprehensive Habitat Amendment (SAFMC 1998b) (dolphin was included within the Coastal Migratory Pelagics FMP at that time).

Areas which meet the criteria for EFH-HAPCs for dolphin and wahoo in the Atlantic include The Point, The Ten-Fathom Ledge, and Big Rock (North Carolina); The Charleston Bump and The Georgetown Hole (South Carolina); The Point off Jupiter Inlet (Florida); The Hump off Islamorada, Florida; The Marathon Hump off Marathon, Florida; The "Wall" off of the Florida Keys; and Pelagic *Sargassum*. This EFH-HAPC definition for dolphin was approved by the Secretary of Commerce on June 3, 1999 as a part of the Council's Comprehensive Habitat Amendment (dolphin was included within the Coastal Migratory Pelagics FMP at that time).

Pelagic *Sargassum* Habitat FMP

The Council through CEBA 2 (SAFMC 2011) designated the top 10 meters of the water column in the South Atlantic EEZ bounded by the Gulfstream, as EFH for pelagic Sargassum.

Actions Implemented That Protect EFH and EFH-HAPCs

Snapper Grouper FMP

- Prohibited the use of the following gears to protect habitat: bottom longlines in the EEZ inside of 50 fathoms or anywhere south of St. Lucie Inlet, Florida; bottom longlines in the wreckfish fishery; fish traps; bottom tending (roller- rig) trawls on live bottom habitat; and entanglement gear.
- Established the *Oculina* Experimental Closed Area where the harvest or possession of all species in the snapper grouper complex is prohibited.

Established deepwater Marine Protected Areas (MPAs) as designated in Snapper Grouper Amendment 14: Snowy Grouper Wreck MPA, Northern South Carolina MPA, Edisto MPA, Charleston Deep Artificial Reef MPA, Georgia MPA, North Florida MPA, St. Lucie Hump MPA, and East Hump MPA.

Shrimp FMP

- Prohibition of rock shrimp trawling in a designated area around the *Oculina* Bank,
- Mandatory use of bycatch reduction devices in the penaeid shrimp fishery,
- Mandatory Vessel Monitoring System (VMS) in the Rock Shrimp Fishery.
- A mechanism that provides for the concurrent closure of the EEZ to penaeid shrimping if environmental conditions in state waters are such that the overwintering spawning stock is severely depleted.

***Pelagic Sargassum* Habitat FMP**

- Prohibited all harvest and possession of *Sargassum* from the South Atlantic EEZ south of the latitude line representing the North Carolina/South Carolina border (34° North Latitude).
- Prohibited all harvest of *Sargassum* from the South Atlantic EEZ within 100 miles of shore between the 34° North Latitude line and the Latitude line representing the North Carolina/Virginia border.
- Harvest of *Sargassum* from the South Atlantic EEZ is limited to the months of November through June.
- Established an annual Total Allowable Catch (TAC) of 5,000 pounds landed wet weight.
- Required that an official observer be present on each *Sargassum* harvesting trip. Require that nets used to harvest *Sargassum* be constructed of four-inch stretch mesh or larger fitted to a frame no larger than 4 feet by 6 feet.

Coastal Migratory Pelagics FMP

- Prohibited of the use of drift gillnets in the coastal migratory pelagic fishery.

Golden Crab FMP

- In the northern zone, golden crab traps can only be deployed in waters deeper than 900 feet; in the middle and southern zones traps can only be deployed in waters deeper than 700 feet.

Northern zone - north of the 28°N. latitude to the North Carolina/Virginia border;
Middle zone - 28°N. latitude to 25° N. latitude; and
Southern zone - south of 25°N. latitude to the border between the South Atlantic and Gulf of Mexico Fishery Management Councils.

Coral, Coral Reefs and Live/Hard Bottom FMP

- Established an optimum yield of zero and prohibiting all harvest or possession of these resources which serve as essential fish habitat to many managed species.
- Designated the *Oculina* Bank Habitat Area of Particular Concern.
- Expanded the *Oculina* Bank Habitat Area of Particular Concern (HAPC) to an area bounded to the west by 80°W. longitude, to the north by 28°30' N. latitude, to the south by 27°30' N. latitude, and to the east by the 100 fathom (600 feet) depth contour.
- Established the following two Satellite *Oculina* HAPCs: (1) Satellite *Oculina* HAPC #1 is bounded on the north by 28°30'N. latitude, on the south by 28°29'N. latitude, on the east by 80°W. longitude, and on the west by 80°3'W. longitude; and (2) Satellite *Oculina* HAPC #2 is bounded on the north by 28°17'N. latitude, on the south by 28°16'N. latitude, on the east by 80°W. longitude, and on the west by 80°3'W. longitude.
- Prohibited the use of all bottom tending fishing gear and fishing vessels from anchoring or using grapples in the *Oculina* Bank HAPC.
- Established a framework procedure to modify or establish Coral HAPCs.
- Established the following five deepwater CHAPCs:

Cape Lookout Lophelia Banks CHAPC;
Cape Fear Lophelia Banks CHAPC;
Stetson Reefs, Savannah and East Florida Lithoherms, and Miami Terrace (Stetson- Miami Terrace) CHAPC;
Pourtales Terrace CHAPC; and
Blake Ridge Diapir Methane Seep CHAPC.

- Within the deepwater CHAPCs, the possession of coral species and the use of all bottom damaging gear are prohibited including bottom longline, trawl (bottom and mid-water), dredge, pot or trap, or the use of an anchor, anchor and chain, or grapple and chain by all fishing vessels.

Council Policies for Protection and Restoration of Essential Fish Habitat
SAFMC Habitat and Environmental Protection Policy

In recognizing that species are dependent on the quantity and quality of their essential habitats, it is the policy of the SAFMC to protect, restore, and develop habitats upon which fisheries species depend; to increase the extent of their distribution and abundance; and to improve their productive capacity for the benefit of present and future generations. For purposes of this policy, "habitat" is defined as the physical, chemical, and biological parameters that are necessary for continued productivity of the species that is being managed. The objectives of the SAFMC policy will be accomplished through the recommendation of no net loss or significant environmental degradation of existing habitat. A long-term objective is to support and promote a net-gain of fisheries habitat through the restoration and rehabilitation of the productive capacity of habitats that have been degraded, and the creation and development of productive habitats where increased fishery production is probable. The SAFMC will pursue these goals at state, Federal, and local levels. The Council shall assume an aggressive role in the protection and enhancement of habitats important to fishery species, and shall actively enter Federal, decision making processes where proposed actions may otherwise compromise the productivity of fishery resources of concern to the Council.

SAFMC EFH Policy Statements

In addition to implementing regulations to protect habitat from fishing related degradation, the Council in cooperation with NOAA Fisheries, actively comments on non-fishing projects or policies that may impact fish habitat. The Council adopted a habitat policy and procedure document that established a four-state Habitat Advisory Panel and adopted a comment and policy development process. Members of the Habitat Advisory Panel serve as the Council's habitat contacts and professionals in the field. With guidance from the Advisory Panel, the Council has developed and approved a number of habitat policy statements which are available on the Habitat and Ecosystem section of the Council website (http://www.safmc.net/ecosystem/Home/EcosystemHome/tabid/435/Default.aspx).

SUBJECT: Red Snapper Guidance Request

The SEFSC concurs with the SEDAR Review Panel and SAFMC SSC's approval of SEDAR 41, the red snapper stock assessment. The SSC developed ABC recommendations based on the projection analysis that allowed the stock to reach a rebuilt status in the time allowed by the rebuilding plan (by 2044). The use of an ABC based primarily on fishery discards for monitoring the effectiveness of management action is likely ineffective due to the high level of uncertainty in measures of discards and the change in the effort estimation methodology that will be implemented in the MRIP survey.

Monitoring progress toward rebuilding will require a departure from the traditional techniques. SEFSC analysts are exploring an Index Projection Methodology as an alternative approach for monitoring stock response to management measures. They plan to discuss this with the SSC at their upcoming meeting to get input on the method. They will also discuss how these results may be used by the SSC to generate future catch level advice, given updated projections have not been provided. Information for the SSC regarding this is attached.

At the last SAFMC meeting we discussed holding a workshop to discuss ways to characterize the uncertainty of MRIP estimates (landings, discards) to provide guidance on: 1) at what point the uncertainty is sufficiently high to warrant alternative methods for accounting for catch; 2) what those alternative methods might be; 3) means to improve the precision of MRIP catch estimates; and 3) means to augment MRIP sampling to improve data quality. The SAFMC recognized this is a region-wide issue so a presentation was made to the GMFMC to request involvement of their SSC, and the GMFMC has agreed to participate. It has also been suggested that representation from the Mid-Atlantic Fishery Management Council may be advisable. We'll begin to stand up a steering committee to refine the workshop objectives, define the deliverables and begin work on the agenda. One deliverable from the workshop could evaluate the precision of red snapper discard estimates to help advise on their use for monitoring stock status when discards are the predominant contributor to fishing mortality. The target timeline for the workshop is this fall, however, we'll have more clarity on the timeline for delivery of advice to the SSC once the steering committee is stood up and begins their work on workshop planning.

SSC Input for April 2017 Meeting

The SAFMC SSC reviewed and approved the SEDAR 41 Red Snapper stock assessment in May 2016. The SSC developed ABC recommendations based on the projection analysis that allowed the stock to reach a rebuilt status in the time allowed by the rebuilding plan (by 2044). In our memo of February 15, 2017, the SEFSC indicated reasons why any further proposed projections would not be appropriate for management. These reasons revolve around the uncertainty and methodology changes for future estimates of discards from the MRIP survey. Non-traditional methods and data sources may need to be used to monitor management action effectiveness and progress toward rebuilding.

The SEFSC proposes creating and an Index Projection Methodology that uses trends in the fishery-independent survey to monitor rebuilding progress and serve as the basis for the SSC's future ABC advice to the Council.

The SEFSC would like to get feedback from the SSC on this proposed approach. Specifically:

1. The SEFSC is actively working on research into using SERFS video data to monitor future effectiveness of management actions, i.e. progress toward rebuilding. We ask the SSC to provide input on this proposed approach and its potential utility for determining management action effectiveness.
2. Discuss options for the appropriate baseline against which to compare the Index Projection.
3. Discuss how the index may be used by the SSC to develop ABC advice.

Dr. Erik Williams will be preparing a brief summary of the proposed approach and will be on hand to answer any questions the SSC may have at their next meeting.

We appreciate the SSC taking time to provide input on new methodology that has the potential to benefit management.

FROM: Gregg Waugh & Michelle Duval

SUBJECT: Red Snapper Guidance Request

At its March 2017 meeting, the South Atlantic Council requested that its SSC and the SEFSC work together to obtain an ABC for Red Snapper. This request was in response to two letters from NMFS addressing the status of Red Snapper. The first letter, from the SEFSC dated February 15, 2017 (**attached**), indicated that projections the Council requested in January 2017 could not be completed due to uncertainty in the assessment and the MRIP discard estimates. This letter also indicated that a complete evaluation of MRIP changes on the Red Snapper assessment (SEDAR 41) is necessary before it can be useful to management. The second letter, from SERO dated March 3, 2017 (**attached**), noted the SSC's concerns with uncertainty in the SEDAR 41 assessment and the resulting inability to reliably determine the degree of overfishing. In addition, NMFS noted that the assessment indicated overfishing was occurring during its terminal year of 2014 but the Council's actions to limit harvest since 2010, including harvest prohibitions in effect since 2015, have addressed overfishing and allowed the stock to continue rebuilding.

The SSC reviewed the SEDAR 41 Red Snapper assessment in May 2016 and considered it Best Scientific Information Available. However, because the Council has been informed in the past that SSC conclusions on BSIA are in fact recommendations, and that NMFS is actually responsible for the BSIA determinations, the Council requests the following:

1. The SEFSC concur with our determination that alternative methods are necessary to specify ABC and MSY for red snapper and that SEDAR 41 (original and revised) cannot be used to specify ABC or MSY for 2017 and beyond for the reasons outlined in your memo to Michelle Duval dated February 15, 2017. This is necessary to inform the SSC on the status of its existing ABC recommendation and to determine which sources of information used in the SEDAR 41 assessment can be considered for future ABC recommendations.
2. The SEFSC provide an evaluation of data limited techniques that can be considered by the SSC to develop an index-based ABC.
3. The SEFSC provide additional details on the proposed evaluation of the effect of MRIP changes on the Red Snapper assessment, particularly the types of evaluations to be considered and when they will be available for SSC review.

Given that the SEFSC will be providing the SSC a revised SEDAR 41 Red Snapper assessment to correct errors with some of the headboat input data, it is critical that a response to these issues

1

also be provided to the SSC. This will help inform the SSC on how to view the revised assessment.

Please provide this information needs to Council staff by noon on April 10, 2017 to be distributed to the SSC for review at their April 25-27, 2017 meeting. This is a complex matter and the SSC needs adequate time to review the revised assessment and responses prior to their meeting.

Please contact John Carmichael to address any questions concerning this request.

15 February, 2017

MEMORANDUM FOR: Gregg Waugh, Executive Director
South Atlantic Fishery Management Council

FROM: Bonnie J. Ponwith, Ph.D.
Science and Research Director

SUJBECT: **Red Snapper Projections**

On January 18, 2017, you sent a memo requesting, "Provide projections to 2044 (the end of the rebuilding period) based on fixed fishing mortality rates at Fmax, F20%SPR, F27%SPR, F30%SPR, and F40%SPR under the assumptions that all fish caught at each F level are subsequently discarded and the scenario mortality level is the total mortality (i.e., there are no additional discard mortalities). For each scenario, provide the full suite of projection outputs as provided for SEDAR 41 projections."

In working on those projections, Southeast Fisheries Science Center staff have advised, and I concur, that the proposed projections are not appropriate for management use for the following reasons:

- The uncertainty in the assessment is already large, and will increase due to the MRIP discard data, especially for the interim period (2015-16), the upcoming changes to MRIP from the new effort survey. For some background: the uncertainty in projections is generally high after 3-5 years, and these projections would have 2-3 years of an interim period (depending on whether 2017 or 2018 was the effective year of regulations).
- The SAFMC SSC has indicated that overfishing for this stock is occurring, but cannot quantify by how much. Fishing mortality rates in the last few years of the assessment are very sensitive to 2014 data and retrospective analyses indicate fishing mortality rates are considerably lower if these data are excluded. This uncertainty in the stock assessment inhibits the ability to set an ABC that can be effectively monitored.
- Fishing mortality in the interim period is calculated using actual landings and discards in 2015, though the status was determined using fishing mortality when there was a fishery occurring during mini-seasons (2012-2014). There were no fishing seasons for red snapper in 2015 or 2016 and final 2016 MRIP data are not yet available.
- The MRIP telephone survey will end this year and be replaced by a new mail-based effort survey. The new effort survey will be calibrated with the old telephone survey and undergo peer-review this summer. Preliminary results from the calibration study will be available in late-2017 and final results incorporating all three years of side-by-

side surveys will be available in 2018. Projections timed to benefit from the completed calibration study would be stronger than if based on the preliminary results.

- We feel that a more complete evaluation of the effect of the upcoming changes to MRIP on the Red Snapper assessment is needed before it can be useful to management.
  - We further recommend a thorough investigation, possibly through a workshop, into the reliability and utility of mail survey based MRIP estimates of catch and discards for many of our offshore species, which are known to have low intercept rates relative to other species covered by MRIP.

Dr. Michelle Duval, Chair
South Atlantic Fishery Management Council
4055 Faber Place Drive, Suite 201
North Charleston, South Carolina 29405

MAR 03 2017

Dear Dr. Duval:

The most recent South Atlantic red snapper stock assessment (SEDAR 41) was completed in April 2016 and indicated that the stock is undergoing overfishing and is overfished, but is rebuilding. The South Atlantic Fishery Management Council's (Council) Scientific and Statistical Committee (SSC) reviewed the assessment and determined the assessment is based on the best scientific information available. However, the SSC noted there is considerable uncertainty in the exploitation status, and thus, the degree of overfishing is highly uncertain. The uncertainty in exploitation status inhibits the Council's ability to set an acceptable biological catch that can be effectively monitored. Additionally, in the February 15, 2017, response to a Council request for red snapper projections, Dr. Bonnie Ponwith, Director of the National Marine Fisheries Service (NMFS) Southeast Fisheries Science Center noted that the overfishing determination was based on fishing mortality levels during 2012-2014 when a limited amount of harvest was allowed. Landings during 2012-2014 represented a high fraction of the overall fishing mortality, but since that time, harvest has been prohibited. Dr. Ponwith also noted that the uncertainty in the assessment is large and is predicted to increase as catch and effort estimates are updated through the new Marine Recreational Information Program (MRIP) effort survey.

NMFS has determined that the latest assessment identified the South Atlantic red snapper stock as undergoing overfishing, and adequate management action has been taken to address overfishing and continue to rebuild the stock through a harvest prohibition in 2015 and 2016. Due to uncertainty in the level of overfishing associated with the assessment and the new MRIP effort survey, data poor assessment methods for the red snapper stock, such as use of fishery independent indices, may be appropriate in the future. I look forward to continuing work with the Council on Amendment 43 to the Fishery Management Plan for the Snapper-Grouper Fishery of the South Atlantic Region to reduce discards of red snapper in the South Atlantic and continue to rebuild the stock.

Sincerely,

Roy E. Crabtree, Ph.D.
Regional Administrator

Appendix K. Calculation of Red Snapper ACLs

Total Annual Catch Limit

The total annual catch limit (ACL) was calculated using two different base values. One value was based on the average landings during the mini-seasons from 2012 to 2014, and the other was based on the highest landings reported during the mini-seasons (2014). **Alternative 3** and **Alternative 5** ACLs were calculated by multiplying an adjustment factor by the average landings (**Alternative 2** ACL) or highest landings (**Alternative 4 ACL**), respectively. The adjustment factor was developed by comparing the average abundance index value from a scientific survey in 2012 to 2014 to the average abundance index from 2015 to 2016 (See **Appendix L** for information on the calculation of the abundance index). Over this time period, the average abundance index for red snapper increased by 1.88 times. Therefore the adjustment factor was 1.88.

Table K.1. Development of the ACL value for **Alternative 3** and **Alternative 5**. The landings were based on landings from 2012 to 2014 when mini-seasons for red snapper were open. The adjustment factor is based on the increase in the red snapper abundance index.

Landings Type	Landings (number)	Adjustment Factor	ACL (number)	Alternative
Average	23,623	1.88	44,411	**Alternative 3**
Maximum	42,510	1.88	79,919	**Alternative 5**

Sector ACL

The total ACL is developed in numbers of fish; however, the method to determine the allocations for each sector is based on pounds of fish. Therefore numbers of fish were converted to pounds of fish. The estimate of fish weight came from averaging four different values of projected red snapper weight in 2018 (SEDAR 2017).

The allocations were developed by using the allocations in Amendment 25 (SAFMC 2011). The allocation was developed using data from 1986 to 2008. The red snapper landings estimates for recreational (rec) and commercial (com) sectors came from SEDAR 41 (2017).

$$RecSum = \frac{1}{2} * Sum\ Rec\ Landings\ 1986\ to\ 2008 + \frac{1}{2} * Sum\ Rec\ Landings\ 2006\ to\ 2008$$

$$ComSum = \frac{1}{2} * Sum\ Com\ Landings\ 1986\ to\ 2008 + \frac{1}{2} * Sum\ Com\ Landings\ 2006\ to\ 2008$$

$$RecSector\% = RecSum/(RecSum + ComSum)$$

The allocation in Amendment 17A was 28.07% commercial and 71.93% recreational.

The commercial ACL in whole weight was calculated by multiplying the total weight of the ACL by the commercial allocation (28.07%) (**Table 2**). The commercial ACL in gutted weight was calculated by using the whole weight to gutted weight ratio developed in SEDAR 41 (2016), which was 1.1.

Table 2. Development of the red snapper commercial ACL for **Alternative 2** through **5** in Amendment 43. ww=whole weight, gw=gutted weight

Alt	ACL Num	Average Weight from SEDAR 41 Projections	Total ACL Weight (ww)	Commercial Allocation	Commercial ACL (ww)	Commercial ACL (gw)
Alt 2	23,623	10.46	247,097	28.07%	69,360	63,055
Alt 3	44,411	10.46	464,539	28.07%	130,396	118,542
Alt 4	42,510	10.46	444,655	28.07%	124,815	113,468
Alt 5	79,919	10.46	835,953	28.07%	234,652	213,320

The recreational ACL in numbers of fish was calculated by removing the commercial sector ACL converted to number of fish from the total ACL in number of fish. Since the commercial ACL is calculated in pounds of fish, pounds of fish were converted to number of fish based on average weight of red snapper caught in the commercial sector from 2012 to 2014 (9.71 lbs ww) (SEDAR 41 2016). The commercial number of fish is then subtracted from the total ACL to get the recreational ACL.

Table 3. Development of the red snapper recreational ACL for **Alternative 2** through **5** in Amendment 43.

Alt	ACL Num	Commercial ACL (lbs ww)	Commercial Avg Weight (lbs ww)	Commercial ACL Num	Recreational ACL Number
Alt 2	23,623	69,360	9.71	7,143	16,480
Alt 3	44,411	130,396	9.71	13,429	30,982
Alt 4	42,510	124,815	9.71	12,854	29,656
Alt 5	79,919	234,652	9.71	24,166	55,753

Appendix L. SERFS Chevron Trap Red Snapper Abundance Index Update

Red Snapper Fishery-Independent Index of Abundance in US South Atlantic Waters Based on a Chevron Trap Survey (1990-2016 & 2010-2016)

Joseph C. Ballenger

Marine Resources Research Institute
South Carolina Department of Natural Resources
P.O. Box 12259
Charleston, SC 29412

SAFMC Amendment Development Team Reference Document
Amendment 43
MARMAP Technical Report # 2017-008

*Report documents development of Red Snapper relative abundance index based on the SERFS chevron trap survey. The document details two versions of the abundance index, one using the full time series of the chevron trap index (1990-2016) and the other only using data derived during the years 2010-2016.

This work was completed under the Marine Resources Monitoring, Assessment, and Prediction (MARMAP, NA16NMF4540320) and the Southeast Monitoring and Assessment Program – South Atlantic (SEAMAP-SA, NA16NMF4350172) funded by the National Marine Fisheries Service (Southeast Fisheries Science Center) and the South Carolina Department of Natural Resources.

Objective

This report presents two standardized relative abundance indices of Red Snapper derived from the SERFS chevron trap survey: one spanning the years 1990-2016 and the other the years 2010-2016. The standardized index accounts for annual sampling distribution shifts with respect to covariates that affect catch of Red Snapper in chevron traps. This report uses the same methodology for index development as documented in Ballenger and Smart (2015) for the chevron trap index during SEDAR41:

http://sedarweb.org/docs/wpapers/SEDAR41_DW54_Ballenger%26Smart_RSChevron2010.2014_8.17.2015.pdf.

Methods

Survey Design and Gear
(see Smart et al. 2015 for full description)

Sampling area

- Cape Hatteras, NC, to St. Lucie Inlet, FL
  - General expansion of geographic coverage through time

Sampling season

- May through September
  - Limited earlier and later sampling in some years

Survey Design

- 1990-2014
  - Simple random sample survey design from a chevron trap universe of confirmed live-bottom and/or hard-bottom habitat stations
- 2015-2016
  - Stratified random sample survey design from a chevron trap universe of confirmed live-bottom and/or hard-bottom habitat stations
    - Depth and latitude strata
      - Depth strata: inner shelf (<30 m deep); mid-shelf (30-42 m deep); outer-shelf (43-63 m deep); slope (≥64 m deep)
      - Latitude strata: southern-latitudes (<29.71°N); mid-latitudes (29.71-32.60°N); northern-latitudes (≥32.61°N)
- In a given year, no two stations are selected for sampling that are closer than 200 m from each other
- Traps deployed on suspected live-bottom and/or hard-bottom in a given year (reconnaissance) are evaluated based on catch and/or video or photographic evidence of bottom type for inclusion in the universe in subsequent years
  - If added to the known habitat universe, data from the reconnaissance deployment is included in CPUE analysis

Sampling Gear – Chevron Traps

(see Collins 1990 and MARMAP 2009 for descriptions that are more complete)

Oceanographic and Environmental Data

- Latitude (°N) data collected via GPS
- Depth (m) data collected via fathometer
- Bottom temperature (°C) data collected via CTD

Data Filtering/Inclusion

(see Ballenger and Smart 2015 for more complete description)

Chevron trap data were limited to:

- Projects conducting monitoring efforts
- Reef fish monitoring samples
- Traps that fished properly
- Traps on live-bottom and/or hard-bottom habitat
- Traps with soak times between 45-150 minutes
    - SERFS targets a soak time of 90 minutes for all chevron trap deployments
- Traps deployed at depths between 15 and 75 m
    - Range of depth for which we have ever observed Red Snapper in our monitoring program
- Excluded any chevron trap samples missing covariate information (Table 1)

Standardized Index Model Formulation

Model Basics

- Response variable – Catch/Trap (Figures 1 and 2)
- Offset term – $\ln(\text{soak time})$
- Dependent variables
    - Year
    - Covariates
        - Depth (m), latitude (°N), bottom temperature (°C), and day of year
            - Annual summary of covariates available in Table 2
            - Distribution of covariates available in Figures 3 and 4
- Model structure – zero-inflated negative binomial GLM (ZINB)
- Annual year effect coefficients of variation (CVs) computed using bootstrapping

Zero-Inflated Model Background

(see Cameron & Trivedi 1998, Hardin and Hilbe 2007, Hilbe 2007, Zeileis et al. 2008, and Chapter 11 in Zuur et al. 2009)

Covariate Treatment

(see Ballenger and Smart 2015 for more complete description)

- Covariates modeled as continuous covariates using polynomials

- Pairs plots, variance inflation factors (Table 3), box plots and violin plots were used to investigate the possibility of collinearity between any of the considered variables
  - No indication of strong collinearity among any considered covariates
- Model selection based on Bayesian information criterion (BIC; Schwarz 1978)

Results

Sampling Summary

- 1990-2016
  - 14,306 chevron trap samples retained and used in the development of the relative abundance index (Table 1)
  - Proportion of traps positive for Red Snapper averaged 0.08 (range: 0.00 – 0.16)
  - Caught on average 148 (range: 5-1088) Red Snapper annually
- 2010-2016
  - 8,073 chevron trap samples retained and used in the development of the relative abundance index (Table 1)
  - Proportion of traps positive for Red Snapper averaged 0.12 (range: 0.09 – 0.16)
  - Caught on average 519 (range: 116-1088) Red Snapper annually

ZINB Index

Model Selection
(see Table 4 for model selection results)

- Both indices, covariate day of year is removed from the count sub-model
- Both indices, the covariates year and bottom temperature are removed from the zero-inflation sub-model
- Both indices, best fit model suggest little to no overdispersion remaining in the data

Covariate Effects
(see Figures 7 and 8)

- Relative effects of latitude and bottom temperature is larger than the effect of sampling depth or day of year
- Predicted covariate effects
  - Depth – catch is above average at depths of ~25-45 m
  - Latitude – catch is higher than average at latitudes 28-30°N
  - Bottom temperature – catch of Red Snapper increases exponentially as bottom temperature increases, over the range of bottom temperatures observed in the survey
  - Day of Year – linear decrease in catch of Red Snapper throughout the survey season

Final Index
(see Table 5 and Figure 8)

- 1990-2016 Index
  - General slight decreasing trend from index start through the mid-2000's
  - Increasing relative abundance from approximately 2006 through the terminal year
  - CV estimates generally decrease through time
    - 1990-2009 – avg. 0.54 (range: 0.35 – 0.98; SD: 0.14)
    - 2010-2016 – avg. 0.17 (range: 0.16 – 0.20; SD: 0.02)
- 2010-2016 Index
  - Increasing relative abundance throughout the time series
    - Rate of increase increases after 2013
  - CV estimates – avg. 0.14 (range: 0.10 – 0.19; SD: 0.03)
- Correlation between the indices was 0.99 for the period 2010-2016 (Table 6 and Figure 9)

Conclusions

Here I present two updated relative abundance indices derived from the SERFS chevron trap survey. Both of these indices were developed using the same methodology used for the development of the chevron trap index during SEDAR 41 (see Ballenger and Smart 2015). They differ only in the length of the time series, one using data from the full chevron trap index time series (1990-2016) and the other only using chevron trap data collected from 2010-2016. During SEDAR41 it was decided to use a reduced time series for the chevron trap index (2010-2014). The three primary reasons for this decision was the low proportion of traps positive for Red Snapper prior to 2010, the low absolute number of Red Snapper captured annually in the survey prior to 2010, and the lower level of sampling effort off the coasts of Georgia and Florida prior to 2010. The consequences of these three factors can be seen in the higher degree of uncertainty of the chevron trap index from 1990-2009 (Table 5), with the annual coefficient of variation being approximately three times higher during this period of time than it is from 2010-2016. However, during the overlapping period both indices depicted the same increase in relative abundance (Table 6 and Figure 9). Both suggest that Red Snapper relative abundance is more than three times higher in 2016 than it was in 2010 and is more than 1.5 times higher in 2016 than it was in 2014.

I also provide a quick comparison to the Red Snapper index of relative abundance presented in the 2016 SCDNR Reef Fish Survey annual trends report. SCDNR Reef Fish Survey staff presented the index as developed for the trends report to the SAFMC SSC in April 2017 and the SAFMC in June 2017. The trends report Red Snapper relative abundance index differs primarily in statistical framework (delta-lognormal versus the ZINB model used here), response variable (catch/(trap*hr) versus catch/trap), and treatment of covariates (discrete versus continuous). Despite these differences, the correlation of the trends report index with either index presented herein exceeds 0.91 (Table 6) and depicts a very similar pattern of increase since 2010. It suggests that Red Snapper relative abundance in 2016 is 3.3 times higher than it was in 2010 and is more than two times what it was in 2014.

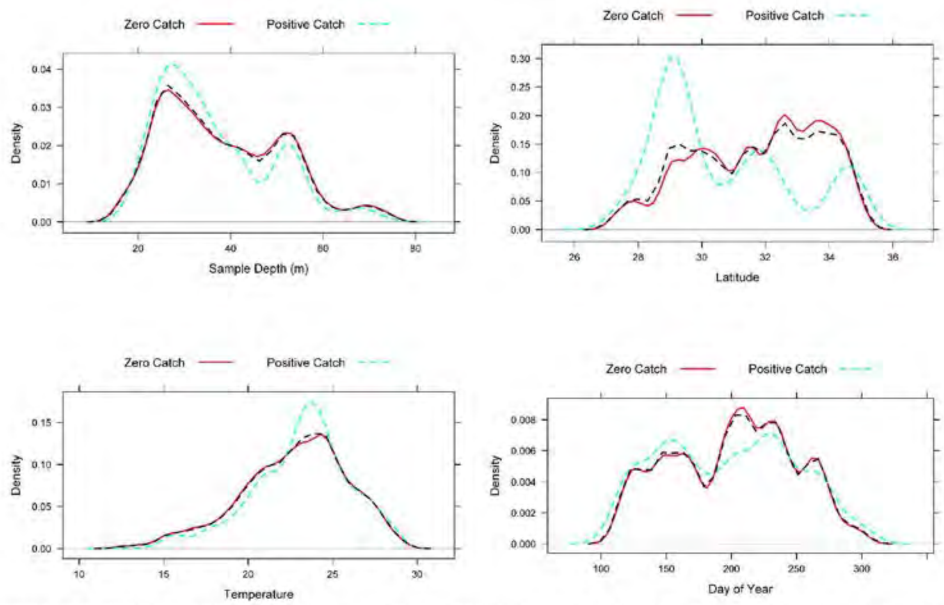

Figure 4: Density plots of all traps (2010-2016; dashed black line), negative (red line) and positive (dashed blue line) for Red Snapper with respect to each covariate considered in the model.

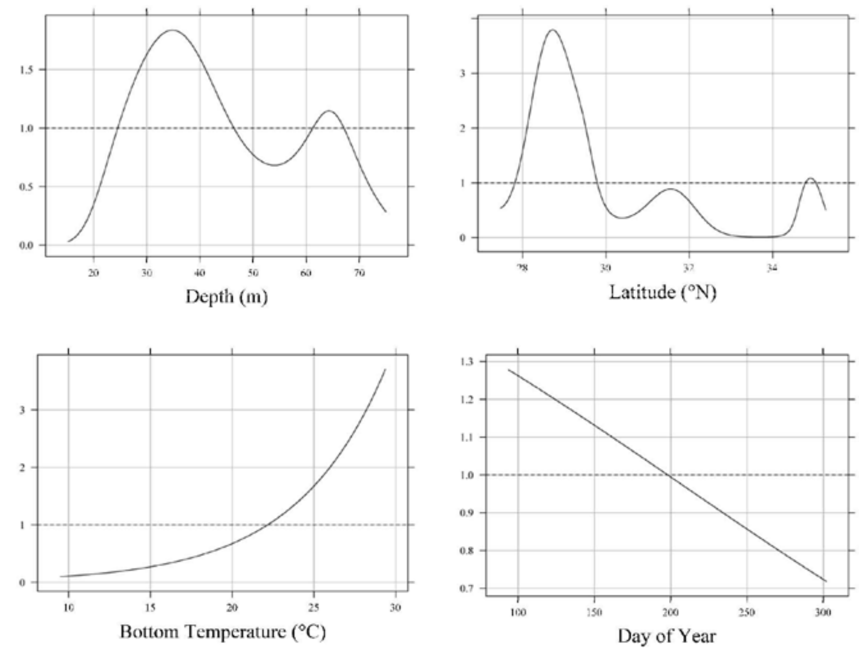

Figure 5: Predicted relative effect of each covariate on the catch of Red Snapper in chevron traps using the 1990-2016 data set. Note that the scale of the y-axis changes among panels, and hence y-axis scale can provide an indication of the magnitude of the effect of individual covariates.

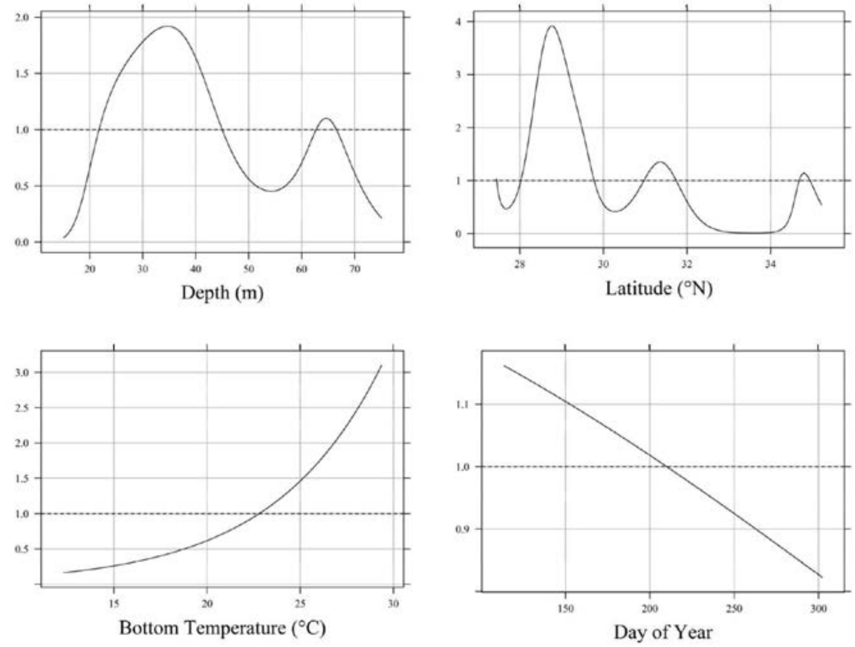

Figure 6: Predicted relative effect of each covariate on the catch of Red Snapper in chevron traps using the 2010-2016 data set. Note that the scale of the y-axis changes among panels, and hence y-axis scale can provide an indication of the magnitude of the effect of individual covariates.

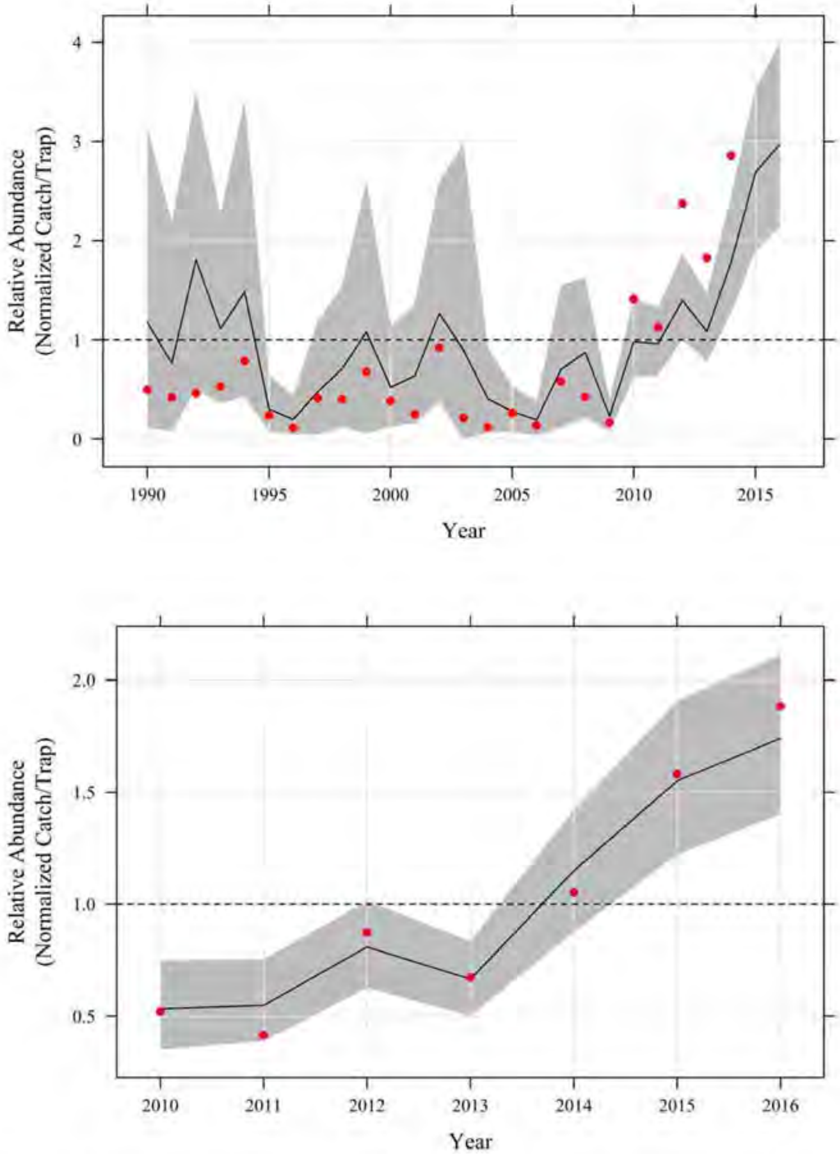

Figure 7: Red Snapper index of relative abundance based on the SERFS chevron trap survey. Top panel is the index based on the years 1990-2016. Bottom panel is the index based on the years 2010-2016. The ZINB standardized catch (solid black line) is normalized to the average relative abundance, as estimated by the model, during each surveys respective time series. Red dots represent normalized nominal annual relative abundance. Gray shaded region represents the 95% confidence interval of annual relative abundance based on 10,000 bootstraps.

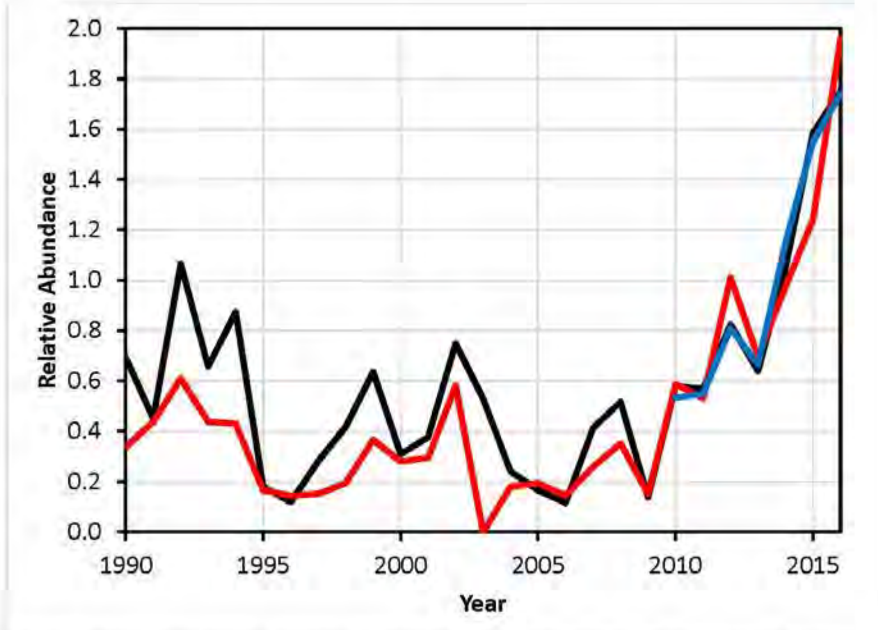

Figure 8: Red Snapper index of relative abundance based on the SERFS chevron trap survey, with annual relative abundance being normalized to the average relative abundance from 2010-2016. The different lines represent the relative abundance index developed using the full chevron trap time series and the methodology reported in Ballenger and Smart (2015; black line), the relative abundance index developed using the full chevron trap time series and the methodology reported in the SCDNR Reef Fish Survey 2016 trends report (red line), and the relative abundance index developed using only chevron trap data collected from 2010-2016 and the methodology reported in Ballenger and Smart (2015; blue line). The surveys are normalized to the average relative abundance from 2010-2016 here so that predicted changes in relative abundance in the overlapping period can be more easily compared.

Appendix M. Scientific and Statistical Committee October 2016 Final Report

SOUTH ATLANTIC FISHERY MANAGEMENT COUNCIL

SCIENTIFIC AND STATISTICAL COMMITTEE

SSC Meeting Report

Oct 18-20, 2016

Charleston Marriott Hotel
Charleston, SC

VERSION
Final Report
November 29, 2016

CONTENTS

revised NS1 Guidelines. Mr. Shepherd Grimes (NOAA General Council) clarified that the phase in needs to be part of the fisheries management plan and the ABC control rule. The requirement that Councils cannot exceed the ABC recommendations of the SSC is not overruled by the flexibility allowance. The FMP and control rule would specify the conditions under which the phase-in would occur and how the ABC is developed when a phase-in is considered.

- *A phase-in that reduces the buffer between the overfishing level and the allowable catch increases the risk of ending up in an overfished situation and a rebuilding plan, especially as overages have occurred in recent (3-4) years.*
- *If council chooses to phase-in the ACL, SSC recommends considering management uncertainty and recent overages. The SSC recommends that the ACL should not exceed 90% of the OFL in year one because the ACL was exceeded in recent years.*
- *In addition to revising the ABC control rule, new projection estimates will need to be provided if a phased-in approach is chosen.*

- Also consider providing a constant ABC for later years, specified in 3-year blocks.

Consistency in the ACL will make it easier for holders of the tilefish endorsements to adjust their business models. However, the economic analysis in Amendment 18B that led to the restriction of tilefish access rights to a limited number of endorsement holders noted that both the ACL and average trip costs would have to remain static in order for the remaining operations to maintain profitability. The IFQ system in the Wreckfish fishery was able to adjust to a much sharper reduction in its ACL through the sale of shares to the members of the fleet that utilized them most profitably.

Amendment 43 ACT alternative: Chip Collier, SAFMC

7.3. Overview

The Committee reviewed the Red Snapper Benchmark assessment prepared through SEDAR 41 and provided fishing level recommendations at their May 2016 meeting. The base assessment run suggested that in the terminal year of 2014 the stock remained overfished. The SSC did not have confidence in the terminal fishing mortality estimates; however they recommended that the assessment results suggested overfishing was likely occurring in the terminal years of the assessment (2012-2014). , although the degree to which overfishing was occurring at that time could not be reliably quantified from the assessment results. Status determination and catch level recommendations provided by the SSC in May 2016 were based on the current F_{MSY} proxy of $F_{30\%SPR}$.

SEDAR 41 estimated the long-term sustainable yield at MSY to be about 25% of what it was estimated to be in SEDAR 24, and projected catch levels from SEDAR 41 at $F_{Rebuild}$ were approximately 21% of the catch levels projected for 2017 based on SEDAR 24. Given the lack of an estimated stock recruitment relationship and the need to fix steepness in SEDAR 41 at a level different than that used for SEDAR 24, and considering the importance of the stock-recruit parameters to the reference point recommendations, the Council directed the SSC to recommend an appropriate F_{MSY} proxy for red snapper that reflects the most recent assessment results. The Council requested additional projection runs and reference point criteria at F_{MAX} and $F_{20\%SPR}$, for the SSC to consider.

There was also concern over the amount of uncertainty in the recreational landings and discard estimates used in SEDAR 41. Recent landings estimates have a high degree of error associated with them, which is partially due to the difficulties of generating estimates during the recent moratoriums and short mini-seasons. Discard estimates also exhibit high sampling error. Due to these recreational data uncertainties the Council requested that the SSC evaluate the current MRIP estimates (landings and discards) for Red Snapper to determine if they are reliable and adequate for management.

The Council has also begun work on Amendment 43 to address alternative management strategies for Red Snapper. Although the Amendment is still in the early stages, there are items the Council would like the SSC's feedback on, such as the MSY (Action 1 in Amendment 43), specifying ABC and Annual Catch Limit (ACL) in landings versus landings and discards (Action 3), and calculating the annual catch target (ACT; Action 4). Attachment 23 has the three actions highlighted here for SSC review copied to the front of the document after the purpose and need for the amendment for ease of SSC review. The full options paper is provided after the Actions 1, 3 and 4 to provide background information and all other proposed action and alternatives.

The Council requested the SSC discuss the risk associated with using different values of MSY (Action 1). The MSY alternatives in the options paper include F_{MAX}, $F_{20\%}$, $F_{26\%}$, $F_{30\%}$, and $F_{40\%}$. Projections are provided for F_{MAX}, $F_{20\%}$, $F_{27\%}$, and $F_{30\%}$ in Attachment 21.

There are slight differences between the alternatives and the projections because the alternatives in the amendment were developed after the request for projections was sent the SEFSC.

The Council requested the SSC comment on the risk of specifying the ABC and ACL in landings or landings + discards (Action 3). The current ABC is based on landings and dead discards and the ACL is based on landings only. The discards are not tracked for any other fish in the South Atlantic and compared to the ABC, which includes landings and dead discards. However, the largest component of fishing mortality for Red Snapper in the last five years came from the dead discards in the recreational fishery.

The calculation of the ACT (Action 5) includes a new method for review by the SSC (Alternative 4). The new method reduces the ACT from the ACL based on the average percentage the annual landings exceeded the ACL based on a selected timeframe. The timeframe for the ACT calculation was based on 2012 to 2014 when short seasons were opened for Red Snapper.

Table 3. Red Snapper Recommendations from the May 2016 SSC Meeting

Criteria			**Deterministic**	**Probabilistic**
Overfished evaluation ($SSB_{2014}/SSB_{30\%}$)			0.16	0.17

2018	204,000	210,000	19,000	37,000
2019	230,000	227,000	21,000	39,000
ABC RECOMMENDATIONS				
Year	Landed LBS	Discard LBS	Landed Number	Discard Number
2017	165,000	179,000	17,000	33,000
2018	195,000	200,000	18,000	35,000
2019	220,000	218,000	20,000	37,000

7.4. Action

- Evaluate the MRIP estimates for Red Snapper

- Determine if they are reliable and adequate for management, including quota monitoring and discard information.

- Consider alternative reference points
  - Comment on the risk of using alternative SPR metrics in lieu of $F_{30\%SPR}$ in determining stock status and running projections.
  - Review the projections at F_{MAX} and $F_{20\%SPR}$.
  - Update or revise fishing level recommendations as appropriate.

- Amendment 43 ACT alternative (Action 4)
  - Discuss the pros and cons of the proposed alternative method for calculating the ACT.
  - What are the benefits to using the proposed methodology over the Council's current ACT rule of (1-PSE)*ACL?

SSC RECOMMENDATIONS:

- Evaluate the MRIP estimates for Red Snapper
  - Determine if they are reliable and adequate for management, including quota monitoring and discard information.
    - *The number of intercepts is relatively low and the expansion factors relatively high, with the highest number of intercepts in Florida.*
    - *The SSC realizes that these estimates are influential in assessments and management. By design, 90% of the effort is focused on "inshore" areas, while the remainder is focused "off-shore". Better data would be ideal, such as surveys focused on off-shore trips. The SSC realizes that while these estimates are influential in assessments and management, they are currently all there is. Uncertainties and use of data was discussed extensively at the SEDAR 41 Data Workshop and during the review.*
    - *The SSC agrees that all sources of mortality should be considered; therefore the ABC should be specified in total yield (landings + discards). Not accounting for dead discards in management increases the risk of overfishing ("a dead fish is a dead fish").*
    - *Discard mortality will remain one of the key issues. Assessment estimates and projections can be significantly improved if reliable estimates of discards and discard mortality are improved. As a result, efforts to better estimate and validate discards and discard mortality should be given a very high research and survey priority.*
    - *Similarly, the proportion of stock yield available for harvest can increase if discard mortality is reduced, e.g. by the use of descending devices or other descending techniques, or avoiding areas with high concentrations of red snapper. Release mortality*

studies could improve discard mortality estimates, and should be given a high research priority. Such studies could include evaluation of existing devices and release methods, and development of alternative methods. It will be important to evaluate acceptance of these techniques by fishers.

- *In addition, other data collection approaches should be studied, such as those in the GOM (stamp), as recommended in the new approach the Council put forth.*
- *The PSE could be informative in determining the adequacy of estimates. An ACCSP Workshop report (available on the ACCSP website) suggested PSEs higher than 40% to 60% may not be usable. However, higher levels were acceptable for short-lived species or those with low levels of recreational catch.*
- *Simulation evaluation could be used to determine the effect of differing PSE values on the resulting reference points.*
- *The incorporation of uncertainty in the catch data is dependent on the chosen method of assessment. We currently use catch-based assessments, which assume the catch is known with very little error. Moving to an effort-based assessment or a Bayesian framework would allow fitting to the catch and better incorporate the estimates of uncertainty (PSE) into the assessment.*

- Consider alternative reference points
  - Comment on the risk of using alternative SPR metrics in lieu of $F_{30\%SPR}$ in determining stock status and running projections.

    By definition F_{MAX} and $F_{20\%}$ have a higher risk of overfishing than $F_{30\%spr}$ or $F_{40\%spr}$. Furthermore, the analyses presented to the SSC indicated that the various alternatives ($F_{20\%}$, $F_{27\%}$, $F_{30\%}$, and F_{max}) showed very similar results and the changes in yield were minimal. It is the opinion of the SSC that there is no compelling reason to change the proxy based on the data presented, and even if a different metric is chosen (other than $F_{30\%}$), the status determination and yield will not change substantially. Scientific literature supports that longer lived species should have a higher percentage of SPR, which supports maintaining $F_{30\%}$ at a minimum.
  - Review the projections at F_{MAX}, $F_{20\%SPR}$, and $F_{27\%SPR}$.

    See above.
  - Update or revise fishing level recommendations as appropriate.
    - *Previous SSC discussions and the RW reports discussed the MSY proxy issues. No new data have become available to justify a revision of the fishing level recommendations.*

- ➢ *A retrospective analysis would be useful to investigate the "overfishing uncertainty" between the proposed F_{MSY} proxies.*

- Amendment 43 ACT alternative (Action 4)
  - Discuss the pros and cons of the proposed alternative method for calculating the ACT.
  - What are the benefits to using the proposed methodology over the Council's current ACT rule of (1-PSE)*ACL?
    - ➢ *The use of an ACT and chosen buffer is a management decision, but having an ACT is preferable over not having one because:*
      - *Provides buffer from the ACL. Using a percentage of the ACL recognizes that catches may not be known precisely.*
      - *Could be used for in-season monitoring, and can be adjusted as time progresses, management changes, and data collection improves.*
      - *It is consistent with Gulf methodology. ACT based on performance – evaluation of proportional overages over time, similar to alternative 6.*
    - ➢ *Does not consider uncertainty in the point estimates of the landings as Alt 2 does. Alt 2 accounts for the observed uncertainty in the catch estimates.*

Changes to the ABC Control Rule: John Carmichael, SAFMC

8.3. Overview

During the October 2014 ABC Workshop, several issues with the ABC Control Rule were identified, including the use of stock status, MRAG Productivity and Susceptibility Analysis scores and catch adequacy in determining the P* value for Tier 1 stocks . Other concerns include the overly prescriptive nature of Levels 2 and 3 that could be viewed as precluding consideration of newly developed data poor assessment methods and the lack of clarity on application of the ABC Control Rule in developing annual catch level recommendations for stocks in a rebuilding plan. The SSC created a sub-committee to develop recommendations for control rule revisions. At the May 2016 meeting, the SSC discussed the results of analyses that had been put together by the ABC Control Rule sub-

Appendix N. Commercial Sector Projected Seasons

Predicting Closure Dates for Amendment 43 Proposed Catch Limits for the South Atlantic Red Snapper Commercial Sector

LAPP/DM Branch
NOAA Fisheries Service
Southeast Regional Office

In 2016, a stock assessment was conducted for the South Atlantic red snapper (SEDAR 41). Results from the assessment showed the red snapper stock is overfished and experiencing overfishing. Amendment 43 to the Fishery Management Plan for the Snapper Grouper Fishery of the South Atlantic Region (Amendment 43) is currently being drafted and its purpose is to establish new Annual Catch Limits (ACL) that will rebuild the stock.

Amendment 43 is currently being drafted and will likely be imposed on the 2018 fishing year. An estimate of future landings is required to determine potential closure dates for the alternative ACLs being considered. Frequently future landings are predicted from taking an average of the most recent years of complete data following the assumption that recent landings will likely reflect future landings. However, the South Atlantic red snapper fishery was closed in 2010, 2011, 2015 and 2016, and was only open for short periods of time (57 days or less) in 2012, 2013, and 2014. The short opening in 2012, 2013, and 2014 occurred over different months; therefore, landings from different months and years were combined to predict future landings. Commercial landings for South Atlantic red snapper came from the Southeast Fisheries Science Center's (SEFSC) updated commercial ACL dataset, which was provided on May 2, 2017. The commercial fishery will open on the second Monday of July and, if the ACL is not exceeded, close on December 31. Future landings were only predicted for July through December. Future landings were determined by calculating the daily catch rate for a month and then applying the catch rate to the total number of days in that month. Predicted landings for each month assumed a uniform distribution within a month, and were partitioned into a daily catch rate by dividing the landings for a month by the number of days in that month. The daily catch rates were projected forward and a closure date was determined when the landings exceeded the various ACLs proposed in Amendment 43. The projections start on July 9 because this is the second Monday of July in 2018, therefore landings were assumed to be zero before July 9.

- July 2014 was the most recent year when the commercial sector was open in July, and the commercial sector was open from July 14 through July 31. The July daily catch rate was applied for 22 days in July to match a potential opening in 2018.

- Future August landings were assumed to match the August 2014 landings because this was the most recent time period when the commercial sector was open for the entire month of August.
- Future September landings were assumed to match the September 2013 landings because this was the most recent year where the commercial sector was open for the entire month of September.
- October of 2013 was the most recent year when the commercial sector was open in October and the sector was open from October 1 through October 8 of 2013. Future October landings were determined from calculating the daily catch rate from October 2013 and then applying the catch rate to the total number of days in October (31 days).
- The most recent years where the commercial sector was open in November and December was in 2012 (8 days in November and 7 days for December). However, a reduced trip limit of 50 pounds gutted weight (lbs gw) was implemented in 2012 which is different than the trip limit of 75 lbs gw which was implemented in 2013 and continues today. A trip limit analysis was done for the red snapper temporary rule in 2012 (Red Snapper Rule 2012) and found that a change in the trip limit from 50 to 75 lbs gw resulted in a 51% increase in landings. Following the trip limit analysis done for the red snapper temporary rule, the landings in 2012 were increased by 51% to adjust for the increased trip limit from 50 to 75 lb gw. These modified landings were used to determine future November and December landings from calculating the daily catch rate within each month when they were open in 2012. The catch rate was applied to the total number of days in each month. Details of the landings used to create the predicted landings are shown in Table 1, and Figure 2 displays landings by month.

Table 1. Details of the commercial landings used to determine the predicted future commercial landings for red snapper.

Month	Most Recent Year	Days open	Method
July	2014	17 days	Determined July 2014 average daily catch rate; applied catch rate to open days in July
August	2014	31 days	Used August 2014 landings
September	2013	30 days	Used September 2013 landings
October	2013	8 days	Determined October 2013 average daily catch rate; applied to open days in October
November	2012	8 days	Landings adjusted for trip limit, then determined November 2012 average daily catch rate; applied to open days in November
December	2012	7 days	Landings adjusted for trip limit, then determined December 2012

			average daily catch rate; applied to open days in December

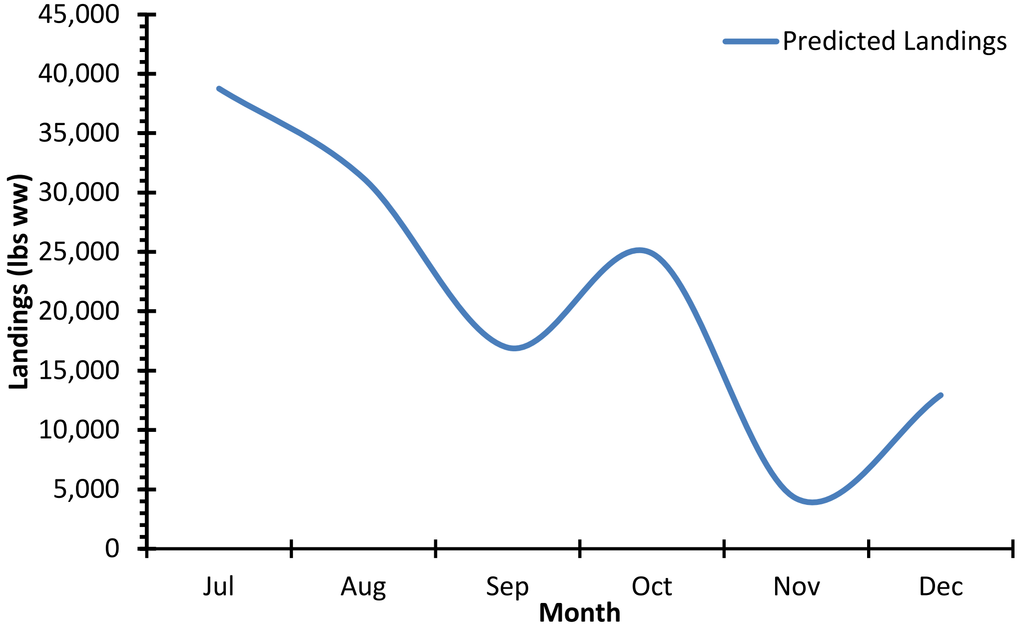

Figure 1. Predicted South Atlantic red snapper commercial landings by month. The commercial sector is expected to open on the second Monday in July and close at the end of December, therefore, landings were only predicted for July through December.

Amendment 43 includes different alternatives to develop ACLs. Some of the alternatives are increased by an adjustment factor due to an increase in red snapper abundance based on a fish trap index of abundance. The adjustment factor is 1.88 and is based on the change in the average index of abundance from 2012 to 2014 compared to the average abundance from 2015 to 2016. Opening the fishery to an increased stock size will likely cause changes in harvest. The question is how will the harvest change in the commercial sector? There likely won't be any new commercial fishermen harvesting red snapper because the number of commercial fishermen is capped because the permit is limited access. Also, the harvest per trip is capped by a 75 pound trip limit. The fishermen could do more trips for red snapper but it is not likely they will go fishing solely for red snapper because of the low trip limit (75 lbs gw). It's more likely that the increased stock size will cause more trips to meet the trip limit. This potential change in pounds per trip was analyzed by first examining the distribution of pounds per trip with the commercial logbook data (accessed April 17, 2017 from SEFSC). Figure 2 displays the pounds per trip distribution for the two most recent years that had the 75 lbs gw trip limit (2013 and 2014). Following the assumption that trips that did not meet the trip limit will now meet the trip limit the logbook landings were modified. For example, trips that harvested red snapper and had less than 60 pounds per trip were modified to meet the 75 lbs gw trip limit. Trips of 60 lbs gw or more were assumed to have been close to meeting the current trip limit and were not modified. This modification leads to an increase in landings of 34%. This percentage was applied to the predicted landings describer earlier to provide a "high landings" estimate. Table 2 provides the predicted closure dates for the proposed

ACL alternatives for Amendment 43 for both landings predictions. If the ACL is not met and there is no closure then the predicted commercial landings expected from July 9 to December 31 are 118,950 pounds whole weight (lbs ww) and the predicted high landings for the same time period are expected to be 159,393 lbs ww.

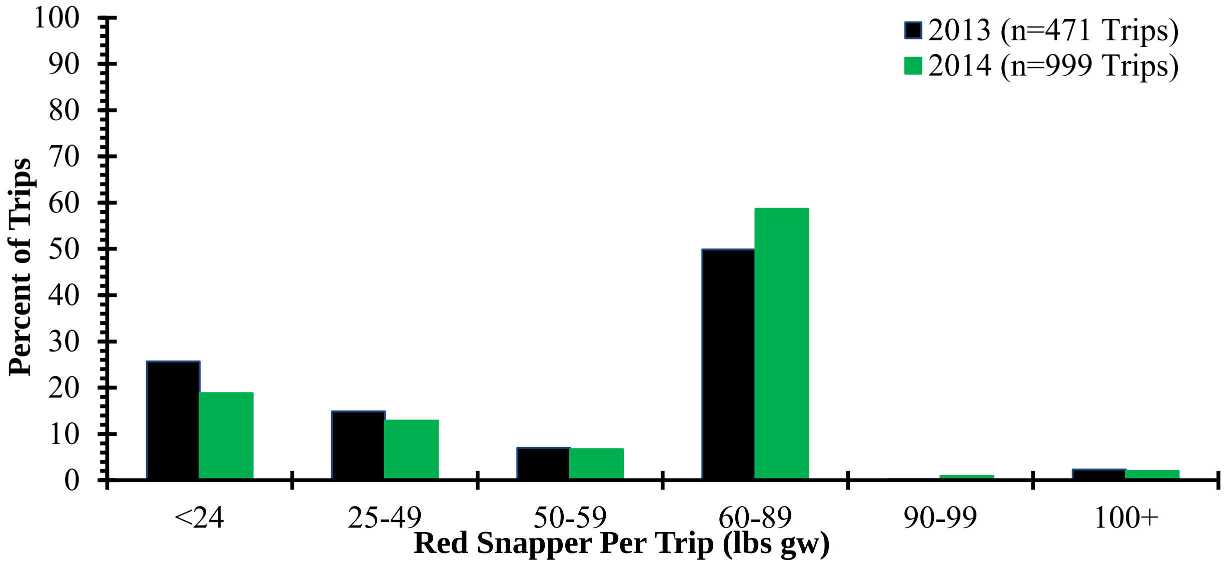

Figure 2. Distribution of the South Atlantic red snapper harvested per trip (lbs gw) in 2013 and 2014. Data comes from the commercial logbook dataset.

Table 2. South Atlantic predicted closure dates for the commercial sector for the different proposed ACL alternatives in Amendment 43. These closure dates assume the commercial sector start on the second Monday in July of 2018 (July 9, 2018). The "Predicted Landings" are a prediction of future landings, and the "High Landings" are the prediction of future landings with a 34% increase in landings following the assumption that more fishermen will meet the trip limit of 75 lbs gw due to an increased stock size. Alternative 1 states to be determined (TBT) because it's dependent on the total removals of 2017 which are not available at this time.

	Alternative 1	Alternative 2	Alternative 3	Alternative 4	Alternative 5
ACL	TBT	69,360 lbs ww	130,396 lbs ww	124,815 lbs ww	234,652 lbs ww
Predicted Landings	TBT	17-Sep	No Closure	No Closure	No Closure
High Landings	TBT	23-Aug	26-Nov	21-Oct	No Closure

As with most projections, the reliability of the results is dependent upon the accuracy of the underlying data and input assumptions. This analysis attempted to create a baseline as a foundation for comparisons, under the assumption that projected past landings will accurately reflect actual future landings. Uncertainty exists in this projection, as economic conditions, weather events, changes in catch-per-unit effort, fisher response to management regulations, and a variety of other factors may cause departures from this assumption.

Appendix O. Recreational Sector Projected Seasons

Predicting Closure Dates for Amendment 43 Proposed Annual Catch Limits for the South Atlantic Red Snapper Recreational Sector

LAPP/DM Branch
NOAA Fisheries Service
Southeast Regional Office

In 2016, a stock assessment was conducted for the South Atlantic red snapper (SEDAR 41). Results from the assessment showed the red snapper stock is overfished and experiencing overfishing. Amendment 43 to the Fishery Management Plan for the Snapper Grouper Fishery of the South Atlantic Region is currently being drafted and its purpose is to establish new Annual Catch Limits (ACL) that will rebuild the stock.
The recreational season for South Atlantic red snapper was closed in 2010 and 2011, then had a very short season in 2012, 2013, and 2014. The season varied each year and included two weekends (6 days) during September 2012, one weekend (3 days) in August 2013, and three weekends (8 days, with the third weekend only open on Friday and Saturday) during July 2014. Due to a short season and limitations of Marine Recreational Fisheries Statistics Survey (MRFSS) the South Atlantic states (North Carolina, South Carolina, Georgia, east Florida) conducted their own state specific red snapper surveys during the short red snapper recreational seasons in 2012, 2013, and 2014. A red snapper mini-season ad-hoc group call and webinar was held to review the MRFSS and individual state red snapper surveys to determine the best estimates to use to characterize the recreational catch. The ad-hoc group compared MRFSS against the specific state surveys for each state looking closely at estimates by wave and year. Then the ad-hoc group determined which survey best characterized the recreational catch. For example, in some years MRFSS was chosen as providing the best estimate of landings in Georgia but other years the Georgia state survey was chosen. Following the recommendations determined from the ad-hoc group the recreational red snapper landings were compiled. However, since the recent assessment (SEDAR 41) used Marine Recreational Information Program (MRIP) instead of MRFSS in any cases where the MRFSS landings were chosen as the best estimate of landings these MRFSS landings were replaced by MRIP landings. The recreational sector was closed in 2015 and 2016 and there were no state specific surveys during these years. Therefore, MRIP landings were used for 2015 and 2016 landings. Also, the Southeast Region headboat survery (SRHS) was conducted from 1972 to 2016 and was used to provide the red snapper landings from the headboat mode. Table 1 reveals which recreational survey was chosen by the ad-hoc group to estimate the recreational landings for each state by mode and year. Table 2 summarizes the South Atlantic red snapper recreational landings in numbers of fish by wave.

Table 1. The recreational survey that was chosen by the ad-hoc group to estimate the recreational landings for each state by mode and year.

Year	State	Charter	Private	Headboat
2012	NC	MRIP	No Landings	SRHS
	SC	SC Survey	No Landings	SRHS

	GA	MRIP	MRIP	SRHS

Table 2. South Atlantic red snapper recreational landings in numbers of fish by wave from 2012 to 2016.

	Jan/Feb	Mar/Apr	May/June	Jul/Aug	Sep/Oct	Nov/Dec	Total
2012	1	478	353	79	14,080	0	14,991
2013	0	2	403	2,050	4,160	14	6,629
2014	1,151	45	722	28,798	19	334	31,069
2015	0	847	467	486	56	14	1,870
2016	0	1	188	205	3	6	403

Amendment 43 is currently being drafted and will likely be implemented in the 2018 fishing year. An estimate of future landings is required to determine if the alternative ACLs being considered will lead to a closure. Frequently future landings are predicted from taking an average of the most recent years of complete data following the assumption that recent landings will likely reflect future landings. However, the South Atlantic red snapper recreational fishery was closed in 2010, 2011, 2015 and 2016, and was only open for short periods of time 2012 (6 days), 2013 (3 days), and 2014 (8 days). The short opening in 2012, 2013, and 2014 occurred over different months; therefore, landings from different months and years were combined to predict future landings. Recreational landings for South Atlantic red snapper came from the annual total removals reports provided by the Southeast Fisheries Science Center's (SEFSC) and then when MRFSS landings were used they were replaced with MRIP landings. MRIP landings were provided by the SEFSC on June 7, 2017. The recreational fishery will open on the second Friday of July and, if the ACL is not exceeded, close on December 31. Future landings were only predicted for July through September because the recreational ACLs proposed in Amendment 43 are relatively low and all of the proposed ACLs will likely be exceeded before the end of September. Future landings were determined by calculating the daily catch rate for a month and then applying the catch rate to the number of weekend days in that month (Friday, Saturday, and Sunday). Predicted landings for each month assumed a uniform distribution within a month, and were partitioned into a daily catch rate by dividing the landings for a month by the number of days in that month. The daily catch rates were projected forward and a closure date was determined when the landings exceeded the various ACLs proposed in Amendment 43. The projections start on July 13 because this is the second Friday of July in 2018, therefore landings were assumed to be zero before July 13. Additionally, the recreational season will only be open on Friday, Saturday, and Sunday. Therefore, landings were only predicted for each Friday, Saturday, and Sunday after July 13, 2018 and landings from Monday to Thursday were assumed to be zero.

- July 2014 was the most recent year when the recreational sector was open in July, and the recreational sector was open for 8 days. The July daily catch rate was applied to the open weekend days in July to match a potential opening in 2018.
- August 2013 was the most recent year when the recreational sector was open in August, and the recreational sector was open for 3 days. The August daily catch rate was applied to the open weekend days in August to match a potential opening in 2018.
- September 2012 was the most recent year when the recreational sector was open in September, and the recreational sector was open for 6 days. The September daily catch rate was applied to the open weekend days in September to match a potential opening in 2018.

Table 1. Details of the recreational landings used to determine the predicted future recreational landings for red snapper.

Month	Most Recent Year	Days open	Method
July	2014	8 days	Determined July 2014 average daily catch rate; applied catch rate to open days in July
August	2013	3 days	Determined August 2013 average daily catch rate; applied catch rate to open days in August
September	2012	6 days	Determined September 2012 average daily catch rate; applied catch rate to open days in September

Amendment 43 includes different alternatives to develop ACLs. Some of the alternatives are increased by an adjustment factor due to an increase in red snapper abundance based on a fish trap index of abundance. The adjustment factor is 1.88 and is based on the change in the average index of abundance from 2012 to 2014 compared to the average abundance from 2015 to 2016. Opening the fishery to an increased stock size will likely cause changes in harvest. The adjustment factor of 1.88 was applied to the landings to provide a “high landings” estimate to replicate what the future harvest will be with an increased stock size. The bag limit is restricted to one fish per person and the recreational ACL is in numbers of fish so the size of fish is irrelevant for monitoring the ACL. Therefore, the “high landings” assumes more recreational trips will harvest red snapper because of the increase in red snapper abundance. Table 2 provides the predicted closure dates and predicted number of open days for the proposed ACL alternatives for Amendment 43 for both landings predictions.

Table 2. South Atlantic predicted closure dates and predicted number of open days for the recreational sector for the different proposed ACL alternatives in Amendment 43. The predicted number of open days is provided in parenthesize after the closure dates. These closure dates assume the recreational sector start on the second Friday in July of 2018 (July 13, 2018). The “Predicted Landings” are a prediction of future landings, and the “High Landings” are the prediction of future landings with a 1.88 adjustment factor following the assumption of a larger stock size. Alternative 1 is stated as to be determined (TBT) because it’s dependent on the total removals of 2017 which are not available at this time.

	Alternative 1	Alternative 2	Alternative 3	Alternative 4	Alternative 5
ACL	TBD	16,480 Fish	30,982 Fish	29,656 Fish	55,753 Fish
Predicted Landings	TBD	21-Jul (4)	28-Jul (7)	28-Jul (7)	15-Sep (28)
High Landings	TBD	15-Jul (2)	21-Jul (4)	21-Jul (4)	29-Jul (8)

As with most projections, the reliability of the results is dependent upon the accuracy of the underlying data and input assumptions. This analysis attempted to create a baseline as a foundation for comparisons, under the assumption that projected past landings will accurately reflect actual future landings. Uncertainty exists in this projection, as economic conditions, weather events, changes in catch-per-unit effort, fisher response to management regulations, and a variety of other factors may cause departures from this assumption.

Science and Research Director

SUBJECT: Red Snapper Guidance Request

The SEFSC concurs with the SEDAR Review Panel and SAFMC SSC's approval of SEDAR 41, the red snapper stock assessment. The SSC developed ABC recommendations based on the projection analysis that allowed the stock to reach a rebuilt status in the time allowed by the rebuilding plan (by 2044). The use of an ABC based primarily on fishery discards for monitoring the effectiveness of management action is likely ineffective due to the high level of uncertainty in measures of discards and the change in the effort estimation methodology that will be implemented in the MRIP survey.

Monitoring progress toward rebuilding will require a departure from the traditional techniques. SEFSC analysts are exploring an Index Projection Methodology as an alternative approach for monitoring stock response to management measures. They plan to discuss this with the SSC at their upcoming meeting to get input on the method. They will also discuss how these results may be used by the SSC to generate future catch level advice, given updated projections have not been provided. Information for the SSC regarding this is attached.

At the last SAFMC meeting we discussed holding a workshop to discuss ways to characterize the uncertainty of MRIP estimates (landings, discards) to provide guidance on: 1) at what point the uncertainty is sufficiently high to warrant alternative methods for accounting for catch; 2) what those alternative methods might be; 3) means to improve the precision of MRIP catch estimates; and 3) means to augment MRIP sampling to improve data quality. The SAFMC recognized this is a region-wide issue so a presentation was made to the GMFMC to request involvement of their SSC, and the GMFMC has agreed to participate. It has also been suggested that representation from the Mid-Atlantic Fishery Management Council may be advisable. We'll begin to stand up a steering committee to refine the workshop objectives, define the deliverables and begin work on the agenda. One deliverable from the workshop could evaluate the precision of red snapper discard estimates to help advise on their use for monitoring stock status when discards are the predominant contributor to fishing mortality. The target timeline for the workshop is this fall, however, we'll have more clarity on the timeline for delivery of advice to the SSC once the steering committee is stood up and begins their work on workshop planning.

SSC Input for April 2017 Meeting

The SAFMC SSC reviewed and approved the SEDAR 41 Red Snapper stock assessment in May 2016. The SSC developed ABC recommendations based on the projection analysis that allowed the stock to reach a rebuilt status in the time allowed by the rebuilding plan (by 2044). In our memo of February 15, 2017, the SEFSC indicated reasons why any further proposed projections would not be appropriate for management. These reasons revolve around the uncertainty and methodology changes for future estimates of discards from the MRIP survey. Non-traditional methods and data sources may need to be used to monitor management action effectiveness and progress toward rebuilding.

The SEFSC proposes creating and an Index Projection Methodology that uses trends in the fishery-independent survey to monitor rebuilding progress and serve as the basis for the SSC's future ABC advice to the Council.

The SEFSC would like to get feedback from the SSC on this proposed approach. Specifically:

1. The SEFSC is actively working on research into using SERFS video data to monitor future effectiveness of management actions, i.e. progress toward rebuilding. We ask the SSC to provide input on this proposed approach and its potential utility for determining management action effectiveness.
2. Discuss options for the appropriate baseline against which to compare the Index Projection.
3. Discuss how the index may be used by the SSC to develop ABC advice.

Dr. Erik Williams will be preparing a brief summary of the proposed approach and will be on hand to answer any questions the SSC may have at their next meeting.

We appreciate the SSC taking time to provide input on new methodology that has the potential to benefit management.

SUBJECT: Red Snapper Guidance Request

At its March 2017 meeting, the South Atlantic Council requested that its SSC and the SEFSC work together to obtain an ABC for Red Snapper. This request was in response to two letters from NMFS addressing the status of Red Snapper. The first letter, from the SEFSC dated February 15, 2017 (**attached**), indicated that projections the Council requested in January 2017 could not be completed due to uncertainty in the assessment and the MRIP discard estimates. This letter also indicated that a complete evaluation of MRIP changes on the Red Snapper assessment (SEDAR 41) is necessary before it can be useful to management. The second letter, from SERO dated March 3, 2017 (**attached**), noted the SSC's concerns with uncertainty in the SEDAR 41 assessment and the resulting inability to reliably determine the degree of overfishing. In addition, NMFS noted that the assessment indicated overfishing was occurring during its terminal year of 2014 but the Council's actions to limit harvest since 2010, including harvest prohibitions in effect since 2015, have addressed overfishing and allowed the stock to continue rebuilding.

The SSC reviewed the SEDAR 41 Red Snapper assessment in May 2016 and considered it Best Scientific Information Available. However, because the Council has been informed in the past that SSC conclusions on BSIA are in fact recommendations, and that NMFS is actually responsible for the BSIA determinations, the Council requests the following:

1. The SEFSC concur with our determination that alternative methods are necessary to specify ABC and MSY for red snapper and that SEDAR 41 (original and revised) cannot be used to specify ABC or MSY for 2017 and beyond for the reasons outlined in your memo to Michelle Duval dated February 15, 2017. This is necessary to inform the SSC on the status of its existing ABC recommendation and to determine which sources of information used in the SEDAR 41 assessment can be considered for future ABC recommendations.

2. The SEFSC provide an evaluation of data limited techniques that can be considered by the SSC to develop an index-based ABC.

3. The SEFSC provide additional details on the proposed evaluation of the effect of MRIP changes on the Red Snapper assessment, particularly the types of evaluations to be considered and when they will be available for SSC review.

Given that the SEFSC will be providing the SSC a revised SEDAR 41 Red Snapper assessment to correct errors with some of the headboat input data, it is critical that a response to these issues also be provided to the SSC. This will help inform the SSC on how to view the revised assessment.

Please provide this information needs to Council staff by noon on April 10, 2017 to be distributed to the SSC for review at their April 25-27, 2017 meeting. This is a complex matter and the SSC needs adequate time to review the revised assessment and responses prior to their meeting.

Please contact John Carmichael to address any questions concerning this request.

15 February, 2017

MEMORANDUM FOR: Gregg Waugh, Executive Director
South Atlantic Fishery Management Council

FROM: Bonnie J. Ponwith, Ph.D.
Science and Research Director

SUJBECT: **Red Snapper Projections**

On January 18, 2017, you sent a memo requesting, "Provide projections to 2044 (the end of the rebuilding period) based on fixed fishing mortality rates at Fmax, F20%SPR, F27%SPR, F30%SPR, and F40%SPR under the assumptions that all fish caught at each F level are subsequently discarded and the scenario mortality level is the total mortality (i.e., there are no additional discard mortalities). For each scenario, provide the full suite of projection outputs as provided for SEDAR 41 projections."

In working on those projections, Southeast Fisheries Science Center staff have advised, and I concur, that the proposed projections are not appropriate for management use for the following reasons:

- The uncertainty in the assessment is already large, and will increase due to the MRIP discard data, especially for the interim period (2015-16), the upcoming changes to MRIP from the new effort survey. For some background: the uncertainty in projections is generally high after 3-5 years, and these projections would have 2-3 years of an interim period (depending on whether 2017 or 2018 was the effective year of regulations).
- The SAFMC SSC has indicated that overfishing for this stock is occurring, but cannot quantify by how much. Fishing mortality rates in the last few years of the assessment are very sensitive to 2014 data and retrospective analyses indicate fishing mortality rates are considerably lower if these data are excluded. This uncertainty in the stock assessment inhibits the ability to set an ABC that can be effectively monitored.
- Fishing mortality in the interim period is calculated using actual landings and discards in 2015, though the status was determined using fishing mortality when there was a fishery occurring during mini-seasons (2012-2014). There were no fishing seasons for red snapper in 2015 or 2016 and final 2016 MRIP data are not yet available.
- The MRIP telephone survey will end this year and be replaced by a new mail-based effort survey. The new effort survey will be calibrated with the old telephone survey and undergo peer-review this summer. Preliminary results from the calibration study will be available in late-2017 and final results incorporating all three years of side-by-

side surveys will be available in 2018. Projections timed to benefit from the completed calibration study would be stronger than if based on the preliminary results.

- We feel that a more complete evaluation of the effect of the upcoming changes to MRIP on the Red Snapper assessment is needed before it can be useful to management.
    - We further recommend a thorough investigation, possibly through a workshop, into the reliability and utility of mail survey based MRIP estimates of catch and discards for many of our offshore species, which are known to have low intercept rates relative to other species covered by MRIP.

Dr. Michelle Duval, Chair
South Atlantic Fishery Management Council
4055 Faber Place Drive, Suite 201
North Charleston, South Carolina 29405

MAR 03 2017

Dear Dr. Duval:

The most recent South Atlantic red snapper stock assessment (SEDAR 41) was completed in April 2016 and indicated that the stock is undergoing overfishing and is overfished, but is rebuilding. The South Atlantic Fishery Management Council's (Council) Scientific and Statistical Committee (SSC) reviewed the assessment and determined the assessment is based on the best scientific information available. However, the SSC noted there is considerable uncertainty in the exploitation status, and thus, the degree of overfishing is highly uncertain. The uncertainty in exploitation status inhibits the Council's ability to set an acceptable biological catch that can be effectively monitored. Additionally, in the February 15, 2017, response to a Council request for red snapper projections, Dr. Bonnie Ponwith, Director of the National Marine Fisheries Service (NMFS) Southeast Fisheries Science Center noted that the overfishing determination was based on fishing mortality levels during 2012-2014 when a limited amount of harvest was allowed. Landings during 2012-2014 represented a high fraction of the overall fishing mortality, but since that time, harvest has been prohibited. Dr. Ponwith also noted that the uncertainty in the assessment is large and is predicted to increase as catch and effort estimates are updated through the new Marine Recreational Information Program (MRIP) effort survey.

NMFS has determined that the latest assessment identified the South Atlantic red snapper stock as undergoing overfishing, and adequate management action has been taken to address overfishing and continue to rebuild the stock through a harvest prohibition in 2015 and 2016. Due to uncertainty in the level of overfishing associated with the assessment and the new MRIP effort survey, data poor assessment methods for the red snapper stock, such as use of fishery independent indices, may be appropriate in the future. I look forward to continuing work with the Council on Amendment 43 to the Fishery Management Plan for the Snapper-Grouper Fishery of the South Atlantic Region to reduce discards of red snapper in the South Atlantic and continue to rebuild the stock.

Sincerely,

Roy E. Crabtree, Ph.D.
Regional Administrator
