SEDAR 38 Update

South Atlantic King Mackerel

Stock Assessment Report

Apr 2020

SEDAR
4055 Faber Place Drive, Suite 201
North Charleston, SC 29405

This information is distributed solely for the purpose of peer review. It does not represent and should not be construed to represent any agency determination or policy.

Table of Contents

1. Executive Summary

- The Stock Synthesis model for South Atlantic King Mackerel (SEDAR 38) was updated to fishing year 2017 (Mar 2017-Feb 2018), incorporating five years of additional data. All life history assumptions, including stock structure and mixing, and model configuration remained unchanged from the final decisions of SEDAR 38. The principal findings included:

- The South Atlantic stock of King Mackerel was determined to be NOT OVERFISHED and the fisheries are NOT OVERFISHING.

- Stock and fishery status determinations were consistent across model sensitivities and diagnostic runs. Primarily, the status determinations did not change under alternative assumptions of steepness that ranged 0.4 to 1.0, and unfished age-0 recruitment levels that ranged 8 million to 12 million fish. For reference, the peak number of fish caught by the recreational fleets was 1.4 million fish in 2007.

- Total biomass and spawning stock biomass estimates increased steadily since 2013. All fishery indicators (fleet CPUEs and scientific survey) showed positive trends since SEDAR 38.

- Stock Synthesis estimated a recent period (2013 to 2016) of above average age-0 recruitments, contrasting the period prior (2008 to 2012) of below average recruitments first detected during SEDAR 38. Two particularly high recruitment years were estimated for 2015 and 2016, supported by the juvenile survey observations in 2016 (SEAMAP trawl survey), as well as fleet length compositions.

- Observations by stakeholders may help validate the model predictions, given the distinct change in signal from five-years of low recruitment up to SEDAR 38 to four years of recent high recruitment. The fish would have entered the fisheries beginning in fishing year 2015, with relatively high abundance beginning in fishing year 2017, particularly of fish between 24 and 36 inches fork length.

- The projected yield estimates (in millions of lbs) of South Atlantic King Mackerel by fishing year were:

Fishing Year	p*=0.1	p*=0.2	p*=0.3	p*=0.4	OFL
2021	27.7	30.0	31.6	33.0	34.3
2022	22.9	25.2	26.8	28.2	29.5
2023	19.8	22.1	23.7	25.1	26.3
2024	17.8	20.0	21.6	22.9	24.2
2025	16.3	18.5	20.1	21.5	22.7

  - The equilibrium yield at the biomass reference point (SPR=30% Unfished) was 18.3 million pounds
  - The optimum yield ($F=0.75*F_{SPR30}$) estimate was 16.7 million pounds
  - For reference, the average yield between 2016 and 2017 was 9.6 million pounds

2. Data Updates

All data were summarized by fishing year (FY), defined as March 1st of the current year to February 28th of the following year (29th during leap years). For example, the 2020 FY is March 1, 2020 to February 28, 2021. The following list summarizes the main data inputs and data assumptions for the assessment:

2.1. Life history
- The life history assumptions of SEDAR 38 remain unchanged.

2.2. Landings
- Commercial Handline: 1929 to 2017 FY, measured in metric tons
- Commercial Gillnet: 1949 to 2017 FY, measured in metric tons
- Recreational Headboat: 1936 to 2017 FY, measured in number of fish
- Recreational Charter/ Private: 1946 to 2017 FY, measured in number of fish
- Recreational Tournament: 1946 to 2017 FY, measured in number of fish

2.3. Discards
- Commercial Combined: 1998 to 2017 FY, measured in number of fish
- Recreational Headboat: 1987 to 2017 FY, measured in number of fish
- Recreational Charter/ Private 1981 to 2017 FY, measured in number of fish
- Recreational Tournament: 1981 to 2017 FY, measured in number of fish
- Shrimp Bycatch: 1978 to 2017 FY, measured in number of fish

2.4. Length composition of landings
- Commercial Handline: 1984 to 2017 FY
- Recreational Headboat: 1984 to 2017 FY
- Recreational Charter/ Private: 1984 to 2017 FY
- Recreational Tournament: 1984 to 2017 FY

2.5. Length composition of discards
- Discards for all fleets were assumed to be age zero based on a review of available observer information.

2.6. Age composition
- Commercial handline: 1991 to 2017 FY
- Recreational Charter/ Private: 1986 to 2017 FY
- Recreational Tournament: 1986 to 2017 FY

2.7. Abundance indices
- Fishery-dependent
    - Commercial hook and line trolling: 1998 to 2017 FY
    - Recreational headboat: 1980 to 2017 FY
    - Recreational charter/private, 1981 to 2017 FY (evaluated but not used in SS3)

- Fishery-independent
    - SEAMAP Age-0 Trawl: 1981 to 1982, 1984 to 2017 FY

Detailed descriptions of the datasets were provided in the SEDAR 38 Stock Assessment Report (https://sedarweb.org/docs/sar/SEDAR_38_SA_SAR.pdf, Section II). CPUE index and survey standardization methods remained unchanged.

2.1 Life history

Stock structure and mixing assumptions remained unchanged from SEDAR 38 (https://sedarweb.org/docs/sar/SEDAR_38_SA_SAR.pdf, SECTION II, Subsection 2.3). The stock delineations and mixing zone boundaries (**Figure 2.1**) were defined to be:

(1) South Atlantic King Mackerel stock ranges from North Carolina to Florida at the Monroe-Dade counties line during November 1st to March 31st, and North Carolina to Florida including Monroe County south of the Florida Keys during April 1st to October 31st,
(2) the Gulf of Mexico King Mackerel stock ranges from Texas to Florida including Monroe County north of the Florida Keys during all months of the year, and
(3) the winter mixing zone is defined to be Monroe County, Florida, south of the Keys during November 1st to March 31st.

King Mackerel natural mortality, fecundity, and maturity assumptions remain unchanged from SEDAR 38 (**Table 2.1)**. Life history parameters with fixed input values (i.e. not estimated in SS3) included natural mortality-, fecundity-, and maturity-at-age. Growth was estimated as gender-specific von Bertalanffy models fitted to empirical observations of annual length-at-age within SS3. Final growth parameter estimates from SEDAR 38 were used as starting values (**Table 2.2**).

2.2 Landings

Commercial landings in the South Atlantic were predominantly from trolling and other hook and line gears (handlines), followed by gillnets (**Table 2.3, Figure 2.2**). Landings (in metric tons) were estimated from 1929 to 2017 for handlines, and from 1949 to 2017 for gillnets.

Recreational landings were predominantly from private and charter boats, followed by headboats, and tournaments (**Table 2.3, Figure 2.3**). Recreational landings were measured in numbers of fish and total landings were estimated for the period 1946 to 2017 for charter and private fisheries; and for the period 1936 to 2017 for the headboat fishery. No direct estimates of tournament landings were available. Tournament landings started in 1980, ramped up to be 3% of recreational private landings to 1990, and assumed 3% of charter/private recreational landings for the duration of the time series. Relative landings by fleet, estimated in metric tons (numbers of fish were converted to biomass using SS3), are compared in **Figure 2.4**.

Recreational landings estimation methods for charter/private (CP/PR) vessels were based on fishing effort statistics from the FES, a notable change in methodology from SEDAR 38. The differences between estimated recreational landings from SEDAR 38 to the current assessment are shown in **Figure 2.5**. There was a clear increase in landings of the recreational CP/PR fleet. An observed decrease in headboat (HB) total removals (**Figure 2.5**) was due to fewer estimated dead discards (based on the ratio of HB to CP/PR landings, so when CP/PR increased the HB ratio decreased). Tournament catches were approximated as 3% of CP/PR and the change in estimated landings follows the CP/PR fleet (**Figure 2.5**). The effect of these changes in recreational landings were evaluated as sensitivity runs of SEDAR 38 with the recreational charter and private landings and discards time series in SEDAR 38 base model replaced with the revised estimates. The effect of decreased HB removals was also evaluated as a sensitivity run of SEDAR 38.

2.3 Discards

Discard estimation methods for commercial gears, including shrimp discards, remain unchanged from SEDAR 38 (https://sedarweb.org/docs/sar/SEDAR_38_SA_SAR.pdf, Section III, subsections 3.5 and 4.4). Commercial discards from the handline and other fisheries that target King Mackerel were minimal (less than 5%) relative to landings (**Table 2.4, Figure 2.6**).

Recreational discard estimates were revised from SEDAR 38, based on FES effort statistics. Estimates of King Mackerel recreational discards were provided for the periods 1987 to 2017 for recreational headboats, and 1981 to 2017 for recreational charter and private fisheries. Headboat discards were minimal in comparison to all other fleets. Discards of King Mackerel from recreational fisheries are predominantly from the private and charter boat fisheries, believed to be a result of size and bag limit regulations. The change to FES resulted in an increase in CP/PR discards, and decrease in HB discards (**Figure 2.7**). These revised estimates were included in the sensitivity analysis of the SEDAR 38 model.

Discard mortality assumptions remained unchanged from SEDAR 38, and were as follows: 20% discard mortality from commercial handline fisheries, 100% discard mortality for the gillnet and shrimp trawl fishery, 22% discard mortality for the recreational headboat fishery, and 20% discard mortality for recreational private, charter, and tournament fisheries.

2.4 Length composition of landings

The annual length compositions of landed King Mackerel during fishing years 2013 to 2017 are shown by fishery in **Figure 2.8**. Length composition from the period prior remain unchanged from SEDAR 38. Length observations were binned across 5cm groups with a minimum size of 20cm and a maximum size of 160cm. Due to defined size limit regulations, length observations below the size limits were excluded from length compositions under the assumption that the harvest of sublegal fish is negligible compared to documented landings and estimated discards. In practice, even small numbers of fish below defined fleet retention limits can create substantial modeling instability or bias. Therefore, the assumption that all retained fish were above the legal size limit for both commercial and recreational fisheries was maintained from SEDAR 38.

2.5 Length composition of discards

The size of discarded fish from commercial and recreational fisheries remained unchanged from SEDAR 38. Fish were assumed to be all age-0, undersized individuals (< 50cm fork length) for all fleets except recreational tournaments. The sizes of fish released during tournaments followed a retention function adopted during SEDAR 38 (Idhe et al 2014, Miller et al 2014).

2.6 Aging data

Age data were collected primarily from the commercial handline fishery, and to a lesser extent, the charter, private, and tournament fisheries. No recent age data were available for the gillnet or headboat fleets. Age observations were summarized by year and fleet for the period FY 2013-17 (**Figure 2.9)**. The distributions of observed sizes-at-age of males and females (**Figure 2.10**), aggregated across time, provided validation of gender-specific growth patterns, a key population dynamic modeled in SEDAR 38.

2.7 Indices

Data standardization methods for the indices of relative abundance remained unchanged from SEDAR 38. Three CPUE indices were included in the assessment that included the commercial trolling handline index, the recreational headboat index, and the SEAMAP trawl fishery independent survey. The updated standardized indices are provided in **Table 2.5** and plotted in **Figure 2.11**. The recreational charter/private index is shown for comparative purposes, but was not modeled in SS3.

2.8 Tables

Table 2.1. Life history assumptions of South Atlantic King Mackerel input as fixed parameters in SS3.

	Age-0	Age-1	Age-2	Age-3	Age-4	Age-5	Age-6	Age-7	Age-8	Age-9	Age-10	Age-11+
Nat. Mort.	0.657	0.247	0.224	0.208	0.195	0.186	0.178	0.172	0.167	0.163	0.160	0.157

2.9 Figures

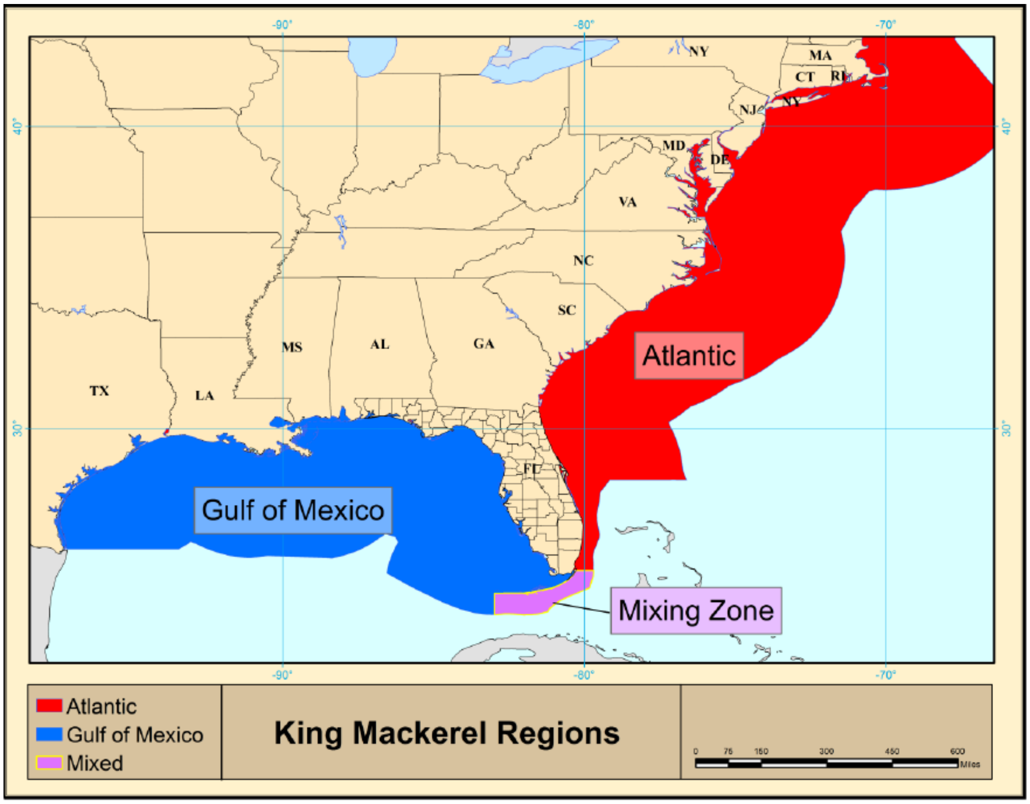

Figure 2.1. Regional stock boundaries used to aggregate landings for the stock assessments of South Atlantic and Gulf of Mexico King Mackerel.

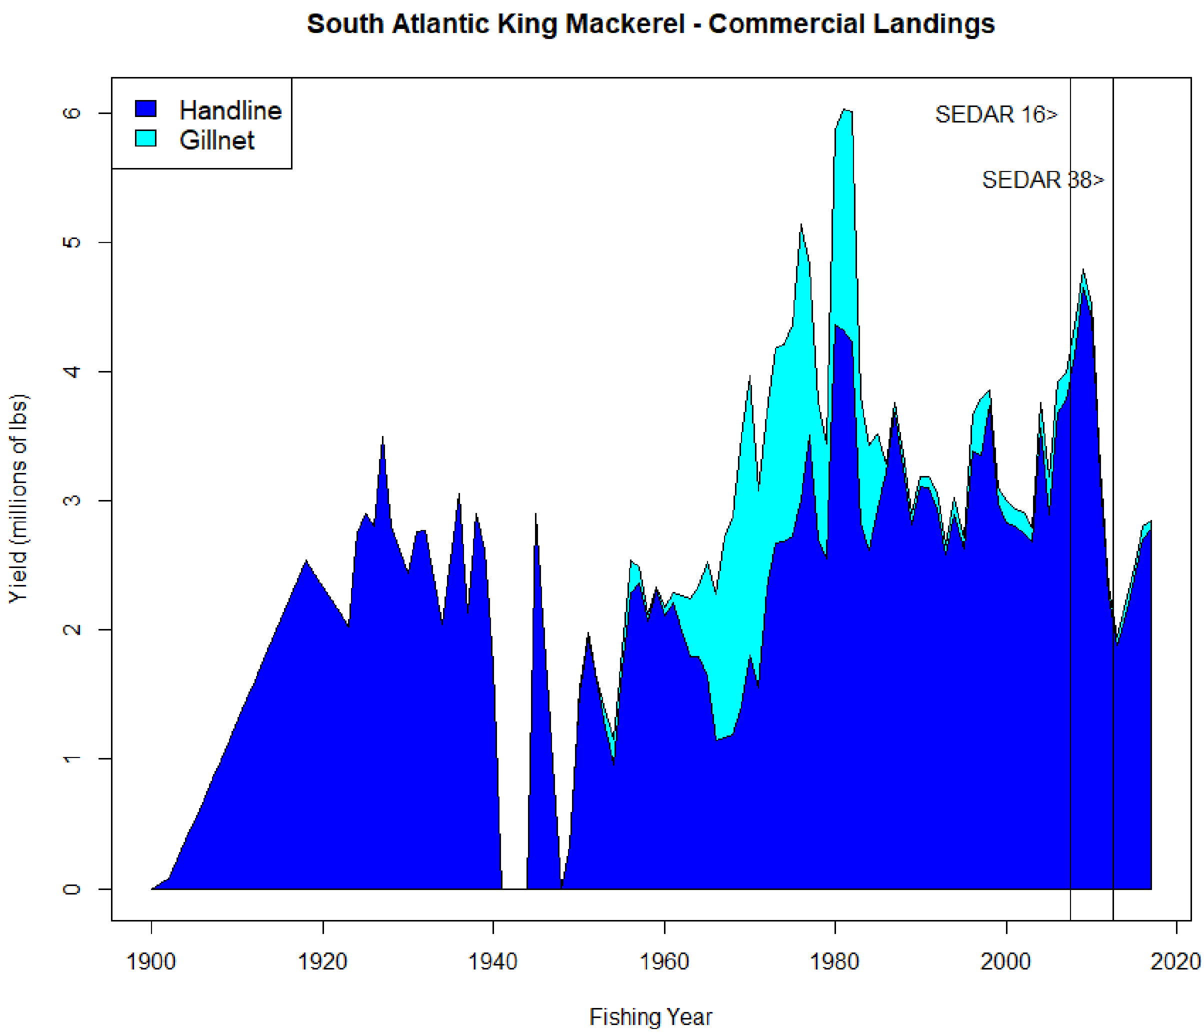

Figure 2.2. Estimated commercial landings of South Atlantic King Mackerel from directed fleets (measured in metric tons whole weight).

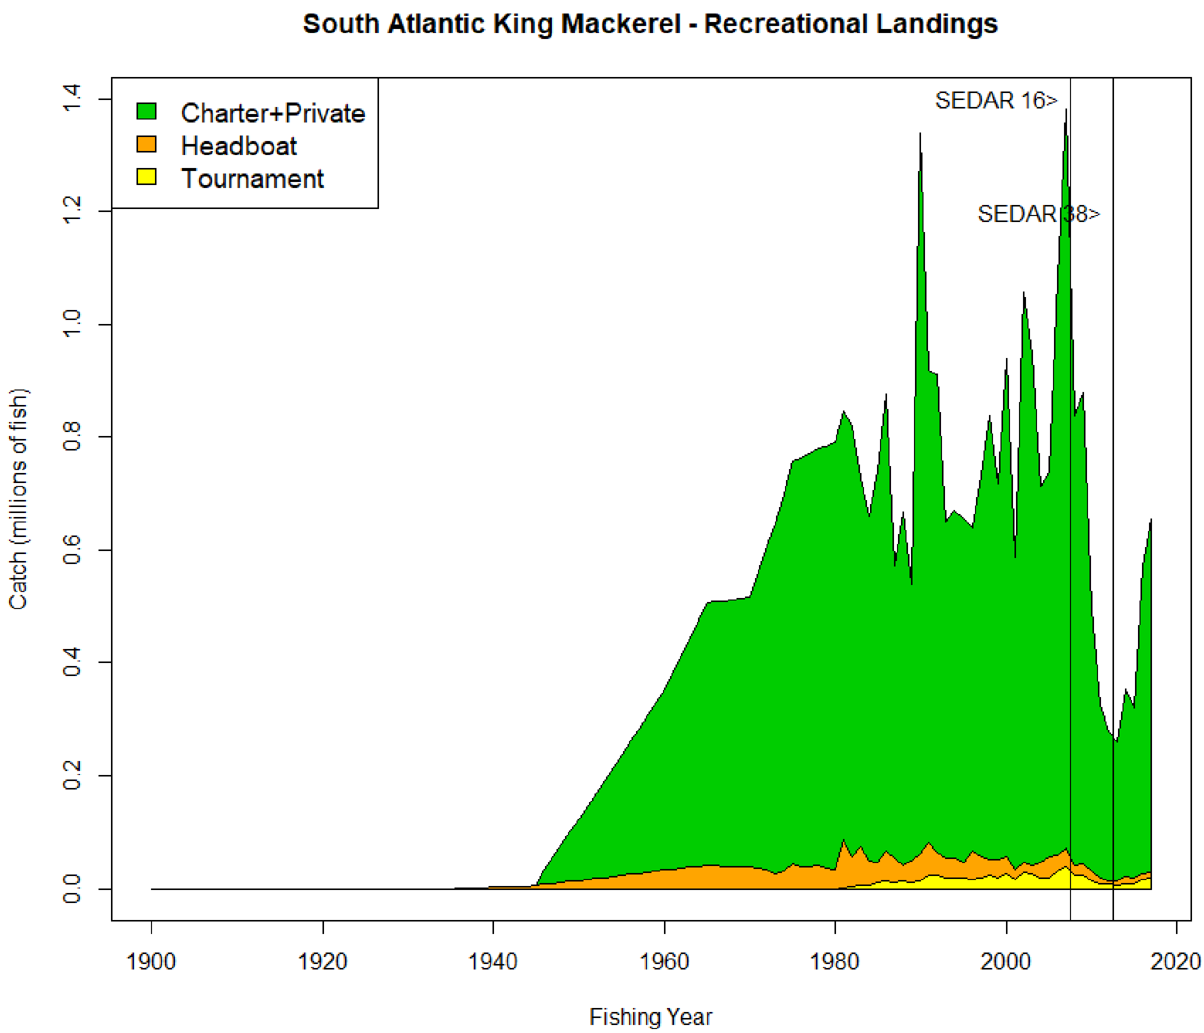

Figure 2.3 Estimated recreational landings of South Atlantic King Mackerel.

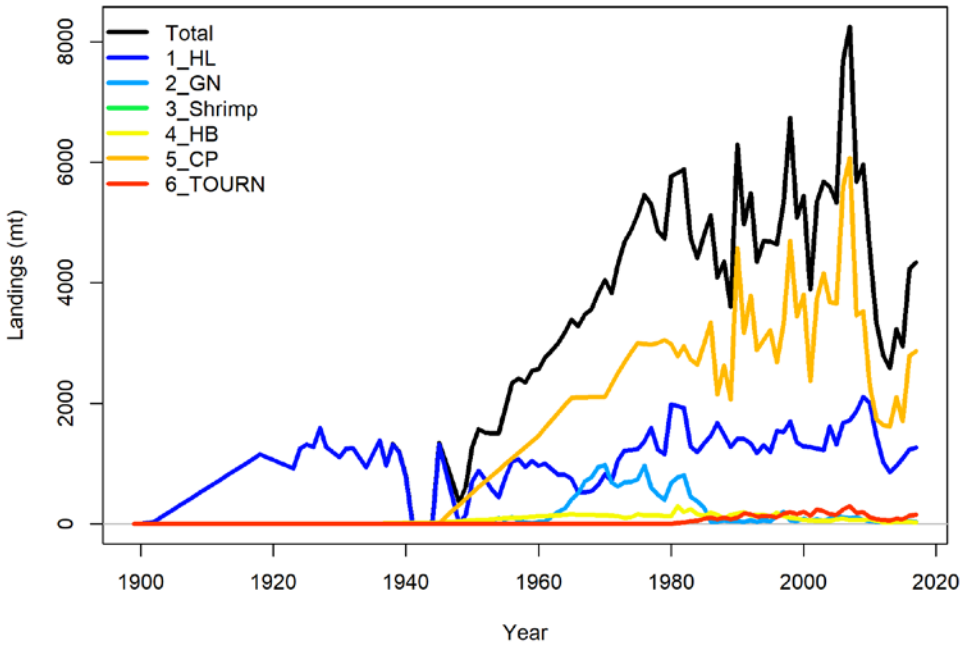

Figure 2.4. Total estimated landings of South Atlantic King Mackerel in metric tons.

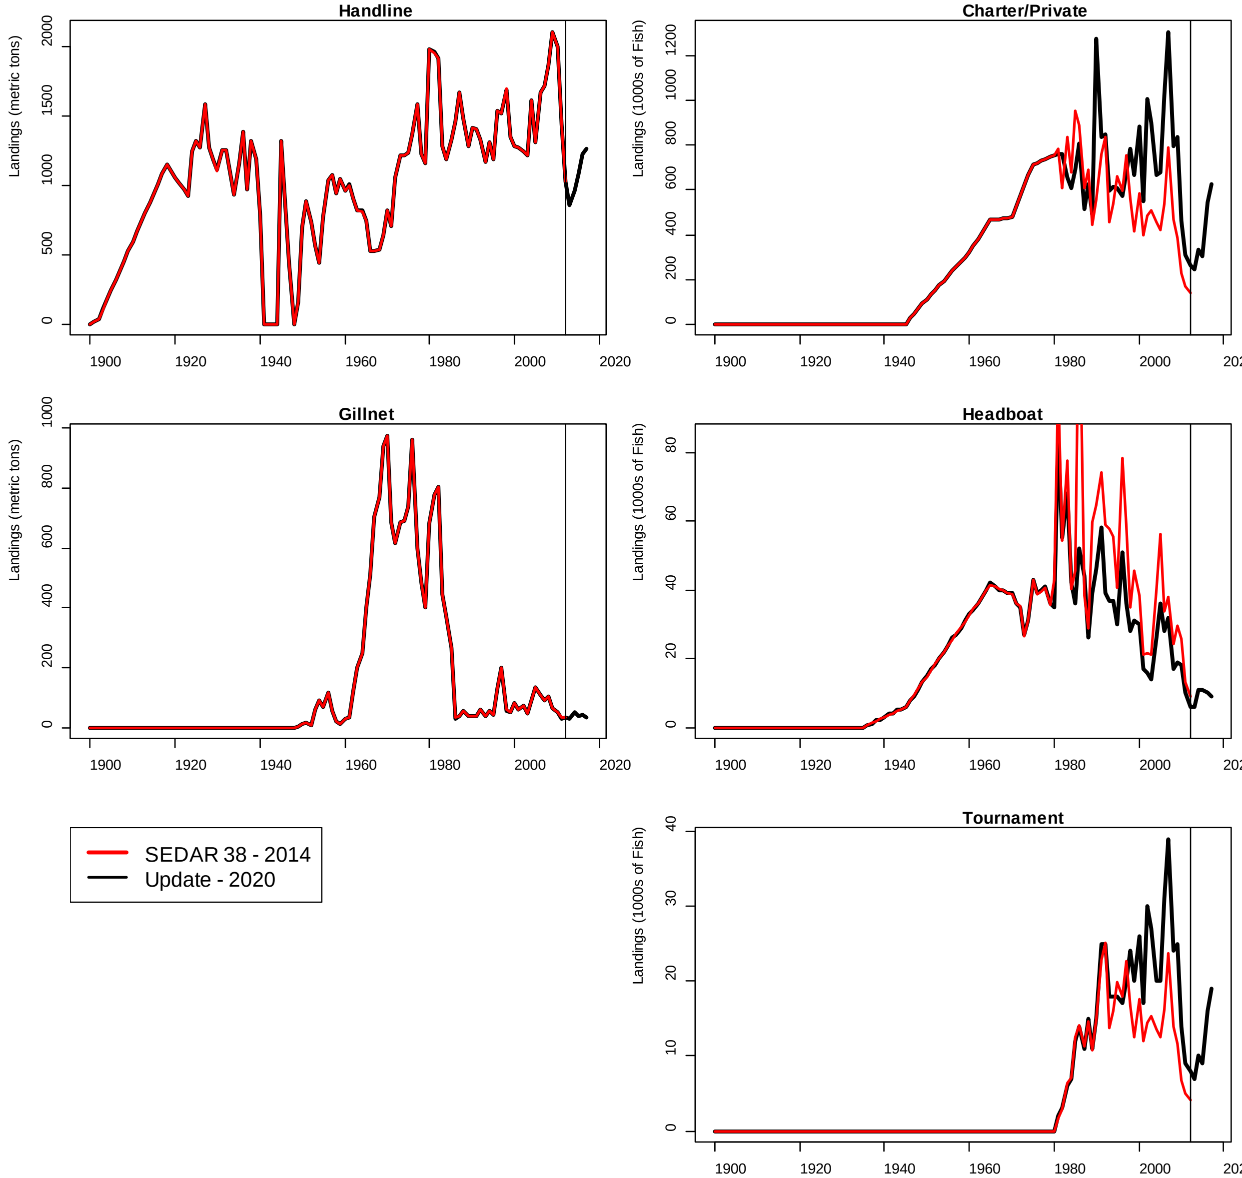

Figure 2.5. Comparison of removal estimates (landings plus dead discards) between SEDAR 38 (red lines) and the 2020 updated assessment (bold black lines). The vertical line indicates the terminal year of data from SEDAR 38. The change in recreational landings estimates was attributed to different methodologies for estimating recreational effort from the MRIP Coastal Household Telephone Survey to the Fishing Effort Survey. There was a notable increase in the estimates of fishing landings and discards of the recreational charter/private (CP/PR) fleet. The decrease in headboat (HB) total removals is due to fewer estimated dead discards (based on the ratio of HB to CP/PR landings, so when CP/PR increased the HB ratio decreased). Tournament catches were approximated as 3% of CP/PR and the change in estimated landings follows the CP/PR fleet.

3. Stock Assessment Methods

The assessment model in SEDAR 38 was Stock Synthesis (Methot 2013) version 3.24s (SS3). Stock Synthesis has been widely used and tested for population assessment, and is the predominant modeling platform for most current SEDAR assessments. Descriptions of SS3 algorithms and capabilities are available in the SS user's manual (https://www.st.nmfs.noaa.gov/Assets/science_program/SS_User_Manual_3.24s.pdf) and Methot and Wetzel (2013).

SS3 is an integrated statistical catch-at-age model that incorporates many of the important processes (mortality, fishery selectivity, growth, reproduction, etc.) that operate in conjunction to predict annual size-at-age, total removals (landed as well as discarded), fleet length compositions, age compositions, and fleet catches-per-unit-effort. Many of these processes are interrelated, and therefore the associated model parameters are correlated. SS3 provides a statistical platform to integrate these different metrics into an overall objective function, and in turn, account for the joint uncertainty of biological processes and fishery dynamics. SS3 is comprised of three subcomponents: 1) a population subcomponent that recreates an estimate of the numbers/biomass at age using estimates of natural mortality, growth, fecundity, etc.; 2) an observational sub-component that consists of observed (measured) quantities such as CPUE or proportion at length/age; and 3) a statistical sub-component that uses likelihoods to quantify the fit of the observations to the recreated population.

Prior to integrating the updated data series into the South Atlantic King Mackerel assessment, two sensitivity runs of the SEDAR 38 SS3 base model were completed to directly estimate the effects on the stock assessment resulting from the change in recreational fishing effort statistics from the MRIP Coastal Household Telephone Survey to the Fishing Effort Survey (FES). This approach provided an efficient method of evaluating the model effects of changes in recreational landings and discards associated with the FES.

Once the analyses of FES effects on the assessment were completed, the model was updated with all revised data series. Biological assumptions and SS3 configurations remain unchanged from SEDAR 38, and a detailed description of the model can be found here: https://sedarweb.org/docs/sar/SEDAR_38_SA_SAR.pdf. Data series timeframes and overlap are shown in **Figure 3.1**. A brief overview of model parameterization follows.

- **Growth** was modeled in SS3 as a three-parameter von Bertalanffy model (Lmin, Lmax, and K) with separate curves (growth morphs) estimated for males versus females.
- **Spawning output** was a function of individual weight under fixed assumptions of maturity-at-age and weight-based fecundity (**Figure 3.2**).
- **Natural mortality** was estimated externally from SS3 assuming a Lorenzen (1996) function based on mean size-at-age, and scaled to an average M value of 0.16, inferred from the maximum observed age of 26 (Hoenig 1983). The Lorenzen natural mortality values were input into SS3 as fixed parameters (**Table 2.1**).

- **Stock-recruitment** assumed a Beverton-Holt relationship with two estimated parameters, the log of unexploited equilibrium recruitment (R0) and standard deviation in recruitment deviations (σR). Steepness (h) was fixed at 0.99.
- **Recruitment deviations** were estimated for the period 1981-2017 during which length composition data exist, as well as aging estimates post-1990.
- **Starting state** assumed unfished conditions at the model start year (1900) when fishing mortalities for all fleets were assumed equal to 0. Historical landings were reconstructed back to the initiation of the fishery during SEDAR 38, and these estimates remained unchanged.
- **Fishing fleets** represented six different commercial and recreational sectors with separate selectivity patterns, including commercial handline, commercial gillnet, shrimp trawl bycatch, recreational headboat, charter/private, and tournament.
- **Indices of relative abundance** included two fishery-dependent indices (commercial handline- trolling only and recreational headboat) and one fishery independent survey (SEAMAP South Atlantic trawl survey). Indices were weighted by standardization model estimated coefficients of variation.
- **Aging data** were input as annual conditional-age-at-length, the count of aged fish by 5 cm length bins, input separately for males and females for the commercial handline and recreational charter/private, and recreational tournament.
- **Length compositions** were input as fork length measurements in 5cm bins ranging from 20 to 160 cm, input separately by gender when known (or as unknown gender when not sexed) and fleet.
- **Fleet selectivities** were estimated as gender-specific, length-based double normal (handline, gillnet, headboat, charter/private) or logistic (tournament) functions for all fisheries except the SEAMAP survey and the shrimp bycatch which were assumed to catch age-0 fish. Due to changes in tournament dynamics from aggregate catch awards to single trophy fish prizes, a time block on selectivity was imposed beginning in 1997 when the change occurred.
- **Time-varying retentions** were defined to account for minimum size limit regulations, which have changed multiple times. The breaks on these time blocks were 1989, 1990, 1992, 1999 and each coincide with a change in the size or retention limit. Retention was modeled as a knife-edged step function of size, with the probability of being retained based on the minimum size regulations, below which, all fish were assumed to be discarded, and above which fish were assumed to be retained.
- **Estimated parameters** included annual fleet-specific fishing mortalities, annual recruitment deviations beginning in1980, fleet selectivity parameters, sex-specific growth parameters, Beverton-Holt stock recruitment parameter (R0) and the catchability coefficient of the shrimp trawl. Steepness was fixed at 0.99 in the base model, and profiled across a range from 0.4 to 1.0 to evaluate estimate robustness to alternative stock productivity assumptions.

- **Model convergence criteria** included successful variance-covariance matrix (Hessian) inversion, the scale of the maximum gradient component (lower is better), and jitter of starting values across a range of plus/minus 20% initial values to validate model convergence to a global solution (maximum likelihood estimate).
- **Model fit diagnostics** included likelihood profiling of key stock productivity parameters including unfished mean recruitment and steepness, evaluation of fits to abundance indices, residuals fits to fleet length compositions, and retrospective analysis removing the most recent one up to five years of data.
- **Benchmarks and fishing reference points** for stock status estimates were based on spawning potential ratio (SPR) of 0.3 of unfished levels. Fishing mortality reference points for all fleets were based on the geometric mean of the Fs for the past three years (FY2015-17). The fishing mortality benchmark was the fishing mortality rate that results in an equilibrium SPR of 30%. The optimal yield fishing mortality was set at 75% of F_{SPR30}, for consistency with SEDAR 38. The allowable biological catches associated with a range of p-star values of 0.1, 0.2, 0.3, 0.4, and 0.5 (overfishing limit) were tabulated for fishing years 2021 to 2025.
- **Forecast assumptions** included (1) fixed selectivity, discard rate, and retention at size equal to the average of the terminal two years of the assessment (FY2016-17), (2) catches in FY 2018, 2019, and 2020 were assumed to be equal to FY2017, (3) fleet catch allocations were assumed equal to the averages of the terminal two years, (4) future recruitments were predicted from the Beverton-Holt stock recruitment curve with a fixed steepness equal to 0.99, (5) stock status probabilities were approximated from a normal distribution with mean equal to parameter maximum likelihood estimates and standard deviation based on the Hessian matrix.

4. Stock Assessment Results

4.1 Sensitivity of SEDAR 38 to the Recreational Fishing Effort Survey

The change from the CHTS to the FES resulted in increased catch and dead discard estimates of the charter/private (CP/PR) fleet by roughly 38% per year on average, and to a lesser magnitude, decreased headboat (HB) discard estimates by approximately 25% on average. The effects on the SEDAR 38 assessment of these changes was straightforward. Increased CP/PR landings resulted in higher mean recruitment estimates (i.e. more fish were created to account for increased removals), and in turn higher biomass and yield estimates (**Figure 4.1, Table 4.1**). The change in HB estimates had minimal effect on SEDAR 38 recruitment or biomass estimates (**Figure 4.1**), since the magnitude of the HB discards are negligible compared to landings and other fleet discards. **Table 4.1** shows the effect of both revisions to SEDAR 38 benchmarks. Notably, the target fishing rate at the 30% spawning potential ratio was similar across the sensitivities.

4.2 SEDAR 38 Update

4.2.1 SS3 model convergence and fit diagnostics

SS3 converged to a stable solution, with a negative log-likelihood consistent across the jittered parameter starting values (**Figure 4.2**). Therefore, the final model solution was considered to be at parameter maximum likelihood estimates. Parameter standard deviations were estimated from the inverse of the Hessian matrix, a key diagnostic of successful model convergence (i.e. estimates of covariance across parameters were obtained). The model gradient was 0.015, higher than a target of 0.001 (lower is better), but was considered acceptable for model convergence since the solution was stable.

Likelihood profiles for steepness (**Figure 4.3**) showed a minimum profile value of 0.55, indicating steepness was, technically, estimable parameter in the model. However, the stock recruitment relationship showed little evidence of a strong relationship leading the SEDAR 38 expert review panel to recommend that it be fixed at 0.99. That parameterization was retained in this update. Similar in pattern to SEDAR 38 analyses, the length composition data dominates the total likelihood, and the age data are in direct conflict with the other information. Given the base model assumption of a fixed steepness at 0.99, evaluating the sensitivity of alternative values across the range of biologically plausibility value provided a dimension of uncertainty of stock trend and status to alternative productivity assumptions. The stock depletion level was determined to be above the target value (i.e. stock was not depleted) across all steepness sensitivity runs (**Figure 4.4**).

Unfished recruitment was well determined in the model (**Figure 4.5**); however, similar to observations of steepness, there is a conflict between the length composition and the age data, which would tend towards higher values. As was found during SEDAR 38, the information taken as a whole provides a defined best estimate for average unfished recruitment near 9.8 million age-0 fish.

The model showed a general good fit to fleet relative abundance inter-annual trends (**Figure 4.6**), but often missed the magnitude of change in some years. For example, the recent period headboat decline and rebound were captured in the model predicted trend but not magnitude (**Figure 4.6**). Given the multiple fleet dynamics incorporated in the model, and the agreement in recent trend between indices (all increased relatively steadily since SEDAR 38), the overall model performance on index fits was considered acceptable. Fits to the SEAMAP trawl fishery independent survey showed a possible offset in the recent period, which might be explained by the series input as an age-0 index, but the data comprised of age-0 plus age-1 fish. An evaluation of alternative reference ages for the SEAMAP index, or modified index that references age-0 and age-1 fish separately is recommended for future research assessments.

Fits to the length composition (**Figure 4.7**) and associated model residuals (**Figure 4.8**) provided a primary diagnostic of model performance. As observed during SEDAR 38, the model demonstrated acceptable fit to the length composition data for both commercial and recreational fleets. Fits to the population size structure appeared adequate for the recreational headboat and charter and private fleets; however, fits to the sex specific length data were less accurate across years. Predicted tournament length composition showed good fit to the population and female data, but predicted lengths of males showed a consistent positive bias. Pearson residuals also demonstrated acceptable model fit across the range of the data, but showed a lack-of-fit to some data sources near the extreme upper and lower tails of the size distributions where few observations were available. In general, the fleet length composition fits for the period 1980 to 2017 and estimates of fleet selectivities (**Figures 4.9 and 4.10**) matched those from SEDAR 38 with great similarity, indicating stable model performance with the addition of five years of data.

One of the major advantages of SS3 in SEDAR 38 was the ability to model gender-specific growth patterns, a known population dynamic for King Mackerel; females grow more rapidly and to larger sizes than males. Estimates of male and female growth patterns were very consistent in the updated model compared to SEDAR 38 **(Figure 4.11**). Since much of SS3 programmed population dynamics are dependent on growth assumptions, the data plotted in **Figure 2.10** in the previous section provides a validation of the modeled asymptotic growth. This agreement between observed size distributions of males and females at the maximum ageclass and the estimated mean asymptotic lengths is an important confirmation that growth was appropriately specified in the model.

Model parameters are presented in **Table 4.2,** including whether the parameter was fixed or estimated, maximum likelihood estimates, associated asymptotic standard errors, initial values, minimum and maximum values, and priors. Overall, parameter estimates were relatively precise; SS3 estimated low standard errors for the majority of parameters with a few exceptions. Standard errors were high for the most recent recruitment deviations and for several of the selectivity parameters. We discuss the selectivity parameters below in more detail in the following section. The standard errors for the two most recent recruitment deviations (2016 and 2017) are much higher (~0.2) than in earlier years likely due to the more limited signal from age and length information compared to when the fish enter the fisheries at older ages.

4.2.2 Fishery Selectivity

Fleet selectivity estimates were very consistent with SEDAR 38 (**Figures 4.9 and 4.10**). Length-based selectivity for all sexes and fleets other than tournaments was strongly dome-shaped. Most selectivity parameters were estimated with good precision; however, a few showed high CVs and were poorly estimated (**Table 4.2**). For the Handline, Gillnet and Charter/private the width of plateau of the dome (parameter 2, SizeSel_1P_2_1_HL, SizeSel_2P_2_2_GN, SizeSel_5P_2_5_CP) had CVs greater than 100% indicating that these were very not well informed by the data, or potentially correlated with other parameters. In addition, the female offset to the first parameter defining the location of peak selectivity was also poorly estimated (SzSel_1Fem_Ascend_1_HL). For the tournament fishery, the logistic selectivities estimated fish at or above 100 cm were fully selected, which contrasts with the other fleets in which fish above 100cm are less vulnerable to capture than smaller sizes. Both the SEAMAP survey and the Shrimp fishery selectivities were fixed to only age-0 fish.

4.2.3 Fishing Mortality

Fishing mortality rates (estimated as exploitation rate in number) have remained relatively constant since SEDAR 38, with 4-5% (0.04-0.05) of the stock (in numbers) removed by fishing activities (landed and discarded dead) annually during 2011 to 2017 (**Table 4.3, Figure 4.12**). Peak fishing mortality occurred during the 1990s, when 8 to 11% (exploitation rate of 0.08 to 0.11) of the stock was removed by fishing each year. Since that time, fishing mortality has generally declined. Overall, recent harvest rates were at the lowest levels since the early 1970s (**Table 4.3**). Similar to the findings of SEDAR 38, the recreational charter/private and the commercial handline fleets are the predominant sources of fishing mortality. In comparison, gillnets, shrimp bycatch, headboats, and tournaments exert considerably lower mortality.

4.2.4 Recruitment

One of the major assumptions of SEDAR 38 was that recruitment to the population is independent across the range of estimated spawning stock biomass, that is the steepness parameter (h) of the Beverton-Holt curve was fixed at 0.99 (**Figure 4.13**). Under this assumption, the main productivity parameter estimated in SS3 was the average level of age-0 recruitment at unfished equilibrium spawning biomass (R0). Similar to SEDAR 38, the likelihood profile indicated a maximum likelihood estimate of steepness was lower than 0.99; however, there was notable conflict between data sources on the best estimate. Further, the log-likelihood profile analysis of steepness indicated that stock trends (e.g. SSB) and status determinations (e.g. SSB/SSB_{SPR30}) were largely consistent across alternative steepness sensitivities, as discussed in Section 4.2.1.

Annual recruitment deviations highlighted the variability in year-to-year recruitments, with a general cyclical pattern of periods of high and low signals (**Figure 4.14**). SS3 estimated many below average cohorts during 1981 to 1995, several above average cohorts during 1995 to 2007, below average recruitment during 2008 to 2012 and most recently, a period of above average recruitments from 2013 to 2016 (**Table 4.4**). Two of the highest recruitments on record were estimated to have occurred in 2015 and 2016 (**Table 4.4**, **Figure 4.15**).

A detailed inquiry was undertaken to assess the evidence for recent high recruitment. A high recruitment signal was detected in the SEAMAP fishery independent juvenile survey in 2016, which showed one of the highest catch rates in the time series; however, less evidence was seen in the index for the 2015 cohort. Leave-one-out analyses and single-information source sensitivities by data type (indices, discards, length composition, age data) showed evidence that handline fleet age data, and multiple fleet length compositions supported the high recent recruitments. However, there was a notable lack of coverage in the age data in the most recent years, particularly from the North Carolina fisheries. Some of the lack of coverage may have reflected challenge in sampling after Hurricane Matthew in 2016. North Carolina fisheries in the past have caught some of the largest and oldest fish, so the loss of data would have required re-partitioning the fleets in the model to avoid a false signal in annual age-at-length data. Hence, the most straightforward option for the update assessment was to remove the age data from the commercial handline fleet in 2016 and 2017.

In general, the model showed consistency in high and low recruitment signals from the data sources. For example, SEDAR 38 detected a period of low recruitments in the terminal years, and the trends were similar in the updated model (five additional years of data). If current recruitment estimates are accurate, the fishers should have noticed an increased abundance of mackerel in recent years compared to prior to 2014. That is, the model estimated a low recruitment period up to SEDAR 38 (2008 to 2012), with a notable decline in commercial and recreational landings. In contrast, the period after (2013 to 2016) showed a series of above average recruitments. Discussions with stakeholders could be a method to validate the model predictions with observations on the water.

4.2.5 Stock Biomass

Estimates of total stock biomass and spawning biomass were consistent between SEDAR 38 and the updated assessment, with exception to the increased magnitude associated with the Fishing Effort Survey described in Section 4.1. Similar to SEDAR 38, estimates of SSB were fairly well determined as evidenced by the 95% intervals (**Figure 4.16**). Stock recruitment and biomass trends did not change between assessments, highlighting model stability in historic estimates. Biomass was estimated to be near unfished levels prior to the 1950s, followed by a period of decline between 1980 and the late 1990s (**Figure 4.16**). Stock biomass reached its lowest point in 1998, after which there was a steady biomass increase up to 2010. Since 2010, the stock has shown a more cyclical pattern associated with the estimated periods of high and low recruitment. Stock biomass increased steadily over the last four years since SEDAR 38 (**Table 4.5**, **Figure 4.16**).

4.2.6 Benchmarks/Reference points

A spawning potential ratio of 30% unfished equilibrium levels (SPR30) marked the target stock biomass and fishing mortality reference points, consistent with the adopted advice framework of SEDAR 38. The reference point estimates of South Atlantic King Mackerel were:

- Unfished equilibrium recruitment, R0 = 9,815,000 age-0 fish
- Spawning Biomass at SPR30, SSB_{SPR30} = 2,439 millions of eggs produced

- Fishing Mortality at SPR30, F_{SPR30} = 0.145 annual exploitation rate in numbers
- Equilibrium Yield at SPR30 = 18.3 million pounds
- Optimum Yield (F=75%F_{SPR30}) = 16.7 million pounds
- For reference, the average yield between 2016 and 2017 was 9.6 million pounds

Time series of fishery mortality relative to the SPR30 reference point (F/F_{SPR30}) followed the period of increasing fishing pressure from 1950 to 1990, and peak fishing mortality occurred during 1998 when the estimated harvest rate was roughly 80% the SPR30 target rate (**Table 4.5, Figure 4.17**). Current fishing mortality rates (ranging 0.04 to 0.05) were markedly lower than the reference point (F_{SPR30}=0.145). The fisheries were determined to be NOT OVERFISHING.

Spawning biomass in 2017 was estimated at 4,232 (millions of eggs), above the SPR30 reference point of 2,439 (**Table 4.6, Figure 4.17**). The stock status was determined to be NOT OVERFISHED.

A summary of stock reference points, fishery status, and stock status is available in **Table 4.7**, and time series trends relative to the benchmarks are plotted in **Figure 4.18**. The estimates of current stock status and fishery status relative to the reference points were:

- SSB_{2017}/SSB_{SPR30} = 1.7
- F_{2017}/F_{SPR30} = 0.29

A probabilistic estimation of biological reference point uncertainty was conducted based on the stock status and benchmark estimate variances. Normal probability density functions provided the 95% quantiles of stock and fishery status. The confidence intervals and probability estimates of current stock and fishery status are summarized here:

- The 95% confidence interval of current stock status (SSB_{2017}/SSB_{SPR30}) = 1.6 to 1.8
- The 95% confidence interval of current fishery status (F_{2017}/F_{SPR30}) = 0.19 to 0.39
- The estimated probability the stock is overfished is less than 1%
- The estimated probability that overfishing is occurring is less than 1%

We conducted a retrospective analysis to evaluate how terminal trends diverge when additional information is added to the model. Overall, there were no severe patterns or systematic bias revealed from the retrospective runs (**Figure 4.19**). All bias diagnostic statistics (Mohn's rho) were below the target threshold (i.e. less than 0.2). There was some evidence for caution in reliability of estimates of the terminal years' recruitments, likely due to the change in information from age-0 survey only to length and age data added in following years.

4.3 Projections

Future catches at the benchmark exploitation rate (F_{SPR30}=0.145) for fishing years 2021 to 2025 were notably higher than recent catches (**Table 4.8**). This was due to the shift in estimated recruitment from a 5-year period (2008-12) of below average recruitment, to a recent four-year period of above average recruitment (2013-16). In general, the catch projection was highest for fishing year 2021, and declined toward to an equilibrium yield of 18.3 million pounds at constant recruitment of 9.8 million fish. The allowable biological catches associated with a range of p-star values from 0.1 to 0.5 are listed in **Table 4.8**, and the probability density distributions around projected yields at F_{SPR30} are plotted in **Figure 4.20**. The allowable biological catches at different p-star values are also highlighted in **Figure 4.20**. **Table 4.9** contains the projected recruitment, spawning biomass, and stock status under constant exploitation at F_{SPR30}.

The distinct cyclical shift in recruitment from the low period occurring up to SEDAR 38 to the recent high recruitment period may provide an opportunity to evaluate how well the assessment model estimates align with observations by stakeholders over the last decade. Particularly, stakeholder comments during SEDAR 38 provided evidence of a recent large cohort of juveniles in the Atlantic. SS3 estimated above average recruitment in 2013 and 2014, and two of the largest cohorts in the time series in 2015 and 2016. These fish would have entered the fisheries beginning in fishing year 2015, with predicted higher abundance beginning in fishing year 2017, particularly of fish between 20 to 36 inches fork length. Conversations with stakeholders may provide additional evidence for these high recruitment events that are expected to result in significantly increased catches at the target exploitation rate over the next five years.

Projected yields and stock spawning biomass trends under four fishing scenarios were compared to highlight the trade-offs between alternative constant exploitation strategies (**Figure 4.21**). The fishing scenarios included zero exploitation (constant F equal to 0), exploitation at the OFL (constant F equal to $F_{SPR30} = 0.14$), exploitation at the constant F equal to 75% of F_{SPR30} (F=0.11), and exploitation at current fishing mortality rates (constant F = 0.05). Fishing at the OFL would result in a three-fold increase over current fishing mortality. In general, fishing at current exploitation levels results in a relatively steady stock biomass near current levels, while fishing at OFL resulted in a rapid decline in spawning biomass toward to SPR target. Lastly, a low future recruitment sensitivity was parameterized to determine the difference in 2021-25 OFLs in the case that recruitment cycles back to a low period, similar to the period 2008 to 2012. This sensitivity fixed the future recruitment deviations from 2018 to 2025 to mimic the low period observed prior to SEDAR 38 (**Figure 4.22**). The results indicated a period of low recruitment beginning in 2018 would result in an approximately 15% to 30% reduction in OFL compared to the average recruitment base projections (**Table 4.10**).

4.4 Summary and Conclusions

Overall, the SS3 model for South Atlantic King Mackerel demonstrated good convergence, acceptable fits to the data sources, and stable performance in terms of solving to a consistent solution, as well as estimating similar growth, selectivity, biomass, and recruitment trends as the previous assessment. The stock was determined to be NOT OVERFISHED and the fisheries are NOT OVERFISHING. In general, all fishery indicators and resulting stock status estimates showed positive trends since SEDAR 38. Comparison of model results between SEDAR 38 and this update highlighted a consistency in stock estimates, particularly the long-term biomass trends and recruitment signals. Recent above average recruitment estimates (2013 to 2016) contrasted the period prior (2008 to 2012) of below average recruitments first detected during SEDAR 38. Two high recruitment years were estimated for 2015 and 2016, supported by the juvenile survey observations in 2016 (SEAMAP trawl survey), as well as fleet length compositions. The distinct shift in recruitment trends would have resulted in an increased abundance of fish available to the fisheries in recent years. Discussions with stakeholders may help validate the model, as the stock abundance was estimated to be at its highest level in over 40 years, with coincident increasing catches and catch rates, and the lowest exploitation rate since the 1970s.

4.5 Research recommendations

In addition to the research recommendations documented during SEDAR 38, additional recommendation were noted during the update assessment. Research aimed at improving the documentation of data series formatting, including index standardization, for SS3 would improve modeling efficiency. This includes statistical coding for consistent database querying and data processing. An evaluation of alternative age references, or age-specific time series, for the SEAMAP fishery independent survey was recommended by the data providers and noted by the analyst for future assessments. An analysis of the effect of excluding sublegal fish size observations on the assessment should be undertaken. Information on the age-composition of discarded fish from all fleets is needed to validate the assumption of exclusively age-0 discards. The conditional age-at-length data had a significant influence on recent recruitment estimates. Future research assessments should evaluate model sensitivity to the age-data and explore alternative parameterizations (such as inverse age-length key), as the fleet coverage was suboptimal with zero information available for several fleets and years.

4.6 Acknowledgements

Many people at various state and federal agencies assisted with assembling the data sources included in this stock assessment. We thank the data providers, assessment analysts, and technical reviewers for all of their efforts.

Table 4.2. List of Non-F SS parameters for South Atlantic King Mackerel, that includes the initial parameter starting values, estimated parameter values and their associated standard errors, and probability density functions assigned as priors. Parameters that were held constant to their input values are labeled as fixed.

Table 4.7. Summary of benchmarks and stock status of South Atlantic King Mackerel. Fishing mortality is exploitation rate in numbers, spawning stock biomass is in millions of eggs, and recruitment is in thousands of age 0 fish.

Metric	Value/Determination
Assessment Year	2020
Data Range in Fishing Years (Mar 1-Feb 28)	1901 to 2017
Fishing mortality_{2017}	0.04
Fishing mortality_{SPR30}	0.14
F_{2017}/F_{SPR30}	0.29
95% Confidence Interval of F_{2017}/F_{SPR30}	0.19 to 0.39
$\text{Recruitment}_{Unfished}$	9,815,000
$\text{Recruitment}_{2017}$	8,310,000
Spawning Stock $\text{Biomass}_{Unfished}$	8,130
Spawning Stock $\text{Biomass}_{SPR\ target}$	2,439
Spawning Stock Biomass_{2017}	4,232
SSB_{2017}/SSB_{SPR30}	1.7
95% Confidence Interval of SSB_{2017}/SSB_{MSY}	1.6 to 1.8
Yield_{2017}	9.5 million lbs
$\text{Yield}_{SPR\ target}$	18.3 million lbs
Optimum $\text{Yield}_{SPR\ target}$	16.7 million lbs
Stock Status	Not Overfished
Fishery Status	Not Overfishing

Table 4.8. Projected catch limits of South Atlantic King Mackerel (in millions of pounds) under constant exploitation rate = F_{SPR30}. The allowable biological catches associated with a range of p-star (p*) values from 0.1 to 0.5 are listed for the next five fishing years. The overfishing limit (OFL) is the median projected retained catch at F_{SPR30}.

Fishing Year	p*=0.1	p*=0.2	p*=0.3	p*=0.4	OFL
2021	27.7	30.0	31.6	33.0	34.3
2022	22.9	25.2	26.8	28.2	29.5
2023	19.8	22.1	23.7	25.1	26.3
2024	17.8	20.0	21.6	22.9	24.2
2025	16.3	18.5	20.1	21.5	22.7

Table 4.9. Projected recruitment (1000s of fish), spawning stock biomass (millions of eggs), and stock status estimates (relative to SSB at 30%SPR) under constant exploitation at $F=F_{SPR30}$.

Fishing Year	Recruitment	SSB	SSB/SSB_{SPR30}
2018	9797	4712	1.94
2019	9801	5160	2.12
2020	9802	5411	2.23
2021	9803	5565	2.29
2022	9799	4995	2.06
2023	9795	4503	1.85
2024	9790	4091	1.68
2025	9786	3749	1.54

Table 4.10. Sensitivity analysis of projected overfishing limits under two alternative future recruitment scenarios, which included average recruitment (base advice) and a low recruitment scenario.

Fishing Year	OFL_average recruitment	OFL_Low recruitment	Difference
2021	34.3	29.3	-0.15
2022	29.5	22.4	-0.24
2023	26.3	18.2	-0.31
2024	24.2	17.2	-0.29
2025	22.7	17.8	-0.21

4.9 Figures

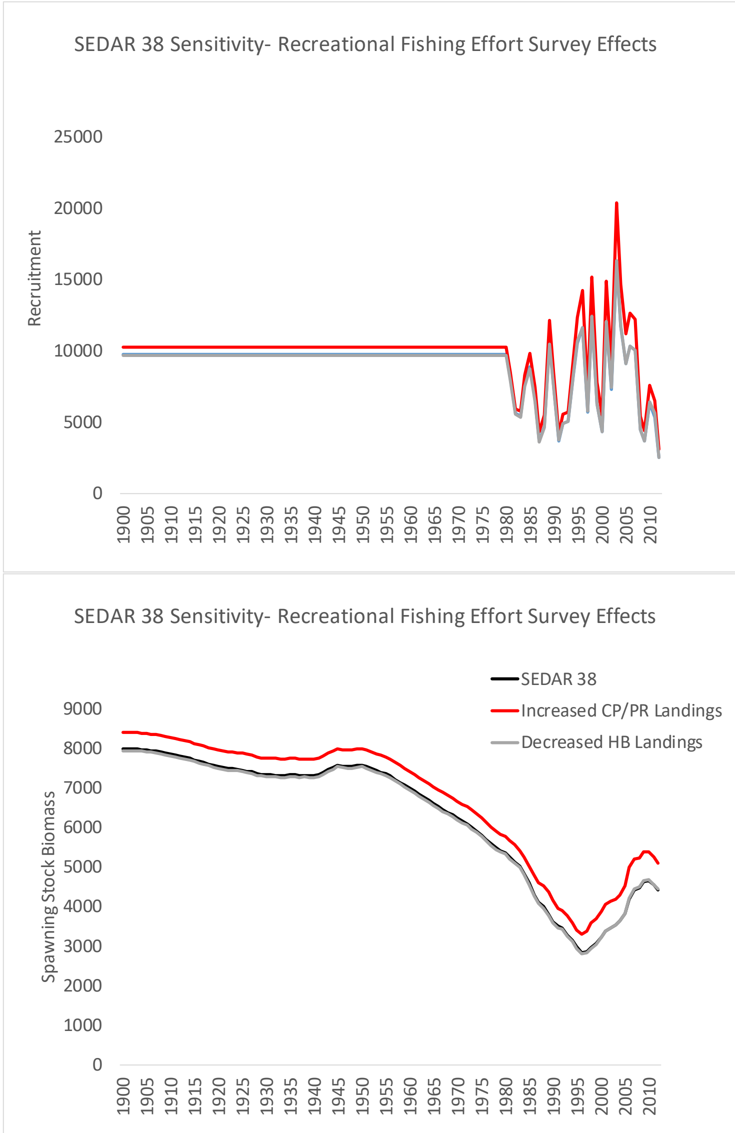

Figure 4.1. Sensitivity analysis of SEDAR 38 demonstrating the effect of revised landings estimates from the recreational Fishing Effort Survey on estimates of recruitment and spawning stock biomass of South Atlantic King Mackerel. Note that SEDAR 38 estimates were based on the MRIP Household Telephone Survey.

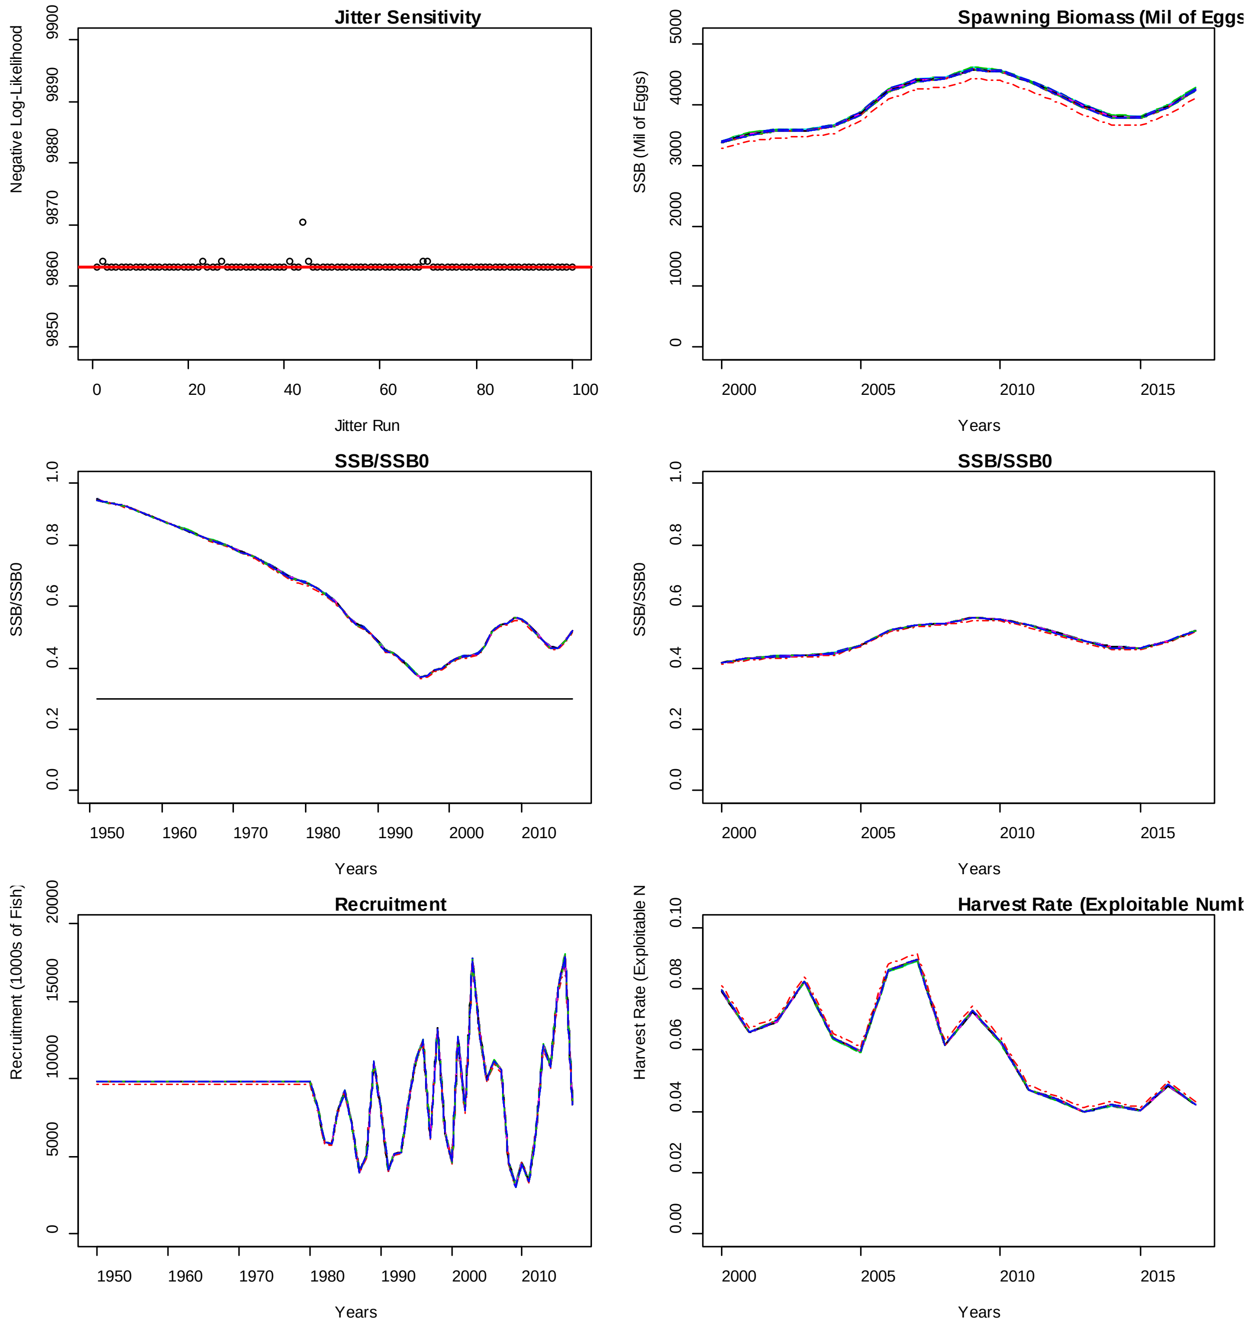

Figure 4.2. Comparison of SS3 runs across jittered starting parameter values (+ or - 10%). Red line in the upper left panel shows the objective function value of the base model.

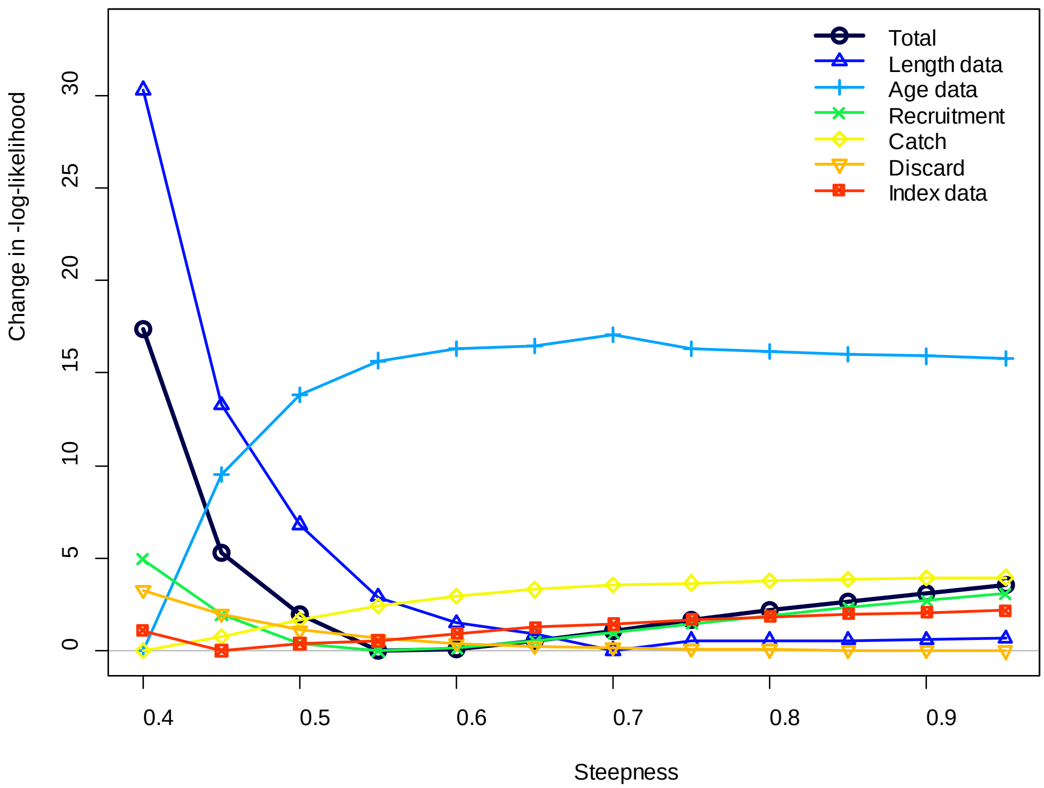

Figure 4.3. Likelihood profile of the Beverton-Holt steepness parameter. The y-values represent the change in negative log-likelihood, by data component.

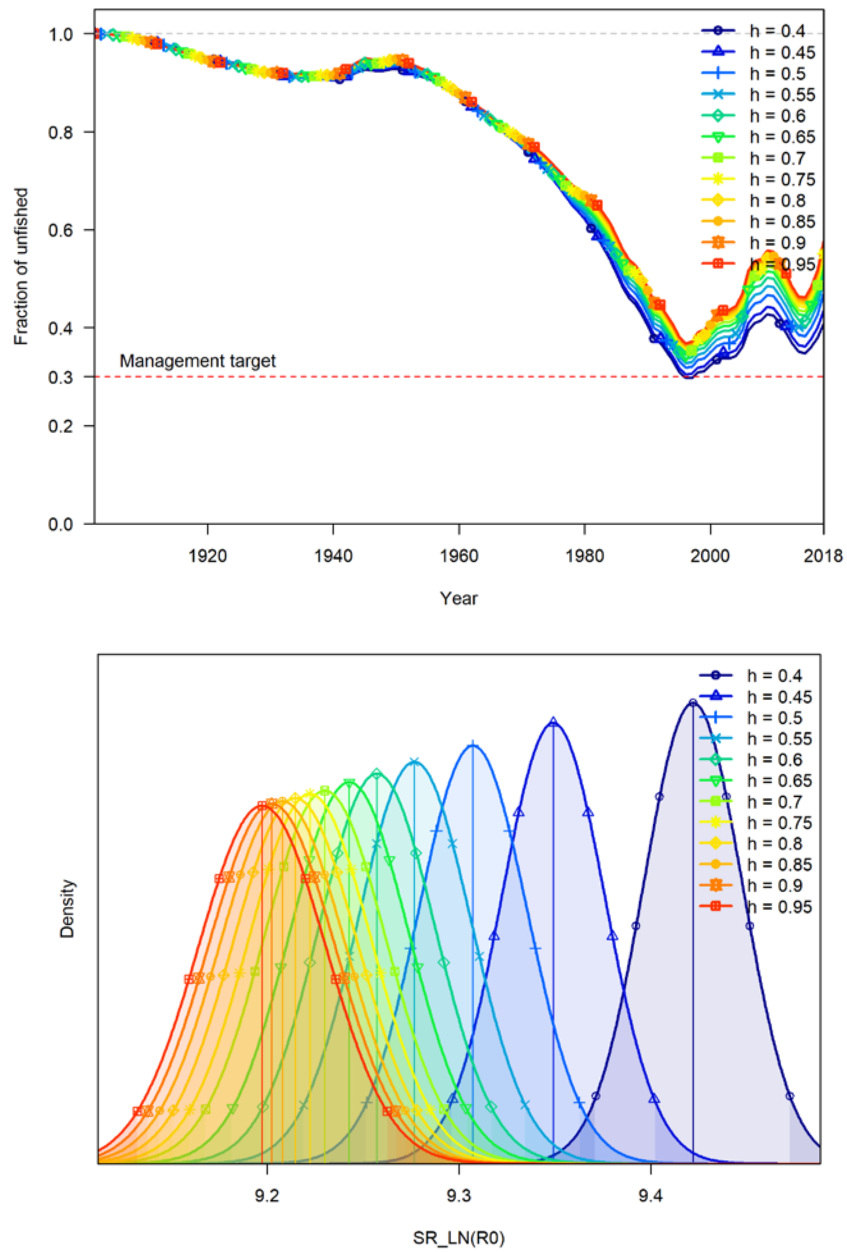

Figure 4.4. Stock status sensitivity of South Atlantic King Mackerel to alternative assumptions of steepness. Upper panel shows the stock depletion ratio relative to the defined management target in SEDAR 38 (SPR30). The lower panel shows the estimate of unfished equilibrium recruitment (R0) associated with alternative steepness assumptions.

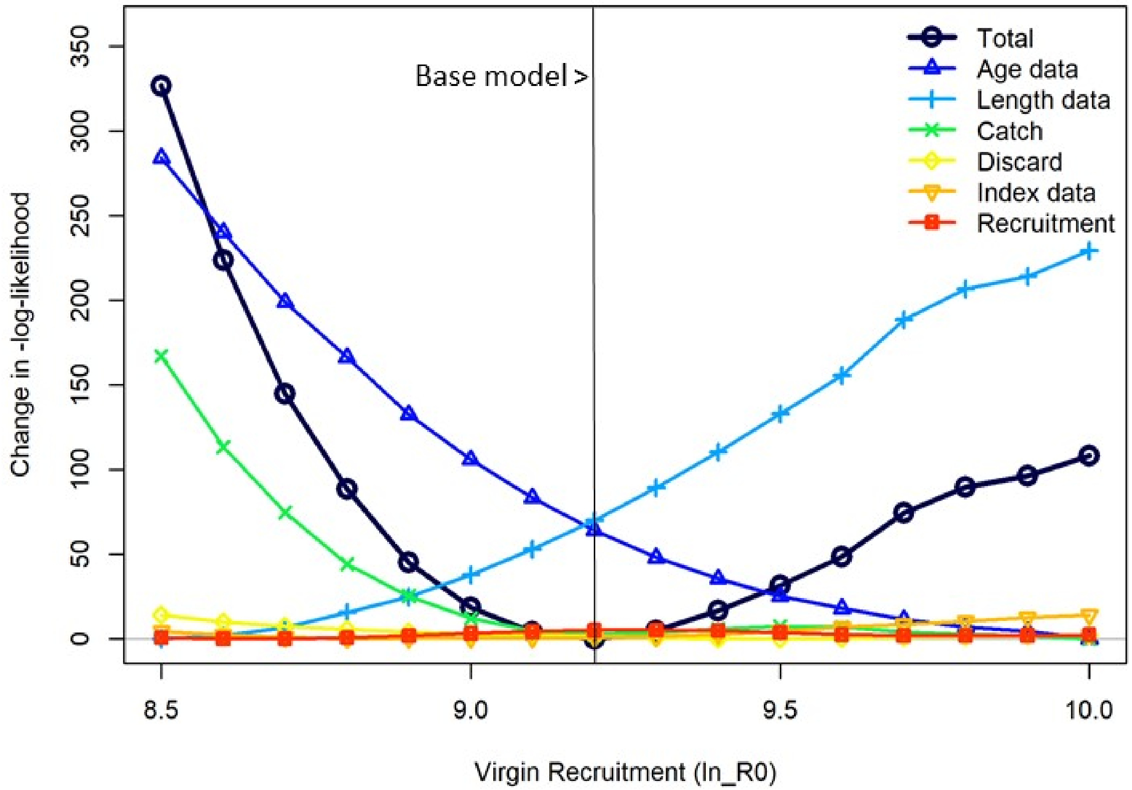

Figure 4.5. Likelihood profile of unfished recruitment (R0) estimates. The dotted line represents the point estimate from the base model. The values represent the change in negative log-likelihood, by component.

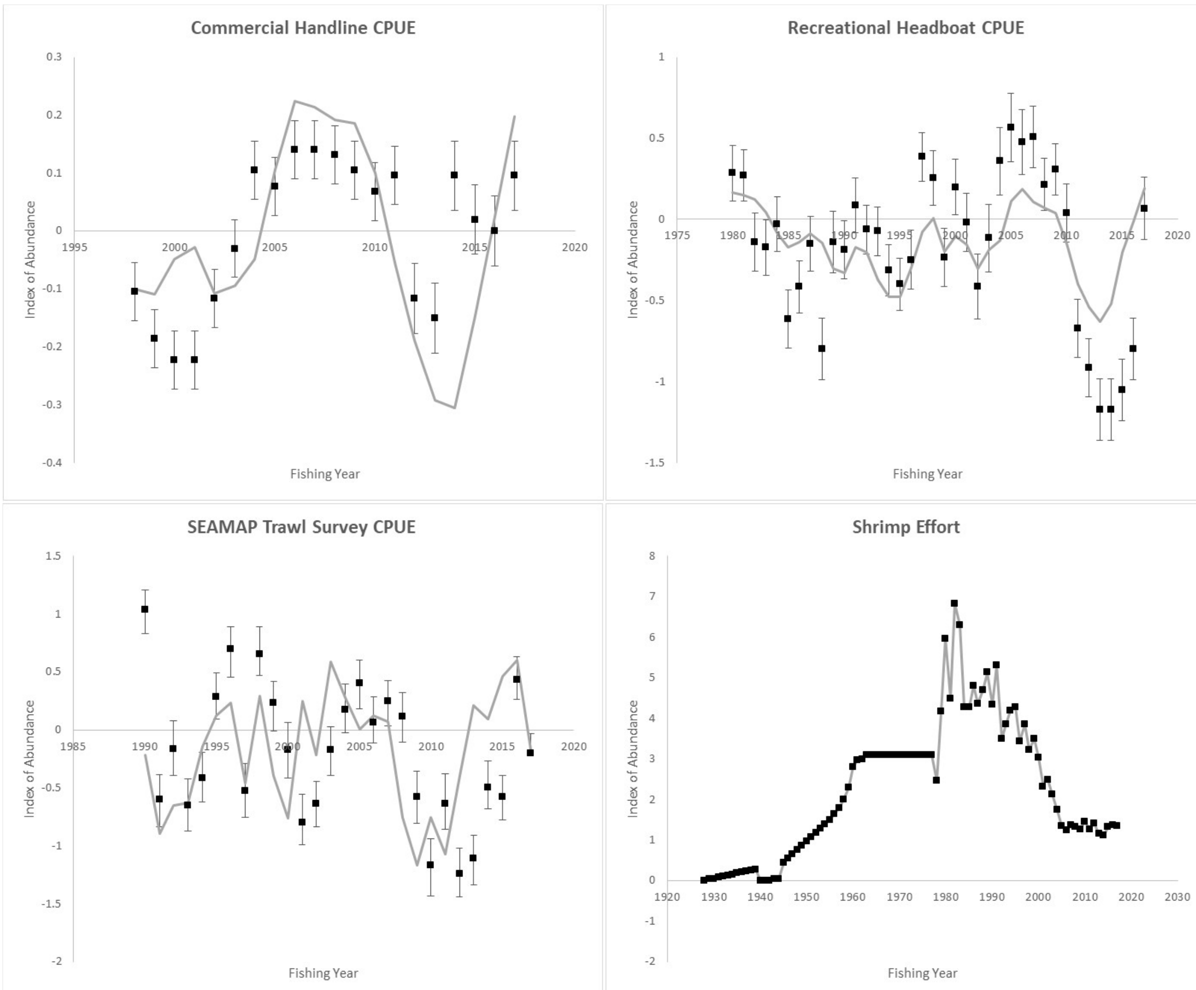

Figure 4.6. Model fit (gray line) to the indices of abundance (shown on the log-e scale as black squares with standard error).

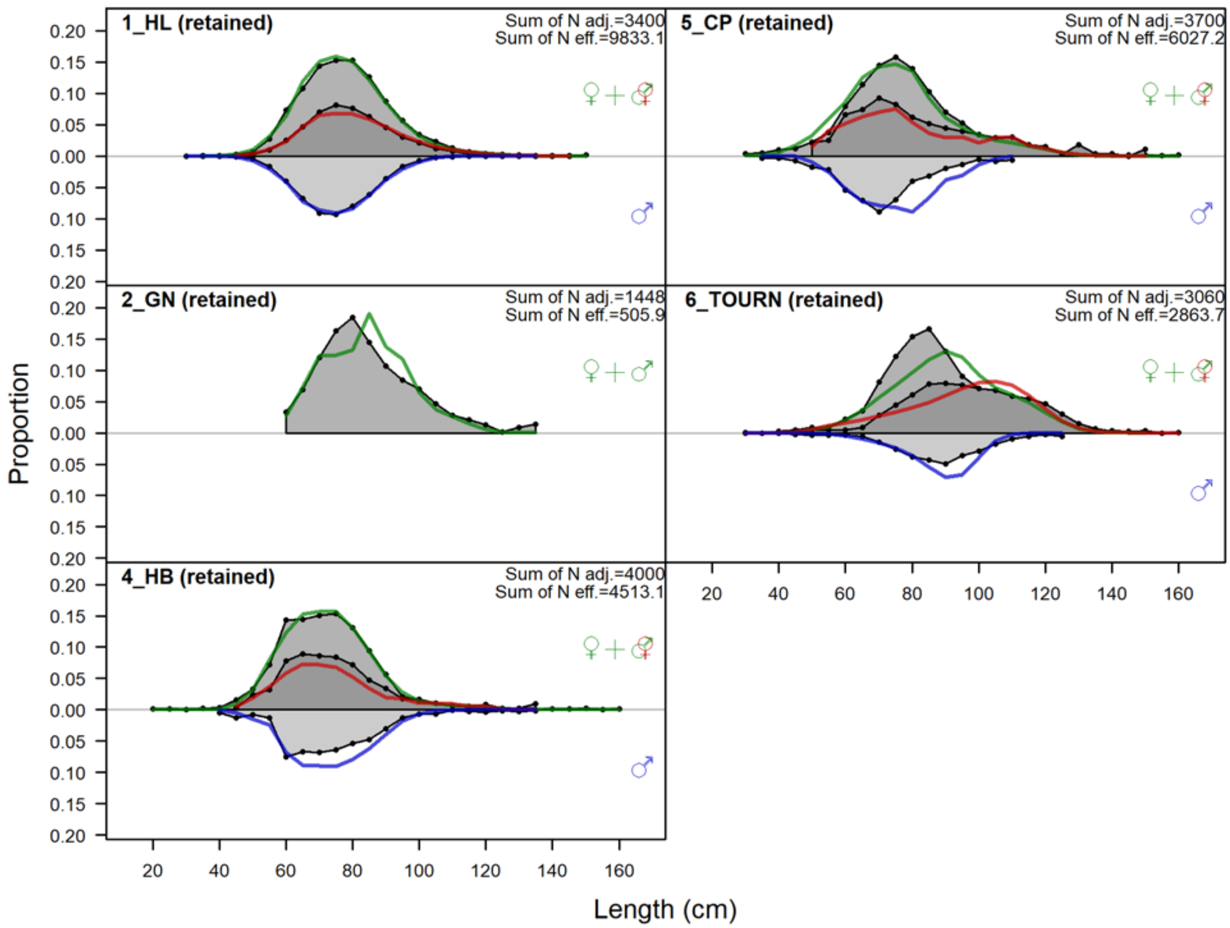

Figure 4.7. Time-aggregated fits to fleet length compositions. The red distribution is the length composition of females, the blue is males, and the green is undetermined gender.

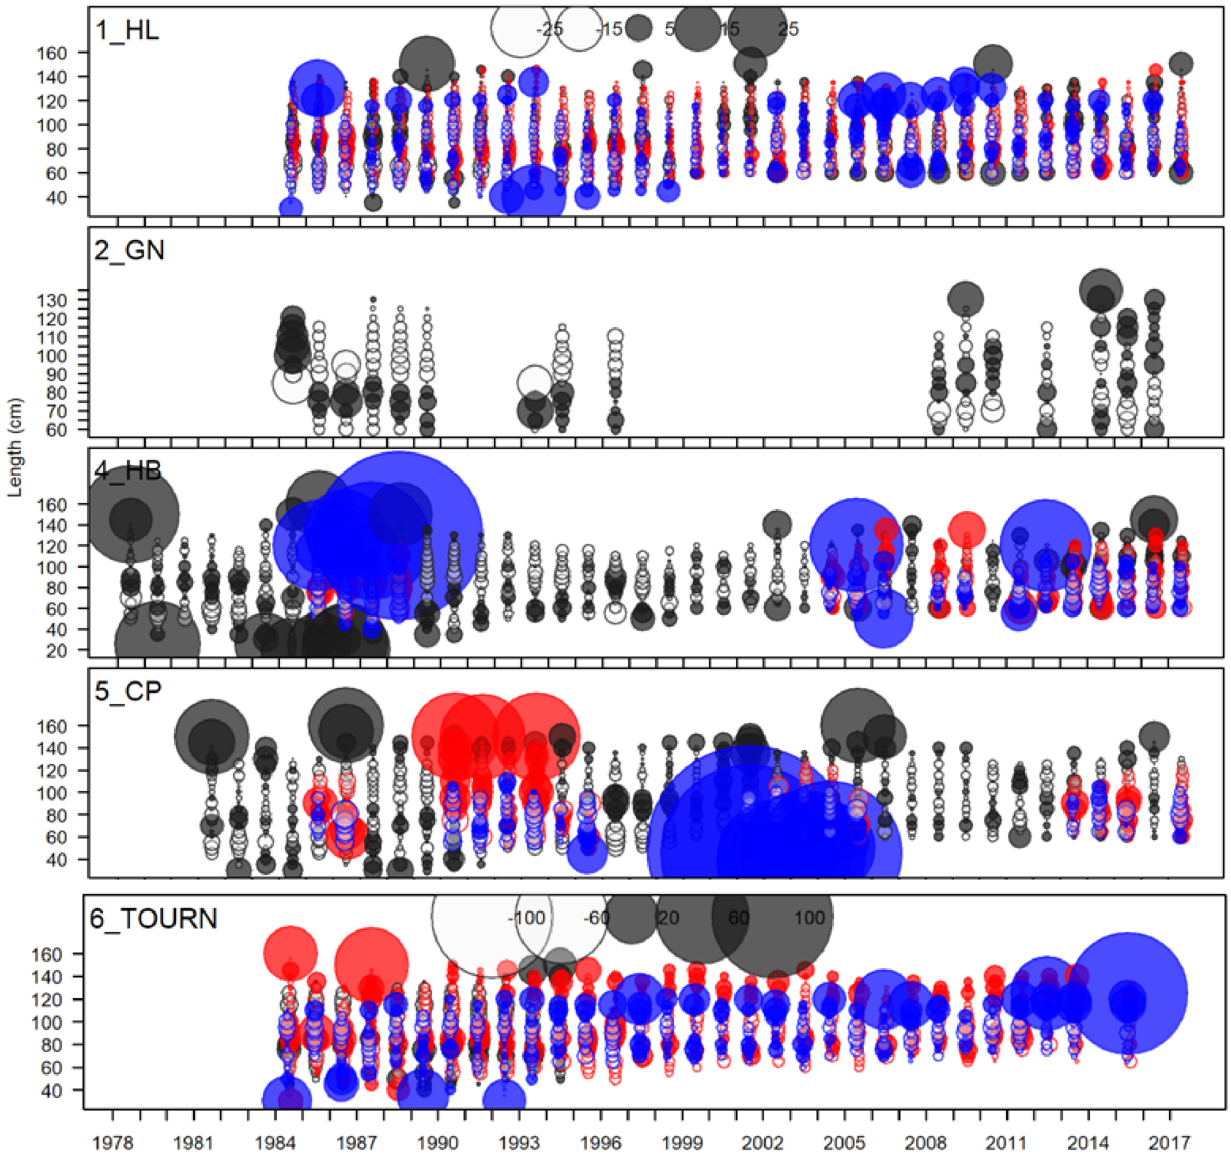

Figure 4.8. SS3 residual fits to fleet length compositions. Filled circles are positive residuals, open are negative. Blue circles are the residual fits to male length measurements, red are to female lengths, and gray are to lengths of fish with unknown gender.

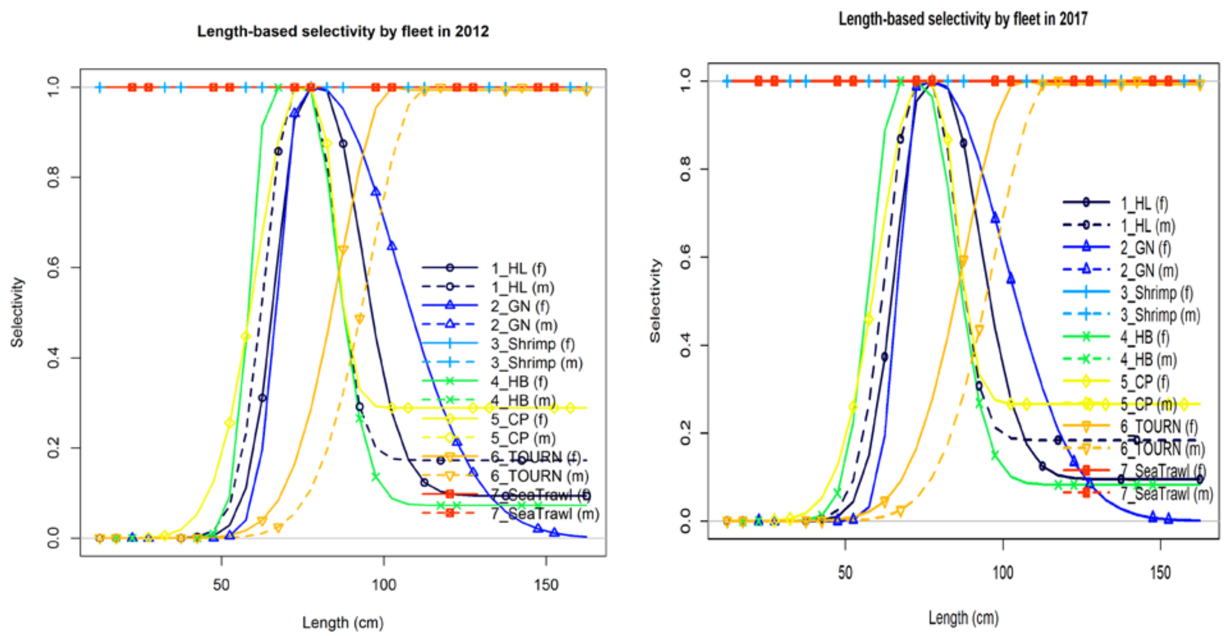

Figure 4.9. Estimated fleet selectivities-at-length by fleet and sex. Left panel shows the estimated selectivities from SEDAR 38, and the right panel are the estimated selectivities of the update model.

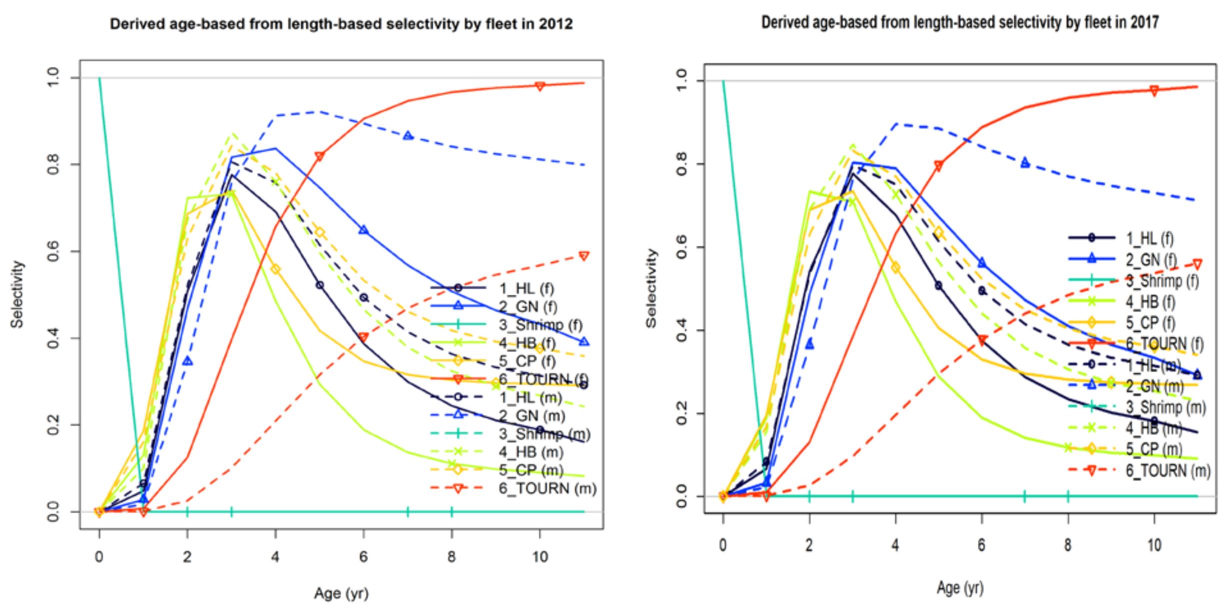

Figure 4.10. Derived age-based selectivities from estimated length-based selectivity by fleet and sex. Left panel shows the estimated selectivities from SEDAR 38, and the right panel are the estimated selectivities of the updated model.

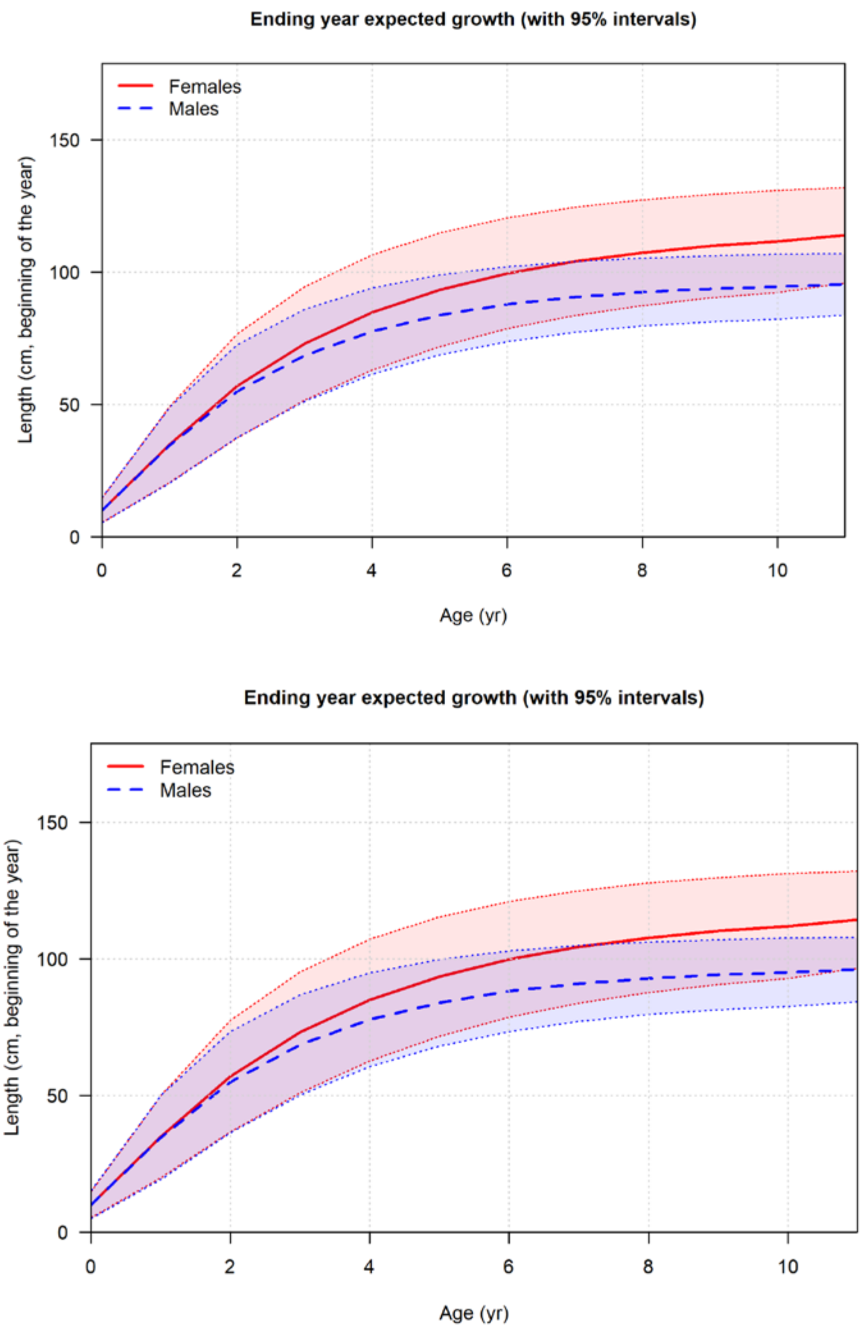

Figure 4.11. Growth relationship and 95% intervals for males (blue line) and females (red line) estimated in SS3. Upper panel is the estimated growth curves from SEDAR 38 and the lower panel is the 2020 update.

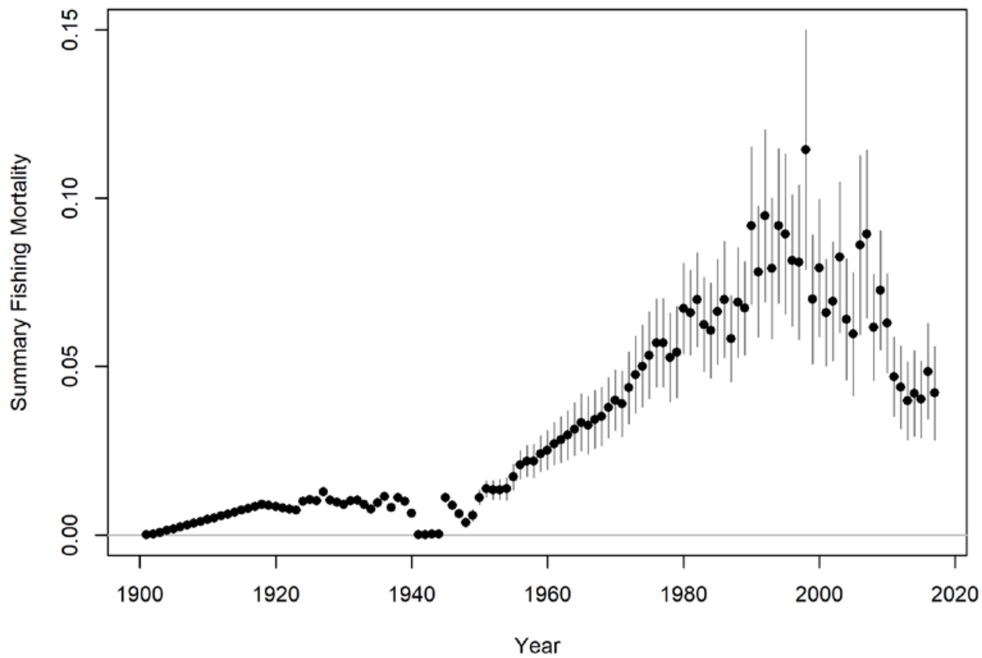

Figure 4.12. Estimated fishing mortality rates (exploitation rate in number) of South Atlantic King Mackerel.

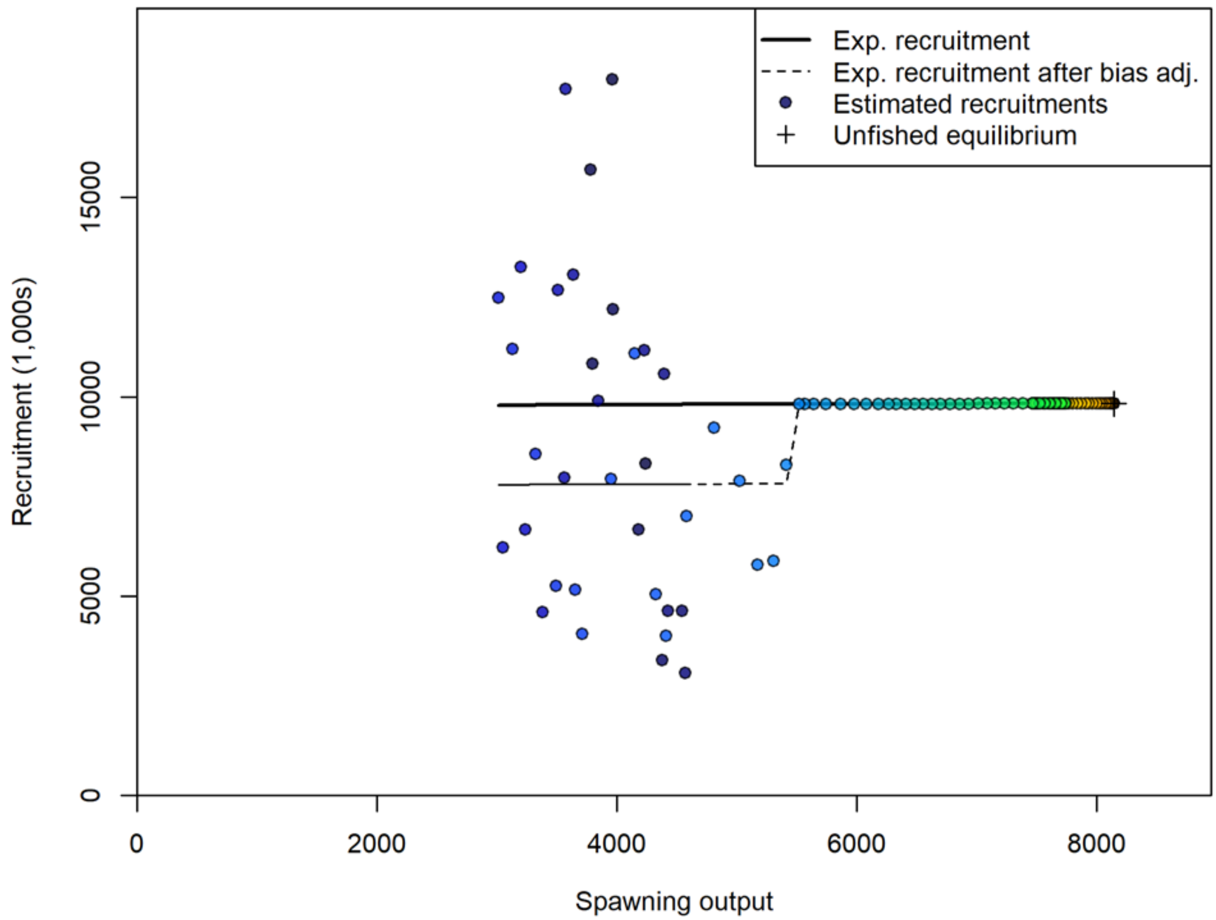

Figure 4.13. Stock-recruitment relationship for South Atlantic King Mackerel with a fixed steepness equal to 0.99. Plotted are predicted annual recruitments from SS (circles), and expected recruitment from the stock-recruit relationship (black line).

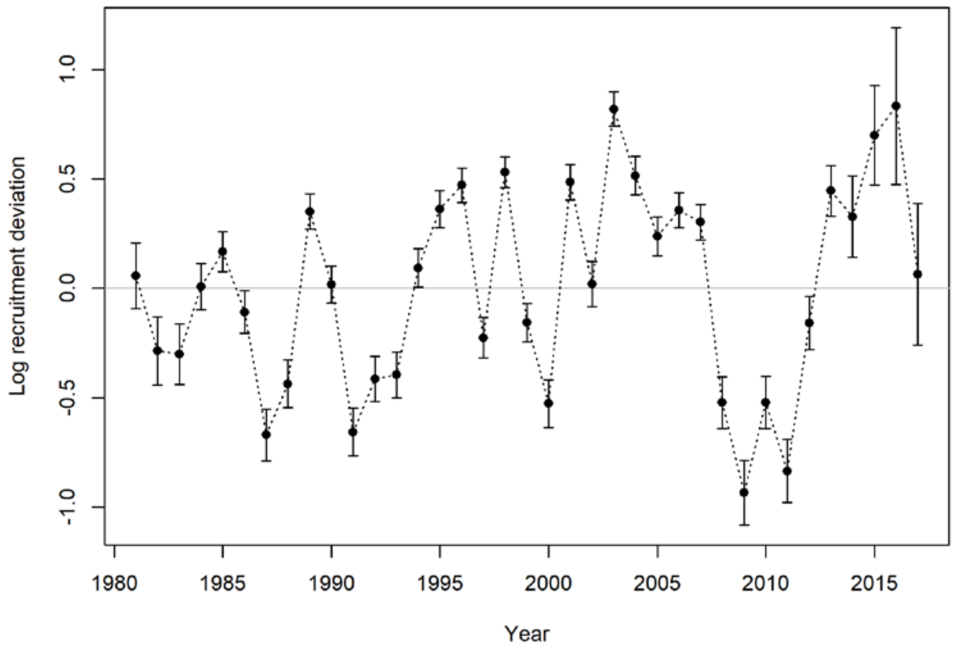

Figure 4.14. Predicted log recruitment deviations with associated 95% asymptotic intervals.

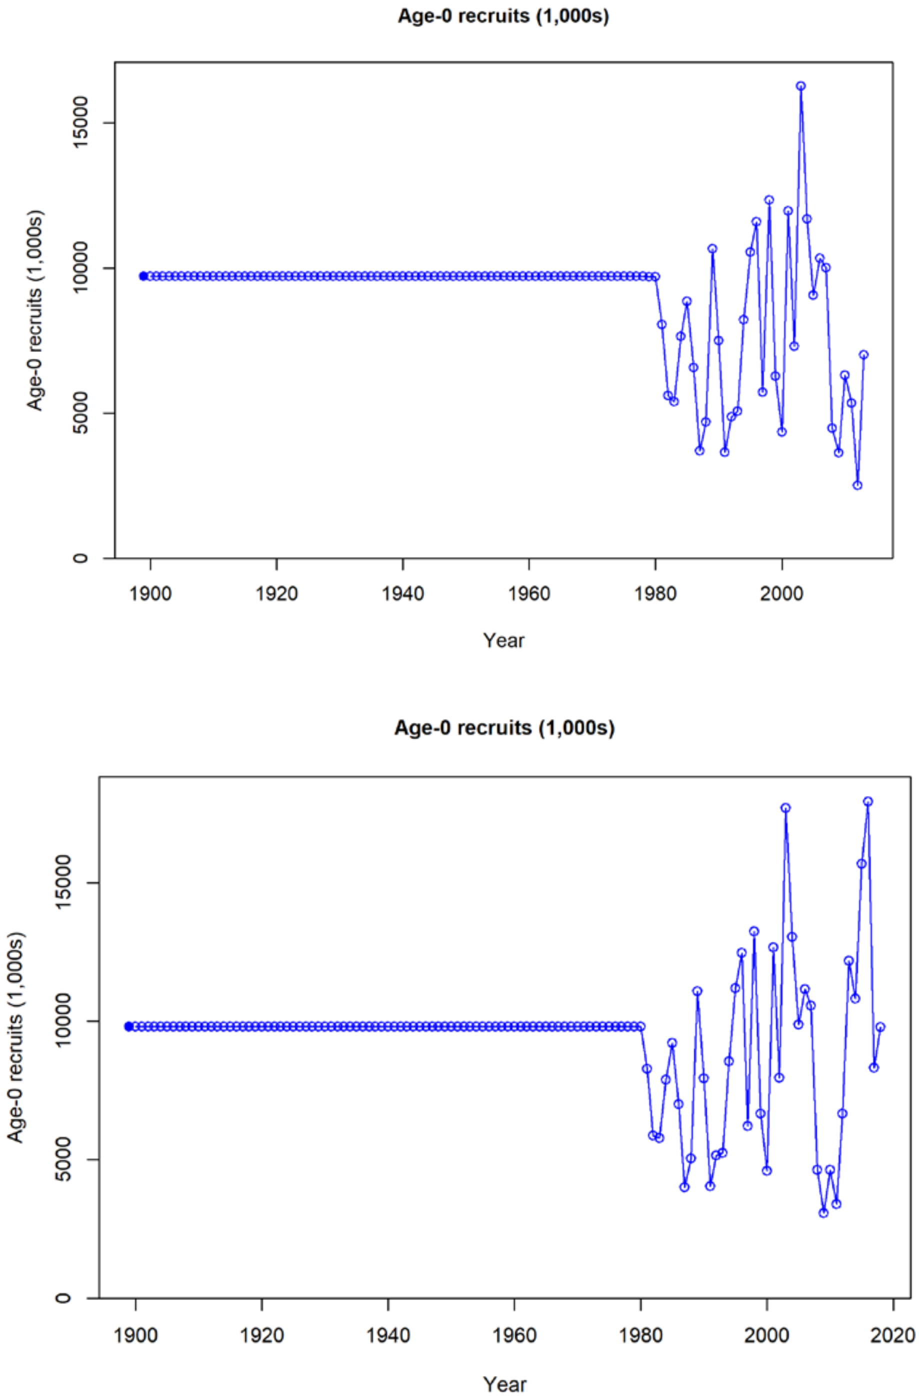

Figure 4.15. SS3 predicted age-0 recruits of South Atlantic King Mackerel. The upper panel shows the estimated recruits from SEDAR 38 and the lower panel shows the 2020 updated model estimates.

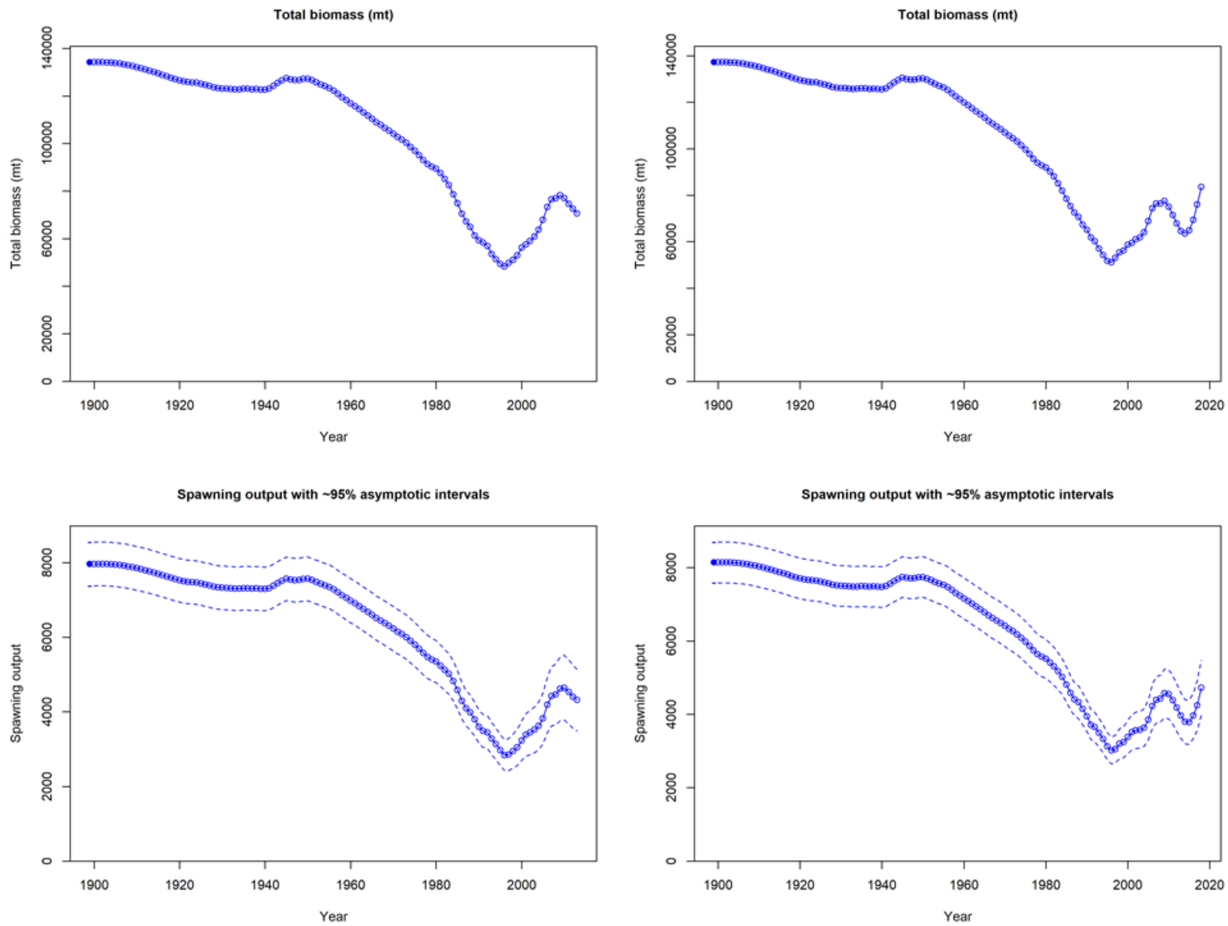

Figure 4.16. Estimated total biomass in whole metric tons and spawning biomass (egg production in millions) with 95% CI. The left panels show the estimated biomasses from SEDAR 38 and the right panels show the estimates from the 2020 updated model.

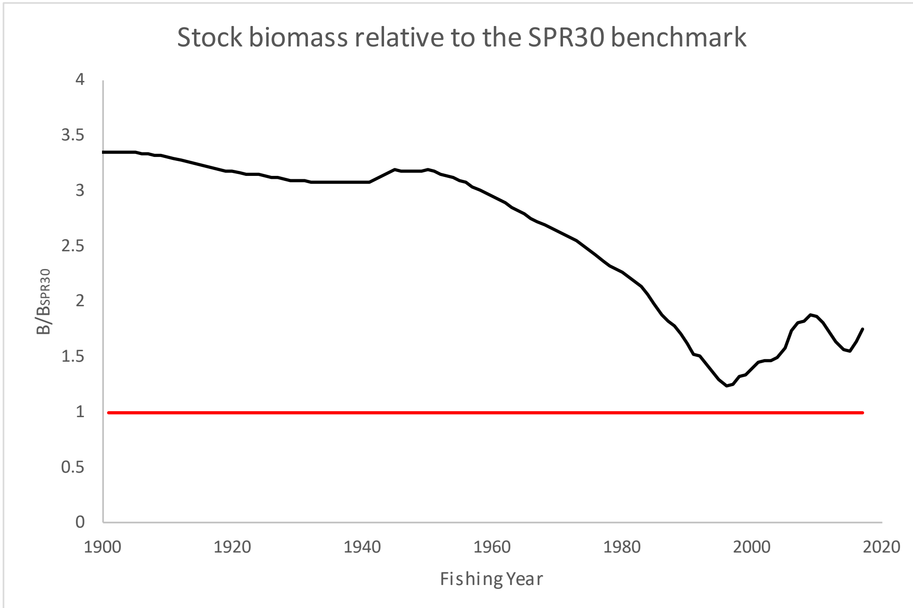

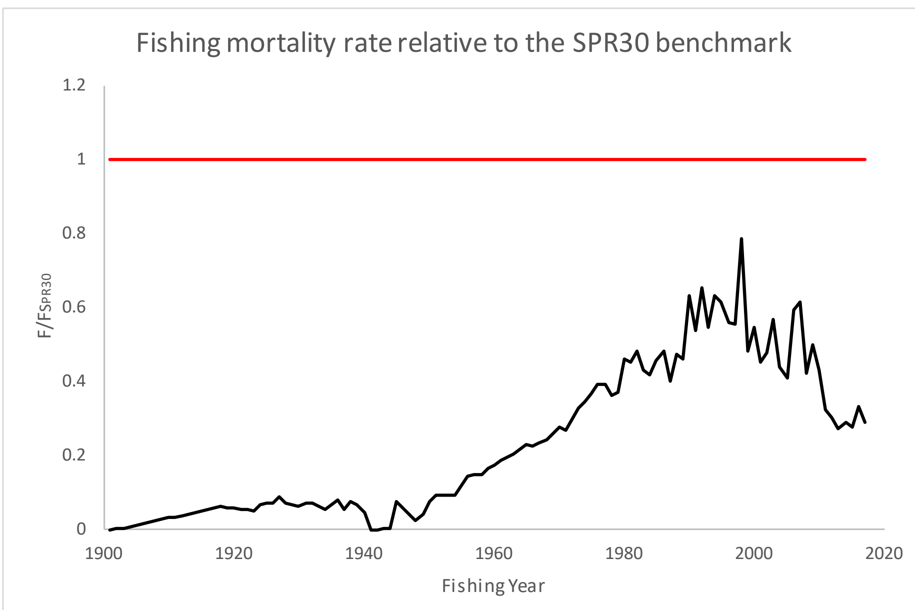

Figure 4.17. Stock and fishery status trends for Atlantic King Mackerel, measured as spawning output relative to 30% of unfished levels (SPR30) and fishing mortality (F) relative to the target fishing mortality rate that produces the target depletion level (F_{SPR30}). The red line shows the benchmark target.

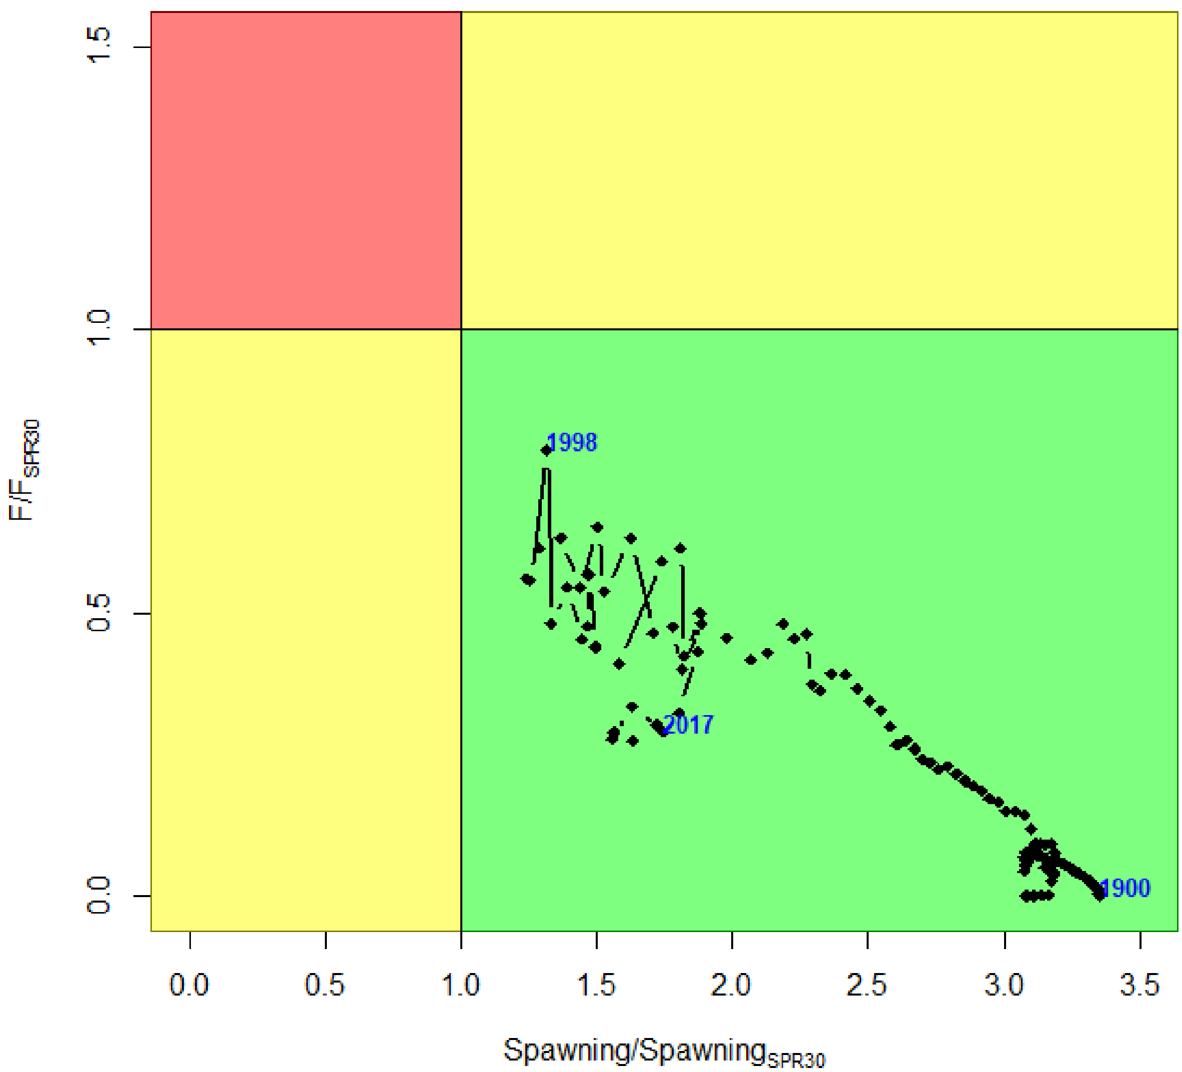

Figure 4.18. Kobe plot showing the combined stock status and fishery status trajectory. Green quadrant (lower right) represents a status of not overfished and not undergoing overfishing. The red quadrant (upper left) represents a status of overfished and undergoing overfishing. The yellow quadrants represent statuses of not overfished but undergoing overfishing (upper left), or overfished but not undergoing overfishing (lower left).

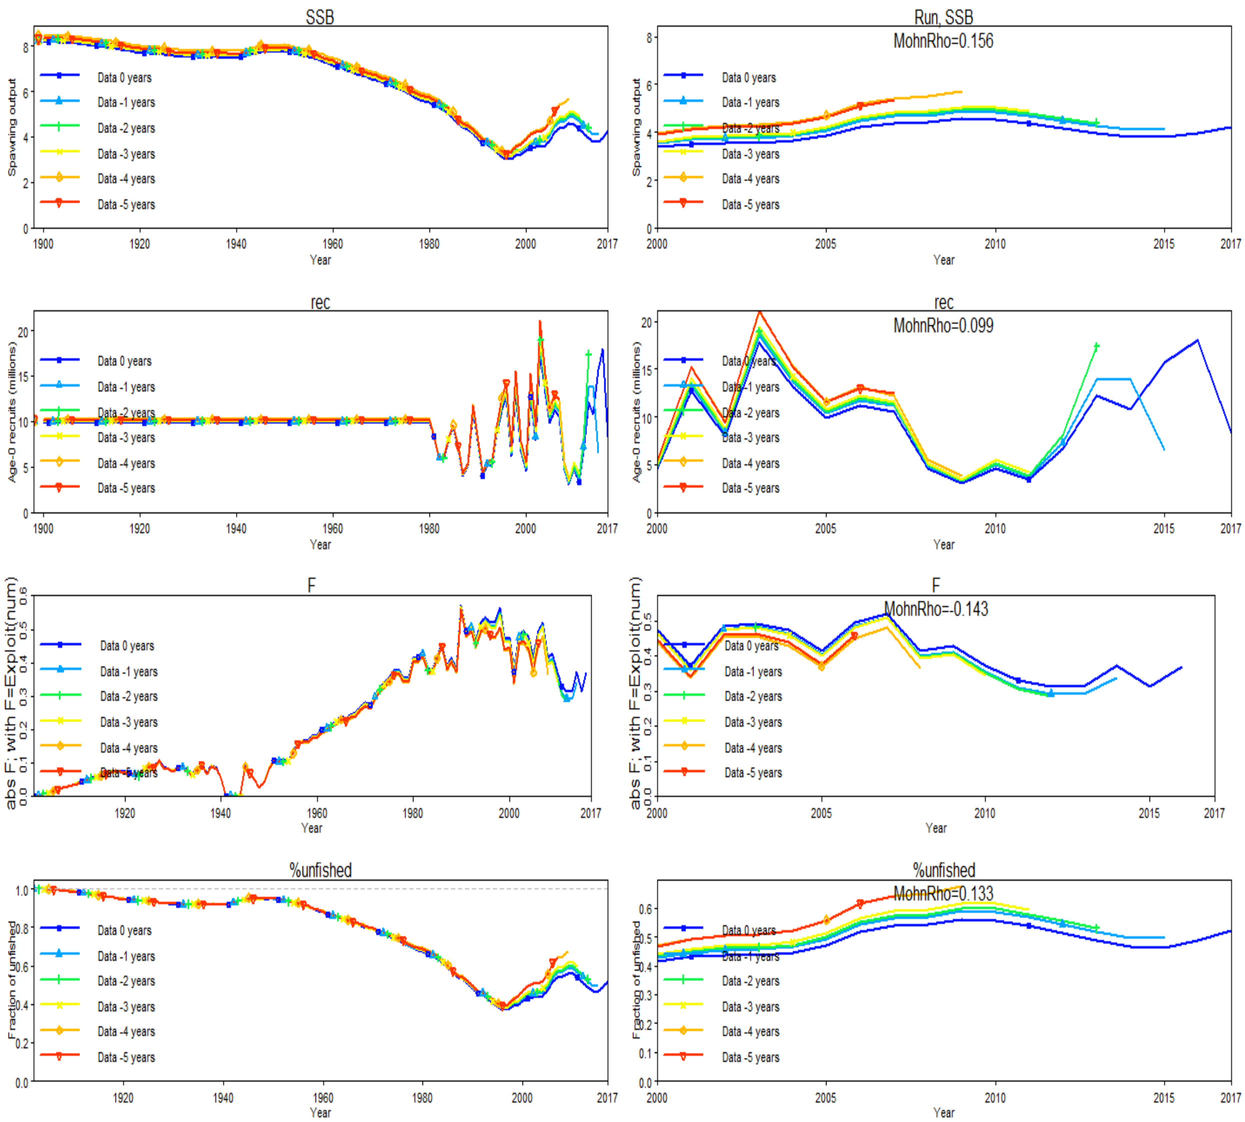

Figure 4.19. Predicted age-0 recruitment, spawning stock biomass (female SSB) and fishing mortality (exploitation rate in numbers) from the retrospective analysis for the entire time series and expanded to1980-2012.

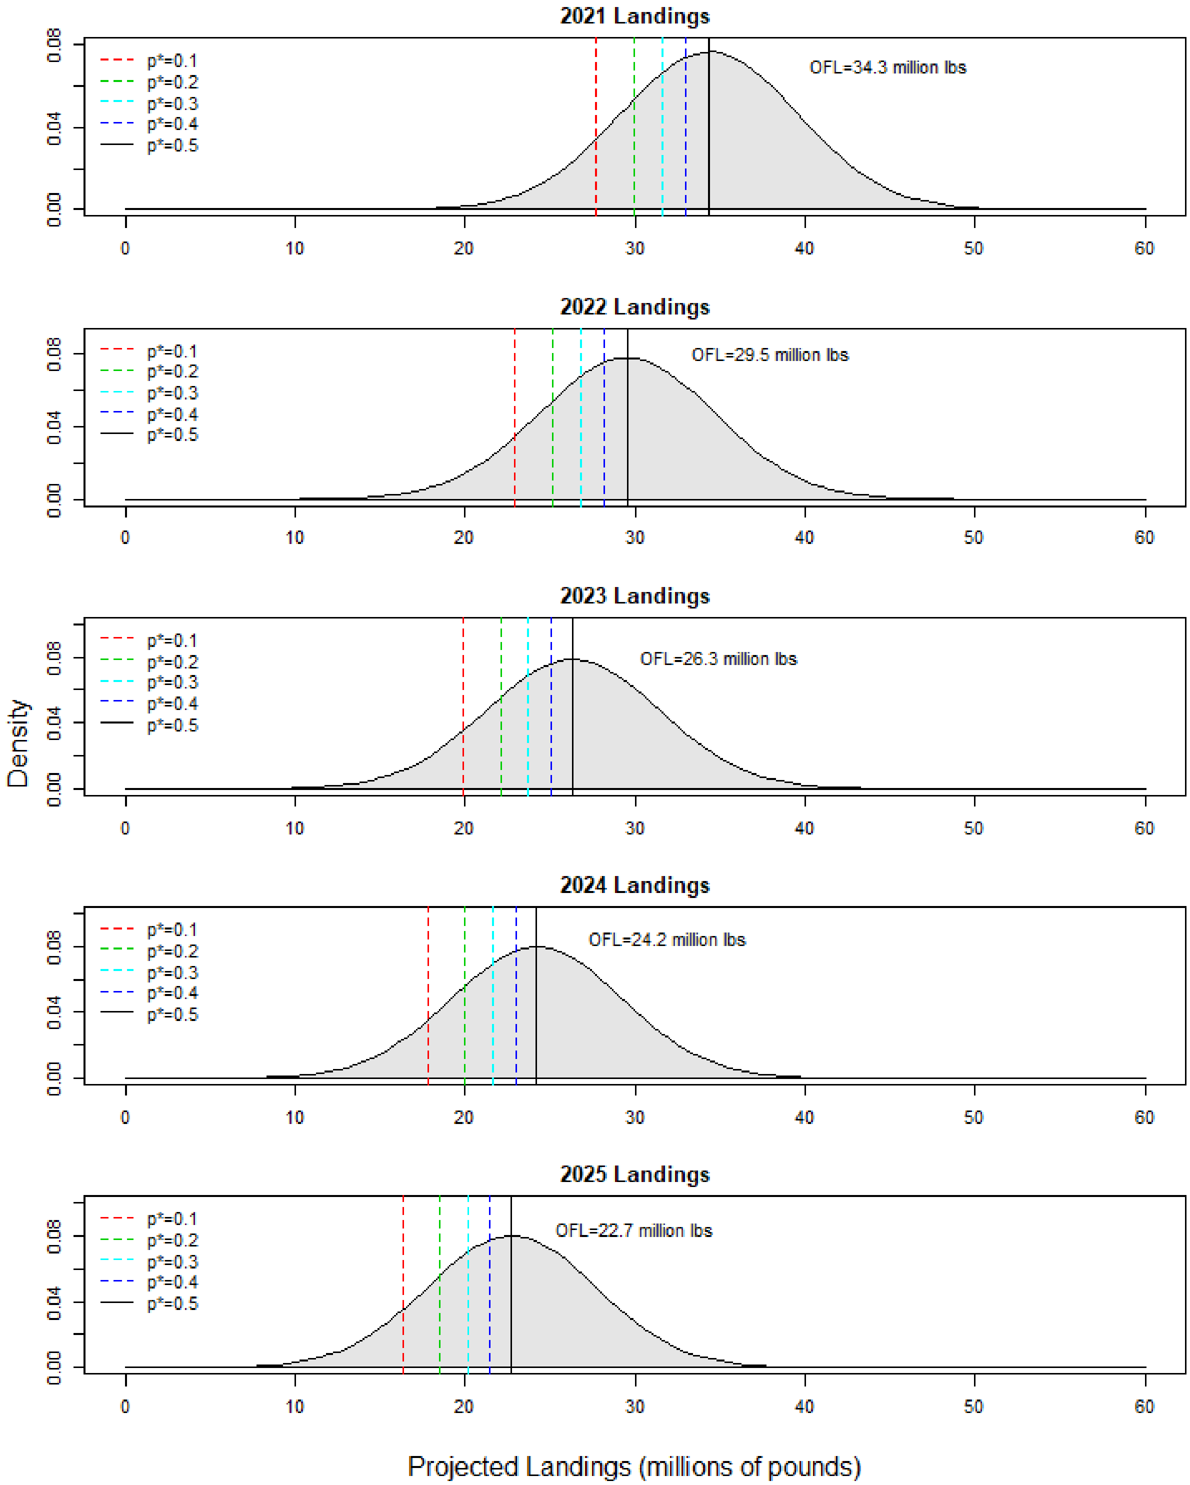

Figure 4.20. Projected catch limits of South Atlantic King Mackerel. The grey shaded areas are the density distributions of forecasted retained yields during fishing years 2021 to 2015. The solid, vertical, black lines show the overfishing limits (OFL, p-star=0.5). The red, green, cyan, and blue dashed lines show the allowable biological catch limits associated with p-stars of 0.1, 0.2, 0.3, and 0.4, respectively.

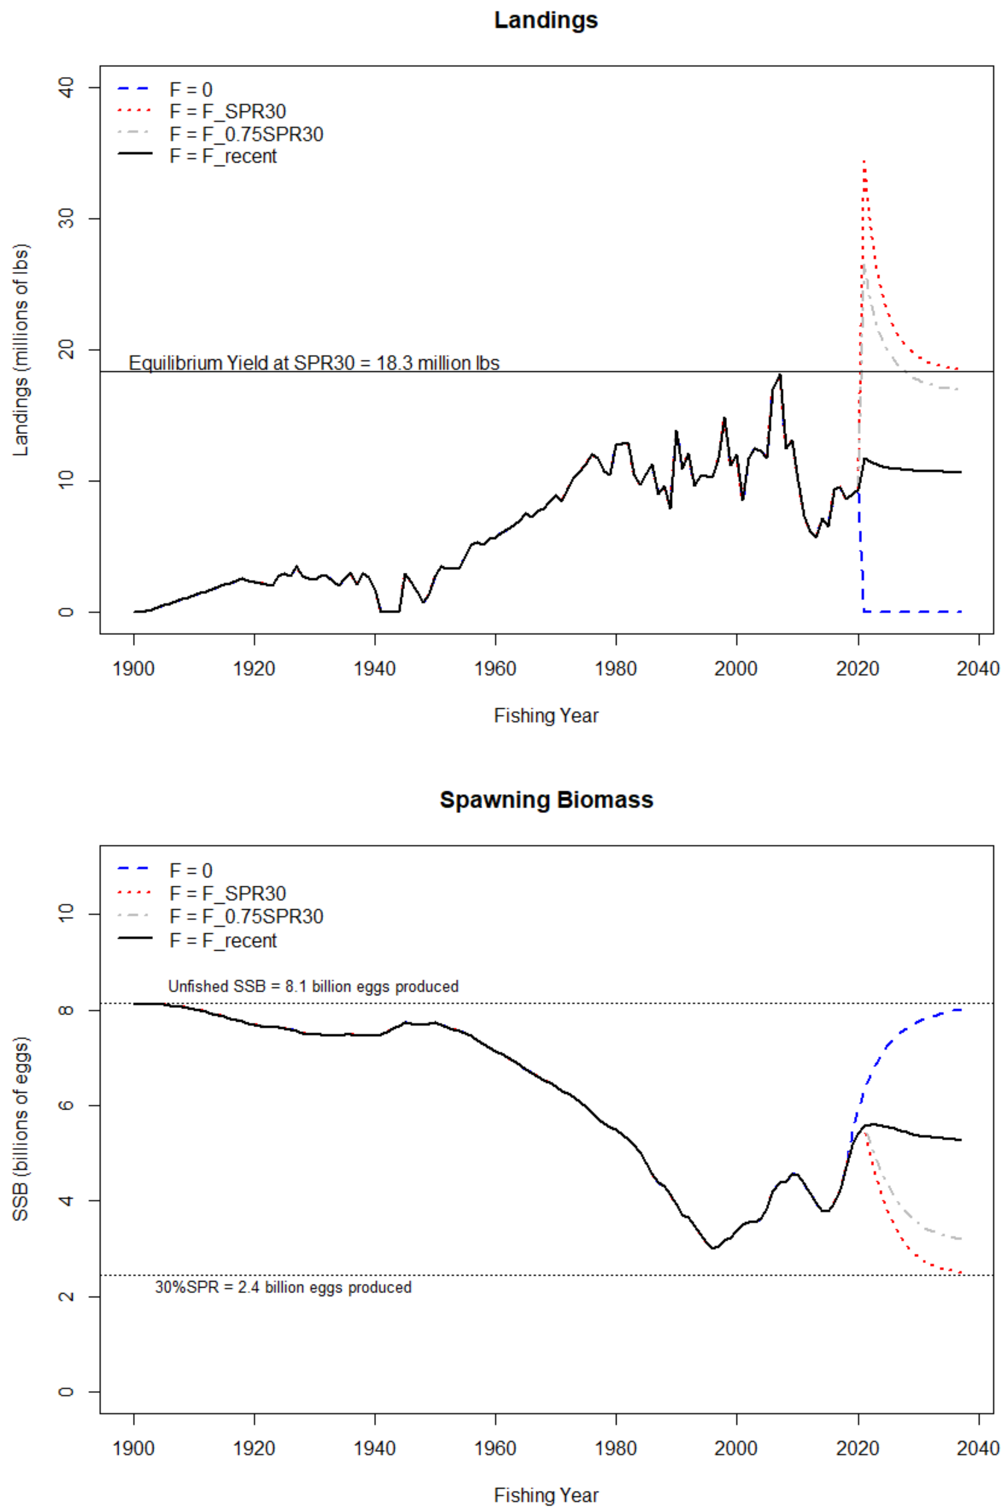

Figure 4.21. Projected landings (upper panel) and spawning biomass (lower panel) under alternative constant exploitation rate scenarios, including no fishing (F=0), fishing at the overfishing limit (F_{SPR30}=0.14), fishing at 75% of F_{SPR30} (F=0.11), and fishing at the recent average exploitation rate (F= 0.05).

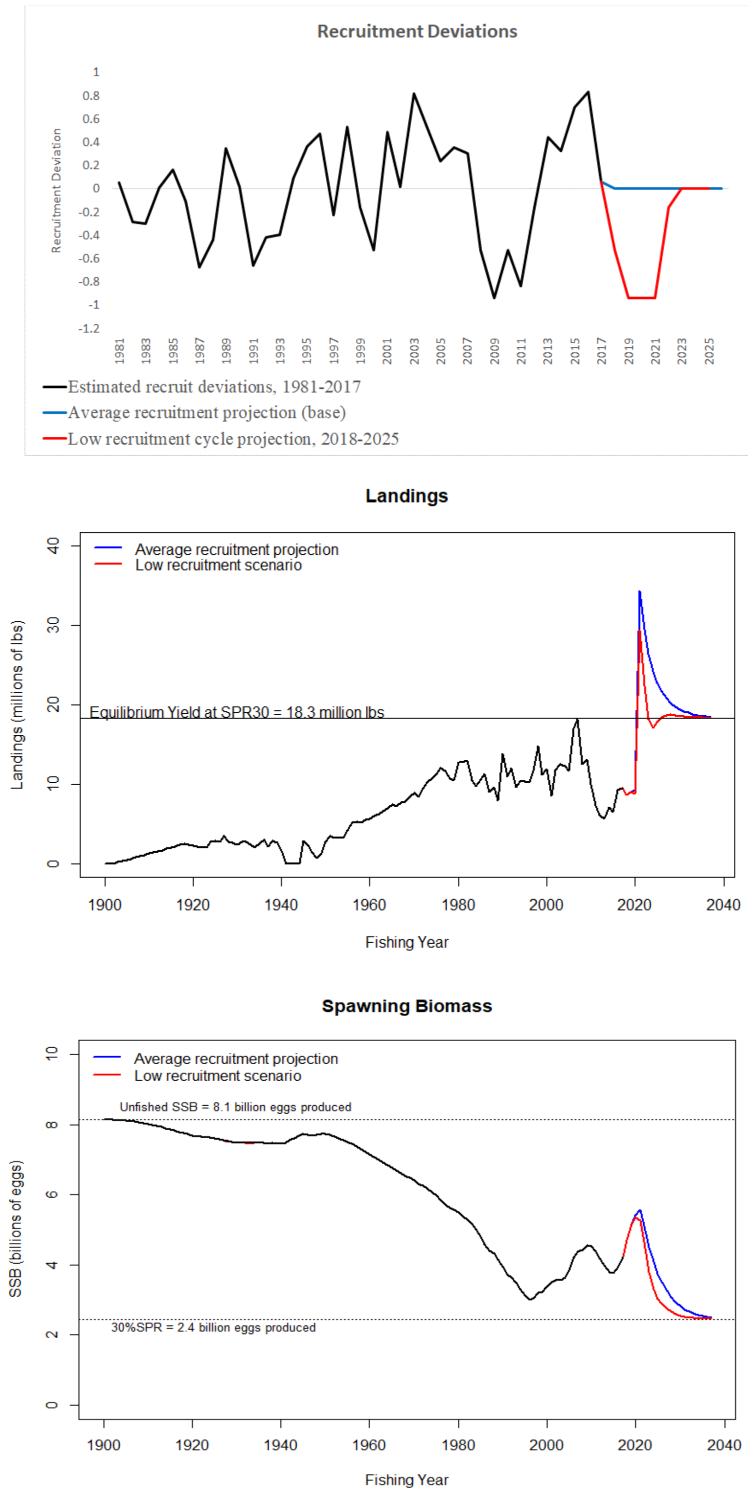

Figure 4.22. Low recruitment projection sensitivity analysis at fixed exploitation ($F=F_{SPR30}$). The upper panel shows the estimated recruitment deviations (1981-2017, black line), the average recruitment projection base parameterization (blue line), and the "what-if" low recruitment sensitivity parameterization that mimicked a low recruitment similar to 2008 to 2012 (red line). The middle panel shows the projected landings, and the lower plot compares the spawning biomass predictions between the two scenarios.
