Dear Sir or Madam,

Please consider our research article 'Evaluating methods for setting catch limits in data-limited fisheries' for publication in Fisheries Research.

The majority of global fish stocks lack adequate data to evaluate stock status using conventional stock assessment methods. This poses a challenge for the sustainable management of these stocks. Recent requirements to set scientifically-based catch limits in several countries and growing consumer demand for sustainably-managed fish have spurred an emerging field of methods for estimating overfishing thresholds and setting catch limits for stocks with limited data. Many of these approaches are now used to manage fish stocks but have not been subject to thorough evaluation.

Using a management strategy evaluation framework we quantified the performance of a number of data-limited methods for a range of life-history types. As part of this analysis we revealed the trade-offs among the management objectives of US managed stocks, for example yield and probability of overfishing. We also determined the value of collecting additional information to support either stock assessments or other data-moderate approaches that use current abundance information. We include a discussion of the implications for data-limited management and provide recommendations on how to approach the management of data-limited fisheries.

In our view this work provides an important step forward in the science of managing data-limited fisheries which is a global fishery problem.

This paper is all our own work and I have the full approval of all co-authors to submit the paper. It is not being submitted for publication anywhere else. The paper did not involve any interactions with animals.

Thank you for your consideration,

Thomas Carruthers

Highlights

- We undertake an MSE of data-limited methods for setting catch limits
- Methods that dynamically account for current abundance or depletion performed best
- Methods that set catch-limits to percentiles of historical catches performed poorly
- DB-SRA and methods that assume a fixed ratio of FMSY/M performed well
- Additional data or expert judgement can greatly improve management performance

Evaluating methods for setting catch limits in data-limited fisheries

Abstract

The majority of global fish stocks lack adequate data to evaluate stock status using conventional stock assessment methods. This poses a challenge for the sustainable management of these stocks. Recent requirements to set scientifically-based catch limits in several countries and growing consumer demand for sustainably-managed fish have spurred an emerging field of methods for estimating overfishing thresholds and setting catch limits for stocks with limited data. Using a management strategy evaluation framework we quantified the performance of a number of data-limited methods. For most life-histories, we found that methods that made use of only historical catches perform worse than maintaining current fishing levels. Only those methods that dynamically accounted for changes in abundance and/or depletion provided good performance at low stock sizes. Stock assessments that make use of historical catch and effort data did not necessarily out-perform simpler data-limited methods that made use of fewer data. There is a high value of additional information regarding stock depletion, historical fishing effort and current abundance when only catch data are available. We discuss the implications of our results for other data-limited methods and identify future research priorities.

Keywords

Data-limited, data-poor, management strategy evaluation, catch limits, simulation evaluation, stock assessment.

1 Introduction

The majority of global fish stocks lack adequate catch, survey, and other biological data to calculate current abundance and productivity using conventional stock assessment methods. In developed countries, the fraction of fish stocks that are assessed ranges between 10-50%. This fraction is generally lower in developing countries where it ranges between 5 and 20% (Costello et al., 2012). This poses a significant challenge for the sustainable management of these stocks. Recent requirements to set scientifically-based catch limits in countries such as Australia, New Zealand, and the United States, along with growing consumer demand for sustainably-managed fish, have spurred an emerging field of methods for estimating overfishing thresholds and setting catch limits for stocks with limited data.

In 2006, the U.S. Magnuson-Stevens Fishery Conservation and Management Act was amended to require annual catch limits (ACLs) to prevent overfishing for most federally-managed fish stocks, including many data-limited stocks. According to the National Marine Fisheries Service's (NMFS's) National Standard 1 Guidelines (2009), setting ACLs is a three-step process that begins by identifying an overfishing limit (OFL). The OFL is the annual catch that is the estimate of the maximum sustainable fishing mortality rate (F_{MSY}) multiplied by an estimate of the stock's current abundance. A harvest control rule is then used to determine the acceptable biological catch (ABC), which is the catch level equal to or less than the OFL that accounts for the scientific uncertainty in the estimate of the OFL. The ACL is the catch limit established by fisheries managers at a level equal to or below the ABC that accounts for various ecological, social, and economic factors, and uncertainty in management controls.

The most established basis for estimating an OFL is by a conventional stock assessment, which typically uses fishery time series data to estimate current stock size and productivity. However, many populations have insufficient fisheries catch data, survey data, or information about life-history characteristics to support a conventional stock assessment, requiring the use of alternative, data-limited methods. Most data-limited methods are designed to operate on a time series of annual catches with additional user-specified inputs for fisheries characteristics, demographic parameters, exploitation rate and/or stock status. Many of these methods are now being used in management, although they have not been thoroughly tested. Management strategy evaluation (MSE) is an appropriate tool to evaluate and compare the performance of existing methods across various types of fish stocks and relative population levels (see Section 2.2 for a detailed description of MSE). In this research we use MSE to test the performance of data-limited methods for various stock types and depletion levels (depletion is defined here as current biomass divided by unfished biomass).

Previous simulation evaluations of data-limited OFL-setting methods and ABC control rules were conducted by Wetzel and Punt (2011) and Wilberg et al. (2011). Wetzel and Punt (2011) evaluated the performance of two methods (DB-SRA and DCAC) over a range of population and fishery dynamics. Limitations of their approach include the simulation of a relatively narrow range of fishery dynamics without simultaneously considering a realistic level of uncertainty and bias in all of the inputs to the methods under scrutiny (e.g., natural mortality rate, *M*). Wilberg et al. (2011) simulation tested a more comprehensive range of data-limited methods. However, not all data-limited methods were applied to all stock types preventing a complete performance comparison (Vaughan et al., 2012). Their approach was also criticised on the basis of a relatively narrow range of simulated life-histories and discrete simulation of error and bias. We aim to address these criticisms by (1) simulating a wide range of fishery and population dynamics and (2) assigning probability distributions for bias and imprecision to more of the inputs to data-limited methods (e.g., depletion, *M*) to better reflect imperfect knowledge to more clearly reveal trade-offs in the performance characteristics of data-limited method.

2 Materials and methods

This research is aimed at evaluating methods that determine an ABC as a basis for setting annual catch limits. Twenty-five methods for determining OFLs and modifying them using ABC control rules are evaluated, including nine that have been used in the management of U.S. fisheries (M1-M9), 12 alternative methods (A1-A12), and four reference methods that can be used to assess comparatively the performance of the other methods (R1-R4).

The methods are classified as follows: (1) those that rely on a time series of recent catch ("catch-based methods"); (2) those that adjust historical catches using assumptions about historic depletion and life history characteristics ("depletion-based methods"), and (3) those that rely primarily on current estimates of abundance ("abundance-based methods"). Methods within these classes can be further distinguished into those methods that dynamically update with current information on abundance or depletion and those that remain static. The following section describes the specific methods selected for evaluation (see Table 1 for a list of all methods). The data requirements of each method tested are summarized in Table 2, and their detailed description can be found in Appendix B.

These methods are subject to modification by two types of ABC control rule. The first is no downward adjustment. For example, methods M1-M3 are catch methods for which ABC equals the OFL. The second type of ABC control rule uses a simple scalar approach in which a point value produced by a method (e.g., the median outcome of DB-SRA or DCAC) is multiplied by a factor. These scalar factors differ depending on a broadly-defined characterization of scientific uncertainty for different groups of stocks (e.g., alternative methods A1, A2 and A7-A12 make use of 75% and 100% scalars).

2.1 Methods evaluated in this study

2.1.1 Catch-based methods

Catch-based methods have generally been employed where insufficient data exist for determining an OFL using more sophisticated methods. For example, the U.S. Southeast and Mid-Atlantic Fishery Management Councils currently apply catch-based methods to dozens of stocks. The South Atlantic Fishery Management Council (SAFMC) has adopted two quantitative approaches to ACL-setting that can be simulation tested: an OFL set to the third highest landing over the last ten years or the median landings over the last ten years (SAFMC, 2011). The Mid-Atlantic Fishery Management Council has adopted an OFL for Atlantic Mackerel that is the median catch from the last three years (MAFMC, 2010; NMFS, 2011). These approaches stem from the work of Restrepo et al. (1998) who suggested the use of average catches with a downward adjustment based on to uncertainty about stock status, although these implementations do not include a downward adjustment. All three of these methods are tested: the median catch over the most recent three years (M1), the median catch over the most recent 10 years (M2), and the third-highest catch over the most recent 10 years (M3).

Other catch-based methods that have been proposed attempt to introduce dynamic updates of simple catch-based control rules based on generally subjective scoring systems, such as the Only Reliable Catch Stocks (ORCS, Berkson et al., 2011) method and Productivity-Susceptibility Analysis (PSA, Patrick et al., 2009. Both of these approaches use biological and fishery characteristics to calculate a single value. Berkson et al. (2011) identify a possible means of using the outcome from ORCS to categorize stocks into exploitation levels. Each level leads to a different multiplication of interquartile mean catch (the average of all catches greater than the 25^{th} percentile and less than the 75^{th} percentile) that is selected as a proxy for OFL or ABC. PSA has been suggested as a basis for an ABC control rule that increases the precautionary buffer with increasing vulnerability of the stock (Berkson et al., 2011). Unfortunately, it proved difficult to test these approaches in this study due to an inability to simulate the subjective scoring systems in a defensible way. The success of the methods is likely to be determined by how they are implemented, so we decided to omit them from the comparative performance analysis. However, a control rule, similar to that proposed by Berkson et al. (2011) is tested. This control rule dynamically scales a catch-based OFL according to periodic estimates of depletion. The OFL is set to half, equal or twice the interquartile mean catch when current biomass is considered to be less than 20% of unfished, greater than 20% and less than 65% of unfished, and greater than 65% of unfished levels, respectively. In lieu of a subjective scoring system to estimate depletion, we test the performance of the catch scalar methods using imperfect knowledge of simulated current depletion. An imperfect estimate of depletion can be simulated by calculating the current level of stock depletion (current biomass divided by unfished biomass) and then adding error according to specified levels of bias and imprecision. This method (referred to as “Depletion Adjusted Catch Scalar”, DACS) is tested with two ABC control rules: 75% and 100% scalars (methods A1 and A2).

2.1.2 Depletion-based methods

These data-limited methods rely on estimates of depletion relative to an unfished population, combined with other inputs to estimate an OFL directly or to adjust historical catch with historical depletion to derive a catch level recommendation. Depletion-Based Stock Reduction Analysis (DB-SRA, Dick and MacCall,

2011) is an method for estimating an OFL based on a complete time series of historical catches and four key inputs: (1) the level of current depletion, (2) the ratio of F_{MSY} to the natural mortality rate (F_{MSY}/M), (3) the natural mortality rate (M) and (4) the most productive stock size relative to unfished (B_{MSY}/B_0). Given input values for M , F_{MSY}/M and B_{MSY}/B_0, DB-SRA finds a stock reconstruction that matches the input level of depletion and historical catch. DB-SRA then calculates the OFL by multiplying together F_{MSY}, depletion, and the reconstructed unfished biomass. The process is stochastic, and samples many values for all four inputs, each sample leading to an estimate of unfished biomass and therefore an OFL recommendation (see Appendix B.1 for details). DB-SRA also requires an estimate of the age at which fish become recruited to the fishery since it assumes delay-difference stock dynamics.

Depletion-Corrected Average Catch (DCAC, MacCall, 2009) provides an estimate of "sustainable catch" based on a time series of historical catches and the same four key inputs as DB-SRA (depletion, F_{MSY}/M, M and B_{MSY}/B_0). In essence, DCAC calculates average catches accounting for the removal of the "windfall harvest" of less productive biomass that may have occurred as the stock became depleted (the equations are included in the Appendix B.1). DCAC requires the same inputs as DB-SRA and is also stochastic in nature, sampling many input values to produce numerous estimates of "sustainable catch."

Both DB-SRA and DCAC are currently being used to set OFLs and ABCs for data-limited stocks by the Pacific Fishery Management Council (PFMC, 2010). Different ABC control rules are applied depending on the degree of scientific uncertainty for different stocks. The Pacific Fishery Management Council's implementation of DB-SRA and DCAC assumes that current depletion is, on average, 40% of unfished biomass – for many stocks this may be considered a productive and healthy stock size (Dick and MacCall, 2010). These methods also do not make direct use of the stochastic OFL output of DB-SRA and DCAC. Instead, a downward adjustment is achieved by superimposing a distribution (with a pre-specified variance) over the median OFL estimate from DB-SRA and DCAC. It is a percentile of this superimposed distribution that is used as the ABC. Three versions of DB-SRA and DCAC are tested that rely on distributions for depletion which are centered on 40% of unfished biomass. The OFL for each method is then adjusted according to the same ABC control rules applied to different categories of data-limited stocks by the PFMC (M4-M9, Appendix B.1).

Two generic implementations of DB-SRA and DCAC were tested (A3-A6) that include dynamic updates in depletion (they are linked to the actual simulated level of stock depletion and do not rely on a fixed assumption of 40% unfished biomass). Additionally these implementations make direct use of the stochastic output of DB-SRA and DCAC to derive the ABC based on pre-specified percentiles (25% and 50%).

2.1.3 Abundance-based methods

As an alternative to data-limited methods that rely solely or primarily on catch data and/or depletion estimates we tested a class of alternative methods that rely on estimates of current abundance and F_{MSY}. While methods such as DB-SRA attempt to reconstruct the historical stock trajectory, abundance-based methods rely only on current data. The methods that use current biomass are also not reliant on historical catch data and there is no positive feedback from previous management recommendations (the catch prescribed in one year does not directly inform the next catch recommendation). These methods also rely on weaker assumptions of stationary population and fishery dynamics.

We examine two methods of quantifying F_{MSY} based on growth and natural mortality rate. Beddington and Kirkwood (2005) describe a method for calculating F_{MSY} using length at first capture and information about maximum growth rate of individuals. Simpler still are methods that assume a fixed value for F_{MSY}/M. The originator of this concept, Gulland (1971), assumed $F_{MSY} = M$. Subsequent publications have recommended lower ratios of 0.8 (Thompson 1993) and 0.5 (Walters and Martell 2002). An estimate of current biomass is required to apply these approaches. The North Pacific Fishery Management Council (NPFMC) currently uses an F_{MSY}/M ratio method for managing stocks for which typical stock assessment reference points are not available ('Tier 5' stocks NPFMC, 2012; 2013, referred to as 'data poor' by DiCosimo et al., 2010). Six variants of the abundance-based method are considered (A7-A12) depending on the assumed ratio of F_{MSY} to M, and the assumed ratio of the ABC to the OFL.

2.1.4 Reference cases

Four reference cases are included to provide a yardstick for the performance of the methods described above (R1-R4). We test a stock assessment method based on a delay-difference model (Deriso, 1980, Schnute,

1985) (R1-R2), which may be applied in instances where catch age- and length-composition data are not available (similar population dynamics are assumed by DB-SRA). The delay-difference assessment also requires auxiliary information regarding the form of the stock-recruit function, the fraction of mature fish-at-age, body growth rate, natural mortality rate, and the vulnerability-at-age curve. It can estimate OFL directly because it estimates current biomass and F_{MSY}. The performance of 100% and 75% scalar ABC control rules is evaluated. Similar to the data-limited methods, the delay-difference stock assessment method has inputs that are subject to imperfect information regarding historical catches. The delay-difference reference cases may be expected to perform better than the data-limited methods that only make use of catch data. Two “status quo” reference cases are simulated to frame the results of the data-limited methods in terms of two non-adaptive methods: (R3) a constant current catch scenario and (R4) a constant current effort scenario.

2.2 Management strategy evaluation

Experimental evaluation of methods for setting OFLs and ABCs through manipulation and monitoring of wild populations is impractical. Previous research has sought to compare the outputs of data-limited methods with those of data-rich assessments given the same data (e.g., Dick and MacCall, 2011). The principal limitation of this approach is the difficulty in assessing risks, and the inability to quantify bias. For example, relatively large differences in predicted fishing mortality rate (F) between an assessment and a data-limited method may not translate to commensurate differences in the risks of certain events occurring (e.g., the probability of reduction in biomass below B_{MSY}). Stock assessment models typically make use of common assumptions that may bias their results in similar ways (e.g., not accounting for habitat degradation, spatial expansion of fishing, or increases in fishing efficiency), and may therefore provide a limited basis for comparative performance evaluation. Equally, the stocks that are subject to assessment may not be representative of those with limited data; perhaps due to economic value they are heavily exploited or conversely subject to stringent management. Fundamentally, it is not possible to evaluate the accuracy of a data-limited method without knowledge of the quantity which is to be estimated (e.g., real abundance or simulated abundance). For these reasons simulation evaluation is recommended as an important first step in testing data-limited methods (Honey et al., 2010, Butterworth et al., 2010).

Management Strategy Evaluation (MSE, Cochrane et al., 1998, Butterworth and Punt, 1999) is a simulation approach which generates many realizations of a real fishery system encompassing a credible range of population and exploitation scenarios. The simulated reality, commonly referred to as the "operating model," is then projected forward in time and updated according to the ACL recommendations generated by a particular management method (the ACL is assumed to be the ABC in this study). The relative performance of each management strategy can then be evaluated relative to defined management objectives. MSE also provides an opportunity to better understand the trade-offs among management objectives for any given management method and to quantify the value of various types of information and data. The core requirements of the MSE approach are the operating model that can describes the "true" simulated population (Section 2.3), a range of candidate management methods (Section 2.1), and criteria for evaluating the performance of management methods (Section 2.7). Figure 1 describes the components of the MSE design as it related to this research.

2.3 Operating model

The operating model is parameterized for six life-history types (also referred to as "stocks" or "simulated stocks"): mackerel (*Scombridae*), butterfish (*Stromateidae*), snapper (*Lutjanidae*), porgy (*Sparidae*), sole (*Pleuronectidae*) and rockfish (*Sebastidae*)[1]. In addition to providing diversity in life-history, these stocks also represent generic versions of real-world stocks that appear in various geographic regions. The historical simulation of population and fishery dynamics lasted 50 years and involved random selections for various parameters. This duration was sufficiently long to develop a range of exploitation patterns over a length of time similar to post-war industrial fishing. Management reference points such as maximum sustainable yield (MSY), B_{MSY}, and F_{MSY} were then calculated for each simulation. Bias and imprecision in the knowledge of the simulated system were generated for all variables and parameters used by the management methods (e.g., *M*, current biomass, etc.). Each simulation was then projected forward subject to the ABC recommendations from each of the management methods. This update of information and setting of a new ABC was simulated every three years of the projection period to approximate a typical assessment cycle. To provide meaningful advice over a time-scale relevant to each stock, generation time was used as a basis for setting the number of

[1] The results of this research should not be interpreted as empirical support for the status of real-world fish stocks.

projected years. Simulations were projected for a maximum of either 30 years or twice the mean generation time. The rockfish stock, with a generation time of 25 years, was projected for 50 years.

A total of 10,000 simulations were conducted for each stock type. A much lower level of replication was required to obtain stability in aggregate performance metrics (the difference was less than 2% between 2,000 and 3,000 simulations for such metrics). However a larger degree of replication was required to provide plots of trends in performance with changing simulation parameters. The simulation evaluation framework was programmed in the statistical environment R (2.15.0 64bit, R Development Core Team, 2012) using the "Snowfall" package for parallel computing.

The "branched" form of experimental design (Figure 2) allows management methods to be compared side-by-side because projections are made from the same set of historical simulations and the same future recruitment patterns. An additional benefit of this design is that the performance of any management method can be phrased in terms of a "best case" reference method based on identical conditions. For example, for any given simulation the predicted yield of a particular management method can be standardized by dividing it by the "best case" yield that could be obtained with perfect knowledge.

The operating model was an age-structured, spatial model (a detailed description can be found in Appendix A). Simulating spatial dynamics provided the basis to account for differences among life-history types that may be considered important, such as low mixing among areas and refuges from fishing. All stocks are assumed to have density-dependent recruitment that does not decrease with increasing stock size, and maximum surplus recruitment is achieved when spawning output is less than half of unfished (Beverton and Holt, 1957). For the purposes of simulation, variability among simulations and where applicable, inter-annual variability within simulations, was generated in a number of biological parameters such as M, stock-recruitment parameters and recruitment deviations. The location and slope of the age-at-maturity curve, weight-at-length curve and scale parameters such as unfished stock size and maximum length did not vary among simulations for the same stock.

Five discrete areas were modelled for each population. The operating model can generate both directed and diffusive movement among areas by adjusting regional gravity parameters and a stock mixing ("viscosity") parameter (Equations App.A.27 and App.A.28). With the exception of recruitment deviations, all population dynamics parameters were assumed to be time-invariant. Simulations were also conducted without spatial structure to evaluate the sensitivity of results.

The exploitation of each stock was simplified by approximating multi-fleet fishing dynamics with a single temporal trend in fishing mortality rate (see Appendix App.A.2 for full details). The underlying trend in effort always increased during the first 25 years. Subsequently fishing effort could range from a strong decline to a steep increase over the last 25 historical years. The same inter-annual variation in effort was simulated for each stock with a Coefficient of Variation (CV) ranging from 0.2 and 0.4. For all stocks, catch observation was sampled over a range for the CV of 0.1 to 0.5, considered to represent the possible uncertainty in catch observations. The same wide range of effort dynamics was generated for each stock to make the results general to life-history type. Some species-specific fishery characteristics were specified, including vulnerability-at-age, spatial targeting (or avoidance) and spatial refuges from fishing. While fishing effort, targeting and fishing efficiency could change temporally, all other fishery characteristics were assumed to remain constant over time.

2.4 Defining simulations for specific stocks

The operating model inputs for each stock are summarized in Table App.A.1. Some of these inputs describe a range from which a value is sampled (e.g., M uniformly sampled between 0.2 and 0.4 yr^{-1}). The number of areas (5), historical simulation years (50), the level of unfished recruitment, the rate of catch observation error and the variability in the simulated trend in effort are the same for each stock.

Fifty years of historical projection prior to first application of the management methods (Figure 3) led to a wide range of depletions that were nevertheless comparable among stocks so that conclusions were not confounded by stock-specific depletion levels. All stocks had mean depletion values close to 45% at the end of the historical simulation period (Figure 3). The exception is butterfish which, due to a short life-span and high recruitment variability, could not be made comparable to the depletion distributions of the other stocks. The six life-history types span a reasonably wide range of values for B_{MSY}/B_0 (mean simulated values in the range of 0.33 for sole to 0.52 for butterfish). The range for F_{MSY} / M among stocks was greater, with mean values between 0.27 (rockfish) and 1.4 (snapper). F_{MSY} varied widely among stocks, with mean rates of 0.05 for sole and 0.6 for butterfish.

2.5 Calculating MSY reference points

B_{MSY} and F_{MSY} are required to evaluate the performance of data-limited methods (Section 2.7). These quantities were computed for each simulation model by projecting it forward for 100 years, numerically optimizing for the fishing effort that provided the maximum yield. Optimizations were undertaken assuming that future recruitment is deterministically related to the stock-recruit relationship, and that there are no changes in fisheries targeting and catchability.

2.6 Simulating imperfect knowledge

There may be considerable uncertainty regarding the inputs to the management methods so imperfect knowledge of these quantities was simulated by adding error to the "true" simulated values of the operating model. Since these inputs are likely to control the relative performance of the methods they are assigned ranges that are considered to be representative of the magnitude of uncertainty in a data-limited setting. An additional purpose for generating imperfect information is to determine the effect of the misspecification of inputs on the performance of a particular management method. A related objective is quantifying the value of more precise and/or accurate information regarding population variables (e.g., current stock depletion) and parameters (e.g., *M*).

Table 3 describes how bias (and in some cases imprecision) was introduced to operating model parameters that are used by the management methods. All such variables have the subscript "*obs*" to denote an observed quantity. For example, M_{obs} is the simulated value of *M*, subject to variable bias determined by a coefficient of variation parameter CV_M. In each simulation the same biased level of M_{obs} is used throughout the projection to determine OFLs and ABCs. In some cases, data-limited methods require inputs that are updated annually as the population is projected (e.g., current biomass $Bcur_{obs}$, current depletion, and current fishing mortality rate). Both bias and imprecision are simulated in such instances. For example, $Bcur_{obs}$ is the simulated "true" current biomass (*Bcur*), subject to error sampled in each projected year according to a bias

(μ_{Bcur}) and imprecision (σ_{Bcur}) that are perpetuated over the whole projection (on average inputs can be positively or negatively biased and precise or imprecise over the whole projection). The rationale for the values of these inputs is explained further in Appendix A.5.

2.7 Evaluating performance

Performance of the data-limited and reference methods were evaluated against the legal standards implied by the Magnuson-Stevens Fishery Conservation and Management Act ("MSA"): preventing overfishing, avoiding becoming overfished, and producing maximum sustainable yield. The MSA's National Standard 1 (NSG, 2009) requires that "[c]onservation and management measures shall prevent overfishing while achieving, on a continuing basis, the optimum yield from each fishery." 16 U.S.C. § 1851(a)(1). The National Standard 1 Guidelines (50 C.F.R. § 600.310(f)(4)) specify that the probability of overfishing cannot exceed 50%, but should be lower based on the degree of scientific uncertainty in the estimate of the OFL. The MSA requires that overfished stocks, which are often defined as $Bcur/B_{MSY}$ < 50% be rebuilt as fast as possible.

Performance was measured in terms of preventing overfishing, avoiding becoming overfished, and producing long-term yield in light of these management objectives. The probability of overfishing is recorded for each simulation by calculating the fraction of projected years in which $F > F_{MSY}$. This can be averaged over multiple simulations to create a probability of overfishing metric (POF) that is the expected probability of overfishing in projected years using a particular management method. We use B_{MSY} as a management reference point for overfished stock status. Similarly to the POF metric, the future stock biomass relative to B_{MSY} (B/B_{MSY}) can be averaged over projected years and simulations to provide the expectation of stock status using a particular management method. Absolute yield of any projection is difficult to interpret because it depends on the specific conditions of each projection (i.e., starting depletion, future productivity, etc.). A standardized measure of yield was calculated by dividing the total projected yield for each simulation by the catch under F_{ref}, the constant F that maximizes catch over the projected time period with perfect knowledge of future recruitment deviations. In this way, yields are standardized by an "upper bound." In some cases it is possible for a method to obtain relatively high yields over the whole projection by depleting the stock (a "mining" strategy). The yield metric was calculated based on the last five years of each projection (e.g., the yield from a method in projected years 26-30 divided by the yield of the F_{ref} strategy in projected years 26-30) since it is of more interest to identify methods that can achieve sustainable long-term yields. This was averaged over simulations to provide the expected relative yield (herein referred to as 'Yield') of a management method. The metrics POF, B/B_{MSY} and Yield relate to the central reference points for overfishing, overfished status and sustainable yield, but cannot be readily interpreted in terms of the average trajectory of biomass using a particular management method. To address this, we derive four additional metrics that relate to stock status in the final three years of the projections. The probability of biomass increasing, P_{inc}, is the fraction of projected simulations for which average biomass in the last three years of the projection is larger than average biomass for the last three years of the historical simulation. B_{end} is the mean biomass over the final three years of the projection divided by B_{MSY} averaged over simulations. The probability of ending below 50% B_{MSY}, $P_{<50}$ is the fraction of runs for which the mean biomass of the last three projected years is below 50% B_{MSY}. Similarly, $P_{<10}$ is the fraction of runs ending below 10% B_{MSY}.

2.7 Quantifying value of information

We evaluated how long-term yield can be expected to vary with the uncertainty in each input to quantify the value of various sources of information for each method. This involved taking each input variable/parameter in turn and subdividing the simulations into ten equally sized blocks relating to the 10th percentiles of the sampled input. For example, those samples lower than the 10th percentile of sampled bias in depletion, those samples greater than or equal to the 10th percentile but less than the 20th percentile of bias in depletion, etc. The mean relative yield for each of the ten subdivisions was calculated for each method. The standard deviation of these relative yield scores can be interpreted as the marginal effect of an input variable on expected yield. These results are unit-less because they are standardized according to the level of simulated uncertainty for each of the input parameters/variables.

3 Results

3.1 Performance

The general results statements below refer to the mackerel, snapper, porgy, sole and rockfish simulations. Since the butterfish simulations behaved very differently from the other stocks these results are discussed separately in Section 3.2. It was instructive to separate the simulations according to the depletion at the start of the projection. Four categories were chosen relating to projections starting (1) below 50% of B_{MSY}, (2) between 50% and 100% B_{MSY}, (3) between 100% and 150% of B_{MSY} and (4) above 150% B_{MSY}. The largest discrepancies in performance were found among the first three categories and for the benefit of brevity the tables for projections starting above 150% B_{MSY} are included in the Appendix C.

3.1.1 Catch-based methods

Methods that set the ABC to average historical catches or a percentile of recent catch (M1-M3) led to the worst performance of the methods tested by a large margin. When starting below 50% B_{MSY}, the probability of overfishing was high – typically above 80% ("P_{OF}", Table 4). While some catch-based methods performed better at moderate levels of depletion (above 50% of B_{MSY}) particularly in regard to yield, they still led to relatively high probabilities of overfishing—in most cases exceeding 60% of the simulated runs (Tables 5 and 6). Below 50% B_{MSY} these static catch-based methods failed to rebuild stocks above 50% B_{MSY} in the majority of simulations (between 60% and 95%; on most occasions the failure rate was over 85% ("$P_{<10}$", Table 7). The static catch based methods could lead to very high probabilities of dropping below 10% of B_{MSY} generally ranging between 40% to 60% when applied to stocks starting below B_{MSY} (Table 8). Relative to other methods, $P_{<10}$ remained high even when stock levels were above B_{MSY} (between 12% and 26% for M1-M3 compared with less than 2% for M4-M9, Table 9). Methods M1-M3 also led to amongst the lowest yields in simulations starting below B_{MSY} (Figures 4 and 5). The performance of these methods was poor for all stocks except butterfish (see Section 3.2), and was not as strongly related to life-history type compared to the other methods. Methods M1-M3 performed worse than the "status quo" current catch and effort scenarios (R3-R4) in several instances. This was particularly the case for method M3 (ABC set at the third highest historical catch) which drove 19 out of 20 stocks that were already below 50% of B_{MSY} at the start of the projection to below 10% of B_{MSY} by the end of the projection (Table 4). This was only somewhat reduced to 7 out of 10 stocks in those simulations starting between 50% and 100% of B_{MSY} (Table 5).

The dynamic catch-based methods A1 and A2 led to intermediate performance at initially low stock sizes (i.e., less than 50% B_{MSY}) in terms of the probability of overfishing and yield relative to the other methods. They performed much better, leading to reasonably high yields (approximately 50%-80% of those corresponding to F_{ref}), with moderate probabilities of overfishing (approximately 30%-40%) at initially moderate stock levels (greater than 50% B_{MSY} less than 150% B_{MSY}) (Tables 8 and 9, Figures 5 and 6). Methods A1 and A2 reduced catches by multiplying historical mean catch by 50% when the stock declines below 20% of unfished levels. This does not appear to be sufficiently responsive to prevent these methods from frequently depleting the stock below the overfished threshold of 50% B_{MSY}, even in simulations that start above 50% B_{MSY} (Tables 8 and 9).

3.1.2 Depletion-based methods

The static implementation of DB-SRA that assumes that stock depletion is, on average, 40% of unfished levels (equivalent to ~100% of B_{MSY}) performed well when this assumption was reasonably close to actual depletion (e.g., 50%-150% of B_{MSY}, Tables 5 and 6). At these stock levels, the probability of overfishing, projected stock status (B/B_{MSY}) and yield were among the best of any method. The probabilities of stocks falling below 50% B_{MSY} were also relatively small, with the majority of cases exhibiting an increasing biomass trend on average ("P_{inc}", Table 8). However, these methods prescribed OFLs that were too high and stocks suffered from high probabilities of overfishing, depletion and consequently reduced yields when starting biomass was much below that assumed (Table 4). Since the PFMC DB-SRA methods do not introduce feedback between stock status and the OFL recommendation, these methods suffer from a similar, but less pronounced phenomenon as the average catch methods. SB-SRA performed relatively poorly, leading to a low probability of recovery from biomass below 50% B_{MSY} regardless of the ABC control rule (scalar multipliers between 69% and 91%) ('$P_{<50}$', Table 7). This was particularly the case for the mackerel and porgy stocks, where the probability of projections ending below half of B_{MSY} was between 50% and 80% when starting below half of B_{MSY} (Table 7).

DB-SRA and DCAC performed somewhat better for long-lived life history types such as snapper and rockfish compared with other methods. This result is a product of the greater "windfall" biomass of older age classes, that is deliberately accounted for by DCAC and is approximated by the delay-difference stock dynamics of DB-SRA.

Performance is improved for stocks starting below 50% B_{MSY} when stock depletion when DB-SRA is updated dynamically (methods A3 and A4), leading to a less than 20% probability of overfishing on average.

Methods A3 and A4 lead to increasing biomass from low levels in over 70% of simulations regardless of life-history type (Table 7). Rebuilding performance was considerably worse for the simulations for mackerel, and while these methods managed better performance than any other method, between 36% and 42% of stocks did not rebuild above the 50% B_{MSY}. The performance of methods A3 and A4 became much worse at higher stock levels in comparison to the other data-limited methods largely due to the high level of uncertainty regarding depletion. This led to many occasions when depletion was assumed to be too high leading to inflated OFL recommendations and consequently stock declines.

MacCall (2009) notes that DCAC is “not directly suitable for specifying catches in a stock-rebuilding program.” This is because it returns an estimate of an MSY proxy (“sustainable catch” which is particular to a productive stock size) and not an estimate of the OFL (which changes with depletion level). It is not surprising, therefore, that DCAC performs relatively poorly at low starting levels (below 50% B_{MSY}, Tables 4 and 7) regardless of whether or not depletion is dynamically updated. The static DCAC provides yields and probabilities of overfishing comparable to the best performing methods at intermediate levels of depletion when the stock is closer to MSY levels (Tables 5 and 8). As is the case with the dynamic update in DB-SRA, the high level of uncertainty in current depletion that was simulated leads to relatively poor performance at moderate depletion levels (50% to 150% depletion).

3.1.3 Abundance-based methods

The method of Beddington and Kirkwood (2005; A7 and A8) that estimates F_{MSY} based on size at first recapture and age at 50% maturity appears to offer intermediate performance overall. Often providing relatively high yields, the method tended to overfish more than the best performing approaches (see trade-off plots, Figures 4 and 5). The propensity to overfish was not reduced substantially for simulations at intermediate depletion levels (between 50% and 150% B_{MSY}, Table 5) unlike other methods that make use of current information regarding stock level. Methods A7 and A8 appeared to perform particularly poorly for mackerel, snapper and rockfish in terms of the probability of ending below the 50% B_{MSY} threshold, even when biomass is initially above this threshold (Table 8).

In general, F_{MSY}/M methods A9 - A12 were among the best performers regardless of life-history and initial depletion level. Along with methods A3 and A4, methods A9 and A10 were unique in their ability to rebuild stocks in a substantial number of simulations while achieving relatively high yields. Overall, F_{MSY}/M method A9 performed somewhat worse than DB-SRA method A3 at low stock sizes, with the exception of higher yields for rockfish and a lower probability of overfishing for porgy. At intermediate stock depletion levels, method A9 compared favorably with method A3 and led to similar yields with lower probabilities of overfishing for all stocks, with the exception of rockfish (Tables 5 and 6).

3.1.4 Reference case methods

The delay-difference assessment had mixed performance despite having unbiased information regarding vulnerability at age, median age at maturity, growth rate and natural mortality rate. The probability of overfishing was generally low, but yields were unremarkable compared with the other methods, particularly when starting from moderate stock sizes (i.e., between 50% and 150% B_{MSY}). Projected biomass increased from low stock sizes in most cases, but the probability of remaining below the overfished threshold was still high for mackerel. As expected, the current catch and effort methods performed poorly due to their lack of feedback between the OFL and stock depletion. It follows that simulations that did not lead to stock collapses coincided with those for which the final historical fishing mortality rate happened to be sustainable.

3.1.5 Trade-offs among ABC control rules

ABC control rules, incorporating varying downward adjustments, were considered for each OFL-setting method. As expected, the reduction in the ABC led to a reduced probability of overfishing and increases in expected population size (e.g., B/B_{MSY}, Figures 7-9). The pattern in long-term yield was less clear, with the largest downward adjustments leading to relatively small reductions in yield. For example: a 75% scalar applied to method A9 led to 27% probability of overfishing and 64% yield for mackerel starting below 50% B_{MSY} compared with the unmodified rule (method A10) that achieved a 34% probability of overfishing and 65% yield. In methods where the probability of overfishing is generally higher, greater downward adjustment increases the long term expectation of yield. For example, a 75% scalar for methods A7 and A8 leads a lower probability of overfishing, higher expected biomass and higher long-term yield for the snapper stock.

3.1.6 Inter-method performance trade-offs

There is a relatively well-defined inverse relationship between the expected probability of overfishing and expected stock status (B/B_{MSY}) across all methods (Figures 7-9). The ranking of methods in terms of these criteria is relatively clear. It is not surprising that a method that provides the lowest propensity to overfish leads to the highest abundance levels. The relationship between the probability of overfishing and long-term yield is clear obvious (Figures 4-6). When simulations start from low stock sizes, the methods are either scattered in this trade-off space (snapper, butterfish and rockfish stocks) or show a weak negative relationship, where higher yields are achieved at lower probabilities of overfishing (mackerel, porgy and sole stocks). This is intuitive since stock recovery to productive biomass levels provides increased longer term yields. This pattern in this trade-off becomes weakly positive from intermediate starting depletion (between 50% and 150% B_{MSY}). The scatter in the trade-off plots indicates opportunities to select methods that can achieve both lower probabilities of overfishing and higher yields than other methods. As identified from Tables 4-6, methods A3, A4, A9 and A10 lead to high yields and low probabilities of overfishing across several starting depletions.

3.2 Performance for butterfish

Butterfish proved to be the most challenging test of the data-limited methods. We include the results of DCAC and DB-SRA even though these methods are not appropriate for stocks such as butterfish that have natural mortality rates higher than approximately $0.2yr^{-1}$ (MacCall 2009, Dick and MacCall 2011). The relative performance of the methods for butterfish was unique. In general, all methods led to high probabilities of overfishing without commensurate stock depletion (Table 4). Similarly, expected yield for butterfish was relatively high compared with other stocks even when applying the worst performing methods. Methods that led to the likely collapse of other stocks (e.g., average catch methods M1-M3) achieved a relatively high rate of rebuilding for butterfish when projections were started from below 50% B_{MSY} (Table 7). This result emphasizes the larger role of temporal changes in stock productivity in determining abundance for species such as butterfish, which are short-lived and exhibit highly variable recruitment. It should be noted that DCAC was not designed for use for stocks is $M > 0.2$ such as butterfish.

3.3 Value of different sources of information for each data-limited method

Current abundance, historical fishing effort, and stock depletion have the highest information content; only those methods that incorporated these sources of data had good performance across all depletion levels (e.g., could recover stocks from low stock sizes and did not lead to declines below 50% B_{MSY} in a high fraction of simulations). This additional value can be expressed in either the difference in the expected long-term yield or the probability of overfishing. Butterfish aside, benefits in yield and the probability of overfishing were very large at very low stock sizes (<50% B_{MSY}), but negligible or non-existent at more intermediate stock sizes (between 50% and 150% B_{MSY}). For example, methods A3, A4, A9-A12 lead to expected probabilities of overfishing that are between 70% and 35% lower than the other methods when biomass is initially below 50% B_{MSY}, while offering expected yields that are between 2 and 6 times higher. Overfishing may occur with higher frequency than other methods at moderate stock sizes, but yields generally remained between 10% - 30% higher for these dynamic approaches.

The yield and probability of overfishing varied more strongly with consistent bias in depletion and current biomass, indicating that accuracy in these inputs is a critical determinant of the performance of the associated methods (Tables 10 and 11). This is particularly important as the methods that make use of these inputs are those that appear to perform best (e.g., methods A3 and A9). This sensitivity is to be expected since these inputs provide the dynamic link to changes in stock size, which is the central reason these methods perform well. Since M is a factor in the calculation of the OFL, it follows that the F_{MSY}/M methods are sensitive to uncertainty in this input. It may not be immediately clear why yields should vary to a larger extent across the bias in current biomass in comparison to M. The simple explanation is that twice the level of potential bias was prescribed for current biomass (a CV of 1 compared with 0.5 for M). While bias in depletion and current biomass led to large changes in yield for some methods, the precision of these inputs was much less important.

There is evidence that methods offering intermediate performance may be somewhat less sensitive to inputs. For example, the DACS methods (A1 and A2) appeared relatively robust to bias in depletion although they did not perform well at low stock levels. This result points to a possible problem in the interpretation of the aggregate performance figures, that they do not convey the extent to which the performance of the methods degrades under misspecification of inputs. On average, bias in inputs was sampled with a mean of 1 (unbiased on average). It follows that it may be possible for a method to lead to a mean probability of overfishing of 20% but this performance is only representative of a small set of unbiased simulations.

Examining the sensitivity of the methods A3, A4, and A9 – A12 reveals this problem. This phenomenon is illustrated in Figures App. D1-D4 where the slope in expected probability of overfishing is very steep at zero bias (a value of 1) in depletion and current biomass, respectively. Methods A3 and A4 that allow for dynamic update of depletion also exhibit considerably more sensitivity to M for snapper and rockfish.

3.4 Sensitivity of performance to population and fishing dynamics

Mackerel and porgy were the most difficult to rebuild. Snapper has the highest probability of increasing stock trends (P_{inc}) and of ending above the rebuilding threshold for all methods, with the notable exception of the average catch methods (Table 4).

There were relatively few interactions between the performance of methods and life-history type; while the absolute performance of most methods changed markedly among stocks, within each stock the ranking of methods was consistent. There are a few notable exceptions. For example, the average catch methods (M1-M3) have similarly poor absolute performance across the life history types with the exception of butterfish. Methods M4-M9 also led to relatively low yields for the more long-lived stocks, such as snapper and rockfish when projections started at intermediate biomass levels (Tables 5 and 6). Mackerel and sole showed unexpectedly a high likelihood of dropping below 50% B_{MSY} for intermediate initial depletion levels for methods A3 and A4. Additionally, the methods A7 and A8 led to markedly better performance for the butterfish.

The most important characteristics determining the probability of overfishing for those methods that do not include dynamic updates in depletion or current biomass are the steepness of the Beverton-Holt stock recruitment curve and the annual increase in fishing efficiency (Table 12). The success of these methods coincides with productive stocks (high steepness) subject to low historical fishing mortality rates due to their lack of feedback between the ABC and stock status. This difference is demonstrated by dynamic abundance-based methods A9-A10, for which probability of overfishing is much less affected by variability in the simulated population and fishery parameters.

Overall, the performance of methods was unaffected by different input values for inter-annual recruitment variability (“Proc. Err”), inter-annual variability in fishing effort (“Eff. CV”), spatial targeting (“Targeting”), the von Bertalanffy growth coefficient (“Von B K”), stock viscosity and the degree of overlap among vulnerability and maturity curves (“50%V-50%M”) (Table 12). The lack of sensitivity to different spatial parameterizations is supported further by a separate simulation that was conducted without any spatial structure (Appendix E). Spatial phenomenon such as refugia and stock viscosity lead to small reductions in the probability of overfishing (typically between 1-3%). In general the tabulated results of the spatially-aggregated simulation were within 2% of those of the spatially-disaggregated simulations, and did not provide any meaningful differences in the ranking of the methods. Only snapper were simulated with refuges, and these averaged only 5% of the population. Much larger differences in the performance results arising from spatially-explicit and spatially-aggregated operating models may be expected where refugia are larger.

4. Discussion

4.1 Performance of data-limited methods

Setting an ABC at average historical catch levels (methods M1-M3) is likely to lead to poor management performance where stocks are often below their most productive levels. Generally, the performance of such methods was comparable to the status quo reference methods that simulated current catch or current fishing effort. Method M3, third-highest catch, generally performed worse than maintaining current fishing levels. The main reason for the poor performance of methods M1-M3 is the lack of feedback between stock depletion and the ABC. Recent historical catches rates were often higher than those associated with F_{MSY}, ensuring that using their average as an ABC perpetuated the overexploitation. Additionally, these methods include positive feedback between past and future ABC recommendations; future ABCs are based on previous ABCs and therefore tend towards a stable value over time. If the initial ABC is too high, exploitation rates become exponentially larger over time. In contrast, if this value is too low the stock tends towards some biomass above B_{MSY}. Consequently, these methods are often divergent and move the stock away from B_{MSY}.

Other static management methods that do not include feedback between the ABC recommendation and stock status can provide good performance, but only when stocks are at intermediate levels of depletion (e.g., the PFMC DB-SRA and DCAC methods M4-M9). While the performance of the static methods was generally poor at low stock levels, the static DB-SRA method still led to lower probabilities of overfishing and higher yields than the average catch methods (M1-M3). Unsurprisingly, methods that dynamically account for population changes achieved better performance when the stock is not near B_{MSY}. This was not the case for DCAC, which is designed to return a proxy for MSY, which is not an appropriate basis for OFLs for stocks at low population levels (as acknowledged MacCall [2009]). The dynamic DB-SRA and F_{MSY}/M ratio methods (A3 and A9) generally led to the best performance by some margin. While the aggregate performance of these methods may appear satisfactory, it is strongly affected by bias in two key inputs: depletion (DB-SRA) and current stock biomass (F_{MSY}/M methods). Methods which involve estimates of biomass or current depletion (rather than assumptions about them) would, however, generally not be considered to be data-poor but rather data-moderate (PFMC 2010, NPFMC 2012).

The simulation testing of ABC control rules (e.g., 75% and 100% scalar multipliers) revealed that the largest downward adjustments in the OFL often led to higher expected long-term yields and lower probabilities of overfishing (e.g., F_{MSY}/M ratio methods A9 and A10). This was particularly the case for simulations starting below 50% B_{MSY} where lower exploitation rates could allow rebuilding to more productive stock sizes. However, the range of downward adjustment was not sufficient in some instances to achieve high probabilities of rebuilding. For example, the three ABC control rules based on methods M4-M9 ranged from a 9% to a 30% reduction in the OFL. The results of all three multipliers were similar, and did not span a sufficiently wide range of adjustment to allow stocks to recover from low levels, when depletion is assumed *a priori* to 40% (e.g., methods M4-M9).

4.2 Sensitivity of performance to inputs and value of information

In general, the performance differences were much greater across methods than across life-history types. The exception to this was butterfish. All methods led to relatively high rates of overfishing for butterfish without necessarily leading to stock declines or reductions in long-term expected yield because of the short life span and high recruitment variability of this stock. The biomass of butterfish can easily depart from the mean by a factor of 2 in the absence of fishing, making natural variability in productivity a much stronger determinate of stock status than exploitation rate. The results for butterfish demonstrate the challenge of developing management systems for short-lived species. MSE for prawn species that examine both input (effort) and output (catch quota) controls (Dichmont et al., 2006, 2012) conclude that the effective use of quotas in such cases is dependent on the ability to predict and monitor recruitment. It may be beneficial to track current abundance and maintain close control of exploitation levels to prevent forgone yields and/or problematic stock declines. It follows that methods that rely on current information and aim for fixed exploitation rates such as the F_{MSY}/M ratio methods may be particularly suitable for species of short life history.

Previous simulation evaluations of DB-SRA and DCAC found sensitivity to misspecification in natural mortality rate for long-lived stocks (Wetzel and Punt, 2011), a result which is corroborated here for snapper and rockfish. This is due to propagating this error over a larger number of age classes and hence a larger fraction of the population.

The simulation of spatial population and fishing dynamics had very little impact on performance. All methods showed relatively weak sensitivity to variability in simulated spatial targeting, stock viscosity or spatial heterogeneity. A separate run of the MSE with no spatial dynamics led to very similar results. Spatial phenomena such as refugia from fishing and stock viscosity led to very small reductions in the probability of overfishing relative to the differences among methods and simulated life-histories. This suggests that the subtleties of spatial stock dynamics are comprehensively overwhelmed by general problems associated with the inaccuracy and imprecision of the principal inputs such as natural mortality rate and stock size for the stocks simulated in this research. It is conceivable that spatial effects may be more critical for other stocks, for example sessile species or those that experience greater refuge from fishing.

All of the methods were most sensitive to imperfect information regarding either current stock depletion or current biomass. Consistent bias in these inputs strongly affected the expected probability of overfishing and long-term yield. On the other hand, relatively high imprecision in these estimates had little effect on performance: year on year, the estimates could vary strongly from the “true” underlying value of depletion or biomass. The dynamic DB-SRA method could lead to high probabilities of declining below 50% B_{MSY} when starting above B_{MSY}. This was due to the specification of OFLs much higher than MSY due to a positively biased input for depletion. An alternative ABC control rule which applies a downward adjustment to the smaller of the OFL or MSY may help to combat this problem and substantially improve the performance of the dynamic DB-SRA method in such instances.

4.3 Quantifying inputs

The inputs to these data-limited methods focus on those that can be developed quickly from existing sources, as opposed to those that require future data collection efforts. Given that the intent of the data-poor assessment is to provide information for immediate use, the latter category of inputs is less relevant to this discussion. However, additional or improved inputs may be needed if an attempt at assessment falls short due to lack of information, or if the results engender an urgent desire for a "more complete" assessment. A wide range of alternatives exist for supplementary data collection, depending on available labor and funding, and the time horizon for data delivery, but the result is to move toward a more data-rich approach that falls outside the scope of this study.

4.3.1 Depletion

The assessment methods that perform best included estimates of current depletion or abundance so it is instructive to discuss how these inputs may be obtained. Of these, depletion is perhaps the most difficult to obtain for data-poor stocks. Depletion is a data-rich quantity in many respects; it requires broad knowledge of stock trend, which in turn defines a data-rich stock in this paper and elsewhere (e.g., Punt et al., 2011). However, a case may be made that expert knowledge about depletion could be derived from anecdotal information such changes in the spatial range of fishing. Expert judgment is especially useful when assessments have been carried out for other local stocks, and the similarity of fishing operations for the data-poor stock is suspected or known. For example, based on a calibration to 30 data-rich stock assessments, Productivity Susceptibility Analysis (Patrick et al., 2009) has been used by the PFMC to determine the mean of the prior for depletion when applying DB-SRA.

In some cases, a time series of fishery-independent surveys exists for other species, and the data-poor species may be caught occasionally. Although the data may contain an excessive number of "zeroes" it is often possible to derive an abundance index or estimate of depletion from a remarkably small number of positive samples, even if the time series has to be collapsed into a few multi-year time blocks. Examples of fishery-independent surveys include the Triennial trawl survey and slope surveys of the US West Coast (NMFS 2013) and the MARMAP (2013) survey of the South Atlantic.

Trends in abundance inferred from catch and effort data can be included in methods such DB-SRA to update the depletion prior (Cope et al., 2013). Although historical effort is usually not known, it may be possible to "borrow" a time series of fishing rate estimates from assessments of other species in the region. Punt et al. (2011) have explored simultaneous assessments of multiple species using this "Robin Hood" approach. Other alternative means of constructing estimates of depletion include recreational fishing databases (e.g. RecFIN, 2013) or the use of scientific observer data (NMFS [2013] includes a discussion of these sources of depletion information).

Our analysis of the value of information indicates that considerable *imprecision* in depletion estimates does not lead to dramatic loss of yield or increase in the probability of overfishing. *Bias* in depletion, on the other hand, strongly determines performance. This is potentially problematic because of difficulties in acquiring new information about past abundance trends.

4.3.2 Natural mortality rate

The DB-SRA, DCAC and F_{MSY}/M ratio methods all rely on an estimate of M, a common input in most stock assessments (the main exception being surplus production models). Although M is an uncertain parameter, stock assessments require only an approximate value. If tentative ages can be determined, covariates such as maximum age and von Bertalanffy growth parameters are estimable from quite small samples; tropical fishes lacking clear age indicators are more difficult. Useful meta-analyses have been published by Pauly (1980), Hoenig (1983), Hewitt and Hoenig (2005), and Gislason et al. (2010), among many others. If uncertainty in the value of M remains problematic, it may suffice to choose a most likely value of M from a simple list of candidate values, e.g., (0.2, 0.1, 0.05, 0.025). Note that many of these data-poor methods fail if $M>0.2$, and values below $0.025 yr^{-1}$ for M are rare in fish.

While DB-SRA and DCAC have low fishery data requirements (historical catches), the remaining inputs are parameters and variables that strongly determine the methods' outcomes. Although direct estimation of these quantities requires conventional approaches used in data-rich assessments or meta-analyses (e.g., Punt et al., 2011, Zhou et al., 2012, Thorson et al., 2012b), data-poor assessments often require us to postulate values of key parameters by analogy to data-rich cases. Development of appropriate meta-analyses is an active area of fishery research that has gained impetus from the requirements of data-poor assessment methodologies.

4.3.3 Current abundance

In instances where it is not possible to estimate current depletion, future data-gathering efforts may focus on the estimation of current abundance which is an input to the F_{MSY}/M, DACS and life-history methods. There are several possible ways to estimate current biomass that differ by cost and the assumptions on which they rely. The most conventional is a “fishery independent” research survey that uses a variety of fishing gears to sample the population from which total biomass may be extrapolated (Doubleday and Rivard, 1981, Gunderson, 1993). In the Gulf of Alaska and the Bering Sea, estimates of abundance from fishery independent surveys are used in the F_{MSY}/M method to set ACLs for several stock complexes such as skates, sculpins, crab, and rockfishes (NPFMC 2012). The principal limitation of surveys is their considerable cost which may not be justified in many data-limited situations, for example where the primary source of exploitation is bycatch. Many species are unlikely to be fully-selected by the survey gear or estimates from density in areas which can be surveyed may be extrapolated incorrectly to areas that cannot be surveyed leading to persistent bias in estimates of abundance. Such bias may dramatically affect the reliability of data-limited methods using these data.

An alternative approach to current abundance is to dividing current catch by an estimate of current exploitation rate. If assessments have been carried out for other species, it may be possible to “borrow” their estimated fishing mortality rates. Punt et al. (2011) use this “Robin Hood approach” in simultaneous assessments of multiple species. Two possible direct means of estimating current exploitation rate are a tagging experiment or a catch curve analysis. The concept of mark recapture analysis has a long history in fisheries science and was discussed at length by Beverton and Holt (1957). Tagging may be expensive, but can provide a relatively precise estimate of current fishing mortality rate and abundance. There are often challenges to the ready interpretation of these data, including tag mortality, shedding, reporting and detection rates, and a program may take many years especially if F is low. To obtain exploitation estimates that can be generalised to the population requires knowledge of spatial distribution that may not be available in many data-limited situations. Perhaps the most important limitations of mark recapture analysis is that many species of fish are difficult to tag in sufficient numbers or not suitable candidates due to high post-release mortality rate or tag-induced mortality rate.

Catch-curve analysis can also provide estimates of current mortality rates, and is likely to be most successful in cases where fishing mortality rate, recruitment strength and age-vulnerability to fishing can be assumed to be relatively constant over recent years. Catch curve analysis (Ricker, 1975) assumes that after a certain age, individuals experience the same fishing mortality rate, allowing the descending proportion of catch-at-age (or catch-at-length) to be interpreted in terms of total mortality. An estimate of natural mortality rate is needed to separate fishing mortality from the total mortality rate estimated by catch-curve analysis. In a data-limited setting the primary advantage of catch-curve analysis is that it does not require historical data and relies only on catch composition data that can be collected today. Catch curves can be based on age- or length-composition data and can be used to form the basis for control rules for data-limited species (e.g., Klaer et al., 2012). There are a number of methods to account for temporal variability in recruitment and selectivity if multiple years of age-composition data are available (e.g., Schnute and Haight, 2007). Despite the limitations of catch-curve analysis, it might produce estimates of current biomass that are no more biased or uncertain than the imperfect knowledge of biomass simulated in this analysis. This should be the focus of future simulation evaluation.

4.4 Methods that could not be simulation tested

There are data-limited assessment methods for setting catch limits that could not be simulation tested. These methods either did not provide estimates for OFLs (the methods of Patrick et al., 2009, Martell and Froese, 2012, Thorson et al., 2012a, Costello et al., 2012 and Cope and Punt, 2009) or involved expert judgement that could not be simulated (the methods of Berkson et al., 2011 and Punt et al., 2011)

The method of Martell and Froese (2012) aims to estimate MSY by reconstructing a stock history according to catches and discarding those simulations that cross certain thresholds (e.g., that fall out of a range of current stock depletion such as 5%-95% of unfished biomass). This “MSY depletion method” is theoretically similar to DCAC. A central finding of Martell and Froese (2012) is that MSY may be well defined despite only weak prior information about maximum stock size, stock productivity and current depletion. However, this finding also explains our inability to include this approach in our analysis. While MSY is a theoretical quantity relating to the most productive level of depletion, the OFL is determined by current stock depletion (e.g., it tends to zero as the stock declines). It follows that MSY does not provide a means of setting the OFL without a control rule. Since the OFL can range from much higher than MSY to zero, the success of the method would rely on the control rule. It could be argued that a control rule should also be applied to DCAC since it is also an approximation of MSY. However in line with the recommendations of the PFMC (PFMC, 2010) we tested DCAC as a method of determining the OFL without such a control rule.

Thorson et al. (2012a) and Costello et al. (2012) use covariate information, such as life history characteristics and landings data to inform a predictive model of current stock depletion. These approaches use correlations between assessed stock status and other covariates to extrapolate the stock status of fisheries that are not assessed. It is possible that these methods could be adapted to provide OFL recommendations. However, doing so would require assumptions about the productivity of the stock with declining biomass (i.e., the shape of the productivity curve). It may be possible to combine these methods or DCAC or the method of Martell and Froese (2012).

Punt et al. (2011) propose a “Robin Hood” method in which data-rich assessments are used to inform the spawning stock biomass and exploitation history of data-limited stocks that are subject to fishing by the same fleets. A central assumption of this method is that the different stocks have comparable trends in exploitation rate. As such, the method relies on the existence of a contingent data-rich stock and a process to assess whether exploitation rates are similar. The choice of which fleets have the same trends in exploitation rate is based on expert judgement, which prevented a full evaluation of the method.

Cope and Punt (2009) outline a length-based approach that relates the observed fractions of fish of different classes (e.g., fraction mature) to stock status. While length-based reference points could provide a basis for designing control rules that provide OFL recommendations, these rules have yet to be established (Cope and Punt, 2009).

4.5 Limitations

At the center of this analysis are assumptions about how accurately and precisely the inputs to the data-limited methods may be quantified. It should be emphasized that the results are a product of the specific conditions of the simulation. For example, we may have found that methods which rely on *M* performed substantially better had the extent of error associated with *M* been assumed to be unrealistically low.

The objective of this research was to evaluate the impact of the data-limited methods regardless of the rate of compliance. In all of the simulations we assumed that the ABC recommendations were taken as catch and no implementation error was simulated. In practice, there are often overages or shortfalls that affect the level of future catch limits. It is possible that implementation error may interact with some data-limited methods and alter their relative performance. However, since all methods provide the same type of advice (i.e., catch limits) it is probable that this additional source of error would have had a comparable impact across methods and would limit the generality of the results while reducing the clarity of the inter-method comparisons.

4.6 Conclusions and recommendations

- In circumstances where only fishery catch data are available, this simulation evaluation indicates that use of average catch methods such as median catch over the most recent 10 years or third highest catch cannot be expected to provide a better basis for management than maintaining current catch or effort levels. These methods often perform even worse than the status quo methods of current catch or current effort when biomass starts below B_{MSY}. However, the catch-based methods appear to provide performance more comparable to that of the other methods if it can be established that a stock is above B_{MSY}.
- Additional information regarding depletion, historical effort, or current abundance can be very valuable. Our analysis points to large expected gains in yield for all stock types (except high-M stocks such as butterfish) when stocks are heavily depleted given information about depletion or trend in relative abundance, with more modest gains for less depleted stocks. When considering how to obtain data in addition to historical catch, perhaps the most cost-effective avenue for investigation is the availability of unprocessed data. For example, fishing effort data that may be used to calculate an index of historical abundance or for estimating current depletion. Multispecies surveys may also be available from which a time-series of abundance could be constructed (e.g., MARMAP, 2013; West Coast trawl surveys NMFS, 2013). A research priority is summarizing these data sources and characterising stocks according to uncertainty regarding stock status and the potential benefits of obtaining additional data. Where historical abundance trends or effort data are not available there is an onus on the collection of current abundance

information, for example using fishery independent surveys, catch curve analysis or tagging studies. Simulation evaluation may offer a basis for determining the cost-benefit of new data-collection programs by quantifying the potential for additional long-term yields and the probability of overfishing.

- The mixed performance of the delay-difference methods provides food for thought for those analysts seeking to evaluate data-limited methods by comparison with stock assessments. The delay-difference models applied in this analysis assumed perfect knowledge of historical effort, growth, natural mortality rate, and the age that individuals are vulnerable to fishing. Nevertheless, these assessments assume stationary stock dynamics and a linear relationship between historical fishing effort and fishing mortality rate, assumptions that are commonly violated in these simulations. That performance for this method was "mixed" runs contrary to the view of data-rich stock assessments as a "gold standard" against which other approaches may be compared. Our simulation evaluation also confirms that classifying stocks solely according to the amount and types of data available may not be appropriate. A large quantity of data is no guarantee of reliable information on which to base decision making (data-rich stocks are often information poor). The way in which data inform management recommendations relies to a large extent on the validity of the assumptions of the assessment tool. For example, detailed historical data for a short-lived species such as butterfish should not necessarily motivate the use of a conventional data-rich assessment approach that may offer less reliable management advice than a simpler approach using a smaller amount of data that instead, provide information about current stock characteristics.
- Some of the terminology surrounding data-limited methods has the potential to be strongly misleading. One example is the term *P** (probability of overfishing). This simulation study and Punt et al. (2012) found that *P**s of 25% and 50% rarely corresponded to these probabilities of overfishing. Nor did a 25% *P** rule lead to half the probability of overfishing exhibited by a 50% *P** rule. Based on this terminology, decision makers may be led to believe they are choosing a specific outcome and this simulation evaluation reveals that this may not be the case.
- We have evaluated a broad suite of data-limited methods. Certain data-limited methods (e.g., the 'Robin Hood' method, the ORCS approach, PSA analysis) have been proposed, but could not be simulation-tested. We recommend that editors of journals who consider publishing new data-poor methods request authors to minimally outline how their method can be tested. Ideally, a reference set of simulation data

sets should be made available to allow the results of this paper to be supplemented with those for new data-limited methods.

- Finally, the focus of this paper is on methods that have been identified for use in the management of fish stocks in U.S. waters. However, establishing data-limited methods is particularly relevant to developing countries where there is often less complete reporting of fishery data and fewer resources dedicated to analysis. Moreover, a broader suite of types of assessment methods could be examined for countries which mandate use of control rules, but are less prescriptive regarding the structure of control rules than the U.S. (see, for example, Smith et al., 2009).

Table 3. Summary of the bias /error parameters and related distributions that control the accuracy and imprecision of knowledge of the simulated system that is subsequently used by the data-limited methods and harvest control rules. The log-normal distribution described in the table below (~LN(μ,CV)) is the exponent of the normal distribution with mean and standard deviation (sd = CV x mean) parameters: $N\left(-0.5\log\left(1+sd^2/\mu^2\right),\sqrt{\log\left(1+sd^2/\mu^2\right)}\right)$.

Variable	Symbol	Related functions	All stocks
The coefficient of variation of the log-normally distributed bias in natural mortality rate M	CV_M	$M_{obs} = M \times \mu_M$ $\mu_M \sim dlnorm(\mu=1, CV_M)$	0.5
The coefficient of variation of the log-normally distributed bias in von Bertalanffy growth rate parameter K	CV_K	$K_{obs} = K \times \mu_K$ $\mu_K \sim dlnorm(\mu=1, CV_K)$	0.2
The coefficient of variation of the log-normally distributed bias in length at first capture, L_c	CV_{Lc}	$Lc_{obs} = Lc \times \mu_{Lc}$ $\mu_{Lc} \sim dlnorm(\mu=1, CV_{Lc})$	0.5
The coefficient of variation of the log-normally distributed bias in biomass at maximum sustainable yield relative to unfished B_{peak} (B_{MSY}/B_0)	CV_{Bpeak}	$Bpeak_{obs} = Bpeak \times \mu_{Bpeak}$ $\mu_{Bpeak} \sim dlnorm(\mu=1, CV_{Bpeak})$	0.2
The coefficient of variation of the log-normally distributed bias in the ratio of maximum sustainable fishing mortality rate to natural mortality rate c	CV_c	$c_{obs} = c \times \mu_c$ $\mu_c \sim dlnorm(\mu=1, CV_c)$	0.2
The coefficient of variation of the log-normally distributed bias in the age at first maturity Am	CV_{Am}	$Am_{obs} = Am \times \mu_{Am}$ $\mu_{Am} \sim dlnorm(\mu=1, CV_{Am})$	0.2
The coefficient of variation of the log-normally distributed bias in the current level of stock depletion D ($Bcur/B_0$)	CV_D	$D_{obs} = D \times j_D$ $j_D \sim dlnorm(\mu_D, \sigma_D)$ $\mu_D \sim dlnorm(\mu=1, CV_D)$	1
The maximum coefficient of variation for log-normal error around bias in current stock depletion μ_D for projected years	σ_{maxD}	$D_{obs} = D \times j_D$ $j_D \sim dlnorm(\mu_D, \sigma_D)$ $\sigma_D \sim U(0, \sigma_{maxD})$	2
The coefficient of variation of the log-normally distributed bias in the current stock level $Bcur$	CV_{Bcur}	$Bcur_{obs} = Bcur \times j_{Bcur}$ $j_{Bcur} \sim dlnorm(\mu_{Bcur}, \sigma_{Bcur})$ $\mu_{Bcur} \sim dlnorm(\mu=1, CV_{Bcur})$	1
The maximum coefficient of variation for log-normal error around bias μ_{Bcur} for projected years	$\sigma_{maxBcur}$	$Bcur_{obs} = Bcur \times j_{Bcur}$ $j_{Bcur} \sim dlnorm(\mu_{Bcur}, \sigma_{Bcur})$ $\sigma_{Bcur} \sim U(0, \sigma_{maxBcur})$	2

Table 4. Overfishing, stock status and yield performance metrics for simulations starting below 50% of B_{MSY}. All of the numbers represent a percentage. The probability of overfishing (P_{OF}) is the fraction of years (across all simulations and all of their projection years) for which fishing mortality rate exceeds F_{MSY}. 'B/B_{MSY}' is the mean biomass (across all simulations and all of their projection years) divided by biomass at maximum sustainable yield. 'Yield' is the mean relative yield over the last five years of the projection (the yield of a simulation over the last five years of the projection divided by that of the F_{ref} policy). Dark grey shading reflects poor scores (P_{OF} greater than 50%, B/B_{MSY} less than 50%, Yield less than 25%). Light grey shading reflects intermediate scores (P_{OF} greater than 25%, B/B_{MSY} less than 100%, Yield less than 50%).

Table 7. Projected biomass for simulations starting below 50% B_{MSY}. All of the numbers represent a percentage. The probability of biomass increasing 'P_{inc}' is the fraction of projected simulations for which average biomass in the last three years of the projection is larger than average biomass for the last three years of the historical simulation. 'B_{end}' is the mean biomass over the final three years of the projection divided by B_{MSY} average over all simulations. The probability of ending below 50% B_{MSY} '$P_{<50}$' is the fraction of runs for which the mean biomass of the last three projected years is below 50% B_{MSY}. Similarly, $P_{<10}$ is the fraction of runs ending below 10% B_{MSY}. Dark grey shading reflects poor scores (P_{inc} less than 25%, B_{end} less than 50%, $P_{<50}$ greater than 50%, $P_{<10}$ greater than 25%). Light grey shading reflects intermediate scores (P_{inc} less than 50%, B_{end} less than 100%, $P_{<50}$ greater than 25%, $P_{<10}$ greater than 10%).

Table 10. The sensitivity in the yield metric to imperfect knowledge. The variables are CV in observation error (Obs err), bias in depletion (Dep bias), CV in depletion error (Dep CV), bias in the ratio of F_{MSY}/M (FMSY/M), bias in the ratio of B_{MSY} relative to unfished (BMSY/B0), bias in natural mortality rate (M), bias in the age at 50% maturity (50% Mat), bias in the current biomass (B bias), CV of error in current biomass (B CV), bias in the von Bertalanffy growth coefficient K (Von B K) and bias in the length at first recapture (L 1st Cap). All numbers are the standard deviation in probability of overfishing across ten divisions of each variable (10 percentile ranges). Sensitivity scores over 10 are shaded light grey, scores over 20 are shaded dark grey.

Table 12. The sensitivity in probability of overfishing to variation in life-history and fishery characteristics. The variables are CV in inter-annual recruitment deviations 'Proc err', the CV in inter-annual variability in effort 'Eff CV', the final effort gradient controlling whether effort declines or increases in the most recent 25 year 'Eff gradient', the spatial targeting parameter 'Targeting', the annual percentage increase in fishing efficiency 'F gain', the steepness of the Beverton-Holt stock recruitment curve 'Steepness', the von Bertalanffy growth coefficient K 'Von B K', the stock viscosity parameter 'Viscosity' and the difference in years between the age at 50% vulnerability and the age at 50% maturity '50%V-50%M'. All numbers are standard deviations in probability of overfishing across ten divisions of each variable (10 percentile ranges). Sensitivity scores over 10 are shaded light grey, scores over 20 are shaded dark grey.

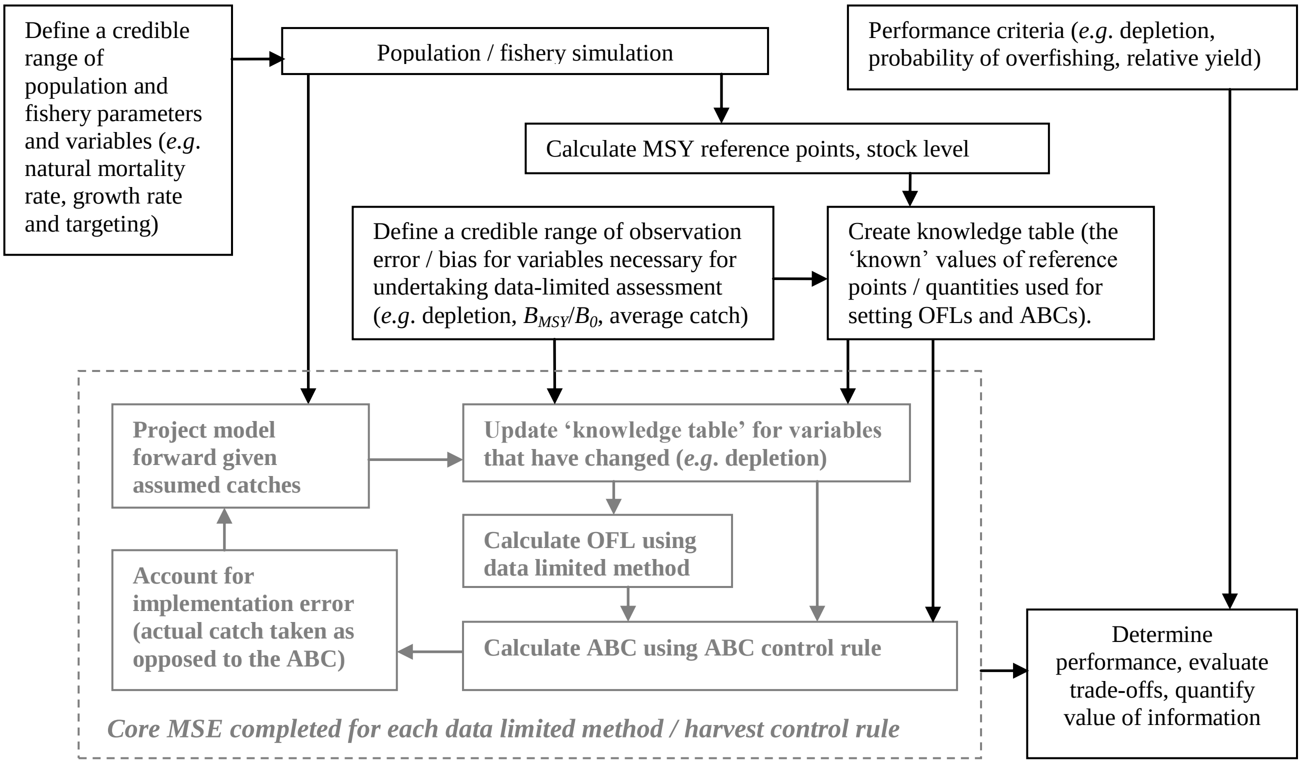

Figure 1. A flow diagram of the components of the MSE for any given stock. The dashed box represents the projection of the model and update according to a particular combination of data-limited OFL setting method (*e.g.*, DB-SRA) and ABC control rule (*e.g.*, the *P** approach).

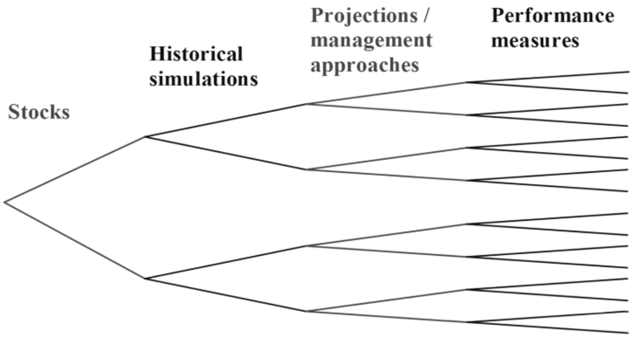

Figure 2. The "branched" design of the simulation evaluation including six stock types, 50 historical years, 30-50 projected years, 25 data-limited and reference methods, and 7 performance measures.

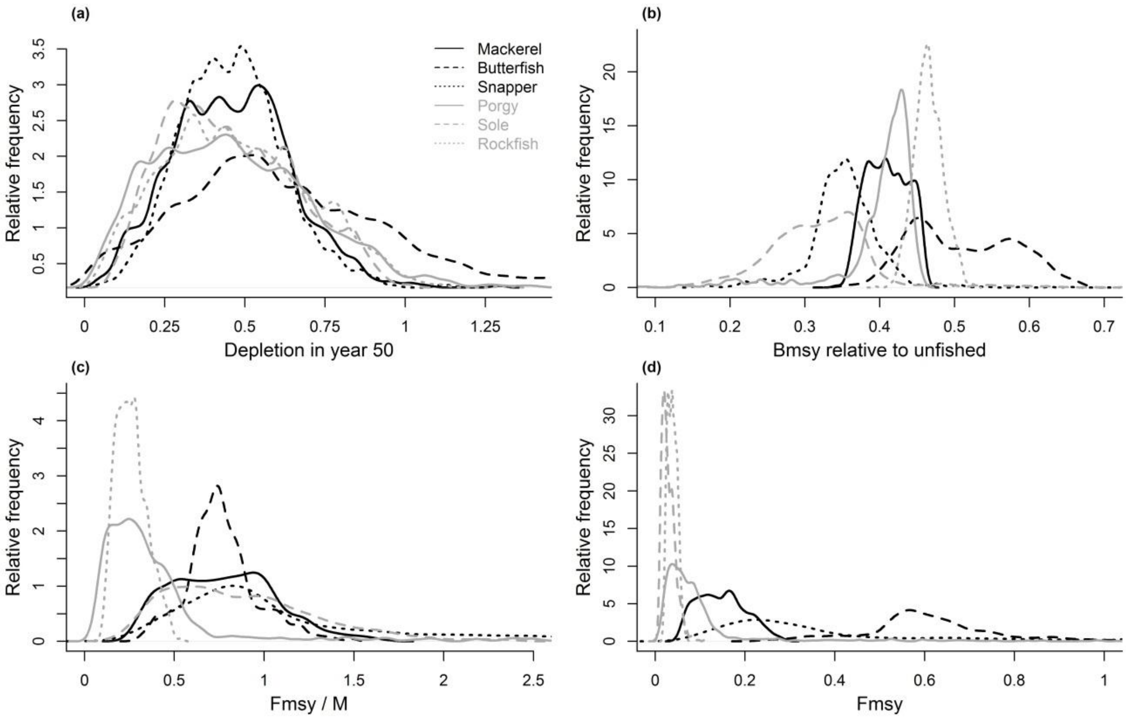

Figure 3. The historical simulation conditions (10,000 simulations). Plotted in panel *a* are the relative frequencies of sampled depletion (the biomass in year 50, the final historical year, divided by unfished biomass). Panel *b* describes the sampled ratio of B_{MSY}/B_0. Plotted in panel *c* are the relative frequencies of the sampled ratio of F_{MSY}/M. Panel *d* describes the sampled distribution of F_{MSY}.

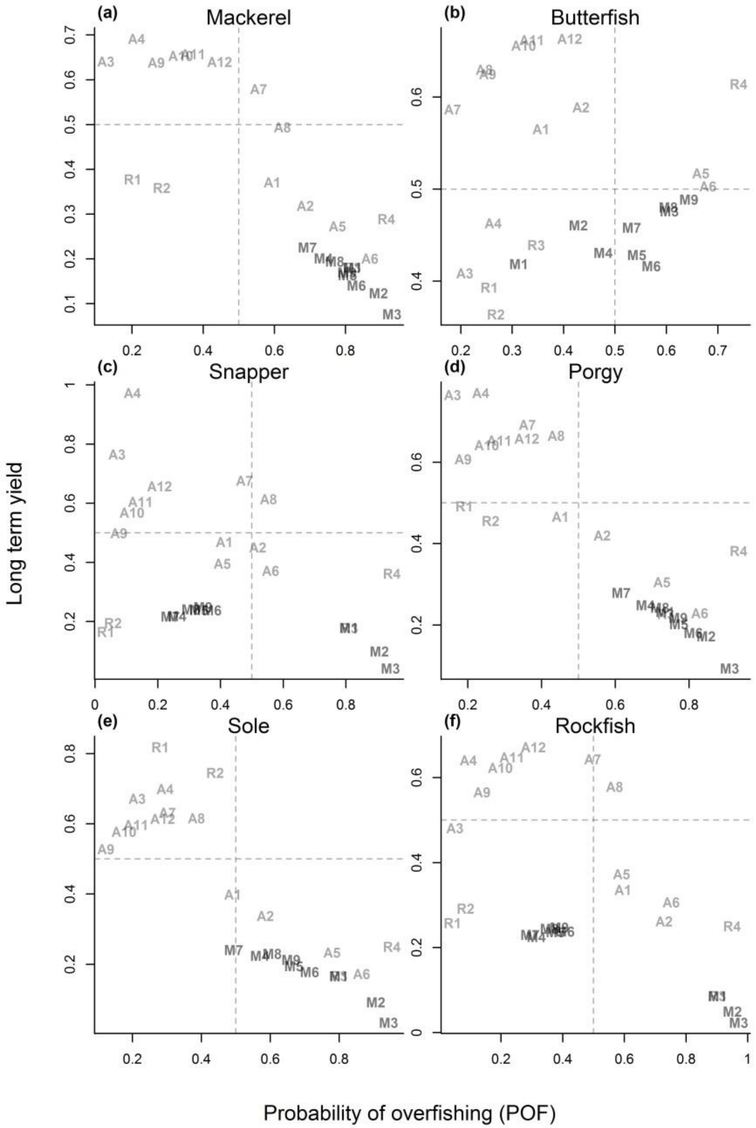

Figure 4. The trade-off between of long term yield (yield over last 5 projected years divided by that of the F_{ref} strategy) and the probability of overfishing (fraction of projected years for which fishing mortality rate exceeded F_{MSY}) for projections starting below 50% B_{MSY}.

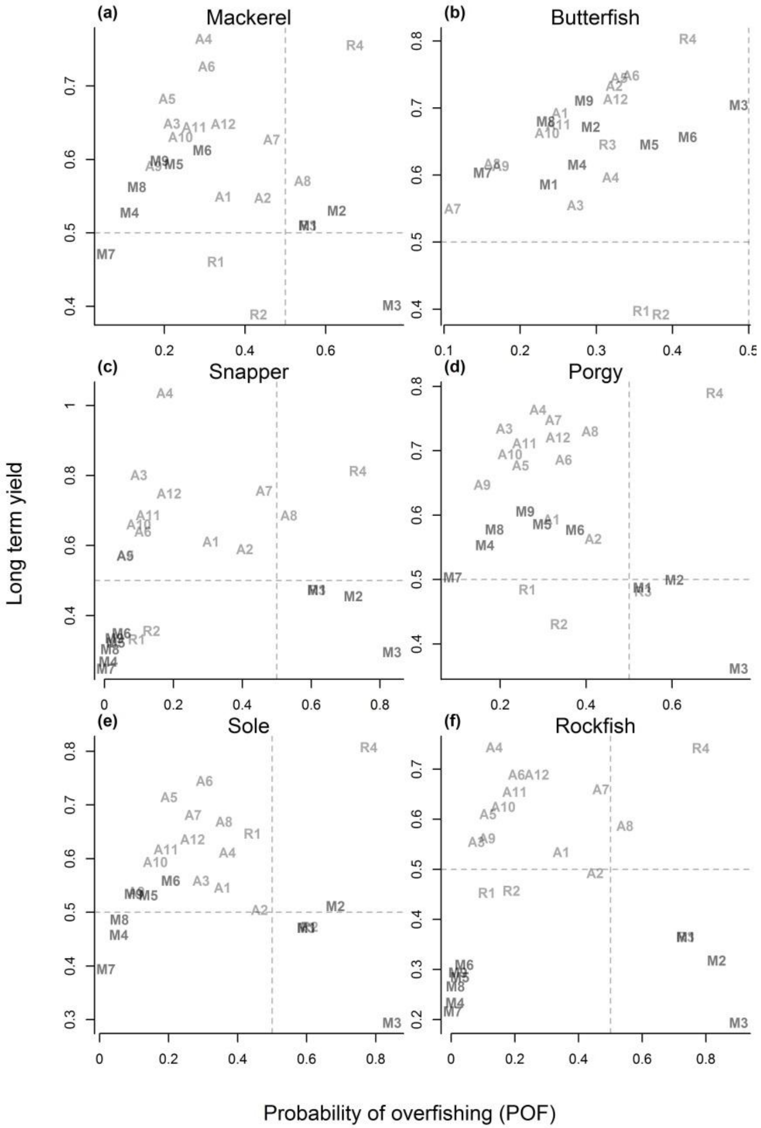

Figure 5. The trade-off between of long term yield (yield over last 5 projected years divided by that of the F_{ref} strategy) and the probability of overfishing (fraction of projected years for which fishing mortality rate exceeded F_{MSY}) for projections starting between 50% and 100% B_{MSY}.

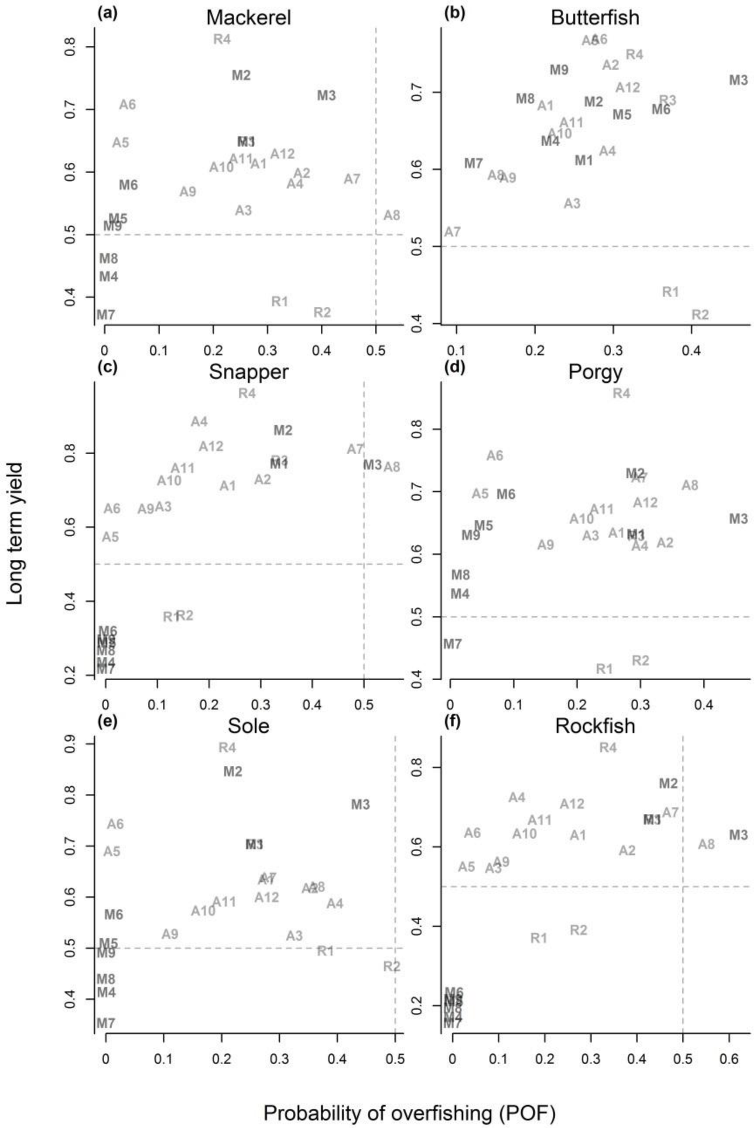

Figure 6. The trade-off between of long term yield (yield over last 5 projected years divided by that of the F_{ref} strategy) and the probability of overfishing (fraction of projected years for which fishing mortality rate exceeded F_{MSY}) for projections starting between 100% and 150% B_{MSY}.

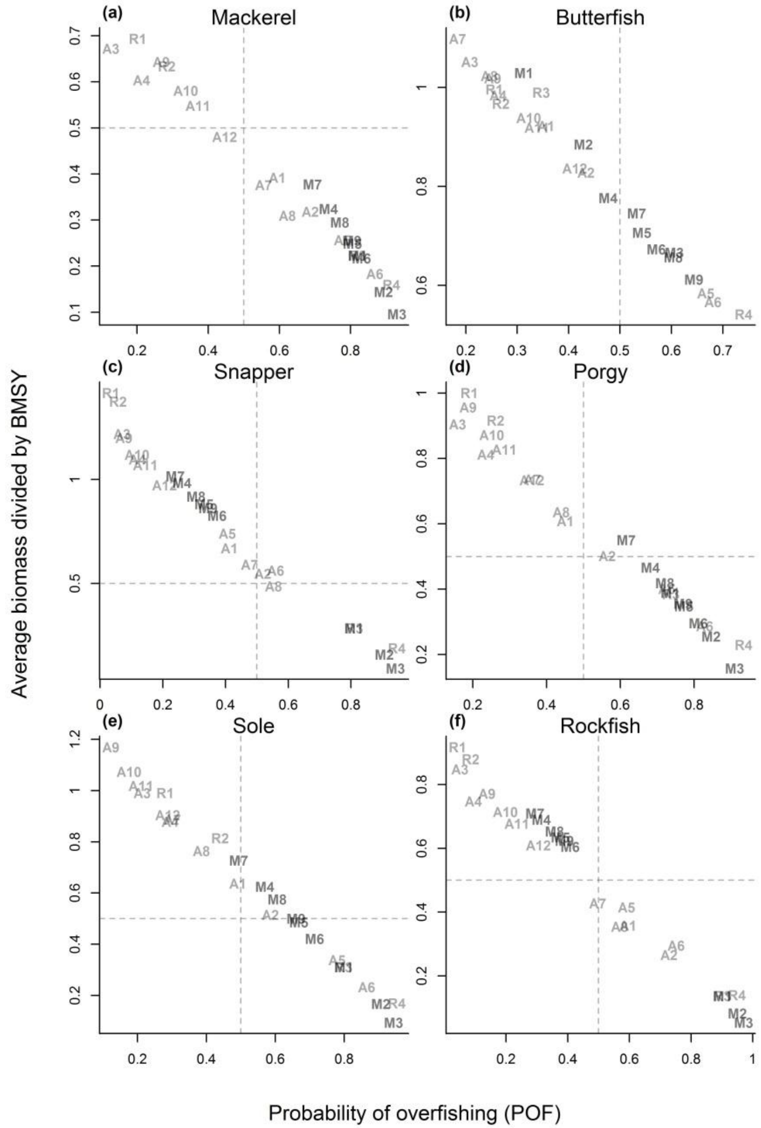

Figure 7. The trade-off between average stock depletion (projected biomass divided by B_{MSY}) and the probability of overfishing (fraction of projected years for which fishing mortality rate exceeded F_{MSY}) for projections starting below 50% B_{MSY}.

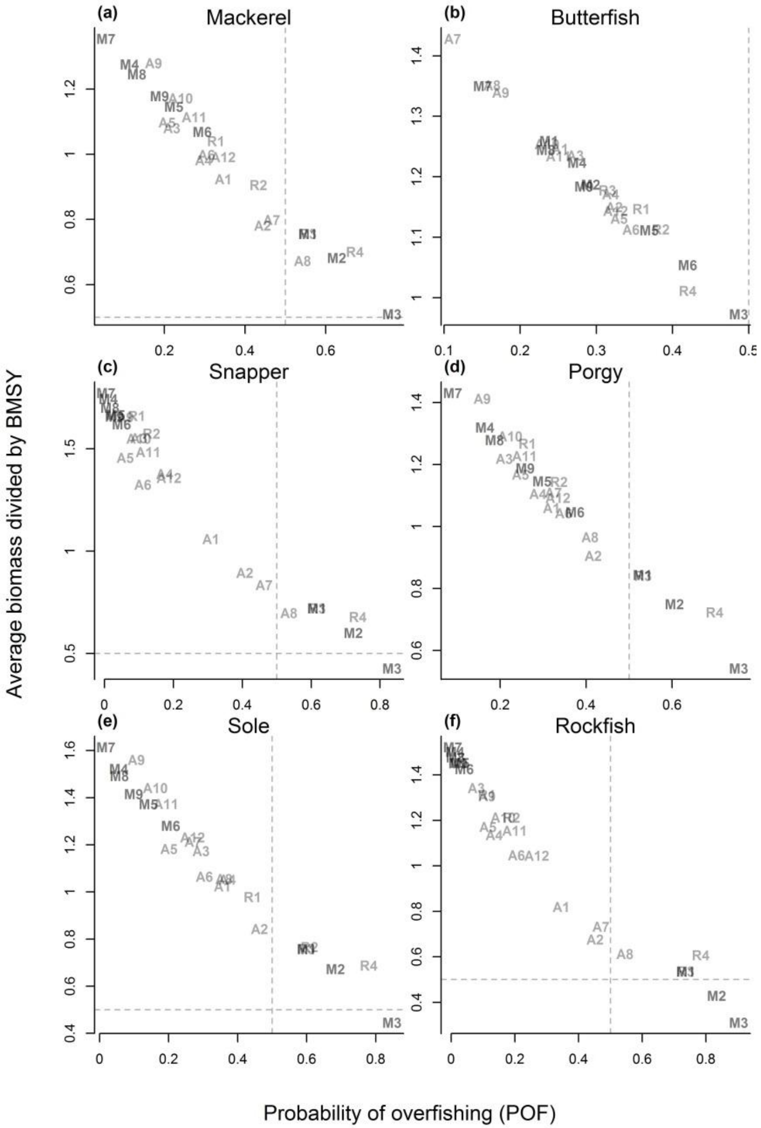

Figure 8. The trade-off between average stock depletion (projected biomass divided by B_{MSY}) and the probability of overfishing (fraction of projected years for which fishing mortality rate exceeded F_{MSY}) for projections starting between 50% and 100% B_{MSY}.

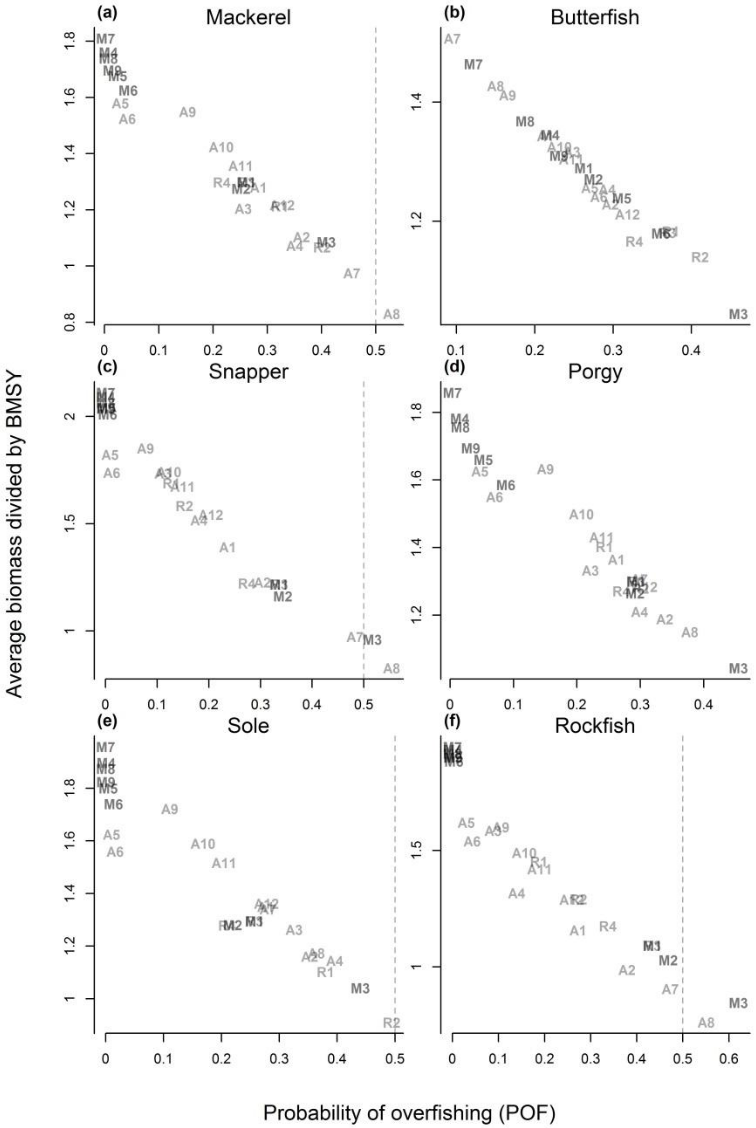

Figure 9. The trade-off between average stock depletion (projected biomass divided by B_{MSY}) and the probability of overfishing (fraction of projected years for which fishing mortality rate exceeded F_{MSY}) for projections starting between 100% and 150% B_M
