Females appear to reach sexual maturity by about age five but have given birth as early as four (Marmontel 1995, Odell et al. 1995, O'Shea and Hartley 1995, Rathbun et al. 1995), and males may reach sexual maturity at 3 to 4 years of age (Hernandez et al. 1995). Manatees may live in excess of 50 years (Marmontel 1995), and evidence for reproductive senescence is unclear (Marmontel 1995, Rathbun et al. 1995). Catalogued Florida manatee CR 28, a wild manatee that overwinters in Crystal River, was last documented with a calf in 1998, at which time she was estimated to be at least 34 years of age (USGS-Sirenia, unpublished data). A captive animal, MSTm-5801, gave birth to a calf in 1990, at which time she was estimated to be 43 to 48 years of age (FWS, unpublished data).

<u>Migration and Movement</u>
When ambient water temperatures drop below 20° C (68°F) in autumn and winter, manatees aggregate within the confines of natural and artificial warm-water refuges (Lefebvre et al. 2001) or move to the southern tip of Florida (Snow 1991). Most artificial refuges are created by warm-water outfalls from power plants or paper mills. The largest winter aggregations (maximum count of 100 or more animals) are at refuges in Central and Southern Florida. The northernmost

natural warm-water refuge used regularly on the west coast of Florida is at Crystal River and at Blue Springs in the St. Johns River on Florida's east coast. Most manatees return to the same warm-water refuges each year; however, some use different refuges in different years and others use two or more refuges in the same winter (Reid and Rathbun 1984, 1986; Rathbun et al. 1990, Reid et al. 1991, 1995). Many lesser known, minor aggregation sites are used as temporary thermal refuges. Most of these refuges are canals or boat basins where warmer water temperatures persist as temperatures in adjacent bays and rivers decline.

During mild winter periods, manatees at thermal refuges move to nearby grass beds to feed, or even return to a more distant warm season range (Deutsch et al. 2000). For example, manatees using the Riviera Power Plant feed in adjacent Lake Worth and in Jupiter and Hobe Sounds, 19 to 24 km (12 to 15 mi) to the north (Packard 1981). Animals at Blue Spring leave the spring run to feed on freshwater aquatic plants along the St. Johns River and associated waters near the spring (Bengtson 1981, Marine Mammal Commission 1986).

As water temperatures rise manatees disperse from winter aggregation areas. While some remain near their winter refuges, others undertake extensive travels along the coast and far up rivers and canals. On the east coast, summer sightings drop off rapidly north of Georgia (Lefebvre et al. 2001) and are rare north of Cape Hatteras (Rathbun et al. 1982, Schwartz 1995); the northernmost sighting is from Rhode Island (Reid 1996).

Abundance and Status of Stock

The Florida manatee is listed as "endangered" under provisions of the ESA. The manatee is considered a "strategic stock" as defined in Section 12 of the Marine Mammal Protection Act. The basis for this designation is the high level of documented mortality (natural and human-related) relative to the estimated population level and continuing, severe threats to critical manatee habitats in the southeastern U.S.

Despite considerable effort in the early 1980s, scientists have been unable to develop a useful means of estimating or monitoring trends in the size of the overall manatee population in the southeastern U.S. (O'Shea 1988, O'Shea et al. 1992, Lefebvre et al. 1995). Thus, the exact population size for Florida manatees is unknown but the minimum population is estimated at 1,822 animals, based on intensive statewide winter aerial surveys at warm-water refuges coordinated by the Florida Department of Environmental Protection in early February of 1995 (FDEP 1995). Even though most, if not all, warm-water refuges are known, direct counting methods (i.e., by aerial and ground surveys) used to estimate manatee abundance at these refuges have limitations. They are unable to account for uncertainty in the number of animals that may be away from these refuges at any given time, the number of animals not seen because of turbid water, and other factors. The use of mark-resighting techniques to estimate manatee population size based on known animals in the manatee photo identification database has also been impractical, as the proportion of unmarked manatees cannot be estimated.

Manatee population trends are poorly known but, based on the results of a carcass recovery program, deaths have increased by an average of 5.9 percent per year in Florida from 1976 through 1992 (Ackerman et al. in press). Garrott et al.'s (1994) analysis of trends at winter aggregation sites suggest a mean annual increase of 7-12 percent in adjusted counts at sites on the east coast from 1978-1992. Reynolds and Wilcox (1994) reported a decline in the percentage and number of calves seen at power plant aggregation sites during recent winter aerial surveys. It is not clear at this time whether this is related to increases in perinatal mortality or to some other factor.

The health of the population in the Atlantic Region (the east coast of Florida, including all of the Florida Key), which represents almost one-half of the entire population, is unclear. Marmontel (1994) conducted a population viability analysis through computer simulations. This study yielded information on age-related aspects of mortality and reproduction for the Florida manatee population. A scenario, calculated from the data, having an initial population size of 2,000 individuals resulted in a gradually declining population (r = -0.003), a probability of persistence of 44 percent in 1,000 years, and a mean final population size of less than 10 percent of the original value. When adult mortality was reduced by 10 percent in the model, population growth improved considerably, but when adult mortality was increased by 10 percent the population quickly dwindled. These results clearly indicate that the Florida manatee population is still at high risk of extinction in the long term. Any negative change in the population parameters, caused by environmental changes or a catastrophe, might tip the balance towards greater risk of extinction.

Atlantic Spotted Dolphin

Description and Distribution

The Atlantic spotted dolphin, *Stenella frontalis*, occurs in two forms which may be distinct sub-species (Perrin et al. 1987, 1994; Rice 1998): the large, heavily spotted form which inhabits the continental shelf and is usually found inside or near the 200-m isobath; and the smaller, less spotted island and offshore form which occurs in the Atlantic Ocean but is not known to occur in the Gulf of Mexico (Fulling et al. 2003; Mullin and Fulling 2003; Mullin and Fulling 2004). The spotted dolphin's body is covered with spots and becomes more densely spotted with age. The spotted dolphin has a long slim beak containing 35 to 48 small conical teeth in each side of the upper jaw and 34 to 47 small, conical teeth in each side of the lower jaw. The dorsal fin is tall and curved; the flippers are small and pointed as are the flukes with a small median notch. Length averages about 7 ft. (2.1 m) with an average weight of 220 pounds (100 kg). Calves measure 32 to 36 inches (80 to 90 cm) at birth (Balcomb and Minasian 1984, Leatherwood and Reeves 1983, Leatherwood et al. 1982, American Cetacean Society Fact Sheet 2007).

Atlantic spotted dolphins are distributed in tropical and warm temperate waters of the western North Atlantic (Leatherwood et al. 1976). Their distribution is from southern New England, south through the Gulf of Mexico and the Caribbean to Venezuela (Leatherwood et al. 1976, Perrin et al. 1994). The large, heavily spotted form of the Atlantic spotted dolphin along the southeastern and Gulf coasts of the United States, inhabits the continental shelf, usually being found inside or near the 200 m isobath (within 250-350 km of the coast) but sometimes coming into very shallow water adjacent to the beach (Waring et al. 2007). Off the northeast U.S. coast, spotted dolphins are widely distributed on the continental shelf, along the continental shelf edge, and offshore over the deep ocean south of 40° N (CETAP 1982). Atlantic spotted dolphins regularly occur in the inshore waters south of Chesapeake Bay and near the continental shelf edge and continental slope waters north of this region (Payne et al. 1984, Mullin and Fulling

2003). Sightings have also been made along the north wall of the Gulf Stream and warm-core ring features (Waring et al. 1992).

Reproduction

This species reaches maturity between 6 and 8 years of age. Most animals are approximately 6.5 ft (2 m) in length when they reach sexual maturity. Mating and calving take place throughout the year; the calving interval is believed to be about every two years. In stressed populations, mating takes place at an earlier age and the calving intervals are shorter. Gestation is 11 1/2 months and calves are nursed for 11 months (Balcomb et al. 1984, Leatherwood and Reeves 1983, Leatherwood et al. 1982, American Cetacean Society Fact Sheet 2007).

Ecological Relationships

Diet, Development, and Growth

Spotted dolphins feed on many varieties of fish and squid found near the surface of the water. In the eastern Pacific, pregnant females feed more on squid and nursing females tend to feed more on fish. The reason for this is unknown (Balcomb et al. 1984, Leatherwood and Reeves 1983, Leatherwood et al. 1982, American Cetacean Society Fact Sheet 2007).

Migration and Movement

Spotted dolphins consist of tropical and subtropical species and are widely distributed in all tropical and warm-temperate waters of the Atlantic, Pacific, and Indian Oceans (Balcomb et al. 1984, Leatherwood and Reeves 1983, Leatherwood et al. 1982, American Cetacean Society Fact Sheet 2007).

Abundance and Status of Stock

Total numbers of Atlantic spotted dolphins off the U.S. or Canadian Atlantic coast are unknown. The best 2004 abundance estimate for Atlantic spotted dolphins is the sum of the estimates from the two 2004 western U.S. Atlantic surveys, 50,978 (CV=0.42), where the estimate from the northern U.S. Atlantic is 3,578 (CV=0.48), and from the southern U.S. Atlantic is 47,400 (CV=0.45). However, this does not account for the potential for a mixed species herd, as has been recorded for several dolphin assemblages. Pending further genetic studies for clarification of this problem, a single species abundance estimate is considered the best estimate of abundance. This combines species-specific data from the northern as well as southern portions of the species' ranges. There are insufficient data to determine the population trends for this species, given that surveys prior to 1998 did not differentiate between species of spotted dolphins (Waring et al. 2007).

Bottlenose Dolphin (coastal stock)

Description and Distribution

This is a relatively robust dolphin with a usually short and stubby beak - hence the name "bottlenose." The bottlenose dolphin, *Tursiops truncatus*, has more flexibility in its neck than other oceanic dolphins, because five of the seven neck vertebrae are not fused together as in the other oceanic dolphins. There are 18-26 pairs of sharp, conical teeth in each side of its jaw. The color of the bottlenose dolphin varies considerably, but generally this dolphin is light gray to slate gray on the upper part of the body shading to lighter sides and pale, pinkish gray on the belly. The dorsal fin is high and falcate (curved) and located near the middle of the back. The flukes are broad and curved with a deep median notch. The flippers are of moderate length and pointed. Adult length is from 8-12 feet (2.5-3.8 m). These dolphins may weigh as much as 1,430 pounds (650 kg) off Great Britain, though most are much smaller in other parts of the world. Males are significantly larger than females (Wells and Scott 2000, 2002; Reynolds et al. 2000, Connor et al. 2000, American Cetacean Society Fact Sheet 2007).

The coastal morphotype of bottlenose dolphin is continuously distributed along the Atlantic coast south of Long Island, around the Florida peninsula and along the Gulf of Mexico coast. Based on differences in mitochondrial DNA haplotype frequencies, nearshore animals in the northern Gulf of Mexico and the western North Atlantic represent separate stocks (Curry 1997; Duffield and Wells 2002). Recent genetic analyses of samples from northern Florida, Georgia, central South Carolina (primarily the estuaries around Charleston), southern North Carolina, and coastal Virginia, using both mitochondrial DNA and nuclear microsatellite markers, indicate that a significant amount of the overall genetic variation can be explained by differences between these areas (NMFS 2001). These results indicate a minimum of five stocks of coastal bottlenose dolphins along the U.S. Atlantic coast (Waring et al. 2007). Photo-identification studies also support the existence of multiple stocks (NMFS 2001).

The movement patterns of animals outfitted with satellite-linked radio transmitters off Virginia Beach, VA, Beaufort, NC, Charleston, SC, and New Jersey, along with photo-identification of freeze-branded animals, indicate that a significant number of dolphins reside in North Carolina in summer and do not migrate. A dolphin tagged in Virginia Beach, VA, spent the winter between Cape Hatteras and Cape Lookout, NC, indicating seasonal migration between North Carolina and areas further north (NMFS 2001).

In summary, several stock identification techniques (i.e., genetic sampling, photo-identification, satellite telemetry, etc.) confirm a complex mosaic of coastal bottlenose dolphin stocks. Therefore, seven management units exist within the range of the coastal morphotype of western North Atlantic bottlenose dolphin (Figure 4.3-1).

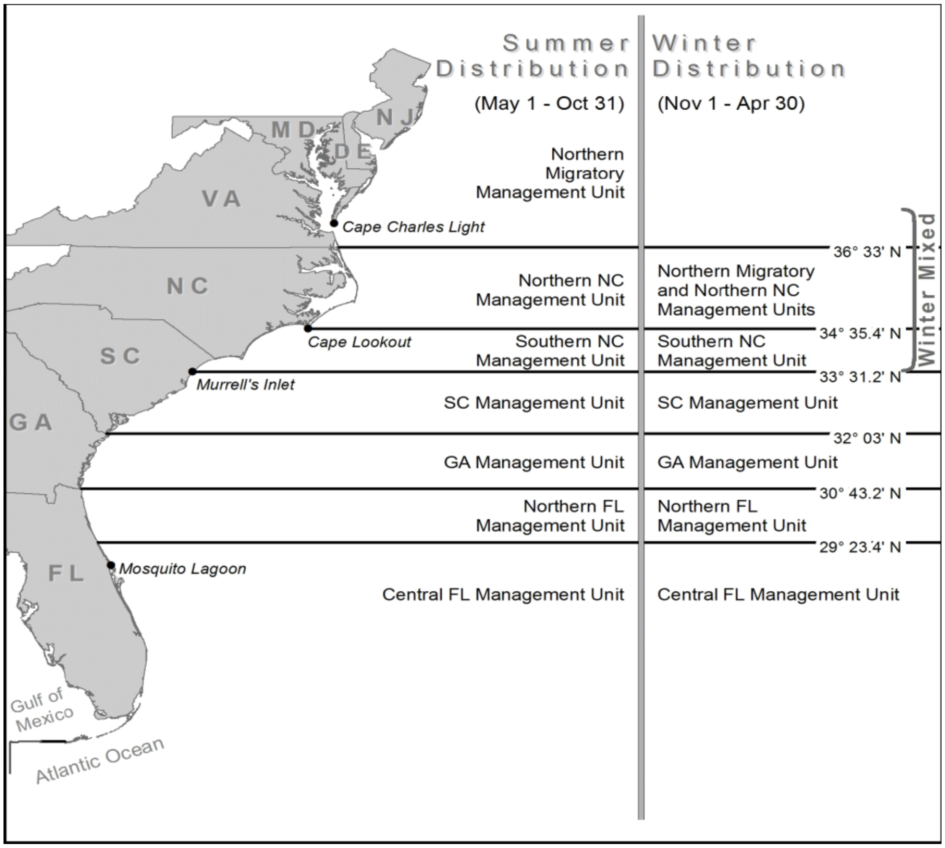

Figure 4.3-1. Management units of the coastal morphotype of bottlenose dolphin along the Atlantic coast of the U.S. as defined from genetic, stable isotope ratio, photo-identification, and telemetry studies (NMFS 2001).

Aerial surveys conducted between 1978 and 1982 (CeTAP 1982) north of Cape Hatteras, North Carolina identified two concentrations of bottlenose dolphins, one inshore of the 25 m isobath and the other offshore of the 50m isobath. The lowest density of bottlenose dolphins was observed over the continental shelf, with higher densities along the coast and near the continental shelf edge. It was suggested, therefore, that the coastal morphotype is restricted to waters < 25 m deep north of Cape Hatteras (Kenney 1990).

Genetic analysis of tissue samples collected during large vessel surveys the summers of 1998 and 1999 indicated that bottlenose dolphins within 7.5 km from shore were most likely of the coastal morphotype. These samples also suggested an area of extensive overlap between the coastal and offshore morphotypes located 7.5 and 34 km from shore south of Cape Hatteras, North Carolina (Torres et al. 2003).

Reproduction

Males reach sexual maturity at about 10 years. Females reach sexual maturity at about 5-10 years. The gestation period is 12 months. Calving can take place year-round with peaks in some areas during spring and fall. Calves nurse for over a year (12-18 months), and stay with their mothers for 3-6 years learning how to catch fish and other important tasks (Wells and Scott

2000, 2002; Reynolds et al. 2000, Connor et al. 2000, American Cetacean Society Fact Sheet 2007).

Ecological Relationships

Diet, Development, and Growth

Feeding behaviors are diverse, primarily involving individual prey capture, but sometimes involving coordinated efforts to catch food, feeding in association with human fishing, and chasing fish into mudbanks. An adult bottlenose dolphin may consume 15-30 pounds (8-15 kg) of food each day. Bottlenose dolphins eat a wide variety of food, including primarily fishes, and sometimes squid, and crustaceans (Wells and Scott 2000, 2002; Reynolds et al. 2000, Connor et al. 2000, American Cetacean Society Fact Sheet 2007).

Abundance and Status of Stock

There are insufficient data to determine the population trend for these stocks. However, the coastal migratory stock was designated as depleted under the MMPA. Table 4.3-2 outlines abundance estimates for each management unit. NMFS conducted abundance surveys during the summer and winter of 2002 in order to update previous abundance estimates from 1995. Current estimates are confounded somewhat by an overlap in distribution between the coastal and offshore bottlenose dolphin stocks, and the difficulty of distinguishing between the two stocks while surveying. However, these estimates are considered more robust than previous abundance estimates conducted in 1995 due to improved experimental design.

Bottlenose Dolphin (offshore stock)

The bottlenose dolphin, *Tursiops truncatus*, offshore stock is distributed primarily along the outer continental shelf and continental slope in the Northwest Atlantic Ocean. North of Cape Hatteras, North Carolina, during summer months, there is a clear distinction between the coastal and offshore stocks of bottlenose dolphins across bathymetry (Waring et al. 2007). Torres et al. (2003) found a statistically significant break in the distribution of the coastal and offshore stocks at 34 km from shore based upon the genetic analysis. The offshore morphotype was found exclusively seaward of 34 km and in waters deeper than 34 m. Biopsy samples of the offshore morphotype have been collected as close as 7.3 km from shore in water depths of 13 m (Garrison et al. 2003).

Seasonally, bottlenose dolphins occur over the outer continental shelf and inner slope waters as far north as Georges Bank (CeTAP 1982, Kenney 1990). Sightings occurred along the continental shelf break from Georges Bank to Cape Hatteras during spring and summer (CeTAP 1982, Kenney 1990). Information from Wells et al. (1999) indicates that the range of the offshore bottlenose dolphin may include waters beyond the continental slope and that offshore bottlenose dolphins may move between the Gulf of Mexico and the Atlantic. Offshore morphotype bottlenose dolphins have stranded as far south as the Florida Keys (Waring et al. 2007).

Table 4.3-2. Estimates of abundance and the associated CV, N_{min}, and PBR for each stock of WNA coastal bottlenose dolphins (Garrison et al. 2003 in Waring et al. 2007). The PBR for the Northern Migratory, Northern NC, and Southern NC management units are applied semi-annually. South of NC, the PBR is applied annually. Except where noted, abundance estimates and PBR values do not include estuarine animals. The recovery factor (Fr) used to calculate PBR for each stock is based upon the CV of the abundance estimate based on the guidelines in Wade and Angliss (1997).

Unit		Best Abundance		N_{min}	Recovery Factor (Fr)	PBR	
		Estimate	CV			Annual	½ Yr
SUMMER (May - October)							
Northern migratory		17,466	0.19	14,621	0.50	(146.2)	73.1
Northern NC							
	oceanic	6,160	0.52	3,255	0.48	(31.2)	15.6
	Estuary[d]	919	0.13	828	0.50	(8.2)	4.2
	BOTH	7,079	0.45	4,083	0.48	(39.2)	19.6
Southern NC							
	oceanic	3,645	1.11	1,863	0.40	(14.9)	7.5
	Estuary[d]	141	0.15	124	0.50	(1.2)	0.6
	BOTH	3,786	1.07	1,987	0.40	(15.9)	7.9
WINTER (November - April)							
NC mixed[a]		16,913	0.23	13,558	0.50	(135.6)	67.8
ALL YEAR							
South Carolina		2,325	0.20	1,963	0.50	19.6	unk
Georgia		2,195	0.30	1,716	0.50	17.2	unk
Northern Florida[b,c]		448	0.38	unk	unk	unk	unk
Central Florida[c]		10,652	0.46	unk	unk	unk	unk

a. NC mixed = northern migratory, Northern NC, and Southern NC
b. Northern Florida estimates are a weighted mean of abundance estimates from the winter 1995 survey and the summer 2002 survey. Due to the age of the winter abundance estimate, PBR cannot be calculated for this stock.
c. Northern and Central Florida estimates include data from the winter 1995 survey and cannot be used to determine PBR due to their age.
d. Read et al. 2003

Reproduction

Males reach sexual maturity at about 10 years. Females reach sexual maturity at about 5-10 years. The gestation period is 12 months. Calving can take place year-round with peaks in some areas during spring and fall. Calves nurse for over a year (12-18 months), and stay with their mothers for 3-6 years learning how to catch fish and other important tasks (Wells and Scott 2000, 2002; Reynolds et al. 2000, Connor et al. 2000, American Cetacean Society Fact Sheet 2007).

Ecological Relationships

Diet, Development, and Growth

Feeding behaviors are diverse, primarily involving individual prey capture, but sometimes involving coordinated efforts to catch food, feeding in association with human fishing, and chasing fish into mudbanks. An adult bottlenose dolphin may consume 15-30 pounds (8-15 kg) of food each day. Bottlenose dolphins eat a wide variety of food, including primarily fishes, and sometimes squid, and crustaceans (Wells and Scott 2000, 2002; Reynolds et al. 2000, Connor et al. 2000, American Cetacean Society Fact Sheet 2007).

Abundance and Status of Stock

During the summer (June - July) of 2002, aerial surveys were conducted along the U.S. Atlantic coast between Florida and New Jersey. The resulting coastwide abundance estimate for the offshore morphotype in waters < 40 m depth was 26,849 (CV = 0.193)(Buckland et al. 2001, Palka 1995, Garrison et al. 2003, Waring et al. 2007).

Another abundance estimate of 9,786 (CV = 0.56) for offshore morphotype bottlenose dolphins was derived from a June 12 to August 4, 2004 ship and plane survey. The survey covered 10,761 km of track line in waters north of 38° N (Palka unpubl.; Palka 1995; Palka and Hammond 2001; Hiby 1999; Waring et al. 2007).

An additional survey of the U.S. Atlantic outer continental shelf and continental slope (water depths > 50m) between 27.5 – 38ºN latitude was conducted during June-August, 2004. Survey effort was stratified to include increased effort along the continental shelf break and Gulf Stream front in the Mid-Atlantic. The survey included 5,659 km of trackline; there were 473 cetacean sightings. Sightings were most frequent in waters North of Cape Hatteras, North Carolina along the shelf break (Palka 1995, Buckland et al. 2001). The resulting abundance estimate for offshore morphotype bottlenose dolphins between Florida and Maryland was 44,953 (CV = 0.26) (Waring et al. 2007).

The best available estimate for offshore morphotype bottlenose dolphins is the sum of the estimates from the summer 2002 aerial survey covering the continental shelf, the summer 2004 vessel survey south of Maryland, and the summer 2004 vessel and aircraft surveys north of Maryland. This joint estimate provides complete coverage of the offshore morphotype habitat from Florida to Georges Bank during summer months. The combined abundance estimate from these surveys is 81,588 (CV = 0.17) (Waring et al. 2007).

The status of this stock relative to its optimum sustainable population in the U.S. Atlantic EEZ is unknown. The western North Atlantic offshore bottlenose dolphin is not listed as threatened or endangered under the ESA. There are insufficient data to determine the population trends for this species. Average 1999-2003 annual fishery-related mortality and serious injury does not exceed the PBR therefore this is not a strategic stock. The total fishery-related mortality and serious injury for this stock is less than 10% of the calculated PBR and, therefore, can be considered to be insignificant and approaching zero mortality and serious injury rate.

Minke Whale

Description and Distribution

The minke whale, *Balaenoptera acutorostrata*, is the smallest member of the rorqual family of whales. One of its most distinctive features is the narrow, triangular rostrum (upper jaw), which is proportionally shorter than in other rorquals. A single ridge extends from the tip of the rostrum to the blowhole. Its body is slender and streamlined. Like all rorquals, the minke has a series of 50 to 70 ventral grooves, or pleats, that expand during feeding. The minke is counter-shaded-black to dark gray on top, white below. Some minkes have a light-colored chevron on the back behind the head. Two areas of lighter gray appear on each side: one behind the flippers and another below and forward of the dorsal fin. Distinctive to minke whales outside of the Antarctic is a white band on each flipper. The dorsal fin of the minke is tall and falcate (curved), and is located two-thirds of the way back on the body. Its flippers are slender and pointed at the tips. Flukes are broad, up to one-fourth of the body length, pointed at the tips, and notched in the center. Adult males average about 26 ft (8 m) with a maximum length of 31 ft (9.4 m), while adult females average 27 ft (8.2 m) with a maximum length of 33 ft (10.2 m). Both males and females weigh about 10 tons. Both sexes are slightly larger in the southern hemisphere (Balcomb and Minasian 1984, Ellis 1980, Leatherwood and Reeves 1983, American Cetacean Society Fact Sheet 2007).

Minke whales have a cosmopolitan distribution, being distributed in polar, temperate and tropical waters. In the North Atlantic, there are four recognized populations — Canadian East Coast, west Greenland, central North Atlantic, and northeastern North Atlantic (Donovan 1991). Minke whales off the eastern coast of the U.S. are considered to be part of the Canadian East Coast stock, which inhabits the area from the eastern half of the Davis Strait (45ºW) to the Gulf of Mexico. The relationship between this stock and the other three stocks is uncertain. It is also uncertain if there are separate stocks within the Canadian East Coast stock (Waring et al. 2007).

The minke whale is common and widely distributed within the U.S. Atlantic Exclusive Economic Zone (EEZ) (CeTAP 1982). There appears to be a strong seasonal component to minke whale distribution. Spring and summer are times of relatively widespread and common occurrence, and when the whales are most abundant in New England waters. During fall in New England waters, there are fewer whales, while during winter, the species appears to be largely absent. Like most other baleen whales, minke whales generally occupy the continental shelf proper, rather than the continental shelf edge region. Records summarized by Mitchell (1991) hint at a possible winter distribution in the West Indies, and in the mid-ocean south and east of Bermuda. As with several other cetacean species, the possibility of a deep-ocean component to the distribution of minke whales exists but remains unconfirmed (Waring et al. 2007).

Reproduction

Sexual maturity is reached at 7 or 8 years in the northern hemisphere. Breeding peaks in summer months. The gestation period is 10 to 11 months, and calving is thought to occur once every two years on average. Calves are 10 ft (3 m) at birth and weigh 1000 pounds (450 kg). Minke calves nurse for approximately 6 months (Balcomb and Minasian 1984, Ellis 1980, Leatherwood and Reeves 1983, American Cetacean Society Fact Sheet 2007).

Ecological Relationships

<u>Diet, Development, and Growth</u>

Minke whales feed primarily on krill in the southern hemisphere and on small schooling fish (capelin, cod, herring, pollock) or krill in the northern hemisphere. They will also eat copepods in certain areas (Balcomb and Minasian 1984, Ellis 1980, Leatherwood and Reeves 1983, American Cetacean Society Fact Sheet 2007).

Migration and Movement

Minkes tend to be solitary animals, though sometimes they are seen traveling in pairs or in small groups of 4 to 6. They are found in all oceans, though they are rarely observed in the tropics. They seem to prefer icy waters, and are found right up to the edge of the icepack in polar regions, and have actually become entrapped in the ice fields on occasion (Balcomb and Minasian 1984, Ellis 1980, Leatherwood and Reeves 1983, American Cetacean Society Fact Sheet 2007).

Abundance and Status of Stock

The total number of minke whales in the Canadian East Coast population is unknown (Waring et al 2007). The best available current abundance estimate for minke whales is 2,998 animals (CV=0.19). This estimate obtained from a July to August 1999 sighting survey conducted by a ship and airplane covering waters from Georges Bank to the mouth of the Gulf of St. Lawrence (NMFS unpublished data, Palka 2006). The status of minke whales, relative to optimum sustainable population, in the U.S. Atlantic EEZ is unknown. However, the minke whale is not listed under the Endangered Species Act (ESA) (Waring et al. 2007).

4.3.2 Sea Turtles

Description and distribution

(from draft SNG Amendment 14)

The following section offers a brief overview of the general life history characteristics of the sea turtles found in the South Atlantic region. Several volumes exist that cover more thoroughly the biology and ecology of these species (i.e., Lutz and Musick (eds.) 1997; Lutz et al. (eds.), 2002).

The ESA status of sea turtles in the South Atlantic was recently evaluated in a section 7 consultation on the continued authorization of snapper grouper fishing under the South Atlantic Snapper Grouper Fishery Management Plan and Amendment 13C (NMFS 2006).

Green sea turtle, *Chelonia mydas*, hatchlings are thought to occupy pelagic areas of the open ocean and are often associated with Sargassum rafts (Carr, 1987; Walker, 1994). Pelagic stage green sea turtles are thought to be carnivorous. Stomach samples of these animals found ctenophores and pelagic snails (Frick 1976, Hughes 1974). At approximately 20 to 25 cm carapace length, juveniles migrate from pelagic habitats to benthic foraging areas (Bjorndal 1997). As juveniles move into benthic foraging areas a diet shift towards herbivory occurs. They consume primarily seagrasses and algae, but are also know to consume jellyfish, salps, and sponges (Bjorndal 1980, 1997; Paredes 1969; Mortimer 1981, 1982). The diving abilities of all sea turtles species vary by life stage. The maximum diving depth of green sea turtles is estimated at 110 m (360 ft) (Frick 1976), but they frequently make dives of less than 20 m (65 ft.)(Walker

1994). The time of these dives also varies by life stage. The maximum dive length is estimated at 66 minutes with most dives lasting from 9 to 23 minutes (Walker 1994).

The hawksbill's, *Eretmochelys imbricata*, pelagic stage lasts from the time they leave the nesting beach as hatchlings until they are approximately 22-25 cm in straight carapace length (Meylan 1988, Meylan and Donnelly 1999). The pelagic stage is followed by residency in developmental habitats (foraging areas where juveniles reside and grow) in coastal waters. Little is known about the diet of pelagic stage hawksbills. Adult foraging typically occurs over coral reefs, although other hardbottom communities and mangrove-fringed are occupied occasionally. Hawksbills show fidelity to their foraging areas over several years (van Dam and Diéz 1998). The hawksbill's diet is highly specialized and consists primarily of sponges (Meylan 1988). Gravid females have been noted ingesting coralline substrate (Meylan 1984) and calcareous algae (Anderes Alvarez and Uchida 1994), which are believed to be possible sources of calcium to aid in eggshell production. The maximum diving depths of these animals are not known, but the maximum length of dives is estimated at 73.5 minutes. More routinely dives last about 56 minutes (Hughes 1974).

Leatherbacks, *Dermochelys coriacea*, are the most pelagic of all ESA-listed sea turtles and spend most of their time in the open ocean; although they will enter coastal waters and are seen over the continental shelf on a seasonal basis to feed in areas where jellyfish are concentrated.

Leatherbacks feed primarily on cnidarians (medusae, siphonophores) and tunicates.
Unlike other sea turtle species, leatherbacks' diets do not shift during their life cycles. Because leatherbacks' ability to capture and eat jellyfish is not constrained by size or age, they continue to feed on these species regardless of life stage (Bjorndal 1997). Leatherbacks are the deepest diving of all sea turtles. It is estimated that this species can dive in excess of 1000 m (Eckert et al. 1989) but more frequently dive to depths of 50 m to 84 m (Eckert et al.. 1986). Dive times range from a maximum of 37 minutes to more routines dives of 4 to 14.5 minutes (Standora et al. 1984, Eckert et al. 1986; Eckert et al. 1989; Keinath and Musick 1993). Leatherbacks may spend 74% to 91% of their time submerged (Standora et al. 1984).

Loggerhead, *Caretta caretta*, hatchlings forage in the open ocean and are often associated with Sargassum rafts (Hughes 1974; Carr 1987; Walker 1994; Bolten and Balazs 1995). The pelagic stage of these turtles are known to eat a wide range of prey including salps, jellyfish, amphipods, crabs, sygnathid fish, squid, and pelagic snails (Brongersma 1972).

Stranding records indicate that when pelagic immature loggerheads reach 40-60 cm straight-line carapace length they begin to live in coastal inshore and nearshore waters of the continental shelf throughout the U. S. Atlantic (Witzell 2002) where they forage over hard- and soft-bottom habitats (Carr 1986). Benthic foraging loggerheads eat a variety of invertebrates with crabs and mollusks being important prey sources (Burke et al. 1993).

Estimates of the maximum diving depths of loggerheads range from 211 m to 233 m (692-764ft) (Thayer et al.,1984; Limpus and Nichols, 1988). The lengths of loggerhead dives are frequently between 17 and 30 minutes (Thayer et al. 1984; Limpus and Nichols 1988; Limpus and Nichols 1994; Lanyan et al. 1989) and they may spend anywhere from

80 to 94% of their time submerged (Limpus and Nichols 1994; Lanyan et al. 1989).

Kemp's ridley, *Lepidochelys kempii*, hatchlings are also pelagic during the early stages of life and feed in surface waters (Carr, 1987; Ogren 1989). Once the juveniles reach approximately 20 cm carapace length they move to relatively shallow (less than 50m) benthic foraging habitat over unconsolidated substrates (Márquez-M. 1994). They have also been observed transiting long distances between foraging habitats (Ogren 1989).

Kemp's ridleys feeding in these nearshore areas primarily prey on crabs, though they are also known to ingest mollusks, fish, marine vegetation and shrimp (Shaver 1991). The fish and shrimp Kemp's ridleys ingest may be scavenged opportunistically from bycatch discards and from discarded bait, and are not thought to be a primary prey item (Shaver 1991). Given their predilection for shallower water, Kemp's ridleys most routinely make dives of 50 m or less (Soma 1985; Byles 1988). Their maximum diving range is unknown. Depending on the life stage a Kemp's ridleys may be able to stay submerged anywhere from 167 minutes to 300 minutes, though dives of 12.7minutes to 16.7 minutes are much more common (Soma 1985; Mendonca and Pritchard 1986; Byles 1988). Kemp's ridleys may also spend as much as 96% of their time underwater (Soma 1985, Byles 1988).

Development, growth and movement patterns

Growth in all species of sea turtles is a relative unknown because direct measurements are not practical given the relatively long life span, specialized habitat requirements, and large spatial scale at which individuals operate, all of which precludes maintaining them in the laboratory or making direct observations in the field. Growth has been inferred from tagging studies (cites), and some bone histology (cites). In general growth rates in all species of sea turtles are hypothesized to be relatively slow. Maturity is thought to be reached in as little as 6 years in Kemps or Leatherbacks, 10-15 years for greens and hawksbills, and 21 to 35 years for loggerheads. Considerable uncertainty exists in all of these estimates, in particular leatherbacks have been hypothesized to reach maturity in as little as 3 years (Pritchard 19xx) and as many as 30 years (Avens pers. comm.).

Most green turtles (*C. mydas*) exhibit particularly slow growth rates, which has been described as a consequence of their largely herbivorous (i.e., low net energy) diet (Bjorndal 1982). Growth rates of juveniles vary substantially among populations, ranging from <1 cm/year (Green 1993) to >5 cm/year (McDonald-Dutton and Dutton 1998), likely due to differences in diet quality, duration of foraging season (Chaloupka et al. 2004b), and density of turtles in foraging areas (Bjorndal et al. 2000; Seminoff et al. 2002c; Balazs and Chaloupka 2004b). Consistent with slow growth, age-to-maturity for the green turtles appears to be the longest of any sea turtle species (Chaloupka and Musick 1997; Hirth 1997).

A variety of studies have addressed growth rates and age to various life stages in Kemp's ridleys. Based on mark-recapture data, skeletal chronological analysis, and growth rates in captivity, it has been estimated that Kemp's ridleys require approximately 1.5 to 2 years to grow from a hatchling to a size of approximately 20 cm straight carapace length (SCL), at which size they are capable of making a transition to a benthic immature stage (B. Higgins, NMFS, personal communication, 2007; Caillouet et al. 1995; Schmid and Witzell 1997; Zug et al. 1997; Schmid 1998; Snover et al. 2007). However, variability in growth rates suggests that the actual time necessary to achieve a 20 cm SCL could range from approximately 1 to 4 years or more (Turtle Expert Working Group (TEWG) 2000).

The state of knowledge of sea turtles movements is increasing rapidly due to a number of factors which include the development and availability of telemetry equipment, and the cooperation and communication between various entities of tagging information. A growing body of literature is available documenting individual movements for many of the species, and some synthetic studies are becoming available that link turtle movements to environmental conditions. Recent examples include, for leatherbacks, the work of Hayes and colleagues (Hayes et al, 2006), and James and colleagues (James, 2006).

Green turtles are highly mobile and they undertake complex movements through geographically disparate habitats during their lifetimes (Musick and Limpus 1997; Plotkin 2003). While offshore, and sometimes while in coastal habitats, green turtles are not obligate herbivores as widely believed, and instead consume invertebrates such as jellyfish, sponges, sea pens, and pelagic prey (i.e., prey that occupy the water column) (Godley et al. 1998; Heithaus et al. 2002; Seminoff et al. 2002b; Hatase et al. 2006; Parker and Balazs in press).

Green turtles spend the majority of their lives in coastal foraging grounds. These areas include both open coastline and protected bays and lagoons. In addition to coastal foraging areas, oceanic habitats are used by oceanic-stage juveniles, migrating adults, and, on some occasions, by green turtles that reside in the oceanic zone for foraging. At nesting beaches, green turtles rely on safe and healthy beaches with intact dune structures, native vegetation, and normal beach temperatures for nesting (Ackerman 1997). Coastal areas denuded of vegetation or with coastal construction can impact thermal regimes on beaches and thus affect the incubation and resulting sex ratio of hatchling turtles.

For leatherback turtles, important nesting areas in the western Atlantic Ocean occur in Florida (USA); St. Croix, U.S. Virgin Islands; Puerto Rico; Costa Rica; Panama; Colombia; Trinidad and Tobago; Guyana; Suriname; French Guiana; and southern Brazil (Marquez 1990; Spotila et al. 1996; Bräutigam and Eckert 2006).

Four leatherbacks tagged on the beaches of Costa Rica and Panama were later found nesting in Cuba, Florida, St. Croix, and Grenada, thereby weakening the concept of a distinct Western Caribbean leatherback population. Among leatherbacks fitted with transmitters in Florida, most remained along the North American continental shelf for three seasons and in winter moved off the shelf. In February 2008, scientists tracked a leatherback turtle that swam from Indonesia to the U.S. coast, an estimated 13,000 mile journey (Associated Press, 2008. Avaialble at www.seaturtle.org).

Ecological relationships

All sea turtles species in the Atlantic impact nearshore terrestrial beach habitats (supralittoral) and a variety of neritic and oceanic habitats. Some stages of nearly all sea turtle species inhabit neritic zones, including benthic and pelagic use, while oceanic zone use is typically epipelagic but some stages of some species (e.g., leatherbacks) are pelagic oceanic for nearly their entire lives (see Bolten 2003). Energy exchange between habitats, and the impact of species specific foraging ecology within habitats may have been substantial historically but due to the hypothesized massive declines in sea turtle populations the impact and potential alterations to these ecosystems could be, in part, responsible for large shifts in ecosystem function (Bjorndal and Jackson, 2003). Unfortunately many of the ecological relationships for most species and stages of sea turtles are based on inference and anecdotal information, thus most of this section is conjecture.

All species of sea turtles come ashore to nest, typically depositing large numbers of eggs. The total biomass deposited into these terrestrial habitats can be large, both from adult female mortality and eggs. Nest failure and partial hatching can leave large quantities of biomass in nutrient poor ecosystems that make up most beach habitat, in addition to transfer of biomass through direct predation on eggs and hatchlings by a variety of terrestrial predators.

After emergence from nests and entering the ocean, all species of sea turtle hatchlings are thought to be pelagic. Little is known about the habitats and foraging ecology, and thus the ecological relationships, of hatchlings after the first few days since entering the sea, and much of this was reviewed above. Most are thought to remain pelagic, passively drifting with some active swimming and inhabiting weed lines or *Sargassum* for many years (Bolten 2003). After this stage leatherbacks become oceanic pelagic, likely eating gelatinous organisms until adult females return to the terrestrial zone for nesting and use the neritic zone as internesting habitat. The remaining species in the Atlantic are thought to move to the oceanic zone and remain pelagic until they reach the large juvenile stage when they return to the neritic zone. Loggerheads are thought to become benthic at this point, inhabiting a wide range of benthic habitat and feeding primarily on hard shelled invertebrates.

<u>Coral reef ecosystems and sea turtles</u>

Sea turtles, particularly Hawksbill and Green sea turtles, impact coral reef ecosystems through selective grazing and predation, and direct disturbance to corals. Loggerheads, and possibly some Kemp's ridleys are known to use coral reefs as resting or hiding spots.

Hawksbill turtles affect the evolution and maintenance of reef structure and dynamics because they prey upon sponges that compete with coral for space on reefs (León and Bjorndal 2002; Meylan 1988). Green turtles primarily forage on seagrass beds (nursery grounds for many reef species) and occasionally on sponges. Green turtles are also known to use coral reefs as 'scratching posts' causing erosions, breaks, and larger scale structural shears and collapses (Bennet and Balaz 2002). Both green turtles and hawksbills use their flippers to pry corals out of the way to access sponges, with green turtles foraging on the periphery of reefs, and hawksbills foraging throughout the reef system. Both of these species can have substantial impacts on the habitats they exploit (see Bjorndal 1997 for review).

Hawksbill turtles diet of demosponges and corallimorpharians, aggressive competitors for space on reefs, makes them important predators, which play a significant role in reef structure and dynamics (León and Bjorndal 2002; Meylan 1988). In spongivore exclusion experiments, Hill (1998) found that the demosponge *Chondrilla nucula* would rapidly overgrow the majority of corals with which it interacts and caused >70% of all coral overgrowths in his Florida Keys study. Similar results have been found with *Ricodea florida*, a corallimorpharians (Vicente 1990). Hawksbills have been reported to positively select both of these species as forage (León and Bjorndal 2002).

Large juvenile and adult green turtles are primarily associated with seagrass beds, their primary forage, and may repeatedly graze patches of seagrass over time. Grazing has been found to substantially increase biomass and productivity without reducing growth rates of *Thalassia testudinum* seagrass beds (Moran et al. 2002). In addition, new growth of *T. testudinum* after grazing has a higher energy and nutrient content than seagrass that did not experience grazing. Grazing activity also has a significant effect on the physical structure of seagrass by decreasing blade length and width, detrital layer, blades/shoot, and above ground biomass (Moran et al. 2002).

While both green and hawksbills turtles are clearly integral components of the dynamics of seagrass and coral habitats, at current population sizes it seems unlikely that they are adequately fulfilling their ecological role in many habitats around the world. Since the arrival of Europeans in the Caribbean, sea turtles have declined drastically. Prior to Columbus' arrival, the population of green turtles may have numbered in the hundreds of millions with hawksbills in the tens of millions (Jackson 1997). Today, it is believed that these populations are at most 5 to 10% of historic levels. Clearly, the absence of these ecosystem engineers from seagrass and coral habitats could have a profound effect on the biodiversity, dynamics, function, and recovery of those habitats. This reduction in sea turtle abundance in seagrass and coral habitats could have a profound effect on the function and recovery of those habitats. Effective management of protected reef areas will require understanding sea turtle distribution and use of coral reefs and other marine habitats.

Abundance and status of stocks

All populations of all species of sea turtles in the North Atlantic are thought to be at fractions of their historic population sizes (Bjorndal and Jackson, 2003). No reliable historic or current estimates are available for any species, although a number of authors have made guestimates. For example Jackson (1997) argued that historical populations of green turtles may have numbered in the hundreds of millions with hawksbills in the tens of millions, and each is now thought to be at only 5 to 10% of previous levels.

By calculating populations based on the annual nests from 2001 to 2005, the abundance of Green turtles in Florida is approximately 5,055 (Meylan et al. 2006). The green turtle nesting population of Florida appears to be increasing based on 18 years (1989-2006) of index nesting data from throughout the state. Although in the last four years there are three 'low' years, this may be due to lesser reproductive effort as a result of environmental variability at foraging grounds rather than a decrease in the number of nesting females.

The most recent population size estimate for leatherbacks in the North Atlantic alone ranges between 34,000 and 94,000 adults (Turtle Expert Working Group 2007). In Florida, a Statewide Nesting Beach Survey (SNBS) program has documented an increase in leatherback nesting numbers from 98 nests in 1988 to between 800 and 900 nests per season in the early 2000s (Florida Fish and Wildlife Conservation Commission, unpublished data; Stewart and Johnson 2006). The estimated annual growth rate was approximately 1.17 with estimated confidence intervals of approximately 1.1-1.21 (Turtle Expert Working Group 2007).

There are increasing impacts to the nesting and marine environment that affect leatherback turtles. Leatherback nesting beaches are affected by development and tourism in several countries (e.g., Maison 2006; Hamann et al. 2006a; Santidrian-Tomillo et al. 2007; Hernandez et al. 2007). In addition, coastal development is usually accompanied by artificial lighting. The presence of lights on or adjacent to nesting beaches alters the behavior of nesting adults and is often fatal to emerging hatchlings as they are attracted to light sources and drawn away from the water (Witherington and Bjorndal 1991; Witherington 1992; Cowan et al. 2002; Deem et al. 2007).

In 2000, the Turtle Expert Working Group (TEWG), convened by the U.S. National Marine Fisheries Service, estimated between 53,000 and 92,000 loggerhead nests per year in the southeastern United States and the Gulf of Mexico, and estimated the total number of nesting females as 32,000-56,000. The Northern Nesting Subpopulation (occurring from North Carolina through northeastern Florida) had an average of 5,151 nests per year from 1989-2005 (Georgia Department of Natural Resources (GDNR), unpublished data; North Carolina Wildlife Resources Commission (NCWRC), unpublished data; South Carolina Department of Natural Resources (SCDNR), unpublished data).

The loggerhead turtle South Florida Nesting Subpopulation occurs from northeastern Florida through Pinellas County, Florida. A near complete census of this nesting subpopulation, undertaken from 1989 to 2006 reveals a mean of 65,460 loggerhead nests per year (approximately 15,966 females nesting per year) (Florida Fish and Wildlife Conservation Commission (FFWCC), unpublished data). During the majority of the 1990's, the South Florida Nesting Subpopulation showed an increase in numbers of nests of 3.6% annually from 1989-1998 (TEWG 2000) and the nesting assemblage was considered "stable or increasing" at that time (Witherington and Koeppel 2000).

However, the most recent and longer time series data from the Florida Index Nesting Beach Survey Program, administered by FFWCC, show a significant decline in nesting of loggerhead turtles. There has been a 22.3% decrease in the annual number of nests over the 17-year period from 1989-2005. In the past decade a decline of 39.5% has been reported (McRae 2006).

Approximately 60% of Kemp's ridley nesting occurs along an approximate 40-km stretch of beach near Rancho Nuevo, Tamaulipas, Mexico (FWS 2006). The Kemp's ridley, like the olive ridley, tends to nest in large aggregations or *arribadas* (Bernardo and Plotkin 2007). It has been speculated that the *arribada* phenomenon may be advantageous for a variety of reasons, including mate finding and enhancing the survival of eggs and hatchlings due to predator swamping (Bernardo and Plotkin 2007). The biological or physical factors that initiate an *arribada* are not clear, but a variety of potential cues have been suggested, including strong onshore wind, lunar and tidal cycles, social facilitation, and olfactory signals (Bernardo and Plotkin 2007).

Data suggest that in adult female Kemp's ridleys, approximately 20% nest every year, approximately 60% nest every 2 years, 15% nest every 3 years, and 5% nest every 4 years (Marquez Millan et al. 1989, TEWG 2000). These data indicate a remigration rate of female Kemp's ridleys from 1.8 (Rostal 2007) to 2.0 years (Marquez Millan et al. 1989, TEWG 2000), suggesting that the total number of adult females in the Kemp's ridley population during 2006 was approximately 7,000 to 8,000 turtles.

The Kemp's ridley occurs in the Gulf of Mexico and along the Atlantic coast of the U.S. There are documented cases of Kemp's ridleys captured in the Atlantic that migrated back to the nesting beach at Rancho Nuevo (Schmid and Witzell 1997, Schmid 1998, Witzell 1998). It is not known what proportion of the Kemp's ridley population migrates to U.S. Atlantic coastal waters.

Listing designations

(from Atlantic Croaker FMP Update 2005)
All sea turtles that occur in U.S. waters are listed as either endangered or threatened under the ESA. The Kemp's ridley (*Lepidochelys kempii*), leatherback (*Dermochelys coriacea*), and hawksbill (*Eretmochelys imbricata*) are listed as endangered. The loggerhead (*Caretta caretta*) and green turtle (*Chelonia mydas*) are listed as threatened, except for breeding populations of green turtles in Florida and on the Pacific coast of Mexico, which are listed as endangered. All five of these species inhabit the waters of the U.S. Atlantic and Gulf of Mexico.

NOAA Fisheries recognizes five loggerhead subgroups within the western Atlantic including two primary subpopulations: (1) a northern nesting subpopulation that occurs from North Carolina to northeast Florida, about 29EN (approximately 7,500 nests in 1998); (2) a south Florida nesting subpopulation, occurring from 29EN on the east coast to Sarasota, Florida on the west coast (mean of 73,751 nests each year). The status of the northern population based on the number of loggerhead nests has been classified as stable or declining (TEWG 2000). Data from all beaches within the south Florida subpopulation where nesting activity has been recorded indicate substantial increases when data are compared over the last 25 years. However, an analysis limited to nesting data from the statewide sea turtle Index Nesting Beach Survey program from 1989 to 2002, a period encompassing index surveys that are more consistent and more accurate than surveys in previous years, has shown no detectable trend (Blair Witherington, Florida Fish and Wildlife Conservation Commission (FFWCC), pers. comm., 2002).

The Kemp's ridley is one of the most endangered of the world's sea turtle species. The only major nesting site for ridleys is a single stretch of beach near Rancho Nuevo,

Tamaulipas, Mexico. Estimates of the adult female nesting population reached a low of 300 in 1985. Conservation efforts by Mexican and U.S. agencies have aided this species by eliminating egg harvest, protecting eggs and hatchlings, and reducing at-sea mortality through fishing regulations. From 1985 to 1999, the number of nests observed at Rancho Nuevo, and nearby beaches increased at a mean rate of 11.3% per year (TEWG, 1998).
Current totals exceed 8,000 nests per year, allowing cautious optimism that the population is on its way to recovery.

Critical Habitat Designations

4.3.3 Birds

Birds are a part of the coastal and oceanic ecosystem of the southeastern United States, occupying roles from grazing herbivores to top predators on many types and sizes of aquatic life. This section on protected species addresses listed bird species occupying habitat from the open ocean and outer continental shelf to coastal wetlands in the Southeast Region of the United States from the Virginia-North Carolina border south to the Dry Tortugas, Florida (Table 4.3-3). These species do not necessarily breed within the area as some breed in Bermuda, the Bahamas, or the West Indies and others breed as far north as the Arctic or as far south as the Falklands.

Bird species are listed for protection in the Migratory Bird Treaty Act (MBTA), the Endangered Species Act (ESA), and the special provisions of state governments. The National Marine Fisheries Service, through the authority of the Magnuson-Stevens Fishery Conservation and Management Act and the High Seas Fishing Compliance Act, has a role in bird conservation. Federal and State governments and non-governmental organizations have joined in bird conservation partnerships and developed bird conservation plans. Those that cover coastal and oceanic birds of the Southeast Region of the U.S. include the North American Waterbird Conservation Plan (Kushlan et al. 2002), the Draft Southeastern United States Regional Waterbird Conservation Plan (Hunter et al. 2005), the North American Waterfowl Management Plan, the U.S. Shorebird Conservation Plan, the South Atlantic Migratory Bird Initiative Implementation Plan (Watson and McWilliams 2005). These plans were sources of information for this description. The U.S. Fish and Wildlife publication, Birds of Conservation Concern 2002, was another source of information. Publications by Lee (1999, 2000) and his recent report in progress (Lee, in prep.) are other major sources. Collier, N. J. and P. Andrew. 1988. Birds to watch: The ICBP World Checklist of Threatened Birds (Collier and Andrew 1988) is another potential information source.

Somewhere near 200 birds occupy habitats extending from the coastal wetlands to the ocean pelagic environment of the South Atlantic Council region. These birds are in 12 orders and 33 families. They fit into eight functional groups of the South Atlantic Council's ECOPATH model and occupy the following habitats: Open Ocean, Coastal Shelf, Beach and Dune, Estuaries, and Coastal Wetlands (marshes and mangroves). In this report, "open ocean" refers to the area at and beyond the shelf break, whereas coastal shelf refers to the area landward of the shelf break. The discussion of birds is organized by habitat, although some bird groups and even bird species occur in more than one habitat. Some species groups that we discuss fit into more than one habitat.

Many oceanic and coastal bird populations of the Southeast Region have declined and are listed as endangered, threatened, or species of concern. Species listed in Table 4.3-3 fit into the above groups. Their highest (most protected) Federal status, State status, and status in the South Atlantic Migratory initiative Implementation Plan (SAMBI) is shown (Table 4.3-3). Only three species, the Bermuda petrel, the roseate tern, and the piping plover, are federally listed as threatened or endangered (the Bermuda petrel listed by Bermuda and Canada, not U.S.), however SAMBI lists 27 of these species as highest priority requiring immediate management attention and another 57 as high priority needing management attention. All birds in Table 4.3-3 are listed by MBTA, and many of these are included on State lists of species of concern.

Table 4.3-3. Selected Bird Species with Protected Status in the Coastal Waters of the Southern United States Atlantic States.

Lee (1999) listed 17 birds of conservation concern with documented occurrences on the Outer Continental Shelf off North Carolina (Table 4.3-4). He divided them into two categories, critical species and species of concern. Most are oceanic pelagic species, but a few occur primarily in coastal shelf waters.

The present status of Southeast Region oceanic and coastal birds listed for special protection or management attention is a result of a variety of factors, including fishing effort, habitat loss, disturbance at nesting sites, pollution, marine debris, disease, and change in food availability. Habitat loss has been a major cause of decline in population number. Introduction and expanding exotic or feral species (e.g., house cats and black rats on nesting islands) is another. In addition, certain native species such as Greater Black-backed, Herring, and Laughing Gulls that prey on the eggs and young of other bird species have greatly increased in number recently and pose a threat to other waterbird species, especially shorebirds. Many seabirds found in the southeast region nest outside the region, where substantial decreases in nesting number have occurred due to human disturbance and predation by both humans and introduced species (e.g., see Schreiber and Lee [2000]). Oil spills are one source of pollution damaging to seabirds. Direct or indirect interactions with fisheries also affects some population groups (i.e., open ocean and coastal shelf species), although these interactions are not well documented or understood in the Southeast Region, and the direct impacts (i.e., capture or entanglement in fishing gear) may be small. Climate change and over fishing, by changing the availability of food supplies may also affect coastal and oceanic bird populations of the Southeast Region.

Table 4.3-4. Seabird species of conservation concern occurring at or near proposed oil exploration sites on the Outer Continental Shelf of North Carolina (from Lee 1999).

Critical Species
Black-capped Petrel
Bermuda Petrel
Herald Petrel
Madeiran or Fea's Petrel ('mollis' group)
Roseate Tern
Species of Concern
Common Loon
Bulwer's Petrel
Greater Shearwater
Sooty Shearwater
Audubon's Shearwater
Band-rumped Storm-Petrel
White-tailed Tropicbird
Red-billed Tropicbird
Masked Booby
Northern Gannet
Bridled Tern
Atlantic Puffin

This presentation will include a brief description and information on distribution, reproduction, development, growth, abundance, movement patterns, population dynamics, and ecological relationships of selected species or species groups. The following discussion starts with birds of the open ocean, followed by birds of coastal waters, then shorebirds, waterfowl, and wading birds, and finally other marsh and coastal wetland birds. Detailed descriptions are given only for a few seabirds, both oceanic and coastal.

Open Ocean Species

Many species of oceanic seabirds breed in the Southeast region or occur in the area regularly. These include boobies, fulmars, petrels, shearwaters, storm-petrels, skuas, jaguars, dovekies, and some species of terns. The Northern Gannet, more coastal than oceanic, is also included with this group in order to be discussed with its relatives, the boobies. The gannet is a boreal breeder. Others, such as the black-capped petrel, the boobies, and the tropicbirds, nest in Caribbean and Gulf of Mexico waters. In addition, some nest in the eastern Atlantic, and others nest in the South Atlantic. Island nesting is the norm. Population numbers range from several million Greater Shearwaters and Wilson's Storm Petrels to less than 100 Bermuda Petrels. This group is characterized by long-lived species in which several years are required to reach maturity and breeding. Movements of juveniles and sexes may be distinct from adults. Age or sex differences in migration routes and destinations may make these populations more vulnerable to disturbances such as oil spills or pollution than they would be if the segments of the population were mixed. The species of this group range in size from the tiny storm petrels (15-22 cm in total length) to the Northern Fulmar (45-51 cm in total length)

Seabirds are a special concern in managing marine fisheries because of their interactions with fishing gear and vessels in both coastal and distant fisheries. Mortalities resulting from fishing gear could complicate efforts to conserve seabird populations threatened with habitat loss or other human caused mortality.

The United States has developed a national plan of action for reducing the incidental catch of seabirds in U.S. longline fisheries (NPOA-S 2005) as a voluntary response to resolution 02-14 of the International Commission for the Conservation of Atlantic Tuna (ICCAT), of which it is a member. Development of the NPOA-S was a collaborative effort between the National Marine Fisheries Service (NMFS) and the U.S. Fish and Wildlife Service (FWS). Action items for continued cooperative effort between the two agencies include a detailed assessment of longline fisheries for seabird bycatch, annual reports on the status of seabird mortality for each longline fishery (in consultation with the appropriate Councils), and measures to reduce seabird bycatch if any problems are found. Such measures include data collection, prescription of mitigation measures, research and development of mitigation measures and methods, and outreach, education, and training about seabird bycatch.

Longline fisheries pose a significant threat to some seabird populations in some parts of the world. The seabird bycatch of U.S. Western North Atlantic (USWNA) longline fisheries is small by comparison. The seabird bycatch of USWNA pelagic longline fisheries has recently been estimated based on data from the observer program, which covers about 6% of the longline effort. From 2002 through 2004, observers recorded two northern gannet (live), one laughing gull (live), and 12 unidentified seabirds (all dead) caught in the South Atlantic Bight (SAB) region. Based on the observer bycatch and longline effort, Hata (2005) estimated an average annual bird bycatch of 27.39 per year in the SAB. Only six taxa have been identified in the USWNA longline bycatch. Besides the northern gannet and the laughing gull, these are the greater and Cory's shearwaters, the herring and great black-backed gulls, and an unknown species of storm petrel. The high percentage of unidentified birds in the bycatch and low observer coverage make estimation of impacts on seabird populations problematic. Population levels are so low for some species that they might be impacted even if catch rates were extremely low. Most seabirds are long-lived (e.g., 10 to >30 yrs) and have low reproductive potential, thus their populations are more sensitive and less resilient to increased mortality than short-lived species.

Eighteen species of open ocean seabird appear in Table 4.3-3. Sixteen of these are included in Lee's (1999) list of seabirds of concern occurring regularly on the Outer Continental Shelf off North Carolina (Table 4.3-4). A set of species profiles by Lee (in prep) is a further source of information on this group. The major component of this group is characterized by long-winged strong fliers that spend months of the year at sea out of sight of land. Most of these species nest outside of the Southeast Region and are in the regional waters during their non-nesting period, winter for northern-nesting species and summer for those that nest in the southern hemisphere.

Others range as far north as North Carolina to feed during their nesting season in tropical latitudes, and they occur in the Southeast Region during the summer. Still others migrate through the region during the spring and fall. These birds are characteristically long-lived with extended adolescence, and they usually raise only one chick per season. This makes their populations especially vulnerable to increased mortality rates of nestlings, fledglings, or adults. Many of these species nest in colonies on islands, where they are especially vulnerable to human harvests and depredation by exploding populations of introduced predator species (e.g., rats, mongooses, and feral cats and pigs).

A set of taxonomic families aptly nicknamed "tubenoses" makes up the largest taxonomic group of open ocean seabirds listed in Table 4.3-3. Of these, the four petrels are of the highest conservation concern (Lee1999). Other tubenoses in Table 4.3-3 include Audubon, Cory, sooty, and greater shearwaters. The smallest tubenoses are the storm-petrels. Lee (1999) suggested that the Wilson's storm-petrel, common in waters of the Southeast Region, may be the most populous bird in the world's open oceans. The band-rumped storm-petrel, Leach's storm-petrel, and white-faced storm petrel also are found in the Western North Atlantic and are included on the MBTA list of protected birds. All four WNA storm-petrels occur on the Outer Continental Shelf off North Carolina (Lee 1999), but only one--the band-rumped storm-petrel--is included on Lee's (1999) list of species of concern.

Petrels nest in burrows on islands and have been subjected not only to predation by humans and introduced animals but also to disturbance of nesting sites by lights, lumbering, forest fires, and other habitat alteration. One egg is laid, and the time from hatching to maturity is 7 yrs and longer for many species. The vulnerability of petrels at their nesting sites has already caused at least three petrel species in the Western Atlantic to become extinct. The remaining four species are in severe jeopardy.

Bermuda Petrel, *Pterodroma cahow*

When first discovered in Bermuda in the 16th century, nesting Bermuda Petrels numbered in the hundreds of thousands. They do not nest anywhere else and were presumed extinct by 1620 as a result of human exploitation and introduced predators. After being considered extinct for over 300 years, 18 pairs were discovered in 1951 on five small islets off Bermuda (Lee, in prep.). Lee (1999) reported 53 pairs but hurricanes in the last decade have destroyed a number of nesting burrows. The Bermuda Government reported 29 pairs actively nesting in 2005 (Lee, in prep.). The only published records of at sea occurrence are for waters around Bermuda and from the Gulf Stream over the Outer Continental Shelf of North Carolina, which appears to be an important foraging area for this rare species. This is a federally listed endangered species and one of the most endangered birds in the world.

Black-capped Petrel, *Pterodroma hasitata*

This highly pelagic species is endemic to the Western North Atlantic. It breeds in the West Indies, where nesting is now confined to the mountains of southern Hispaniola, and forages regularly off the southeastern coast of Cuba and in the deep Gulf Stream waters off the southeastern United States, mostly from Cape Canaveral north to Cape Hatteras (Lee 2000). Nesting occurs in the winter (Lee 2000). This petrel was thought to be extinct until nesting colonies were discovered in Haiti in 1961, when population estimates were made of 2,000 to

20,000 pairs, the latter likely an overestimate. Subsequent habitat destruction may have reduced the population to a current 1,000 to 2,000 pairs (Lee, in prep.). Material in caves from Haiti suggest the birds were once much more abundant and widespread in Hispaniola than they are today, and human consumption and habitat alternation had probably already reduced their number by the time the Haitian colonies were discovered by Wingate (1964). This is one of the most threatened species in America.

Herald Petrel, *Pterodroma arminjoniana*

This is a rare, highly pelagic tropical petrel confined in the Atlantic to two breeding sites, South Trinidade Island and Martin Vas Rocks off Brazil (Lee in prep.). This petrel disperses great distances from its breeding sites. Of several hundred sighting reports in the Western North Atlantic, most are from off Cape Hatteras, but the species has also been reported from Virginia, Puerto Rico, and the mid Atlantic. Most records are from summer along the Outer Continental Shelf and well within the Gulf Stream. This species is highly endangered in the Atlantic basin because of human disturbance and introduced house cats affecting nesting, and the population appears to continue to decline (Lee 2000). Evidence suggests that the Atlantic population is specifically different from ones nesting in the Indian Ocean and tropical Pacific, and the two color morphs nesting on South Trinidade Island may actually represent two different species (Lee 2000).

Fea's Petrel, *Pterodroma feae*

The Fea's petrel breeds in the Cape Verde Islands and Bugio, Desertas Islands off Maderia. A sister species Maderian petrel, *P. maderia*, breeds in remote high elevation sites on Maderia. These two species, known as soft-plumaged petrels, both occur in the North Atlantic and are so similar that even experts cannot agree on how to tell them apart. The population of Fea's petrels is only a few hundred pairs while the Madeira population is less than 50 pairs, possibly only 20 pairs. Both are extremely rare, declining, globally endangered species.

Shearwaters

The shearwaters are another group of tubenoses. In the Western North Atlantic, these include Audubon's, Greater, Manx, Cory's, and Sooty shearwaters. The shearwater species of greatest concern is Audubon's Shearwater, *Puffinus iherminieri*, a tropical species that occurs in the Atlantic as two subspecies. The current nominate population, *P. I. iherminieri*, consists of 3,000 to 5,000 pairs (Lee 2000), and the western Caribbean subspecies, *P. I. loyemilleri*, is close to extinction (van Halewyn and Norton 1984). Nesting site disturbance by rats and feral cats on islands is the greatest threat to this species.

The other shearwaters in Table 1 are obligate trans-equatorial migrants. In the western Atlantic, the sooty shearwater, *Puffinus griseus*, is limited to 1,000-10,000 pairs, although it also occurs in the Pacific. The greater shearwater, *Puffinus gravis*, is of conservation concern not because of low population numbers in the Atlantic basin (populations are estimated at over 5 million breeding pairs in Tristan de Cunha, Gough Island, and a single island in the Falklands [Williams 1984]) but because they aggregate for both nesting and feeding. The Cory's shearwater, *Calonectris diomedea*, is endemic to the Atlantic, where three subspecies exist, none of which are considered imperiled. Young disperse to the Western Atlantic, and two subspecies have been found in the area from Cape Hatteras south. Two shearwaters, the greater and Cory's, have been identified in the observed catch of the U.S. WNA longline fleet, where they usually are found dead on the line rather than being released alive. The greater shearwater is the most frequently identified species in the observed catch. The greater shearwater also is caught in gillnets in New England fisheries. Unexplained greater shearwater mortalities were observed along the Atlantic coast in June 2007, particularly in Florida. The strongest hypothesis for this mortality event is that these were young-of-the-year birds starving to death on their first migration (Lee, pers. comm.).

Gannets and Boobies

Gannets and boobies form another taxonomic group (Sulidae) included in Table 4.3-3. In all members of this group, different plumages are exhibited at different stages of maturity, at least four immature plumages and an adult plumage. The northern gannet and NWA boobies have similar physical characteristics; however the gannet is a boreal breeder whereas the boobies breed tropically.

The northern gannet, *Sula bassana*, is the most coastal of the WNA sulid species and, although it winters at sea, is rarely out of sight of land. In the NWA, the gannet breeds in Newfoundland, Labrador, and Quebec. Canadian waterbird sites list about 194,000 breeders as of 2005 (from data compiled by D. Forsell from Canadian wet sites (see note at end of this section). This estimate does not include Iceland. Since numbers are increasing, there may now be 200,000 breeders and maybe 50,000 -100,000 immatures and fledglings. The northern gannet is seen regularly off North Carolina and might be found anywhere along the South Atlantic coast. Adults winter from the Carolinas to Maryland and northward. The youngest birds winter further south (Florida, Cuba, and Upper Gulf of Mexico). New tracking data also shows some adults now going to the Florida Gulf coast. Gannets often concentrate around fishing vessels and may be vulnerable to various fishing gear. The northern gannet is an observed bycatch species of the WNA longline fishery, but usually is retrieved alive and released. This species has also been observed caught in both anchored and drift gillnets of several coastal and offshore fisheries and also is caught in paired trawls in the Gulf of Maine (D. Forsell, pers. comm). Large numbers of gannets have been found dead and dying off the Atlantic coast on several occasions (e.g., thousands died during the winter of 2002-2003). “Emaciation syndrome” is suggested by autopsies, implicating stress or starvation. Drowning in deep-set gill nets and disease have also been proposed as possible factors in the large mortalities. Despite the die-offs, population numbers are increasing (D. Forsell, pers. comm.).

The masked booby, *Sula dactylatra dactylatra*, is the least common booby species in the WNA, but it is the one most likely to be encountered away from nesting sites because individuals disperse great distances from their breeding grounds. Nesting is on remote islands lacking mammalian predators, often with other boobies. This is a deepwater, pelagic species occurring northward in the Gulf Stream to the Carolinas, where it is usually associated with *Sargassum*. Its diet is flying fish, jacks, and squid. The current NWA population consists of 550-650 pairs in eight known colonies in the West Indies, another 4,000 to 5,200 pairs nesting on islands off Venezuela and Mexico (Schreiber 2000), and a few pairs nesting in the Dry Tortugas. Although the species is pan tropical, it is rare everywhere, and the Atlantic population is considered endangered in the West Indies where over half the breeding stock occurs on a single island off Jamaica. Other WNA boobies are less likely to occur in the waters off the Southeast Region.

Oceanic Terns
The sooty tern, *Sterna fuscata*, and the bridled tern, *Sterna anaethetus melanoptera*, are more oceanic than coastal and so are included in this section on oceanic birds. Both species are found far at sea. Neither species is a plunge diver. Both feed by dipping prey from near the water surface.

The sooty tern is a common high-flying circum-tropical oceanic species. It does not dive nor land on the water, but scoops small fish from the surface of the water while in flight. It often occurs in large flocks; sometimes thousands are in a single flock. Feeding flocks form over foraging schools of surface feeding fishes. Flocks of Sooty Terns have been seen in association with schools of tuna that drive concentrations of small forage fish to the ocean surface where they are accessible to capture by the terns (A. Sprunt IV, pers. comm.). This species has a substantial nesting colony in the Dry Tortugas National Park off the Florida Keys, where carangids and clupeid fish, as well as squid make up the major part of the diet (Browder et al. 1996), and also breeds in the Bahamas and off Central and South America. Small groups occasionally nest along the Gulf coast and north to the Outer Banks. Young WNA sooty terns live primarily off the west coast of Africa after dispersing from their natal areas. Adults occur in tropical seas and, in summer, wander north in the Gulf Stream. This species is the most abundant seabird breeding in the tropical Atlantic. The total Greater Caribbean population is estimated at 230,000-500,000+ pairs (Lee, in prep.). This species occurs throughout the world's tropical seas.

The bridled tern is a pelagic tropical and subtropical species. This tern often is seen resting on boards, the backs of sea turtles, and other floating material far at sea, distinguishing them from sooty terns, which do not have this habit (Sibley 2003). Much of its foraging is in Sargassum, so it is frequently associated with large Sargassum mats. It occurs singly or in small flocks. The bridled tern is distributed throughout the Caribbean, but it is not a common species. Non-breeding birds occur in the Gulf of Mexico and regularly in the Gulf Stream north to the Carolinas. It nests in widely scattered, mostly unprotected sites. Several subspecies collectively form a composite circum-equatorial distribution. Nesting occurs primarily in the West Indies, but also on islands off the northern South American coast, and, minimally, in the Florida Keys. The total WNA population is estimated at 7,000 pairs (Lee, in prep.). This species is not of conservation concern globally or regionally, but individual breeding populations for some countries are quite small (Lee, in prep.), as is the WNA total.

Coastal, Shelf, Beach and Dune Species

Birds of these habitats form three groups: gulls and terns; loons, ducks, geese, and other waterfowl; and shorebirds. These species are listed in their three groups in Table 1. Many species in these groups also occur in estuaries and wetlands, but will be described only in this section. Most gulls and terns listed in Table 1 are in this coastal group. The sooty and bridled terns are discussed in the previous section with other oceanic birds. Other tern species are found far at sea occasionally. The northern gannet, although more coastal than oceanic, was included in the previous section to be discussed with its close relative, the masked booby.

Coastal avian species have a variety of feeding habits and food items, and the diets and feeding modes of some are more varied than others. Gulls are found along beaches and on mudflats of river mouths and estuaries where they may feed on mollusks and benthic infauna (small organisms that live in the sediment) as well as fish and the eggs of other waterbirds. Most gulls (in winter) are roosting along inlets because they are following fishing boats to feed on offal or discarded bait or bycatch or scavenging on beaches. The food of most tern species, cormorants, and brown pelicans is more confined to fish and squid. Most tern species feed on the wing by dipping prey from the water surface, however a few terns plunge dive.

These avian species also are varied in the degree of concern expressed for them and protection they are afforded. The roseate tern is the only coastal pelagic bird species Federally listed as endangered. Some other members of this group listed in Table 1—black skimmer and least, common, sandwich, Forester's, and gull-billed terns—are listed as "species of concern" in one or more of the southern east coast states where they nest. The black tern, although not listed anywhere as a species of concern, probably should be listed because it has been declining since the 1960s. Two other, primarily tropical, terns that nest in the southeast coastal region also are included in Table 1 and in the below discussion, although they are not listed as species of concern either by states or Federally. SAMBI classified three gull species—great-black-backed, herring, and laughing gulls—as "nuisance or depredating" (N/D) species because their expanding populations pose a threat to other birds, especially shorebirds. While the herring gull may be in the N/D category and expanding in the southern states, its population may be declining at about the same rate that the great- black-backed gull is increasing in the New England and Mid-Atlantic states (D. Forsell, pers. comm.) The laughing gull has been listed as a species of concern in South Carolina and, for this reason, is listed in Table 1. Observers have reported all three above-mentioned gull species in the bycatch of the WNA U.S. longline fishery. The Bonaparte gull is the only gull species listed by SAMBI as a priority species for conservation and also is listed in Table 1.

Roseate Tern, *Sterna dougalli dougalli*

The Roseate Tern is Federally listed as "endangered" in North Carolina and the Northeast Region and federally listed as "threatened" from South Carolina to Florida, as well as in Puerto Rico and the U.S. Virgin Islands. It also occurs in—and is listed as "endangered" by the governments of Bermuda and Canada (Newfoundland, Nova Scotia, and Quebec). Breeding areas are disjunct from Nova Scotia to the West Indies. This tern feeds over breaking surf, particularly over the backwash of outgoing tides of estuaries, and roosts on rocks rather than sand or mudflats. It dives on shoals of fish. In Massachusetts, where the principal food of both species is sand lance, the roseate tern feeds with common terns and captures food mainly by plunge-diving (diving from heights of 1-12 m above the surface and often submerging to ≥ 50 cm) (Mostello 2002). The breeding ecology of the roseate tern is closely linked with that of the common tern in Massachusetts; roseate tern nests form clusters inside larger common tern colonies, where the more aggressive species may reduce the overall level of predation (Mostello 2002). The total WNA population presently is probably less than 8,000 pairs (Lee, in prep.). The nominate subspecies, endemic to the North Atlantic, is in sharp decline. A population of the subspecies also exists in Europe.

Common Tern, *Sterna hirundo*
The common tern is a common and widespread tern found in both the eastern and western hemispheres. Nesting in the western hemisphere occurs on inland lakes and rivers and along the Atlantic seaboard from Canada to islands off the Gulf coast states and also in Bermuda, the Bahamas, the Virgin Islands, and islands off Venezuela (Harrison 1983). The common tern feeds by plunge diving (Harrison 1983). This species is found at sea in small to modest-sized flocks often associated with other tern species during migration and when wintering (Lee, in prep.). Off Massachusetts, it feeds closer to shore than the roseate tern (Mostello 2002). Based on independent estimates from the various regions of nesting, the population estimate for the WNA from Lee (in prep.) is 129,473 pairs.

Gull-billed Tern, *Sterna nilotica*
The gull-billed tern is another near-cosmopolitan species that breeds along the eastern seaboard, nesting locally from Long Island south through the Gulf coast states to Cuba and the West Indies. This species' feeding habits differ from that of other terns. According to Sibley (2003), it feeds mainly on insects and crabs, acquired by swooping to the surface, never plunge diving and almost never foraging in water. According to Harrison (1983), it usually obtains prey by hawking over exposed mud flats, but it occasionally plunges into the water, although not from great height. It feeds along coasts, over marshes, lakes, mudflats and even fields, dipping swiftly to pluck prey from the surface or seize insects in mid air (Harrison 1983). Lee (in prep.) estimates the total Western North Atlantic population at: 3,100-3,500 pairs.

Forster's Tern, *Sterna forsteri*
The Forster's tern breeds only in North America and mostly at inland sites in the middle and western portion of the continent, but it also nests in marshes along south eastern Atlantic states north to New Jersey and upper Gulf coasts. These terns migrate and winter primarily inland and along the coast of the southeastern states, Mexico, the California coast, and in the upper Gulf of Mexico. Birds are found in the West Indies in winter indicating some at-sea migration, but this species is only rarely found at sea in the western North Atlantic. The WNA population, including Inland Canada, consists of about 30,000 pairs, most of which occur on the Gulf coast. This is listed as a species of conservation concern in South Carolina.

Sandwich Tern, *Sterna sandvicensis*
This species breeds in North America, Eurasia, and northern South America. Nesting occurs from Virginia southward and along the Gulf coast and also in the West Indies, islands off Central America, and on the coasts of northern and northeastern South America. This is a coastal foraging species and, excluding migration periods, it is almost never seen more than 12 miles from land. A subspecies, the Cayenne tern (*Sterna s. eurygnata*), is recognized that occurs along the South American coast and in the Caribbean. This is not a species of concern except for the Cayenne subspecies. The total WNA population of *Sterna s. sandvicensis* is estimated at 48,000 pairs, and the Cayenne tern population is estimated at 12,000 pairs (Lee, in prep.).

Least Tern, *Sterna antillarum*
The least tern is a cosmopolitan species. The subspecies *S. a. antillarum*, breeds along the eastern seaboard to the Gulf of Mexico and the Caribbean. This tern is coastal species and rarely

seen out of sight of land even during migration. It nests on sand dunes just above the high-tide line among grass and debris, as well as on flat rooftops near water. Its habits are similar to common and other terns, and it mixes freely with other terns at roosting and foraging sites. Wintering birds are found along the South American coast south to Northern Brazil. It also occurs inland. Other subspecies breed in other parts of the Western Hemisphere and the world, however not in the South Atlantic. Protection in the United States has greatly increased the number of viable breeding colonies in the last several decades, and population estimates of 32,000+ pairs for the eastern seaboard group may not reflect the recent increase (Lee, in prep.).

Black Tern, *Chilidonias niger*
Black terns breed in inland freshwater marshes and feeds on insects. They migrate over land, along the coast, and out at sea. The terns nesting in North America winter primarily along the Pacific coast of Central and South America and in the Atlantic along the north coast of South America. The eastern Atlantic subspecies winters primarily along the coast of West Africa. Although not listed as a species of concern at this time, it probably should be; populations have been in sharp decline since the 1960s, and North American breeding bird survey data shows a sharp and significant decline, perhaps as much as 60%, between the 1970s and the late 1990s (Lee, in prep.). Kushlan et al. (2002) estimate the total North American population at 500 to 2,500 adult pair.

Royal Tern, *Sterna maxima*
The royal tern is a large, crested, orange-billed tern second only in size to the Caspian tern, *Sterna caspia*, the largest tern in the world, which also has an orange bill. In the Western Hemisphere, the royal tern breeds on the Atlantic coast from Virginia to Texas and also in the West Indies, Central America, and on the Pacific coast. It also breeds in northern West Africa. This tern usually is found along ocean beaches. It forages by flying over the water to scout out prey and then diving below the water surface (Sibley 2003). It makes its nest scrape on the ground on low-lying natural islands or shoals or dredged-material islands. Royal terns nest in large colonies ranging from a few hundred to over 5,000 nesting pairs (NC Audubon Chapter 1998, (http://www.audubon.org/chapter/nc/nc/wb_07.html). Within a day of hatching, chicks leave the nest to become part of a group that can consist of thousands of chicks from 2 to 35 days old (Cornell Lab of Ornithology website http://www.birds.cornell.edu/AllAboutBirds/BirdGuide). Parent chicks feed only their own chick, which they are able to locate in the crowd (op. cit.). The North Carolina population consists of about 11,000 pairs and is declining (NC Audubon 1998). SAMBI (2005) estimates 5,500 in South Carolina, 8,000 in Georgia, and 2,500 in Florida. The major threats are human disturbances at nesting sites, loss of nesting habitat, fish kills, and discarded monofilament fishing line (op. cit.).

Black Skimmer, *Rynochops niger*
The black skimmer is a strictly coastal species in North America, although it lives along rivers in South America. Skimmers feed by skimming the water surface with their knife-like bills. They rest on mudflats and sandy beaches. They breed along the Atlantic coast from Massachusetts south through the Gulf of Mexico to northern Brazil (but not the Bahamas or West Indies). In winter northern populations migrate southward to Florida and the Gulf of Mexico. Several states with small numbers of colonies and declining populations (NC, SC, and FL) list this as a species

of concern. Lee (in prep.) estimates that the total Atlantic population is in excess of 27,500 pairs.

Laughing Gull, *Larus atricilla*
The laughing gull is a small gull that breeds in the WNA from Maine south to Florida (including Florida Bay), throughout the Bahamas and West Indies, Gulf of Mexico, Mexico and the northern South American coast. It winters in coastal areas within its breeding range and at sea from the Carolinas southward. During the summer the species is restricted to coastal areas, but during the winter it often occurs in flocks in open ocean environments. Laughing gulls follow ships and form feeding flocks around fishing operations. There may at present be about 270,000 pairs of laughing gulls in the Southeast Region (Lee, in prep.).

Great Black-backed Gull, *Larus marinus*
The great black-backed gull is the largest gull in the world (total length 71-79 cm, with a wing span of 152-167 cm). It is confined to the North Atlantic and breeds in North America along coastal areas from Labrador and Quebec south to New York, with individual nesting as far south as North Carolina. Birds from North America and Greenland winter in marine environments from Labrador south to Florida. It is found mostly in coastal areas but can occur far at sea. This species currently is expanding in both distribution and numbers and is viewed (Hunter et al. 2005) as a species that may need to be controlled because of its predation on other beach-nesting bird species. Lee (in prep.) estimates abundance for the WNA is at least 40,000 pairs.

Herring Gull, *Larus argentatus*
The Herring Gull is another large gull of the WNA. It is common and widespread and is known to hybridize on a regular basis with greater black-backed gulls. Most of the breeding range is inland, but nesting occurs from southeastern Alaska east to Greenland and south along the coast to North Carolina. Wintering individuals are found along the coast to southern Florida. In some areas, immatures are more likely to be found far at sea than adults. Kushlan et al. (2002) estimate the North American breeding population at 132,000 pairs. More than 1,000 pairs nested along the NC coast by 1988 (Lee 1995), expanding south into areas where they had not nested prior to 1970. The population is increasing partly because of this gull’s use of landfills as winter-feeding sites. In some areas this gull needs to be controlled because it is detrimental to breeding populations of roseate terns and other species of conservation concern (Hunter et al. 2005, Lee, in prep.). Although the herring gull may be expanding south, the herring gull population may be decreasing in New England and the Mid-Atlantic coast, where the great-black-backed gull is increasing (D. Forsell, pers. comm.).

Loons
Two loon species occur in coastal and inland waters of the south Atlantic states, the common loon (*Gavia immer*) and the red-throated loon (*Gavia stellata*). The common loon is the larger, and more oceanic, of the two. The Atlantic populations of common loon breeds in inland lakes of the mid-west and New England States to arctic Canada. According to Lee (in prep.), common loons winter primarily at sea, and some migrate as far south as Florida. Once on wintering grounds they completely molt their flight feathers and are flightless for an extended period. They are typically seen floating on the water surface and are more likely to dive to avoid approaching ships than to fly. They feed on fish that they capture on extended deep dives. Oil spills are a

major problem for the birds at sea, but mortalities from oil spills are localized. Mass mortalities with loons washing up on coastal beaches all along the coast may result from drowning in nearshore gillnets D. Forsell, pers. comm.), although mercury-contamination picked up on their breeding lakes is another possible reason for these deaths (Lee, in prep.). Populations reportedly are declining, but currently still high overall. Haney (1990) estimated up to 200,000 (a significant portion of the total population) wintering off the Atlantic coast of North America between Latitudes 29° and 35°N. Common loons are the second most abundant North American breeding bird captured in gillnets in the Atlantic offshore waters (Forsell 1999).

The red-throated loon breeds in the northern hemisphere only in the High Arctic and winters in estuaries and coastal waters of the Atlantic coastal states. Nests are reportedly not only in Alaska but also in Canada, Greenland, and Russia. Canada and Greenland are the most likely sources of those that winter along the Atlantic coast., which Lee (in prep.) conservatively estimates at 50,000+. The actual population size may be much larger as the New Jersey (Avalon) Seawatch reported 51,645 seen at Cape May in 2004, http://www.njaudubon.org/Research/PDF/Avalon_totals.pdf , and many migrate overland to the coast south of there (D. Forsell, pers. comm.). This species is the most abundant North American breeding bird caught in mid-Atlantic coastal gillnet fisheries in both coastal and estuarine waters (Forsell 1999).

Shorebirds

Shorebirds, by number, form a major component of the WNA marine bird fauna. All but a few of the shorebirds listed in Table 4.3-3 are of conservation concern in one or more of the southeastern states. There is much concern for these species because of loss and disturbance of habitat and predation by feral animals, raccoons, and certain gulls with expanding populations. Besides development, recreational activities on beaches and dunes have affected both breeding and feeding habitat. High quality breeding habitat is viewed as the key to protecting shorebird populations. An immediate SAMBI objective is to maintain the habitat supporting the present breeding populations of 900 pairs of American oystercatchers, 45 pairs of snowy plovers, 850 pairs of Wilson's plovers, and 55 pairs of piping plovers. The piping plover is now Federally listed as an endangered species. The SAMBI goal is to double the breeding population size for each of these shorebird species in the southern coastal plain states or, through population analyses, to determine the population levels needed to ensure the long-term viability of breeding populations. Another immediate SAMBI objective is to provide high quality managed habitat to support successful migration through, and over-wintering within, the southern coastal states, particularly during fall migration. This means maintaining wash-overs, sand flats, and mudflats, especially on barrier islands created by hurricanes. Another emphasis is on reducing the populations of great black-backed gulls, which prey on shorebirds.

Waterfowl

Ducks, geese, and swans make up the other major component of the coastal avifauna. Most members of this group migrate, following various migration pathways. Some reach only to the northern part of North Carolina and others reach the southern tip of Florida and even into the Caribbean. There are three major groups of ducks: dabbling ducks, bay ducks, and sea ducks. Both the bay ducks and the sea ducks are divers.

Of all the waterfowl groups, the greatest conservation concern is for the sea ducks and greater and lesser scaup. Included in this group called sea ducks are scoters, eiders, harlequin ducks, mergansers, long-tailed ducks, goldeneyes and buffleheads (Bellrose 1976), not all of which occur along the southeastern seaboard. The 15 species of sea ducks constitute 42% of the ducks breeding in North America, yet these are the least known waterfowl (Sea Duck Joint Venture, SDJV). Our knowledge of most sea ducks was very limited until the past decade when new emphasis on estuaries and declining sea duck populations began to focus interest of scientists and managers. Unfortunately most studies have been conducted on breeding grounds or in Canada or waters north of the Carolinas. Little is known about their distribution and habitat requirements during their winter at sea off the southeastern states. There are few reliable population estimates or indices. They breed in low densities in remote parts of the continent, making population surveys logistically difficult, and discouraging the accumulation of even basic natural history information, much less information on life-history, population dynamics, and ecology. Sea ducks may represent no more than 5% of the continental waterfowl harvest, however surveys are not designed to accurately estimate the harvests of these species. Sea ducks have long life spans and, consistent with this, low reproductive rates. Unlike other ducks, most sea duck species are not sexually mature until they are 2 or 3 years old.

Population declines in 10 of the 15 sea duck species have been reported based on surveys conducted in the 1990s (SDJV). The eastern population of harlequin ducks has been listed as endangered in Canada (SDJV). Causes of population losses are unknown. Sea ducks spend about nine months in marine environments, where they occupy a range of habitats—bays, lagoons, estuaries, and coastal shelf waters. They often occur in large aggregations, making them more vulnerable to catastrophic events. Contaminants have been found in tissues of some sea duck species at concentrations known to affect survival and reproduction in other birds (SDJV). Their long life spans make them vulnerable to bioaccumulation of persistent pesticides and heavy metals. Direct mortality from lead poisoning has been documented on Alaskan breeding grounds. Offshore oil production, oil spills, and chronic exposure to low levels of petroleum contamination from bilge dumping are potential threats to the future well being of sea duck populations. In addition, they are exposed to loss of breeding habitat, and their wintering areas have been changed by urban and industrial development.

Commercial gillnet fisheries encountered along their migration routes and on their wintering grounds are an under-recognized threat to diving waterfowl and may be partly responsible for the unexplained declines in populations of scaup and other divers, including the sea ducks. A recent unpublished report by Doug Forsell (U.S. Fish and Wildlife Service, Annapolis) summarizes both published and antidotal information to determine the species affected by gillnetting in both fresh and salt water. The Forsell report and two recent reports by Price and Van Salisbury (2007) and Price (2007) indicate the following avian bycatch in commercial gillnet fisheries: brown pelican, canvasback, common loon, cormorant, diving ducks, double-crested cormorant, great black-backed gull, grebes, pied-billed grebe, red-breasted mergansers, red-throated loon, ruddy duck, scaup, and surf scoter.

Snow geese, Canada geese, and mute and tundra swans, along with numerous species of dabbling ducks and bay ducks, make up the remaining component of the waterfowl of coastal waters in the Southeast. Based on Sibley (2003), ducks notable for occurrence in southeastern coastal waters are the mallard, gadwall, American wigeon, canvasback, greater and lesser scaup, redhead, bufflehead, and hooded, red-breasted, and common mergansers. The American black duck and Florida duck inhabit salt marshes. In the coastal environment, dabbling ducks and bay ducks feed on stems of aquatic vegetation and seeds of marsh grasses. Some species also feed on small crustaceans and mollusks. Sea ducks such as long-tailed ducks feed predominately on animals, including crustaceans and fish, but plant foods make up about 10% of their diet. Mollusks are more important than crustaceans in the diets of black scoter, which also consume plants—frequently eelgrass.

Almost all waterfowl species that use the Atlantic flyway have been affected by the loss of coastal wetland and changes in the flow of fresh water to the coast, brought about by dams, levees, canals, roads, and other structures. While changes in the timing, volume, or distribution of freshwater flow may not affect the birds directly, it affects their aquatic habitat and their food supply, made up of species of plants and animals that benefit from natural estuarine gradients of salinity and river-influenced estuarine circulation. The largest threats to diving ducks are changing habitats, over fishing, sand mining, loss of benthic reef habitats, sedimentation, disturbance, and many other anthropogenic effects of coastal development. Hunting is, of course, a major cause of mortality to those species sought after in this sport.

Estuarine and Coastal Wetland Species

Pelicans and cormorants, wading birds, certain raptors, shorebirds, and waterfowl are major avian groups inhabiting bays, lagoons, and wetlands. They feed on shallow mud flats and along tidal creeks and shorelines. Shorebirds and waterfowl have already been discussed in the previous section. The pelican group, wading birds, and marsh birds will be discussed in this section.

Pelicans and Their Relatives

Brown pelicans, double-crested cormorants, and magnificent frigate birds are characteristic species of coastal waters and estuaries, catching prey by various methods. They congregate around fishing boats and docks where they often find a free meal. Prey acquisition is facilitated by the expandable lower bill of these species, which belong to the taxonomic order Pelicaniformes, along with the boobies and gannets. The principal threats to populations of these species are loss or degradation of nesting or feeding habitat, blooms of toxic algae, and contaminants such as chlorinated hydrocarbons and heavy metals that accumulate in aquatic food chains. They are potentially vulnerable to inshore trawl, seine, gillnet fisheries, and hook and line fisheries. Entanglement in monofilament line is a common source of death or disablement of pelicans and cormorants. Bycatch of both brown pelicans and double-crested cormorants has been documented in North Carolina gillnet fisheries. Pound nets are a big attractant for cormorants and increasingly, pelicans, both for foraging and roosting, thus increasing conflicts with fishers (D. Forsell, pers. comm.).

The brown pelican, *Pelecanus occidentalis*, is confined to coastal regions of North and South America. Plunge diving is this bird's primary mode of fishing, although juveniles sometimes feed by dipping bills while floating on the water surface. Widespread use of DDT led to a serious decline of Brown Pelican populations, however population numbers stabilized and began increasing in the 1980s, and the range of this tropical to southern temperate species has been increasing northward (i.e., from North Carolina to Maryland). Surveys conducted in Atlantic states in the 1980s suggested the WNA population of Brown Pelicans was 18,000 pairs; but present numbers likely are considerably higher (Lee, in prep.). Kushlan et al. (2002) estimate there are 95,800-96,850 adult pairs in North America, not distinguishing Atlantic, Gulf of Mexico-Caribbean, and Pacific coasts.

The double-crested cormorant, *Phalacrocorax auritus*, is the most common and widespread WNA cormorant. Like the pelican and other cormorants, it resides in marine habitats only in coastal areas, feeding in bays and sounds and near inlets and nesting on cliffs, islands, and in trees. Only rarely is it seen at sea out of sight of land. This species occurs throughout much of North America, with northern freshwater populations migrating to ice-free coastal marine and estuarine habitats outside the breeding season. Cormorants often are seen in small groups and occasionally in flocks of thousands around inlets and other areas where fish concentrate. This cormorant forages by diving from the water surface and swimming underwater to catch prey, propelled by its webbed feet. There are three subspecies in the WNA; the most widespread Florida race (*P. a. floridanus*) nests from the Carolinas south into the Northern Bahamas and Cuba. Lee (2007) provides a total WNA population estimate of about 55,000 pairs, based primarily on surveys from the 1980s, however the population has been growing. The Kushlan et al. (2002) estimate for North America is 370,000 breeder pairs.

The magnificent frigatebird, *Fregata magnificens*, is primarily a tropical species of both the Atlantic and Pacific oceans. Nesting is mainly in the West Indies region, but also in the Marquesas and Dry Tortugas (off the Florida Keys), off Brazil, and in the Cape Verde Islands. Birds spend much of their time soaring over waters of the Caribbean and the Bahamas and off the southern and eastern coast of Florida, occasionally wandering north along the Atlantic coast to the Carolinas. This is a large, graceful, highly aerial seabird with long, forked tail streamers. It feeds in nearshore waters, snatching food from the water surface while in flight and pirating food from other seabirds. It can neither walk nor swim. Frigate birds cannot land on water and resume flight. Lee's (in prep.) population estimate for the North Atlantic region is 9,900-10,700 pairs.

Wading Birds

Wading birds form a major portion of the avifauna of coastal wetlands and estuaries, serving the important role of higher trophic level consumers. Wading birds are prominent members of estuarine ecosystems, notable for their graceful flight, beautiful plumage, stately appearance on the water, and interesting feeding behavior, which differs in detail from species to species. From the Outerbanks to Florida Bay and the Florida Keys, wading birds are characteristic wetland species. They form nesting colonies in both inland and coastal wetlands of the southeastern seaboard states and other places. The largest colonies may once have been in south Florida, but this has changed over time, following the drainage of large parts of the Everglades. Substantial population declines are thought to have occurred but are generally not well documented. Loss and degradation of wetland habitat are thought to be a major factor for declines.

Found coastally and in our region, there are many species of wading birds, which can be simply thought of as organized taxonomically into three main groups: the herons and egrets, the ibis and spoonbills, and the wood stork. Best-known species in this group that nest and/or forage in coastal wetlands are the great blue heron, great white Heron, common egret, snowy egret, little blue heron, white ibis, glossy ibis, roseate spoonbill, and wood stork. The great white heron occurs primarily in south Florida (i.e., mainly the southern Everglades, Florida Bay, and the Florida Keys), and not in the other southeastern states, but appears genetically to be a color morph of the great blue heron, whose range extends into Canada. . Most wading birds nest in colonies and forage within a multi-mile radius of their nesting sites. Some, such as the white ibis, feed in salt marshes but depend on freshwater wetlands for crustacean prey to raise young. Expanding and contracting water areas and consistent dry-downs to concentrate prey are important to the nesting success of some, especially the wood stork. Several wading birds are listed as of special conservation concern (Table 4.3-3). The wood stork is a Federally listed endangered species. Populations in south Florida have declined substantially since the 1960s, although new colonies have formed further north to other southeastern states. The new colonies all are small by comparison to the colonies that once existed in south Florida. Another species needing special mention is the reddish egret, which has recently raised concern because of limited known nesting sites and population numbers that are thought to be very low Great blue herons in the Chesapeake Bay utilize pound nets to forage for small fish. One study found half of the foraging flights from a colony were to pound nets.

Marsh Birds

Birds that live among the reed beds, lakes, ponds, and mudflats of the coastal wetlands form another group of Atlantic coast birds defined by habitat. In particular, these include, the American coot, the pied-billed grebe, the American woodcock, the limpkin, the Wilson's snipe, the purple gallinule, the American and least bitterns, several species of rails, and several species of sparrows—all listed in Table 4.3-3. Some, e.g., the limpkin, which feeds on apple snails, will be found primarily in freshwater areas of the coastal wetlands. Four sparrow species are listed as priority species for conservation by SAMBI, and three are of special concern in Georgia. South Carolina and Florida lists of species of conservation concern contain most of the other species. The limpkin is a species of special concern in Florida.

Abundance and status of stocks

(from Atlantic Croaker FMP Update 2005)

The population status and trend data on many species of seabirds are limited especially for small portions of the coast such as the mid-Atlantic. Of the species likely to interact with the croaker fishery the status of the red-throated loon is the least known, but it thought to be declining in the Pacific and probably on the East Coast. The common loon is listed by the Fish and Wildlife Service as a species of concern. Common loons breed on lakes where they face a number of hazards including mercury and lead poisoning, poaching, disturbance, loss of habitat and gillnet fishing. In their migration, molting, and wintering habitat along coastal Atlantic waters the major threat to both loons is from gillnets and oil spills. Northern gannets, brown pelicans, and double-crested cormorants have increasing populations. Of the ducks likely to interact with the fishery, the redbreasted merganser, bufflehead, common goldeneye, ruddy duck, and hooded merganser have populations that are increasing or stable, while the black, surf, and white winged scoters, long-tailed duck, and greater and lesser scaup have populations that are declining or thought to be declining.

4.3.4 Marine Fish

4.3.4.1 Smalltooth sawfish

Description and distribution

The smalltooth sawfish is a tropical marine and estuarine elasmobranch (sharks, skates, and rays) that have a circumtropical distribution. In the western Atlantic Ocean, the smalltooth sawfish has been reported from Brazil through the Caribbean Sea and, the Gulf of Mexico, and the Atlantic coast of the United States (Bigelow and Schroeder, 1953). Historic capture records within the U.S. range from Texas to New York. Water temperatures no lower than 16-18 °C and the availability of appropriate coastal habitat appear to serve as the major environmental constraints limiting the northern movements of smalltooth sawfish in the western North Atlantic Ocean. As a result, most records of this species from areas north of Florida occur during spring and summer periods (May to August) when inshore waters reach warmer temperatures. These larger individuals (> 3.0 m) captured along the Atlantic coast north of Florida represent seasonal migrants from a core population in southern states rather than being members of a continuous, uniform-density population (Bigelow and Schroeder, 1953). It is likely that these individuals migrated southward toward Florida as water temperatures declined in the fall, as there is only one winter record from the Atlantic coast north of Florida.

Reproduction

Fertilization in smalltooth sawfish is internal. Development in sawfish is believed to be ovoviviparous. The embryos of smalltooth sawfish, while still bearing the large yolk sac, already resemble adults relative to the position of their fins and absence of the lower caudal lobe. During embryonic development the rostral blade is soft and flexible. The rostral teeth are also encapsulated or enclosed in a sheath until birth. Shortly after birth, the teeth become exposed and attain their full size proportionate to the size of the saw. The size at birth is approximately 80 cm, with the smallest free-living specimens reported during field studies in Florida being 77 - 84 cm (Simpfendorfer, unpublished data). Bigelow and Schroeder (1953) reported gravid females carry 15-20 embryos. Simpfendorfer (2000) estimated age at maturity between 10 and 20 years. Studies of largetooth sawfish in Lake Nicaragua (Thorson 1976) report brood sizes of 1-13 individuals, with a mean of 7.3 individuals. The gestation period for largetooth sawfish is approximately 5 months and females likely produce litters every second year. Although there are no such studies on smalltooth sawfish, its similarity in size and habitat to the largetooth sawfish implies that their reproductive biology may be similar.

Development, growth and movement patterns

To date, no formal studies on the age and growth of wild smalltooth sawfish have been conducted. Individuals have been maintained in public aquaria for up to 20 years (Cerkleski, pers. comm., 2000) which can provide some information on growth. For example, Bohoroquez (2001) reported three specimens in Columbia grew at an average rate of 19.6 cm/year (one animal grew from 84 cm to 320 cm in 12 years). In a more comprehensive study, Clark et al. (2004) reported an average growth rate of 13.9 cm/year for16 captive smalltooth sawfish (size from 80 cm to 412 cm) in North American. Based on their growth parameters Clark et al. (2004) estimated an age at maturity of 19 yr for males and 33 yr for females while Simpfendorfer (2000) estimated age at maturity between 10 and 20 years, and a maximum age of 30 to 60 yr.

Sawfish in general inhabit the shallow coastal waters but recent data suggests adults can be found to much greater depths. Simpfendorfer and Wiley (2005) reported close associations between encounters and mangroves, seagrasses, and the shoreline than expected at random. Encounter data have also demonstrated that smaller smalltooth sawfish occur in shallower water and larger sawfish occur regularly at depths greater than 10 meters. Poulakis and Seitz (2004) reported that almost half of all sawfish < 3 meters in length were found in water less than 10 meters deep and 46% of encounters with adult sawfish (> 3 meters) in Florida bay and the Florida Keys occurred at depths between 70 to 122 meters. Simpfendorfer and Wiley (2005) also reported a substantial number of larger sawfish in depths greater than 10 meters. Encounter data bases have also identified river mouths as areas where many people observe sawfish. Seitz and Poulakis (2002) noted that many of the encounters occurred at or near river mouths in southwest Florida. Simpfendorfer and Wiley (2005) reported a similar pattern of distribution along the entire west coast of Florida. It is unclear whether this observation represents a preference for river mouths because of physical characteristics. Acoustic tracking results for very small smalltooth sawfish indicate depth and red mangrove root systems are potentially important in helping them avoid predators (Simpfendorfer 2003). Small juveniles have many of the same habitat use characteristics seen in the very small sawfish. However, their association with very shallow water (< 1 ft deep) is weaker, possibly because they are better suited to predator avoidance due to their larger size and greater experience. They do, however, still have a preference for shallow water, remaining in depths mostly less than three feet (90 cm). Information on the habitat use of adult smalltooth sawfish suggests that adult sawfish occur from shallow coastal waters to deeper shelf waters.

Abundance and status of stocks

There are few long-term abundance data sets that include smalltooth sawfish. Catch data from shrimp trawlers off Louisiana from the late 1940's to the 1970's suggests a rapid decline in the species from the period 1950-1964. However, this data set has not been validated nor subjected to statistical analysis to correct for factors unrelated to abundance. The Everglades National Park has established a fisheries monitoring program based on sport fisher dock-side interviews since 1972 (Schmidt et al. 2000). Analysis of these data using a lognormal generalized linear model to correct for factors unrelated to abundance (e.g., change in fishing practices) indicate a slight increasing trend in abundance for smalltooth sawfish in the park (Carlson et al. 2007). From 1989-2002, smalltooth sawfish relative abundance has increased by about 5% per year.

Using a demographic approach and life history data for smalltooth sawfish and similar species from the literature, Simpfendorfer (2000) estimated intrinsic rates of natural population increase as 8-13% per year and population doubling times from 5.4 years to 8.5 years. Musick (1999) and Musick et al. (2000) noted that intrinsic rates of increase less than ten percent were low, and are particularly vulnerable to excessive mortalities and rapid population declines, after which recovery may take decades. As such, smalltooth sawfish populations will recover slowly from depletion, confounding recovery efforts. Simpfendorfer (2000) concluded that recovery was likely to take decades or longer depending on how effectively sawfish could be protected.

Ecological relationships

Unknown.

Listing Designations

The National Marine Fisheries Service (NMFS) added the smalltooth sawfish to its list of candidate species in 1991 (56 FR 26797). Smalltooth sawfish were removed from the list in 1997 (62 FR 37561), but returned on a revised list published June 23, 1999 (64 FR 33466). On November 30, 1999, NMFS received a petition from the Center for Marine Conservation requesting listing of the North American population of smalltooth sawfish as endangered under the Endangered Species Act. Subsequently, NMFS announced the initiation of a smalltooth sawfish formal status review (65 FR 12959) and published a proposed rule (66 FR 19414) to list the U.S. population of smalltooth sawfish as endangered under the Endangered Species Act. On April 1, 2003, NMFS listed the U.S. population of smalltooth sawfish as an endangered species (50 CFR 224). A recent proposal by the United States of America to list all sawfish under Appendix 1 of the Convention on International Trade in Endangered Species of Wild Fauna and Flora banning international trade was approved. The convention made an exception for one species of sawfish, listing them on Appendix II, allowing Australia to continue trade in live animals if it does not hinder the conservation of the species.

4.3.4.2 Shortnose sturgeon

Description and Distribution

The shortnose sturgeon (*Acipenser brevirostrum*) is a federally-listed endangered species, for which a Recovery Plan has been prepared (NMFS 1998). The species occurs in South Atlantic rivers, and on occasion in marine waters. There are apparently no documented records from the EEZ in the South Atlantic (Mark Collins, SC Department of Natural Resources, personal communication to R.W. Laney); however, the species is included here since the Council also must consider the impacts of its plans on federally listed protected species. It is an anadromous species which historically, with the Atlantic sturgeon, formed the basis for a valuable commercial fishery. Information in this account is taken largely from the December 1998 Final Recovery Plan for the species (NMFS 1998), with supplementation from other sources as cited.

The shortnose sturgeon occurs in large coastal rivers of eastern North America, historically from the St. John River in New Brunswick, Canada to the Indian River, Florida (NMFS 1998). NMFS currently recognizes 19 distinct population segments of shortnose sturgeon inhabiting 25 river systems ranging from the Saint John River in New Brunswick, Canada, to the St. Johns River, Florida. Genetic analysis of 11 of these population segments indicate most rivers and estuaries currently harboring shortnose sturgeon and identified as population segments in the NMFS 1998 Recovery Plan contain genetically distinct populations. Of the 11 population segments tested, at least 9 genetically distinct population segments of shortnose sturgeon were identified. Most comparisons among collections in the southeast showed significant genetic discontinuities between adjoining rivers, despite geographic proximity of their river mouths (20-100 km) (Wirgin et al. 2006).

Shortnose sturgeon historically occurred in most rivers of the four South Atlantic states from the Albemarle Sound system in NC through the Indian River system in FL. One relatively recent capture (1998) of a shortnose sturgeon in the Albemarle Sound system has been documented (Wayne Starnes, North Carolina Museum of Natural Sciences, personal communication). There have been no recent documented captures in the Pamlico Sound and its tributaries (Tar, Neuse Rivers). However, there are two recent reports of sturgeon from the Pamlico Sound identified by commercial fishery observers that were allegedly shortnose, but no photographs or tissue were taken for confirmation by professional fishery biologists or geneticists (Wilson Laney, USFWS, personal communication). There is currently a small population of shortnose in the Cape Fear River, North Carolina. At least one population presently exists in the Winyah Bay system (Waccamaw, Pee Dee and Black Rivers), as well as the Santee River, the Cooper River, the ACE Basin (Ashepoo, Combahee and Edisto Rivers) and the Savannah River. Georgia populations occur in the Savannah, Ogeechee, Altamaha, St. Marys and Satilla Rivers. Florida has shortnose presently only in the St. Johns River.

The shortnose is a small species of sturgeon, reaching maturity at fork lengths of 45-50 cm (18-20 in) and maximum size of approximately 120 cm (47 in) (Dadswell et al. 1984). It differs from juvenile Atlantic sturgeon in having a shorter nose, wider mouth, and no enlarged bony plates between the base of the anal fin and the lateral row of scutes (Gilbert 1989). Shortnose sturgeon are found in rivers, estuaries and the sea, but populations spend most of their time in their natal rivers and estuaries (NMFS 1998). In the southeast, the species is estuarine anadromous (i.e., spends most of the year in estuaries and ascends the freshwater portions of rivers to spawn in the spring). Adults in rivers in the south Atlantic forage at the interface of fresh tidal water and saline estuaries and migrate to the upper reaches of rivers to spawn during early spring (Savannah River: Hall et al. 1991; Altamaha River: Heidt and Gilbert 1979; Flouronoy et al. 1992, Rogers and Weber 1995a; Ogeechee River: Weber 1996).

Reproduction

Length and age at maturity

Length at maturity (45-55 cm FL) is similar throughout the shortnose sturgeon's range, but because fish in southern rivers grow faster than those in northern rivers, southern fish mature at younger ages. Males spawn first at 2-3 years in Georgia and 3-5 years in South Carolina, whereas females first spawn at 6 years or less in the Savannah River (Dadswell et al. 1984). Most shortnose sturgeon probably survive spawning, although there is some post-spawning mortality (B. Kynard, United States Geological Survey, personal observation).

Spawning periodicity

Spawning periodicity is poorly understood, but males seem to spawn more frequently than females. At least some males and females in the Savannah River may spawn in consecutive years, but most apparently do not (Collins and Smith 1993). Males may spawn every 1-2 years, but the minimum duration between spawning events for females is generally 3 years (Dadswell 1979, Cooke et al. 2002).

Fecundity and sex ratio

Gonadal maturity and fecundity of females were characterized by Dadswell (1979) for the Saint John River, Canada. Just prior to spawning, egg diameter was 3.1 mm and the ovaries composed 25 percent of the body weight. The number of eggs released ranged from 27,000 to 208,000 (11,568 eggs/kg body weight). Males were most abundant in the sex ratio estimate for the Savannah River (3.5:1, Collins and Smith 1997).

Spawning behavior

The shortnose sturgeon spawning period is estimated to last from a few days to multiple weeks. Sturgeon in the Savannah River remained on the spawning grounds for 2-3 weeks (Hall et al. 1991). Altamaha River fish remained on suspected spawning grounds for as long as nine weeks (Rogers and Weber 1995a). Cooper River fish residenced the spawning site for 89 days, longer than reports from other populations. It is hypothesized that these individuals were actively searching for an upstream route past Pinopolis Dam, but to no avail (Cooke and Leach, 2004a). Males fertilize the female's eggs as the eggs are released close to the substrate. In captivity, males nuzzle the anal and head areas of females, suggesting that females attract males with a chemical attractant (B. Kynard, personal observation).

Spawning habitat

In populations that have free access to the total length of a river, (e.g., no dam within the species' range in the river) spawning areas are located at the most upstream reach of the river used by sturgeon (Saint John, Kennebec, and Altamaha rivers: Dadswell et al. 1984, Rogers and Weber 1995a; Savannah River: Hall et al. 1991). Characteristic channel spawning habitats vary slightly among rivers: in curves with gravel/sand/log substrate in the Savannah River (Hall et al. 1991) and areas near limestone bluffs with gravel to boulder substrate in the Altamaha River (Rogers and Weber 1995a).

Timing of spawning and river conditions

Spawning begins in freshwater from late winter/early spring in southern rivers when water temperatures increase to 8-9°C. Spawning usually ceases when water temperatures reach 12-15° C (Dadswell et al. 1984; Buckley and Kynard 1985b; Hall et al. 1991; O'Herron et al 1993; Squiers et al. 1993; Kynard 1997). However, shortnose sturgeon may spawn at higher temperatures. For example, when high river flow conditions delayed spawning in the Connecticut River, shortnose sturgeon had the physiological flexibility to spawn successfully at 18° C (Kynard 1997). Spawning was detected from 11.5-19°C in the Cooper River, SC (Cooke and Leach, 2004a). In general, spawning occurs earlier in the year in southern rivers and at moderate river discharge levels (relative to northern rivers). For example, spawning occurs in early-February to mid-March in the Savannah River (Hall et al. 1991) and has been documented in late February to late March in the Cooper River (Cooke and Leach, 2004a). Shortnose spawning generally occurs earlier and at lower temperatures than Atlantic sturgeon. Dadswell et al. (1984) report that most shortnose spawn between 9 and 12°C.

Physical factors affecting spawning success

As observed in the Connecticut River, high river flows during the normal spawning period can cause unacceptably fast bottom water velocities and prevent females from spawning (Buckley and Kynard 1985b; Kynard 1997). Buckley and Kynard (1985b) speculated that the reproductive rhythm of females may be under endogenous control and suitable river conditions must be available or endogenous factors prevent females from spawning. Thus, reproductive success depends on suitable river conditions during the spawning season.

Development, growth and movement patterns

Habitat and Environmental Requirements

Shortnose sturgeon in the South Atlantic portion of the range require the use of large coastal rivers from the estuarine portions to upstream spawning areas. Habitat and environmental requirements of shortnose sturgeon are reviewed in Gilbert (1989). Shortnose require large rivers unobstructed by dams, or in which the dams are above their preferred spawning areas, or at which fish passage has been provided. Shortnose are apparently able to maintain completely freshwater populations, such as in the Santee-Cooper system (Collins et al. 2003). Preferred temperature ranges and upper and lower lethal temperatures for shortnose are not currently known. Shortnose sturgeon are seldom found in shallow water where water temperatures exceed 22°C; however, in the Altamaha they were found at temperatures as high as 34°C. Temperatures at wintering sites ranged from 5-10°C in Winyah Bay.

Shortnose sturgeon prefer waters of lower salinity than Atlantic sturgeon. The maximum salinity at which shortnose were found is 30-31 ppt, slightly less than sea water. In areas where shortnose sturgeon and Atlantic sturgeon co-occur, shortnose are typically found in waters less than 3 ppt. Adult sturgeon are typically found in areas with little or no current throughout their lives, especially when they are present in the lower portions of rivers and in the estuaries. Shortnose have been reported from shallower waters in the summer (2-10 m; 6.5-33 ft) and deeper water in the winter (10-30 m; 33-99 ft). They have been observed feeding in heavily vegetated, muddy backwater areas; however, in general submerged aquatic vegetation does not appear to be an important factor in their life history.

Early life stages

At hatching, shortnose sturgeon larvae are blackish-colored, 7-11 mm (0.3-0.4 in) long and resemble tadpoles (Dadswell et al. 1984). Larvae have a large yolk-sac, poorly developed eyes, mouth and fins, and are capable of only limited swimming. In laboratory experiments, 1 to 8-day–old shortnose sturgeon were photonegative, actively sought cover under any available material, and swam along the bottom until cover was found (Richmond and Kynard 1995). It is likely that they hide under available cover at spawning sites. The yolk-sac is absorbed in 9-12 days, and larvae resemble miniature adults by about 20 mm (0.8 in) in length. They likely begin swimming downstream at this size. Larvae collected in the wild were in the deepest waters of the channel. Laboratory studies suggest that there is a two-stage downstream migration: a 2-day migration by larvae, followed by a residency period of young-of-the-year fish, then a resumption of migration by yearlings the second summer of life.

Juveniles

Juveniles occur in or at the saltwater/freshwater interface in most rivers (Savannah: Hall et al. 1991; Altamaha: Flournoy et al. 1992; Ogeechee River: Weber 1996). Juveniles in the Ogeechee River moved into more saline areas (0-16 ppt) and were most active when water temperature dropped below 16°C (Weber 1996). In the Savannah River, juveniles use sand/mud substrate in depths of 10-14 m (33-46 ft) (Hall et al. 1991). Warm summer temperatures above 28 degrees F may severely limit available juvenile nursery habitat in some southern rivers. Summering habitat in the Altamaha River was limited mainly to one cool, deepwater refuge (Flournoy et al. 1992). Likewise, a similar distribution was observed in the Ogeechee River (Rogers and Weber 1994; Rogers and Weber 1995b, Weber 1996).

<u>Adults</u>
Adults that occur in freshwater or tidal fresh reaches of rivers in summer and winter often occupy only a few short reaches of the total river length (Savannah River: Hall et al. 1991; Altamaha River: Flouronoy et al. 1992). In the Connecticut and Merrimack Rivers, the "concentration areas" used by fish were reaches where natural or artificial features cause a decrease in river flow, possibly creating suitable substrate conditions for freshwater mussels (Keiffer and Kynard 1993), a major prey item for adult sturgeon (Dadswell et al. 1984). Summer concentration areas in southern rivers are cool, deep, thermal refugia, where adults and juveniles congregate (Flouronoy et al. 1992; Rogers and Weber 1994; Rogers and Weber 1995b; Weber 1996).

<u>Growth</u>
Growth of juvenile shortnose sturgeon is fast throughout the species' range (Dadswell et al. 1984). YOY are 14-30 cm TL after the first year. Fish reach 50 cm after only 2-4 years in the southern part of the range. Fish grow faster in the South, but do not attain the large sizes of northern fish (Dadswell et al. 1984).

<u>Survival and Recruitment</u>
There is no information on survival of eggs or early life stages in the wild. Many eggs reared in captivity die of fungus infections (Dadswell et al. 1984). Richmond and Kynard (1995) maintain that the availability of spawning substrate with crevices is critical to survival of eggs and embryos. Year class strength of shortnose sturgeon populations is probably established early in life, perhaps in the initial few weeks. Although there is no commercial fishery for shortnose sturgeon (and thus, no fisheries recruitment information), some fisheries incidentally catch adult sturgeon and poaching impacts all populations to an unknown degree.

Incidental capture of shortnose sturgeon also occurs in gill net fisheries in the southern portion of the shortnose sturgeon's range. Gill net fisheries for American shad (Alosa sapidissima) and trawl fisheries for shrimp (Penaeus spp.) in Georgia and South Carolina captured about 2% of a tagged sample of shortnose sturgeon (Collins et al. 1996). The gill net fishery was responsible for 83% of the total shortnose sturgeon captures. Moser and Ross (1993) reported that 4 of 7 telemetered adult sturgeon in the Cape Fear River were captured in the gill net fishery for American shad or striped bass (Morone saxatilis). In addition, apprehension of poachers operating in South Carolina indicates that illegal directed take of shortnose sturgeon in southern rivers may be a significant source of mortality (D. Cooke, personal communication).

<u>Natural mortality</u>
Estimates of total instantaneous mortality rates (Z) are available for several river systems, albeit mainly northern populations. Total mortality for the Pee Dee-Winyah River in South Carolina

was estimated at 0.08 to 0.12 (Dadswell et al. 1984). This estimate and the estimates for the other populations were based on catch curves which were adjusted for gill net selectivity and effort.

Annual egg production

Annual egg production is determined by the fecundity of females and the number of spawning females. Estimates of egg production from the Saint John River indicated mean fecundity per female was 94,000 eggs (Dadswell 1979). Monitoring of spawner abundance in the Connecticut River indicated that abundance varies greatly from year to year (Kieffer and Kynard unpublished data). Smith et al. (1992) also suggested that spawner abundance in the Savannah River can fluctuate greatly from year to year. This information indicates that the number of eggs spawned annually varies greatly (possibly by several magnitudes) over the species' range and complicates estimation of annual egg production.

Migration and Movements

Movement patterns in shortnose sturgeon vary with fish size and home river location. Juvenile shortnose sturgeon generally move upstream in spring and summer and move back downstream in fall and winter; however, these movements usually occur in the region above the saltwater/freshwater interface (Dadswell et al. 1984; Hall et al. 1991). Adult shortnose sturgeon are generally estuarine anadromous in southern rivers (Keiffer and Kynard 1993).

Spawning migrations are apparently triggered when water temperatures warm above 8°C (Dadswell et al. 1984). Consequently, spring spawning migrations occur earlier in southern systems than in northern ones: January-March (Altamaha River: Gilbert and Heidt 1979, Rogers and Weber 1995a; Savannah River: Hall et al. 1991; Pee-Dee/Waccamaw Rivers: Dadswell et al. 1984; Cape Fear River: Moser and Ross 1993). In the Altamaha River, Rogers and Weber (1995a) also documented upstream movement of most adults to suspected spawning grounds in autumn (late November-early December). A second spawning migration occurred in that system during mid-winter (late January-early February).

A shortnose sturgeon spawning migration is characterized by rapid, directed and often extensive upstream movement. Hall et al. (1991) tracked adults during pre-spawning upstream migrations of up to 200 km in the Savannah River and Dadswell et al. (1984) noted that a migration of 193 km occurred in the Altamaha River. Telemetry studies have documented maximum ground speeds of 20-33 km d-1, although mean ground speeds during riverine spawning migrations were around 16 km d-1 (Buckley and Kynard 1985a; Hall et al. 1991; Moser and Ross 1993). Both Hall et al. (1991) and Moser and Ross (1993) observed that spawning migrations are easily interrupted by capture and handling or by dams. Non-spawning movements include rapid, directed post-spawning movements to downstream feeding areas in spring and localized, wandering movements in summer and winter (Dadswell et al. 1984; Buckley and Kynard 1985a; O'Herron et al. 1993). Shortnose sturgeon usually leave the spawning grounds soon after spawning. Keiffer and Kynard (1993) reported that post-spawning migrations were correlated with increasing spring water temperature and river discharge. Post-spawning migration rates range from 3.5-36 km d-1 (Buckley and Kynard 1985a; Hall et al. 1991; Kieffer and Kynard 1993). During these movements shortnose sturgeon apparently move singly and "home" to very specific sites (Dadswell et al. 1984; Kieffer and Kynard 1993; Savoy and Shake 1992).

Continuous tracking of shortnose sturgeon provides detailed information on their migratory behavior. Moser and Ross (1994) demonstrated that, in the Cape Fear River estuary, upstream spawning migration in saltwater was slower (10 km d-1) than migration in freshwater (15 km d-1). This was due to the saltatory nature of movement in the estuary and faster swimming (0.8 body lengths (BL) s-1) in freshwater than in the estuary (0.6 BL s-1). Estimated swimming speed during summer, 0.07-0.37 BL s-1, is considerably slower than during spawning migrations (McCleave et al. 1977), while shortnose sturgeon are even less active in winter (Seibel 1993). Moser and Ross (1994) and McCleave et al. (1977) estimated swimming speed to be greatest when sturgeon oriented against rapid ebbing currents. Moser and Ross (1994) and McCleave et al. (1977) reported that shortnose sturgeon do not display any diel activity pattern, traveled in the upper part of the water column (within 2 m of the surface), and that their movement was apparently unaffected by temperature and salinity.

Abundance and status of stocks

As stated earlier, shortnose sturgeon historically occurred in most rivers of the four South Atlantic states from the Albemarle Sound system in NC through the Indian River system in FL. One relatively recent capture (1998) of a shortnose sturgeon in the Albemarle Sound system has been documented (Wayne Starnes, North Carolina Museum of Natural Sciences, personal communication). There have been no recent documented captures in the Pamlico Sound and its tributaries (Tar, Neuse Rivers). However, there are two recent reports of sturgeon from the Pamlico Sound identified by commercial fishery observers that were allegedly shortnose, but no photographs or tissue were taken for confirmation by professional fishery biologists or geneticists (Wilson Laney, USFWS, personal communication). There is currently a small population of shortnose in the Cape Fear River, North Carolina. At least one population presently exists in the Winyah Bay system (Waccamaw, Pee Dee and Black Rivers), as well as the Santee River, the Cooper River, the ACE Basin (Ashepoo, Combahee and Edisto Rivers) and the Savannah River. Georgia populations occur in the Savannah, Ogeechee, Altamaha, St. Marys and Satilla Rivers. Within the State of Florida, shortnose sturgeon are known only in the St. Johns River.

Total population estimates are not available for the Cape Fear, Winyah Bay, Santee, Cooper, ACE Basin, Savannah, Satilla, St. Marys and St. Johns Rivers. For the Ogeechee River, the total population estimate using Modified Schnabel methodology was 361 (95% CI= 326-400) in 1993 and 147 (95% CI= 104-249) in 2000 (Rogers and Weber 1994; Fleming et al. 2003). For the Altamaha River, the total population estimate using Modified Schnabel methodology was 2,862 (95% CI= 1,069-4,226) in 1988, 798 (95% CI= 645-1,045) in 1990, and 468 (95% CI= 316-903) in 1993 (Rogers unpublished data). A more recent study conducted in the Altamaha system from 2004-2006 resulted in a Schnabel population estimate of 6048 (95% CI= 4526-9110) (Peterson unpublished data).

Analysis of data for 1996, 1997, and 1998 resulted in estimates of 87 (95% CL 56-170), 193 (95% CL 123-319), and 301 (95% CL 150-659) adult fish, respectively residing in the Pinopolis Dam tailrace area during the spawning season (Cooke and Leach, 2004c). The population in the Cape Fear River is thought to be less than 50 fish (Moser and Ross 1995). Some of these population estimates should be viewed with caution as sampling biases may have violated the assumptions of the abundance models, effort may be limited therefore biasing data, or sampling periodicity may have been inadequate (NMFS 1998).

Albemarle Sound/Roanoke and Chowan Rivers
A historic record of a shortnose sturgeon in this area, confirmed by a museum specimen, was from Salmon Creek in the lower Chowan River, April, 1881 (USNM 64330, Vladykov and Greeley, 1963). More recently, an individual was caught in the north Batchelor Bay portion of Albemarle Sound (i.e., ca. mouth of Roanoke River) on 18 April 1998. It died in a net, was brought to the North Carolina Museum of Natural Sciences by Jim Armstrong of United States Fish and Wildlife Service, and is vouchered at the museum (NCSM 27062, Wayne Starnes, North Carolina Museum of Natural Sciences, personal communication). Additionally, an unconfirmed record from Oregon Inlet (Holland and Yelverton 1973) was also reported in Gruchy and Parker (1980), Dadswell et al. (1984), and Gilbert (1989).

Pamlico Sound/Pamlico and Neuse River
Yarrow (1877) reported that shortnose sturgeon were abundant in the North, New, and Neuse Rivers, but these records are doubtful due to their apparent basis in hearsay (Ross et al. 1988). Shortnose sturgeon were also reported from the Beaufort (Jordan 1886) and Neuse Rivers by Fowler (1945). Nearshore records of shortnose sturgeon in this area (Holland and Yelverton 1973) may be misidentifications (Ross et al. 1988). There are two recent reports of sturgeon from the Pamlico Sound identified by commercial fishery observers that were allegedly shortnose, but no photographs or tissue were taken for confirmation by professional fishery biologists or geneticists (Wilson Laney, USFWS, personal communication).

Cape Fear River
Since the first confirmed capture of shortnose sturgeon in the Cape Fear River (January 1987, Ross et al. 1988), an extensive sampling program has produced eight additional specimens (Moser and Ross 1993). All nine specimens captured were adults; no juveniles were collected. The river is dammed in the coastal plain, a short distance upstream of Wilmington, North Carolina. The river channel near the coast is channelized and heavy industries exist near the port. At least two additional records have been reported from fishermen (Fritz Rohde, North Carolina Division of Marine Fisheries, personal communication).

Winyah Bay Drainages
Shortnose sturgeon were documented in the Winyah Bay system during the late 1970's and early 1980's (Dadswell et al. 1984). Fed by the Waccamaw, Pee Dee, and Black Rivers, this coastal plain watershed produced over 100 collections of juveniles and adults during the study period. Within North Carolina, a vouchered specimen was collected from the North Carolina portion of the Pee Dee River in 1984 (Wayne Starnes, North Carolina Museum of Natural Sciences, personal communication), most likely the same individual that was collected below Blewett Falls Dam (Mark Collins, SCDNR-MRD, personal communication). In South Carolina, shortnose sturgeon have been located in the Waccamaw River, although it is possible that they were seasonal migrants from the Pee Dee River. Shortnose sturgeon from the Winyah Bay/Pee Dee River population are able to migrate upstream to the base of Lake Waccamaw (within North Carolina) if so inclined; however, there are currently no evidence/data to support the existence of

a separate Waccamaw River shortnose sturgeon population. Shortnose sturgeon spawning has been verified in the Pee Dee River, South Carolina via egg collection (Mark Collins, SCDNR-MRD, personal communication).

Santee River

Seven shortnose sturgeon were recorded from the Santee River drainage in 1978, and one fish was captured in a gillnet in 1992 (Collins and Smith 1997). In addition, 20 specimens were recovered from a fishkill in the Lower Rediversion Canal, St. Stephen Dam tailrace that occurred during a low dissolved oxygen event below the dam. During the period from 1979-1991, shortnose sturgeon were also recorded from Lake Marion, and in the Congaree and Wateree rivers above the dam (Collins and Smith 1997). These fish may represent an essentially landlocked population (Collins et al. 2003). However, during a very high water year, 15 of 16 (94%) Cooper River adult transmittered shortnose sturgeon that were released in Lake Moultrie were able to exit the Santee-Cooper Lakes (Lakes) (1 possible mortality within the Lakes), primarily to the Santee River, although one individual appears to have exited through the lock at Pinopolis Dam on the Cooper River. At least 14 of the 15 (93%) shortnose sturgeon that exited the Lakes are thought to have survived downstream passage (Cooke and Leach 2004b, Cooke and Leach 2004d). Of the 13 shortnose sturgeon that successfully survived downstream passage specifically into the Santee River, all appear to have exited the Santee River system. Eight were relocated in the Winyah Bay system, two in the Cooper River, two in the Intracoastal Waterway, and one disappeared altogether. This behavior appears to be similar to four shortnose sturgeon that were implanted with transmitters in the Santee River. Albeit a small sample size, one was relocated in the Savannah River, the other seemed to disappear from the Santee River only to reappear approximately a year and a half later, and two disappeared altogether (Cooke and Leach 2004d).

Cooper River

Shortnose sturgeon were documented in what is now the metro Charleston area during the late 1800's (Jordan and Evermann 1896). Shortnose sturgeon were collected in this heavily altered (dammed and urbanized) drainage in the 1980's during research on the American shad (*Alosa sapidissima*) fishery. A functionally landlocked segment may exist in Lake Marion (Collins et al. 2003) above the dam that blocks the system in the lower coastal plain (Pinopolis Dam). However, during a very high water year, 15 of 16 (94%) Cooper River adult transmittered shortnose sturgeon that were released in Lake Moultrie were able to exit the Santee-Cooper Lakes (1 possible mortality within the Lakes), primarily to the Santee River, although one individual appears to have exited through the lock at Pinopolis Dam on the Cooper River. At least 14 of the 15 (93%) shortnose sturgeon that exited the Lakes are thought to have survived downstream passage (Cooke and Leach 2004b, Cooke and Leach 2004d). 14 of 15 (93%) Cooper River adult transmittered shortnose sturgeon that were placed in Pinopolis Lock did not pass upstream into the Santee-Cooper Lakes (Lakes), indicating that upstream passage in the Cooper River into the Lakes is extremely limited (Cooke and Leach 2004b). Below Pinopolis Dam, the lowermost dam on the Cooper River, eleven sturgeon were taken in gillnets in the tailrace in February 1995 (Collins et al. 1996). Cooke and Leach (1999) found that shortnose sturgeon congregate and spawn below Pinopolis Dam. Successful egg fertilization and development is occurring, but only one newly hatched yolk sac larva and no juveniles have been documented (Duncan et al. 2004).). Analysis of data for 1996, 1997, and 1998 resulted in estimates of 87 (95% CL 56-170), 193 (95% CL 123-319), and 301 (95% CL 150-659) adult fish, respectively residing in the Pinopolis Dam tailrace area during the spawning season (Cooke and Leach 2004c). Limited gillnet sampling in 2003 in the spawning area resulted in 8 of the 12 adults (67%) as recaptured fish from previous years (Cooke and Leach 2004a).

Ashepoo, Combahee and Edisto Rivers (The "ACE" Basin)

The Ashepoo, Combahee, and Edisto drainages form one of the most pristine coastal plain watersheds in the southeastern United States. Shortnose sturgeon were incidentally collected during American shad studies in the Ashepoo and Edisto Rivers in the 1970's and early 1980's (Collins and Smith 1997). Ripe adults, as well as YOY/age-1 fish, have been more recently collected by the South Carolina Department of Natural Resources-Marine Resources Division (SCDNR-MRD) from the Edisto River. It is possible that these are actually Savannah River fish that were stocked into the Savannah River and then strayed to colonize the Edisto River (Mark Collins, SCDNR-MRD, personal communication).

Savannah River

The Savannah River is a heavily industrialized and channelized drainage that forms the South Carolina/Georgia border. The river is dammed, but not below the fall line. Shortnose sturgeon were first documented in the system in the mid-1970's (Dadswell et al. 1984). During 1984-1992, over 600 adults were collected by shad fishermen and researchers using gillnets and trammel nets (Collins and Smith 1993). The ratio of adults to juveniles in this study was very high, indicating that recruitment is low in this river (Smith et al. 1992). Adult population estimates were calculated using Jolly Seber (96-1075) and Schnabel (1676) techniques, but were deemed unreliable as not all basic assumptions were met (M. Collins, South Carolina Department of Natural Resources, personal communication). During 1984-1992, approximately 97,000 shortnose sturgeon (19% tagged) of various sizes were stocked in the Savannah River to evaluate the potential for shortnose sturgeon stock enhancement (Smith and Jenkins 1991). Subsequent investigation showed that stocked fish were at large for an average of 416 days and comprised 41% of all juvenile sturgeon collected (Smith et al. 1995). It is thought that the Savannah River population and the Altamaha River population are the two largest populations in the Southeast (Wirgin et al. 2006).

Ogeechee River

The Ogeechee is primarily a coastal plain drainage with 5% of its watershed in the piedmont. The river is undammed, but water quality has changed (eutrophied) during the last 30 years (Weber 1996). Shortnose sturgeon were first documented in the system during the early 1970's (Dadswell et al. 1984). A survey of shortnose sturgeon occurrence, distribution, and abundance, including a 1994-1995 mark/recapture experiment, was conducted from 1993 to 1995 and then from 1999 to 2004 in the tidal portion of the drainage (Rogers and Weber 1994; Weber 1996). The size distribution of shortnose sturgeon sampled indicated that, as in the Cape Fear and Savannah Rivers, the Ogeechee population is dominated by adults. Mark/recapture analysis indicated that abundance is low and possibly declining in the Ogeechee system; the highest point estimate yielded less than 400 individuals from all age classes in 1993 (Weber 1996) and less than 200 individuals from all age classes in 2000 (Fleming et al. 2003). Size frequency, abundance, and catch rate data indicate that natural recruitment does occur in the Ogeechee River system but shortnose sturgeon may be experiencing higher juvenile mortality rates in this system than in the Altamaha (below), with evidence of total recruitment failure in some years. A portion of the shortnose sturgeon that were stocked in the Savannah system have migrated to the Ogeechee River and have contributed substantially to some year-classes in this system (Fleming et al. 2003). Coalescence-based migration estimates suggest that populations south of the Pee Dee River exchange between 1-9.8 individuals per generation, with the highest rate occurring between the Ogeechee and the Altamaha Rivers (Wirgin et al. 2005).

Altamaha River

The Altamaha River system drains the largest watershed east of the Mississippi River and comprises the confluence of the Ocmulgee and Oconee Rivers plus additional, smaller piedmont and coastal plain drainages. The system is moderately industrialized including two kraft process paper mills and a nuclear generating plant. The watershed landscape has been heavily altered by urbanization, suburban development, agriculture, and silviculture. The system is also dammed, but not below the fall line. Shortnose sturgeon were first documented in the Altamaha in the early 1970's (Dadswell et al. 1984), and, later, in a cursory study of spawning movements conducted in the late 1970's (Heidt and Gilbert 1979).

A two-year study of population structure and dynamics was conducted during the early 1990's (Flournoy et al. 1992), building on three additional years of survey data from the late 1980's (B. T-A.Woodward, Georgia Department of Natural Resources, unpublished data). Over 650 individuals were collected during the five years of study, with samples heavily dominated by juveniles (90%). Subsequent analysis of tag/recapture data indicated that, during the two-year study period in the 1990's, abundance did not exceed 6,055 individuals for all size and age classes. However, under the more rigorous constraints imposed by the assumptions of the recapture model and (probably) met under the conditions experienced during the summer of 1990, the point estimate is 798 individuals with a 95% confidence interval (CI) of 645-1,045 fish. The next time that those conditions were met (during the late summer of 1993), a similar 95% CI of 316-903 individuals was generated with a point estimate of 468 fish. An estimate generated from 1988 data, which met the same criteria, yielded 2,862 fish (95% CI 1,069-4,226). A more recent study conducted in the Altamaha system from 2004-2006 resulted in a Schnabel population estimate of 6048 (95% CI=4526-9110) (Peterson unpublished data). Based on these data, the Altamaha population segment is likely the largest and most viable one south of Cape Hatteras, NC (Joel Fleming, GDNR, personal communication). Similarly, Wirgin et al. (2006) suggested that the Savannah River population and the Altamaha River population are the two largest populations in the Southeast (Wirgin et al. 2006).

Satilla and St. Marys

The Satilla and St. Marys Rivers are relatively small coastal plain drainages emptying into the Atlantic Ocean between the Altamaha River, GA and St. Johns River, FL. There are no dams and few human impacts beyond agriculture and timber management along the Satilla system. The St. Marys system (draining the eastern portion of the Okefenokee Swamp and forming a portion of the GA/FL border) is likewise undammed, but is heavily channelized in its estuary to support a small port and military installation. The estuary also receives effluents from three major forest product plants. Collections of shortnose sturgeon were made in the estuaries of both systems during the late 1980's and early 1990's during crustacean monitoring (G. Rogers, Georgia Department of Natural Resources, personal communication). Surveys for sturgeon in the St. Marys (1994 and 1995, 117 net hours) and in the Satilla (1995, 74 net hours) failed to yield any shortnose sturgeon (Rogers and Weber 1995b).

St. Johns River

The St. Johns River in FL is a heavily altered system flowing northward from the east-central portion of the state and emptying into the Atlantic Ocean near Jacksonville, FL. The system is dammed by Rodman Dam in the headwaters (although currently scheduled for removal), heavily industrialized and channelized near the sea, and affected by urbanization, suburban development, agriculture, and silviculture throughout portions of the basin. Shortnose sturgeon have been reported from the system since 1949 (Kilby et al. 1959). Five shortnose sturgeon were collected in the St. Johns in the late 1970's (Dadswell et al. 1984) and, in 1981, three sturgeon were collected and released by the Florida Game and Freshwater Fish Commission. A shortnose sturgeon tagged in Georgia by Georgia Department of Natural Resources near St. Simons Island in March 1996 was captured from the St. Johns River in August 2000 (Jay Holder, FLFWC, personal communication).

Most recently, a shortnose sturgeon was collected by Florida Fish and Wildlife Commission personnel in 2002 on the south side of Federal Point near Palatka, Florida during a 2002-2003 study to determine presence/absence of shortnose sturgeon in the St. Johns River. This single shortnose sturgeon was collected in 4,493 hours of 100-m gillnet sets. Preliminary analysis by Joe Quattro at the University of South Carolina indicated that the sample was genetically similar to other shortnose sturgeon populations found in the southern United States (FLFWC 2005). Historically, few shortnose sturgeon in the St. John's River have been positively identified by biologists and commercial landings were relatively low compared to other southern states. However, there have been several verified incidental captures off the coast of Daytona Beach (Allan Brown, United States Fish and Wildlife Service, personal communication). No sturgeon reproduction has ever been documented in the St. Johns River and the spawning habitat that is currently accessible seems to be marginal (FLFWC 2005).

Ecological relationships

Feeding

Shortnose sturgeon are benthic omnivores but have also been observed feeding off plant surfaces (Dadswell et al. 1984). Based on the high incidence of non-food items in juvenile shortnose sturgeon, Dadswell et al. (1984) concluded that juveniles randomly vacuum the bottom while adults are more selective feeders. Dadswell (1979) determined that adult shortnose sturgeon in the Saint John River, Canada are not opportunists and only switch to other prey when preferred food are unavailable. The presence of food in the gut during all times of day indicated that shortnose sturgeon are continuous feeders (Dadswell 1979).

Shortnose sturgeon feed on crustaceans, insect larvae, worms, and mollusks; however, they apparently undergo ontogenetic shifts in preferred foods. Insect larvae (*Hexagenia* sp., *Chaoborus* sp., *Chironomous* sp.) and small crustaceans (*Gammarus* sp., *Asellus* sp., *Cyathura polita*) predominate in the diet of juveniles (Dadswell et al. 1984; Carlson and Simpson 1987) while adults feed primarily on small mollusks (Dadswell 1984; Hastings 1983). Molluscs ingested by adults captured in freshwater include *Physa* sp., *Heliosoma* sp., *Corbicula* *manilensis*, *Amnicola limnosa*, *Valvata* sp., *Pisidium* sp., and small *Elliptio complanata* (Dadswell et al. 1984). In saline areas molluscan prey include small *Mya arenaria*, and *Macoma balthica* (Dadswell 1979).

Probable foraging activity in southern rivers has been described at the saltwater/freshwater interface during fall and winter in the Pee Dee and Savannah rivers (Dadswell et al. 1984; Hall et al. 1991) and just downstream of the saltwater/freshwater interface in the Altamaha and Ogeechee rivers (Rogers and Weber 1995a; Weber 1996). During summer, shortnose sturgeon in these southern systems appear to reduce activity, fast, and lose weight (Dadswell et al. 1984; Rogers et al. 1994).

Predators, Parasites, and Diseases

There is very little documentation of predation on any life stage of shortnose sturgeon. Young-of-the-year shortnose sturgeon (approximately 5 cm FL) were found in the stomachs of yellow perch (*Perca flavescens*) in the Androscoggin River, Maine (Dadswell et al. 1984). It is likely that sharks and seals may occasionally prey on shortnose sturgeon based on the occasional specimen lacking a tail (Dadswell et al. 1984).

Parasites recorded from shortnose sturgeon (all data from northern populations) include Coelenterata (*Polypodium* sp.), Platyhelminthes (*Diclybothrium armatum*, *Spirochis* sp., *Nitzschia sturionis*), Nematoda (*Capillospirura pseudoargumentosus*), Acanthocephala (*Fessesentis friedi*, *Echinorhynchus attenuatus*), Hirudinea (*Calliobdella vivida*, *Piscicola milneri*, *Piscicola punctata*), Arthropoda (*Argulus alosa*), and Pisces (*Petromyzon marinus*). The degree of infestation has been reported as being quite low with the exception of *Capillospirura* sp. (Dadswell et al. 1984). Sturgeon do not appear to be harmed by these parasites. There have been no reported incidences of disease for shortnose sturgeon in the wild, although an epizootic of *Columnaris* sp. occurred at the FWS' Orangeburg Hatchery in South Carolina (Willie Booker, FWS, South Carolina, personal communication).

Listing designations

4.3.5 Marine Plants

(material from the 2002 Recovery Team Status Review)

Description and distribution

Description

After many years of confusion over identification, Johnson's seagrass (*Halophila johnsonii*) was formally proposed as a separate species by Eiseman and McMillan (1980). *Halophila johnsonii* was previously referred to either as *H. decipiens* or *H. baillonis* Ascherson, but it most closely resembles *H. ovalis* (R. Brown) Hooker f., an Indo-Pacific species, both morphologically and genetically (McMillan and Williams 1980). Plant classification schemes based on anatomical (den Hartog 1970) and molecular phylogenetic (Les et al. 1997) methods both place the seagrass genus *Halophila* in the angiosperm family Hydrocharitaceae, along with two other seagrass genera, *Thalassia* and *Enhalus*. Morphologically, Johnson's seagrass is recognized by the presence of pairs of linearly shaped foliage leaves, each with a petiole formed on the node of a horizontally creeping rhizome (Figure 4.3-2)(NMFS 2001).

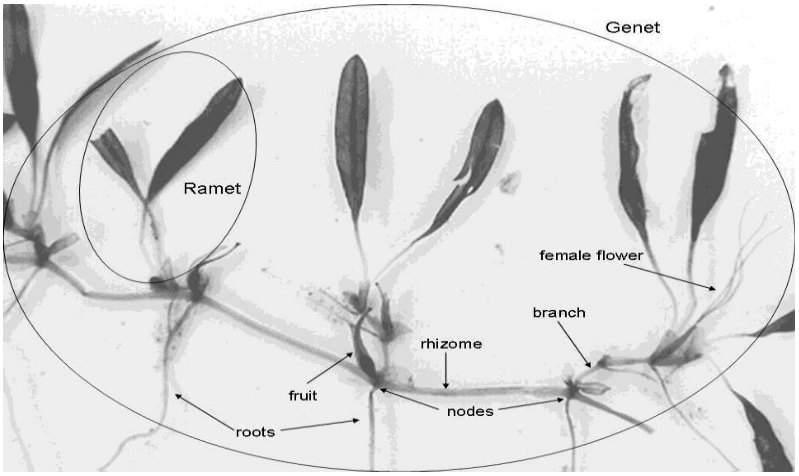

Figure 4.3-2. Photograph of *Halophila johnsonii* showing the genet and individual ramets, the rhizome, a female flower, fruit, nodes, and lateral branching of rhizome

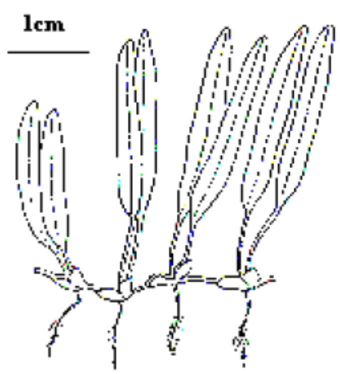
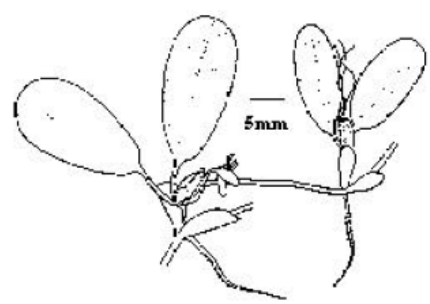
The rhizome is located at or just below the sediment surface and is anchored to unconsolidated substrate by unbranched roots. The leaves are generally 2-5 cm long (including the petioles), and the rhizome internodes rarely exceed 3-5 cm in length, making this species appear diminutive relative to the larger seagrasses. *Halophila johnsonii* differs from *H. decipiens* in a number of morphological, reproductive, and genetic characteristics (Table 4.3-5). The diagnostic characteristics of *H. johnsonii* remain relatively unchanged when plants are cultured in artificial conditions; thus, differences between the two species are not due to phenoplasticity (NMFS 2001).

Table 4.3-5. Morphological, reproductive, and genetic characteristics of *H. johnsonii* and *H. decipiens.* Illustrations adapted from Phillips and Menez, 1988.

H. johnsonii	***H. decipiens***
Linear leaves with entire (smooth) margins.	Oblong-elliptical leaves with serrate margins.
No hairs on blade surface.	Unicellular prickle hairs on both surfaces (unique to *H. decipiens*).
Leaf cross veins diverge at ca. 45° angles.	Leaf cross veins at ca. 60° angles.
Only pistillate (female) flowers are known so it is possibly dioecious (male and female plants) or apomictic (produces seeds without pollination or meiosis so seeds are clones of female parent).	Monoecious (both sexes on one plant).
Populations of *H. johnsonii* collected in the Indian River Lagoon (IRL) differed from *H. decipiens* in five isozymes of the seven isozyme systems tested, with major differences in three of the enzymes (Jewett-Smith et al. 1997).	See box at left.
	




Distribution

Johnson's seagrass is found only in southeastern Florida from near Sebastian Inlet (27.85°, -80.45°) to Virginia Key (27.74°, -80.14°) (Figure 4.3-3). Recently, however, the St. Johns River Water Management District (SJRWMD) observed *H. johnsonii* 3 km north of the Sebastian River mouth on the western shore of the lagoon (27.88°, -80.50°) – a discovery that slightly extends the species known northern range. Where it does occur, its distribution is patchy, both spatially and temporally (Virnstein and Morris 2007).

Halophila johnsonii is a perennial species showing no consistent seasonal or year-to-year pattern in surveys of the Indian River Lagoon (IRL). Although perennial, it exhibited some winter decline. However, during exceptionally mild winters, as in the winter of 2004, *H. johnsonii* can maintain or even increase its abundance from summer to winter (Virnstein et al. 1997, Virnstein and Morris 2007).

Depth of occurrence ranged from 0.03 to 2.5 m within transects monitored in the IRL (Virnstein et al. 1997, Virnstein and Morris 2007). When data from all transects were combined, there was no correlation of *H. johnsonii* abundance with depth. However, the deep edge at some transects was only 0.1 m; at other transects, it was 2.5 m. When all depths of occurrence were standardized (as percent of maximum depth of a transect), *H. johnsonii* was more abundant in the deeper parts of the transects. Most (78% or 574 out of 733) occurrences of *H. johnsonii* were at >70% of maximum transect depth; half were at >90% of maximum depth (Virnstein et al. 1997, Virnstein and Morris 2007).

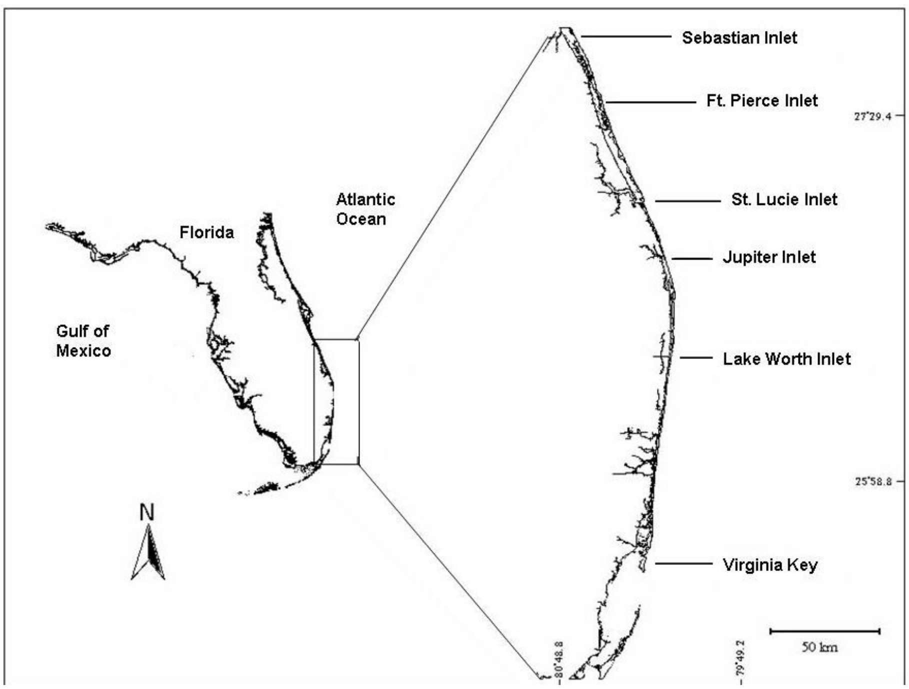


Figure 4.3-3. Geographic range of *Halophila johnsonii*: Sebastian Inlet to northern Virginia Key (Kenworthy 1997).

Observations of its distribution and the results of limited experimental work suggest that *H. johnsonii* has a wider tolerance range for salinity, temperature, and optical water quality conditions than *H. decipiens* (Dawes et al. 1989; Gallegos and Kenworthy 1996; Durako et al. 2003; Kunzelman et al. 2005; Torquemada et al. 2005). *Halophila johnsonii* has been observed growing perennially near the mouths of freshwater discharge canals (Gallegos and Kenworthy 1996), in deeper turbid waters of the interior portion of the Indian River Lagoon (Kenworthy 2000; Virnstein and Morris 2007), and in clear water associated with the high energy environments and flood deltas inside ocean inlets (Kenworthy 1993, 1997; Virnstein et al. 1997; Heidelbaugh et al. 2000; Virnstein and Morris 2007).

While *H. johnsonii* is negatively affected by both extreme hypo- and hyper-salinity conditions, it does tolerate hypersaline conditions better than hyposaline conditions. Most other seagrasses, conversely, are thought to be more sensitive to increased salinity (Ogata and Matsui 1965; Biebl and McRoy 1971; Zieman 1975; Adams and Bate 1994; Doering and Chamberlain 1998). Torquemada et al. (2005) and Dawes et al. (1989) concluded that *H. johnsonii* could be seriously affected by salinity variations produced by human activities, such as freshwater discharges through water management practices or brine discharges from seawater desalination plants. Interestingly, salinity changes do not seem to alter the tolerance of this species to other environmental factors, such as temperature or pH (Torquemada et al. 2005).

Reproduction

Like all other seagrasses, *H. johnsonii* is clonal, which refers to plants that have many semi-independent units (ramets) acting together as a single organism (Cook 1983). Reproduction is achieved primarily by asexual means. While all other species of seagrass reproduce sexually, there is still no evidence of sexual reproduction in *H. johnsonii*. All attempts to find seeds and seedlings have failed to detect any evidence of their occurrence (Jewitt-Smith et al. 1997; Hammerstom and Kenworthy 2003). Likewise, despite widespread sampling and surveys throughout the entire range of the species, no male flowers have ever been reported and confirmed. Female flowers, however, have been documented in both culture and nature (Eiseman and McMillan 1980; Heidelbaugh et al. 2000). They are common and often very abundant (Heidelbaugh et al. 2000). They have been observed throughout the entire range of the species during all times of the year, but no consistent patterns of spatial or temporal distribution have been observed or reported.

Although male flowers have never been observed, it is not possible to completely rule out their existence and the potential for sexual reproduction. They may occur cryptically in isolation or in the vicinity of females. They may be extremely rare, or they may express themselves only at night, as was the case in a related species, *Halophila hawaiiana* (Herbert 1986).

While sexual reproduction of *H. johnsonii* remains somewhat of a mystery, reproduction by asexual means and clonal growth is well understood. Asexual reproduction occurs when rhizome apical meristems divide and form new leaf pairs, flowers, or rhizome apices (Posluszny and Tomlinson 1990) (Figure 4.3-2). The divisions and subsequent differentiation of meristems (meristem dependence) into the various attributes of the ramets are the foundation of growth and productivity in all seagrasses (Tomlinson 1974). *Halophila johnsonii* grows by division of apical meristems on horizontal rhizomes which branch, forming leaf pairs, female flowers and new lateral branches (Figure 4.3-4). On average, new meristems are formed on rhizomes every 2 to 4 days (Kenworthy 1997, Bolen 1997) and meristem densities can reach hundreds to thousands per square meter (Kenworthy 1997, Heidelbaugh et al. 2000).

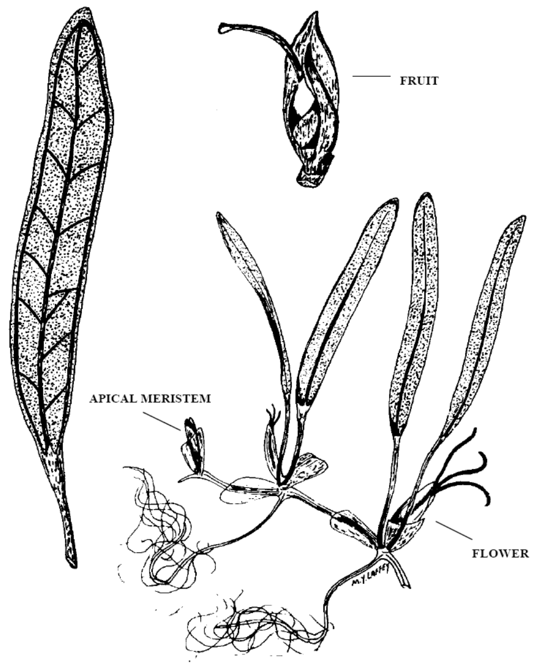

Figure 4.3-4. Johnson's seagrass, *Halophila johnsonii*. Leaves are generally 2-5 cm long. Adapted from Eiseman and McMillan (1980).

Development and growth

The species spreads as clones expand in local space by rhizome extension and leaf pair formation, eventually forming high density "patches." Rhizomes can elongate at rates approaching 0.5 cm per day (Bolen 1997, Kenworthy 1997), and when combined with prolific branching, individual patches (clones) can expand at extraordinary rates, ranging from 0.3 to 1.0 m^{-2} per month (Kenworthy 1997, 2003; Greening and Holland 2003). This expansion can lead to coalescence of adjacent patches and the formation of larger meadows. Widely spaced patches, usually on the order of 1-20 square meters in size, are the most commonly encountered feature of *H. johnsonii* meadows (Virnstein et al. 1997, Kenworthy 1997, 2000; Virnstein and Morris 2007; Kenworthy 2003). Although it is more commonly found in monotypic patches, *H. johnsonii* can also grow among low to moderate densities of *Halodule wrightii* and *Syringodium filiforme*, and in deeper water mixed with *H. decipiens* (Kenworthy 1993, 1997, 2000; Virnstein et al. 1997, Virnstein and Morris 2007).

Patches can also disappear rapidly. Sometimes they will disappear for several years and then re-establish: a process referred to as "pulsating patches" (Heidelbaugh et al. 2000, Virnstein and Morris 2007). Mortality, or the disappearance of patches, can be caused by a number of processes, including burial from bioturbation and sediment deposition, erosion, herbivory, desiccation, and turbidity. *Halophila johnsonii*'s canopy is only 2-5 cm tall and may be easily covered by sediments transported during storms or redistributed by macrofaunal bioturbation during the feeding activities of benthic organisms (Heidelbaugh et al. 2000).

In the absence of sexual reproduction, one possible explanation for the pulsating patches is dispersal and re-establishment of vegetative fragments, a process which commonly occurs in aquatic plants and has been demonstrated in other seagrasses (DiCarlo et al.; 2005). While *H. johnsonii* is vulnerable to uprooting by wind waves, storm events, tidal currents, bioturbation, and motor vessels, these are also mechanisms capable of disturbing patches and creating clonal fragments for dispersal. Hall et al. (2006) showed that drifting fragments of *H. johnsonii* can remain viable for 4 to 8 days, after which time they can settle, root, and grow.

Ecological relationships

Seagrasses have recently received increasing attention from scientists and managers because of the valuable functional roles they play in coastal ecosystems (Costanza et al. 1997; Larkum et al. 2006). Seagrass beds are one of the primary nursery habitats because of their abundance of prey items as well as the protection they provide from predators (Zieman and Zieman 1989; Heck et al. 2003). Other functions associated with seagrasses include nutrient recycling, detrital production and export, and sediment stabilization. Very little work has been done on the functional value of *H. johnsonii*, therefore, the functional roles of its closest relative, *H. ovalis*, and other *Halophila* spp. are used a proxy in this discussion.

The most well-known function of seagrasses is their role as habitat for numerous fishes and invertebrates. Some species spend their entire lives within seagrass beds and others utilize it only during certain stages of their life cycle (usually the postlarval and juvenile stages). Heidelbaugh (1999) conducted one of the only studies that examined benthic fauna associated with *H. johnsonii*. In this study, differences in benthic fauna among *H. johnsonii*, *H. wrightii*, and bare sand were compared on the flood tidal delta just inside Sebastian Inlet, Fl. *Halophila johnsonii* beds yielded a total of 126 species (69 epifauna and 57 infauna), while 117 species were collected from *H. wrightii* beds and 99 species from bare sand. The most abundant infaunal organisms belonged to Nematoda while the most abundant epifaunal species were amphipods and tanaids. The majority of macrofaunal organisms consisted of decapod crustaceans (*Callinectes sapidus*), fishes (*Eucinostomus* sp.), and some gastropods (especially *Bursatella leachii*). Three hundred and twenty macrofaunal organisms were collected from *H. johnsonii* beds compared to 690 from *H. wrightii* beds and 78 from bare sand.

Rapid growth, high turnover rates, and labile tissues make *Halophila* spp. a good source of nutrition for several marine herbivores (Kenworthy et al. 1989, Lanyon 1991, Preen 1995, Bolen 1997). The Florida manatee (*Trichechus manatus latirostris*) has been observed grazing on *H. johnsonii* near a power plant in Palm Beach, Florida (J. Reid, Sirennia Project, U.S.G.S., Gainesville, FL, personal observation). Green turtles (*Chelonia mydas*) are known to eat several species of *Halophila* (Hasbun et al. 2000; Kannan and Rajagopalan 2004; Russell et al. 2003; Whiting and Miller 1998). *Halophila* species also provides nutrition for herbivorous fish. Through consumption, the stareye parrotfish (*Calotomus carolinus*) has the ability to control the abundance and distribution of short lived seagrass species such as *H. stipulacea* in Kenya (Mariani and Alcoverro 1999). Even invertebrates such as the queen conch (*Strombus gigas*) (Thayer et al. 1984) and various species of harpacticoid copepods (Shimode and Shirayama 2006) have been observed feeding on *Halophila* species.

Seagrasses play an important role in nutrient cycling within systems and can act as both a source and sink for nutrients. Processes that lead to a loss of nutrients from the system include: exudation/leaching from living and dead plant material, export of sloughed leaves and leaf fragments, nutrient transfer by foraging animals, denitrification, and diffusion from sediment. Processes that result in an increase of nutrients include: nitrogen-fixation, sedimentation, and nutrient uptake by leaves. It is the fluctuation of these processes that leads to interannual variations in net losses or net gains of nutrients, and therefore, fluctuations in the productivity of seagrass meadows (Hemminga et al., 1991).

Bacteria mediate the recycling of nutrients and may be important in regulating the flow of energy from seagrass detritus to consumer organisms (Robertson et al. 1982). Studies in the Salt River Submarine Canyon at St. Croix, US Virgin Islands show that *H. decipiens* is an important source of organic matter and detritus for the Canyon (Josselyn et al. 1983; Josselyn et al. 1986; Kenworthy et al. 1989). Despite its production being less than other seagrasses, *H. decipiens* has a fast turnover time and is a major source of primary production on the floor of the Canyon (Kenworthy et al. 1989). Disturbance and burial of plant material are important mechanisms influencing the disposition of organic matter (Williams et al. 1985; Josselyn et al. 1986). Burial of *H. decipiens* through wave action and animal activities increases the rate of detrital input and retains the detritus within the Canyon (Kenworthy et al. 1989).

Seagrasses have long been recognized for their ability to stabilize sediments. It was once assumed, however, that due to its small size and sparse biomass, *Halophila* spp. were not capable of stabilization (den Hartog 1970). Fonseca (1989) proved this assumption incorrect using a surface-supplied, inverted seawater flume. He found the cumulative effect of *H. decipiens* in reducing sediment erosion was significantly greater than adjacent, unvegetated sand.

Abundance and status

Johnson's seagrass has only relatively recently been identified as a distinct species (Eiseman and McMillan 1980) and no historical information on the species' distribution is available. However, since 1994, the St. Johns River Water Management District has monitored 73 permanent transects in the Indian River Lagoon (IRL) in both summer (June-July) and winter (January-February) (Virnstein et al. 1997, Virnstein and Morris 2007). Despite extensive ground-truthing since 1986 and monitoring all 73 transects throughout the IRL beginning in the summer of 1994 (a total of about 25,000 quadrats), *H. johnsonii* has never been found more than 3 km north of the Sebastian Inlet area. Where it does occur, its distribution is patchy, both spatially and temporally.

Halophila jonsonii is a perennial plant with no strong seasonal pattern, although it generally exhibits some winter decline. Monitoring in the IRL indicates that there is spatial and temporal variation in the abundance of *H. johnsonii* patches (Virnstein et al. 1997). Although the monitoring data are limited, no large distributional gaps have been detected in the IRL, and there has been no overall increase or decrease in abundance or geographic range over the period from summer 1994 to summer 1999.

Halophila. johnsonii was listed as threatened under the Endangered Species Act on September 14, 1998 (63 FR 49035). NMFS concluded that Johnson's seagrass is rare, has a limited reproductive capacity, and is vulnerable to a number of anthropogenic and natural disturbances. It also exhibits the most limited geographic distribution of any seagrass. Within its small geographic range (lagoons on the east coast of Florida from Sebastian Inlet to central Biscayne Bay), it is one of the least abundant species. Because of its limited reproductive capacity and energy storage capacity, it is less likely to survive environmental perturbations and to be able to repopulate an area when lost. Finally, environmental degradation and habitat loss have continued despite existing federal and state conservation efforts. Completion of a report reviewing the current status of *H. johnsonii* is anticipated in the fall of 2007.

Critical Habitat

Ten areas in the geographic range of Johnson's seagrass were designated as critical habitat on April 5, 2000 (65 FR 17768). These areas and their approximate acreage include: a portion of the Indian River Lagoon, north of the Sebastian Inlet Channel (5.7); a portion of the Indian River Lagoon, south of the Sebastian Inlet Channel (2.0); a portion of the Indian River Lagoon near the Fort Pierce Inlet (4.3); a portion of the Indian River Lagoon, north of the St. Lucie Inlet (2770); a portion of Hobe Sound (900); a site on the south side of Jupiter Inlet (4.3); a site in central Lake Worth Lagoon (15.0); a site in Lake Worth Lagoon, Boynton Beach (95.5); a site in Lake Wyman, Boca Raton (20.0); and a portion of Biscayne Bay (18,757). This designated area accounts for approximately 22,574 acres or 9,139 hectares.

4.3.6 Marine Invertebrates

(all information below from *Acropora* Status review)

Description

All Atlantic *Acropora* spp. are considered to be environmentally sensitive, requiring relatively clear, well-circulated water (Jaap et al. 1989). Atlantic *Acropora* spp. are almost entirely dependent upon sunlight for nourishment compared to massive, boulder-shaped species in the region (Porter 1976; Lewis 1977), with these latter types of corals more dependent on zooplankton. Thus, Atlantic *Acropora* spp. are much more susceptible to increases in water turbidity than some other coral species. Dredging or pollution activities that reduce long-term water clarity can also reduce the coral photosynthetic to respiration ratio (P/R ratio) below unity. Therefore, *Acropora* spp. may not be able to compensate with an alternate food source, such as zooplankton and suspended particulate matter, like other corals.

Optimal water temperatures for *A. palmata* range from 25 to 29°C, although colonies in the U.S.V.I. have been known to tolerate short-term temperatures around 30°C without obvious bleaching (loss of zooxanthellae). Jaap (1979) and Roberts et al. (1982) note an upper temperature tolerance of 35.8°C for *A. palmata*. All Atlantic acroporids are susceptible to bleaching due to adverse environmental conditions (Ghiold and Smith 1990; Williams and Bunkley-Williams 1990). Major mortality of *A. palmata* and *A. cervicornis* occurred in the Dry Tortugas, Florida, in 1977 due to a winter cold front that depressed surface water temperatures to 14 to 16°C. Some reduction in growth rates of

A. cervicornis was reported in Florida when temperatures dropped to less than 26°C (Shinn 1966). All *Acropora* spp. require near oceanic salinities (34 to 37 ppt).

Staghorn Coral

Historically, *A. cervicornis* (Figure 4.3-5) was reported from depths ranging from <1 to 60 m (Goreau and Goreau 1973). It is believed that 60 m is an extreme situation and that the coral is relatively rare below 20 m depth. The common depth range is currently observed at 5 to 15 m. In southeastern Florida, this species historically occurred on the outer reef platform (16 to 20 m) (Goldberg 1973), on spur and groove bank reefs and transitional reefs (Jaap 1984; Wheaton and Jaap 1988), and on octocoral-dominated hardbottom (Davis 1982). In the Florida Keys *A. cervicornis* can occur from 1 to 34 m depths (Wells 1933; Davis 1982; Jaap 1984; Jaap and Wheaton 1988; Jaap et al. 1989). Colonies may also be common in back- and patch-reef habitats (Gilmore and Hall 1976; Cairns 1982).

Although *A. cervicornis* colonies are sometimes found interspersed among colonies of *A. palmata*, they are generally in more protected, deeper water or seaward of the *A. palmata* zone and hence, protected from waves. Historically, *A. cervicornis* was the primary constructor of mid-depth (10 to 15 m) reef terraces in the western Caribbean, including Jamaica, the Cayman Islands, Belize, and some reefs along the eastern Yucatan peninsula (Adey 1978).

Figure 4.3-5a. Staghorn coral, *Acropora cervicornis* (Source: Walt Jaap).

As depth increases, *A. cervicornis* colonies tend to be less compacted, have longer branches, and branching tends to be at greater intervals. Gladfelter (1982) demonstrated that infilling occurs as the branch elongates. Thus, at the tip, the porosity of the axial calyx is >90% and the wall is 60%, while at 60 cm from the tip, the porosity of the axial calyx is dead and the porosity of the wall is about 20%. This strengthens the branch as it elongates and the momentum of the branch increases. At depths of 20 to 40 m, where currents and wave force are minimal, branch diameter is thinner, being approximately half the diameter of a colony in the shallow surge zone. The porosity of the skeletons of *A. cervicornis* ranges from 35 to 65% by volume, with the mechanical strength of the skeleton proportional to the porosity (Schumacher and Plewka 1981). Because the skeleton is quite porous, it breaks readily in strong wave forces.

Elkhorn Coral
The maximum range in depth reported for *A. palmata* Figure 4.3-5b is <1 m to 30 m, but the optimal depth range for this coral is considered to be 1 to 5 m depth (Goreau and Wells 1967).

Figure 4.3-5b. Elkhorn coral, *Acropora palmata* (Source: W. Jaap).

Currently, the deepest known colonies of *A. palmata* occur at 21 m in the Flower Garden Banks National Marine Sanctuary (Hickerson, pers. comm.) and at Navassa National Wildlife Refuge (Miller, pers. comm.). The preferred habitat of *A. palmata* is the seaward face of a reef (turbulent shallow water), including the reef crest, and shallow spur and groove zone (Shinn 1963; Cairns 1982; Rogers et al. 1982). At low tide, colonies are sometimes exposed. Colonies of *A. palmata* often grow in nearly mono-specific, dense stands and form interlocking framework known as thickets in fringing and barrier reefs (Jaap 1984; Tomascik and Sander 1987; Wheaton and Jaap 1988). Storm-generated fragments are often found occupying back reef areas immediately landward of the reef flat/reef crest, while colonies are rare on lagoonal patch reefs (Dunne 1979). *Acropora palmata* formed extensive barrier-reef structures in Belize (Cairns 1982), the greater and lesser Corn Islands, Nicaragua (Gladfelter 1982; Lighty et al. 1982), and Roatan, Honduras, and built extensive fringing reef structures throughout much of the Caribbean (Adey 1978). Colonies generally do not form a thicket below 5 m depth, with maximum water depths of framework construction ranging from 3 m to 12 m (see Table 1 in Lighty et al. 1982).

Distribution and Abundance

When discussing historic distribution and abundance, it is important to briefly mention the environmental setting of the wider Caribbean region (tropical western Atlantic, Caribbean-

Atlantic province), insofar as environmental differences across the region influence the extent to which *Acropora* spp. have been able to build extensive reef structures. Specifically, although both *A. cervicornis* and *A. palmtata* are found throughout the Caribbean Sea, their historical abundance patterns are not necessarily similar and there is ample evidence to suggest that many reef systems were constructed without significant contributions by acroporids. Early reviews of western Atlantic reefs and coral species, as well as discussions of reef geomorphology in the western Atlantic, are provided elsewhere (e.g., Glynn 1973, Milliman 1973, Adey 1977; 1978), but provide context to the historical patterns of these corals.

The entire Caribbean-Atlantic province is characterized as microtidal and is impacted by largely unidirectional trade winds and waves subject, in part, to strong ocean flows. The most northern reefs in the province (i.e. Florida, northwestern Bahamas, and Bermuda) are cyclically stressed by the occasional effect of polar air during winter months and thus have limited reef development by *Acropora* spp. or lack these species altogether (Bermuda). Throughout the Caribbean, wave energy influences the degree to which crustose coralline algae and *Acropora* spp. dominate as reef-building elements (Adey 1977; Geister 1977). For example, large swells from the Atlantic Ocean limit acroporid reef development in the Windward Islands (eastern Caribbean) and the eastern flanks of the Bahamas (Roberts et al. 1992). In the Lesser Antilles, neither *A. cervicornis* nor *A. palmata* are significant agents of reef framework construction, due principally to higher wind strength, easterly consistencies, and longer fetch; this area is also subjected to longperiod swells or rollers during the winter months that further limits shallow and middepth reef construction (Adey 1977). In the southwestern Caribbean (e.g., Panama), reef terraces are present that are potentially conducive to acroporid-reef development, but seasonally rough seas batter the area resulting in wave-swept pavements (Glynn 1973).

In contrast, the northwestern Caribbean (e.g. Cuba, Cayman Islands, Jamaica, eastern Yucatan, Belize) is characterized by relatively low winds of medium to high easterly consistencies, that allows extensive acroporid growth at shallow and mid-depth (10 to 25 m). For example, the Belize Barrier Reef, the largest barrier reef in the province, appears to be based upon an *A. cervicornis* framework (Adey 1977).

The current range for both *A. cervicornis* and *A. palmata* remains unchanged from the historical (Figure 4.3-6) as far as data are available; there is a paucity of quantitative data for many locations throughout the wider Caribbean. Historically most data collected has been from a few specific reef sites that may or may not represent the regional condition of the acroporids or coral reefs in general. In contrast, there are many qualitative data/observations indicating drastic declines in abundance of both *A. palmata* and *A. cervicornis* throughout their geographic range (e.g., Aronson and Precht 2001a).

Figure 4.3-6. Approximate range of *Acropora* spp. (highlighted), including the Gulf of Mexico, Atlantic Ocean and Caribbean Sea. The highlighted areas are not specific locations of the corals, rather reflect general distribution.

Recently, there have been two publications that have summarized status (abundance and distribution) of *A. cervicornis* and *A. palmata*. The Status of Coral Reefs in the western Atlantic: Results of initial Surveys, Atlantic and Gulf Rapid Reef Assessment (AGRRA) Program (Lang 2003) provides results (1997–2004) of a regional systematic survey of corals, including *Acropora* spp., from many locations throughout the Caribbean. While data from this survey represent a snapshot in time of the reef, the geographic scope of the survey is great; targeted areas are visited by data collectors of varying expertise, and data represent a single survey. AGRRA data (1997-2004) indicate that the historic range of both species remains intact, that *A. cervicornis* is rarely found throughout the range (including areas of previously known occurrence) and a moderate occurrence of *A. palmata*.

An AGRRA bio-area index for *A. palmata* was recently developed to summarize data for nearly 300 sites throughout the wider Caribbean (Garza-Perez and Ginsburg pers. comm.). This bio-area index utilizes maximum diameter and partial mortality values of *A. palmata* colonies per site (total area of living tissue/10 transects) and is presented in Figures 4.3-7a and 4.3-7b. Results from the spatial analysis are as follows:

1. most (n=61) bio-areas (Figure 4.3-7a) ranked as moderate to high (100 to 500 m^2/10 transects) are concentrated in Andros Barrier Reef (Bahamas) and the northern Caribbean (Cuba and Belize);
2. 195 sites (Figure 4.3-7b) distributed throughout the geographic area were ranked as low bio-areas (from 0.01 to 100 m^2/10 transects)

3. standing dead colonies of *A. palmata* were found throughout the geographic range (Figure 4.3-7b).

It is important to note that the data for the Andros Barrier Reef AGRRA surveys were conducted prior to the Caribbean-wide 1998 coral die-off and the site has not been resurveyed since 1997. Furthermore, status of *A. palmata* has not been updated following the 2004 hurricane season where Hurricanes Charley passed over Cuba, and Hurricanes Frances and Jeanne passed over the Bahamas.

Prior to the AGRRA summary, Bruckner (2002) provided a comprehensive summary of the best-known quantitative and qualitative data on the status of the Atlantic acroporids resulting from a NOAA-sponsored workshop wherein participants compiled data and summarized conditions throughout the range. Much of the data from the Bruckner (2002) report are summarized below, and some are updated and included in the case studies at the end of this section.

Abundance and distribution (historic and current) of *Acropora cervicornis*

Historically, *A. cervicornis* so dominated the reef within the 7 to 15 m depth that the area became known as the staghorn zone (Figure 4.3-8) throughout much of the Caribbean. In many other reef systems in the wider Caribbean, most notably the western Caribbean areas of Jamaica, Cayman Islands, Belize and eastern Yucatan (Adey 1977), *A. cervicornis* was a major mid-depth (10 to 25 m) reef-builder. Principally due to wind conditions and rough seas, *A. cervicornis* has not been known to build extensive reef structures in the Lesser Antilles and southwestern Caribbean.

Acropora cervicornis has also been documented in deeper water (16 to 30 m) (Goldberg 1973) and as far north as Palm Beach, Florida (26° 3'N). It is also distributed further south and west throughout the coral and hardbottom habitats of the Florida Keys (Antonius et al. 1978; Burns 1985; Dustan 1988; Dustan and Halas 1987; Glynn et al. 1989; Jaap 1984; Jaap and Wheaton 1975; Jaap et al. 1988; Wheaton and Jaap 1988), and Dry Tortugas (Vaughan 1915; Davis 1982; Dustan 1985, 1988; Jaap et al. 1989). In Biscayne National Park (upper Florida Keys), *A. cervicornis* was more abundant on reefs further from tidal passes (e.g., Ajax and Long Reefs) than those nearby, with historical coverage ranging from 0.1% to 2.7% in the 1980s (Burns 1985).

Because Florida is one of the few areas where multi-year quantitative data are available for *A. cervicornis* at more than a single location (Carysfort Reef; Dustan and Halas 1987, Looe Key Reef; Wheaton and Jaap 1988, Dry Tortugas; Davis 1982 and Porter et al. 1982) (Figure 4.3-9), those data are further analyzed and presented as a case study in section 4.5.3 of the *Acropora* Status Review document.

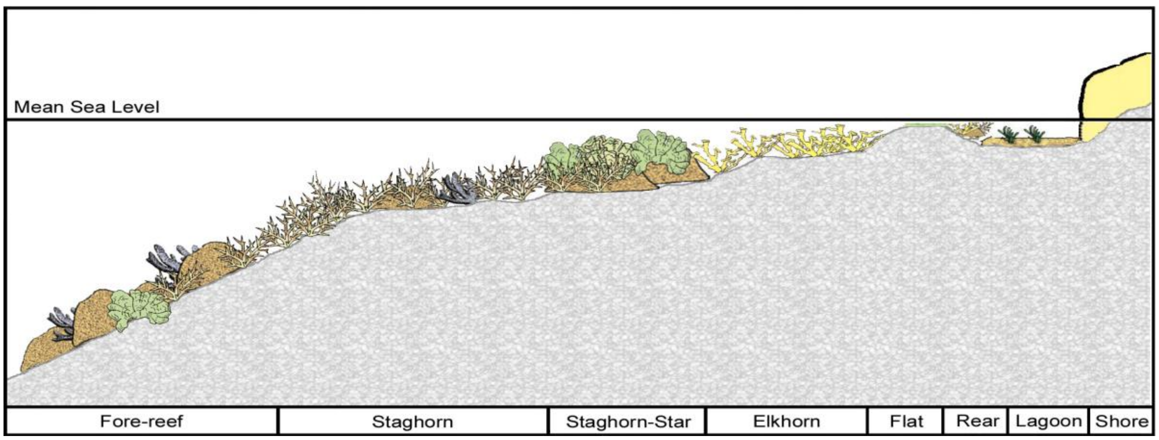

Figure 4.3-8. Reef zonation schematic example modified from several reef zonation-descriptive studies (Goreau 1959; Kinzie 1973; Bak 1977).

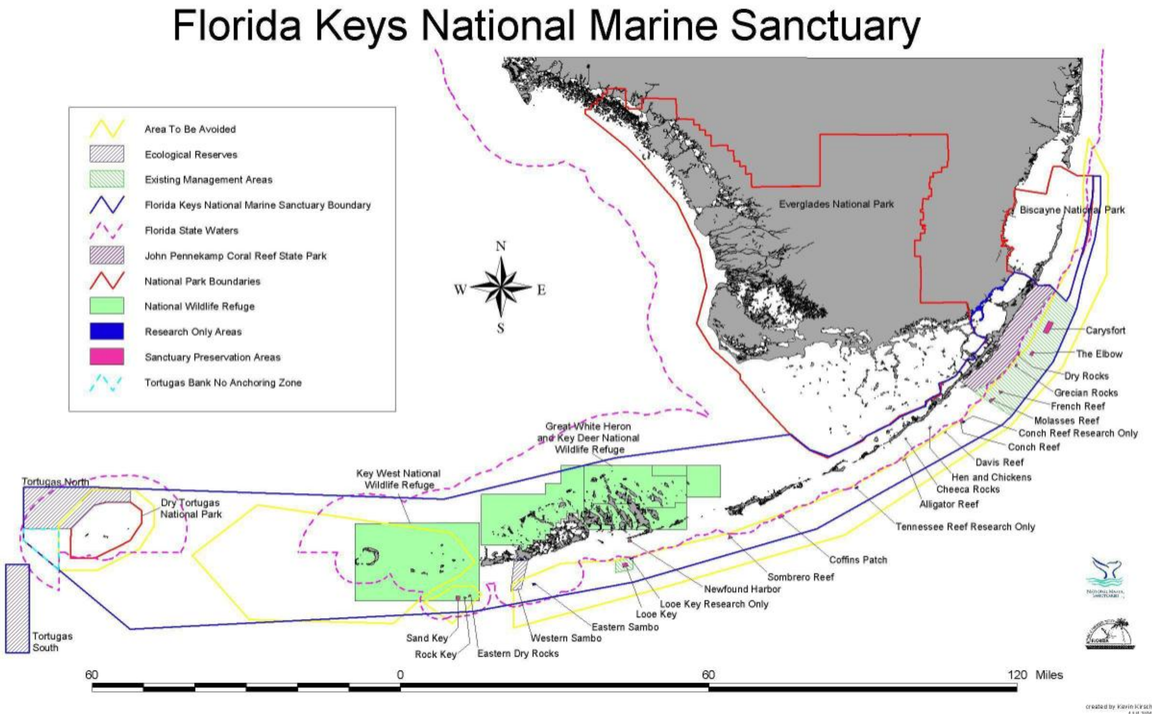

Figure 4.3-9. Map of the Florida Keys National Marine Sanctuary and reefs of the Florida Keys.

<u>Historical and current distribution and abundance of *Acropora palmata*</u>

Throughout much of the Caribbean, *A. palmata* historically occupied the 1 to 8 m depth range (reef flat, wave zone, reef crest) known as the 'elkhorn zone' (Figure 4.3-8). *Acropora palmata* occupied this zone in Jamaica (Goreau 1959), Alacran Reef, Yucatan peninsula (Kornicker and Boyd 1962), Abaco Island, Bahamas (Storr 1964), the southwestern Gulf of Mexico, Bonaire (Scatterday 1974), and the Florida Keys (Jaap 1984; Dustan and Halas 1987).

The predominance of *A. palmata* in shallow reef zones is related to the degree of wave energy. In areas with strong wave energy conditions only isolated colonies may occur, while thickets may develop in areas of intermediate wave energy (Geister 1977). Although considered a turbulent water species, *A. palmata* is sensitive to breakage by wave action, and is often replaced by coralline algae in heavy surf zones throughout the province (Adey 1977).

While *A. cervicornis* has been documented further north along the Florida east coast, the northern extension of *A. palmata* is at Fowey Rocks offshore the Miami area (25° 37' N) (Porter 1987). This area technically begins the Florida Reef Tract where all of the major reef-building corals appear in shallow water in the southeastern U.S. (Burns 1985).

Surveys in the early 1970s north of Miami (e.g., Palm Beach) did not note the occurrence of *A. palmata* (Goldberg 1973). Between Fowey Rocks and Carysfort Reef, *A. palmata* has been historically rare as the significant reef development or framework construction by *A. palmata* begins further south at Carysfort Reef (25° 20'N), extending discontinuously southwestward to the Dry Tortugas (Jaap 1984). Notably, recent surveys have reported a few colonies of *A.*

palmata off Pompano Beach, Broward County, FL (Figure 4.3-10). The status of these few northern-most colonies presently is unknown.

Figure 4.3-10. *Acropora palmata* off of Pompano Beach, Broward County, Florida, in 2003; (Photo credit: J. Sprung).

Distribution records of *A. palmata* for the southeast Florida coast include: upper Florida Keys (Burns 1985; Dustan 1985, 1988; Dustan and Halas 1987; Jaap et al. 1988), lower Florida Keys (Jaap and Wheaton 1975; Antonius et al. 1978; Jaap 1979; Wheaton and Jaap 1988), and Dry Tortugas (Davis 1982; Jaap et al. 1989). Offshore reefs built primarily by *A. palmata* are situated along the outer margin of an arc-shaped limestone plateau (south Florida shelf). "Flourishing" *A. palmata* reefs (i.e., those with a shallow or emergent reef flat) are limited to the northern seaward half of Key Largo where an *Acropora* zone (reef flat/reef crest) was present. At Molasses Reef (see Figure 4.3-9) living *A. palmata* was almost absent in 1959-60 (Shinn 1963) and it was later suggested that conditions necessary for the growth of this coral changed since the coralline spurs were originally accreted (Shinn et al. 1981).

Numerous other studies describing *A. palmata* abundance and distribution in the Florida Keys are available. When possible, data (e.g., Chiappone and Sullivan 1997) were further analyzed and presented as a case study in section 4.5.3 of the *Acropora* Status Review document. Other data from short-term projects throughout the Florida Keys are summarized below:

- From 1984 to 1991, a decline in *A. palmata* abundance at shallow depths (4 to 6 m) but not deeper were noted in coral communities on six reefs (including sites in both the upper Keys and lower Keys) (Porter and Meier 1992). These changes were attributed to disease and the demise of the long-spined sea urchin (*Diadema antillarum*).
- Living and dead assemblages of corals on two offshore sites and two patch reefs were compared and significant differences in taxonomic composition between live and dead

coral assemblages were found between reef types (Greenstein and Pandolfi 1997). While both the patch and offshore reefs historically had more *A. cervicornis* and *A. palmata*, they were now dominated by other corals (*Porites astreoides* and *Siderastrea siderea*). Interestingly, massive growth forms were under-represented in the dead assemblage, while branching growth forms (*Acropora* spp.) were underrepresented in the live coral assemblage.

Reproduction

The distribution and abundance of Atlantic *Acropora* spp., like other coral species, reflects patterns of larval recruitment, asexual reproduction via fragmentation, mortality, regenerative capabilities, and aggressive interactions (Richmond and Hunter 1990). Interspecific differences in the mechanisms of recruitment, dispersal, and mortality are likely important in determining the species composition of reef corals in different environments. These differences reflect the differential allocation of energy to the basic life history functions of growth (rate and rigidity of the skeleton), reproduction (fecundity, mode of larval dispersal, recruitment success), and colony maintenance (intra- and interspecific interactions, competitive ability, regeneration) (Connell 1973; Lang 1973; Bak and Engel 1979; Szmant 1986). Populations of Atlantic *Acropora* spp. are dependent upon sexual recruits for recovery after catastrophic disturbance, but can locally dominate hardbottom and coral reef habitats when colonies fragment and propagate across the bottom.

Extensive research has been conducted on the diverse reproductive strategies employed by scleractinian corals (Fadlallah 1983; Szmant 1986; Richmond and Hunter 1990). Atlantic *Acropora* spp., like many stony coral species, employ both sexual and asexual reproductive propagation. Sexual reproduction in corals includes gametogenesis (i.e., development of gametes) within the polyps near the base of the mesenteries. Some coral species have separate sexes, while others such as the Atlantic *Acropora* spp., are hermaphroditic. *Acropora cervicornis* and *A. palmata* in particular do not differ substantially in their sexual reproductive biology. Both species are spawners, meaning that coral larvae develop externally to the parental colonies (Szmant 1986) and both species are simultaneous hermaphrodites, meaning that a given colony will contain both female and male reproductive parts during the spawning season. Gametes (eggs and sperm) are located in different mesenteries of the same polyp (Soong 1991). The development period is longer for eggs than sperm, lasting approximately 10 months (Szmant 1986).

The spawning season for *A. cervicornis* and *A. palmata* is relatively short; with gametes released only a few nights during July, August, and/or September. In some populations, spawning is synchronous after the full moon during any of these three months. Annual egg production in *A. cervicornis* and *A. palmata* populations studied in Puerto Rico was estimated to be 600 to 800 eggs per cm^2 of living coral tissue (Szmant 1986). Eggs from both corals are ~300 µm in diameter. Colonies of *A. cervicornis* studied on the Caribbean coast of Panama during 1987-88 produced eggs 0.3 to 1.0 mm in length along the long axis that were elliptical in shape (Soong 1991). Spermaries were present during July and August and not during other times of the year. In the same study, *A. palmata* eggs were 0.2 to 1.0 mm in length along the long axis and shaped as irregular ellipses.

Spermaries were present during July, August, and September. In a subsequent study, Soong and Lang (1992) observed that large axial polyps and basal tissues (1.0 to 4.5 cm from the colony base) in *A. cervicornis* were infertile, whereas gonads located within 2 to 6 cm of the branch tips always had smaller eggs than those in the mid-region of the branches. In *A. palmata*, small eggs were found in the whole colony, while infertile areas were observed in the encrusting base and along the growing edges of branches (Soong and Lang 1992). Upper surfaces of *A. palmata* colonies had significantly greater fecundity (more fertile polyps per unit surface area) and larger numbers of eggs within fertile polyps.

Colonies of *A. cervicornis* and *A. palmata* studied on the Caribbean coast of Panama indicated that larger colonies of both species (as measured by surface area of the live colony) have higher fertility rates (Soong and Lang 1992). For *A. palmata*, no colonies with a surface area between 4 and 15 cm^2 (n=4) or between 15 to 60 cm^2 (n=9) were fertile, while 7% of those 60 to 250 cm^2 in tissue surface area were fertile (n=14). Over 30% of the colonies between 250 and 1000 cm^2 in tissue surface area were fertile (n=16), 43% of colonies between 1000 and 4000 cm^2 (n=7), and 88% of colonies larger than 4000 cm^2 (n=33). In the same study, only colonies of *A. cervicornis* with a branch length larger than 9 cm were fertile, with 38% fertility for those 9 to 13 cm in branch length (n=13), 59% for 13 to 17 cm (n=17), and 89% for colonies with branches longer than 17 cm (n=18). Estimated size at puberty for *A. palmata* was 1600 cm^2 (n=84 colonies sampled) and for *A. cervicornis* was 17 cm in branch length (n=52 colonies sampled). The smallest reproductive colony of *A. palmata* was 16 x 8 cm^2 and for *A. cervicornis* was 9 cm in branch length (Soong and Lang 1992).

In corals, fertilization can occur internally or externally, but in Atlantic *Acropora* spp., fertilization and development are exclusively external. Embryonic development culminates with the development of planktonic larvae called planulae. Little is known concerning the settlement patterns of planula larvae of Atlantic *Acropora* spp. (Bak et al. 1977 ; Sammarco 1980 ; Rylaarsdam 1983). In general, upon proper stimulation, coral larvae, whether released from parental colonies or developed in the water column external to the parental colonies, settle and metamorphose on appropriate substrates. Unlike most other coral larvae, *A. palmata* planulae appear to prefer to settle on upper, exposed surfaces, rather than in dark or cryptic ones (Szmant and Miller, accepted), at least in a laboratory setting. Initial calcification ensues with the forming of the basal plate and the initial protosepta, followed by the theca or polyp wall and axial skeletal members. Buds that form on the initial corallite develop into daughter corallites. Both externally and internally produced coral planula larvae presumably experience considerable mortality (up to 90% or more) from predation or other factors prior to settlement and metamorphosis (Goreau et al. 1981). Once larvae are able to settle onto appropriate hard substrates, metabolic energy is diverted to colony growth and maintenance. Because newly settled corals barely protrude above the substrate, juveniles need to reach a certain size to reduce damage or mortality from impacts such as grazing, sediment burial, and algal overgrowth (Bak and Elgershuizen 1976; Birkeland 1977; Sammarco 1985). Recent studies examining early survivorship of lab cultured *A. palmata* settled onto experimental limestone plates and placed in the field indicate that survivorship is substantially higher than for *Montastraea faveolata*, another spawner, and similar to brooding species over the first nine months after settlement (Szmant and Miller, accepted).

This pattern corresponds to the size of planulae; *A. palmata* eggs and larvae are much larger than those of *Montastraea* spp. Overall, older recruits (i.e., after they have survived to a size they are visible to the human eye, probably 1 to 2 yrs after settlement (Figure 4.3-11) appear to have similar growth and post-settlement mortality rates across species (Van Moorsel 1988).

Figure 4.3-11. *Acropora palmata* sexual recruit, St. John, U.S.V.I. Photo credit: C. Rogers.

Spatial and temporal patterns of coral recruitment have been intensively studied on Caribbean reefs (Birkeland 1977; Bak and Engel 1979; Rogers et al. 1984; Baggett and Bright 1985; Chiappone and Sullivan 1996). Biological and physical factors that have been shown to affect spatial and temporal patterns of coral recruitment include substrate availability and community structure (Birkeland 1977), grazing pressure (Rogers et al. 1984; Sammarco 1985), fecundity, mode and timing of reproduction (Harriot 1985; Richmond and Hunter 1990), behavior of larvae (Lewis 1974; Goreau et al. 1981), hurricane disturbance (Hughes and Jackson 1985), physical oceanography (Baggett and Bright 1985; Fisk and Harriot 1990), the structure of established coral assemblages (Lewis 1974; Harriot 1985), and chemical cues (Morse et al. 1988).

Relatively few studies, however, have examined variation in Caribbean coral recruitment over larger spatial scales (10 to 100 km) or among different structural types of reefs (Wallace and Bull 1981; Harriot and Fisk 1987; Fisk and Harriot 1990). Many studies of Caribbean reefs have used the quantification of juvenile coral densities as a proxy to measure recruitment success, with juvenile corals defined as metamorphosed corals visible underwater to the unaided eye ranging up to 4 cm in maximum diameter (Bak and Engel 1979). Newly settled corals are visible in the field at approximately 5 to 10 mm in diameter, and colonies approaching 4 cm in diameter are approximately 1 to 3 years old (Van Moorsel 1988).

Studies of *Acropora* spp. from across the Caribbean confirm two overall patterns of sexual recruitment: (1) Low juvenile densities relative to other coral species and (2) low juvenile densities relative to the commonness of adults (Porter 1987). This pattern suggests that the composition of the adult population is dependent upon variable recruitment. It also likely reflects the dominance of asexual reproduction by fragmentation for these species (for example, surviving fragments are usually larger than 4 cm and thus never undergo a "juvenile" stage by this definition). In both Curaçao and Bonaire in the 1970s, densities of juvenile *A. palmata* reached 0.13 per m^2, while no *A. cervicornis* juveniles were found (Bak and Engel 1979). On the north coast of Jamaica, juvenile *A. cervicornis* densities were as high as 4.3 per m^2 at 11 m depth on barren substrate (Rylaarsdam 1983). However, phototransects revealed no *Acropora* spp. recruitment in 1976 or 1980 at <20 m depth, with smaller colonies presumably originated from the larger colonies via fragmentation (Porter et al. 1981). In Salt River, St. Croix, *A. palmata* juveniles occurred at densities of 0.1 to 0.3 per m^2 at 3 to 9 m depth, while densities of juvenile *A. cervicornis* ranged from 0.01 to 0.30 per m^2 at 9 m depth (Rogers et al. 1984). Similar results were obtained in the Florida Keys (Dustan 1977; Porter and Meier 1992; Chiappone and Sullivan 1996). Surveys of nine sites representing three different offshore reef types from 3 to 15 m depth yielded no juveniles of *Acropora* spp. from 450, 1-m^2 quadrats (Chiappone and Sullivan 1996). To date, however, the settlement rates (number of larvae settling per unit area) of Atlantic *Acropora* spp. have still not been quantified; the juvenile density measurements cited above represent larvae that have not only settled, but metamorphosed (i.e., excreted a calcium carbonate skeleton) and survived to a specific size visible to surveyors underwater. Anecdotal evidence and observations in the Caribbean indicate that both *A. cervicornis* and *A. palmata* sexually recruit onto reefs, and in several instances, populations that have experienced major declines (>90%) are showing signs of recovery in terms of newly settled sexual recruits (Bruckner 2002).

Besides sexual reproduction, most coral species, including Atlantic acroporids, also reproduce asexually. Asexual reproduction involves fragmentation, wherein colony pieces or fragments are dislodged from larger colonies to form new colonies (Highsmith 1982). The budding of new polyps within a colony can also be considered asexual reproduction. Fragmentation can occur during storms (Porter et al. 1981; Tunnicliffe 1981; Highsmith 1982), with susceptibility to mechanical breakage of colony branches influenced by the boring activities of sponges and lithophagus bivalves. Fragmentation is a common means of propagation in many species of branching corals and historically has been considered to be the most common means of forming new colonies in Atlantic *Acropora* spp. (Gilmore and Hall 1976; Davis 1977; Tunnicliffe 1981; Bak and Criens 1982; Hughes 1985). The perception of the dominance of fragmentation as a reproductive mode for *A. palmata* and *A. cervicornis* implies that colonies derived from fragmentation can be distinguished from those derived from larvae. However, this may not always be the case. Recently developed genetic tools can detect colonies with the same genotype (implying one was fragmented from the other). Application of these tools in the field to a population of *A. palmata* (where individual small colonies were scored by field experts as larval or asexual recruits) indicated very poor correlation (Miller et al. in review). It appears that the reliability of assessing the contribution of sexual versus asexual reproduction in *Acropora* populations by field survey is limited, but is an area of study that warrants further investigation.

Asexual reproduction can play a major role in maintaining local populations when sexual recruitment is very limited. Fragmentation, followed by stabilization, survivorship, and growth can provide a mechanism for maintaining and expanding Atlantic *Acropora* spp. populations.

However, region-wide declines have increased the reliance of *Acropora* spp. on sexual recruitment as a means of establishing and sustaining populations (Bruckner 2002). Atlantic *Acropora* spp. may require a certain storm frequency to maintain and expand populations through asexual reproduction, principally by fragmentation, when sexual recruitment is limited (Bruckner 2002). Frequent occurrence of storms or a single intense storm, however, may negatively impact colony survival, since a fragment may become abraded during the storm or may not encounter suitable substrate to reattach after the storm passes.

Development and growth

Staghorn Coral

The growth rate for *A. cervicornis* has been reported to range from 3 to 11.5 cm/yr (Table 4.3-6). This growth rate is relatively fast in comparison to that of other corals and historically enabled the species to construct significant bioherms (reef structures) in several locations throughout the Caribbean (Adey 1978).

Table 4.3-6. The annual growth rate for *Acropora cervicornis* as reported from several sources.

Growth rate (cm/yr)	Location	Record
4	Dry Tortugas	Vaughan (1915)
10.9	Key Largo, Florida	Shinn (1966)
11.5	Eastern Sambo, Florida	Jaap (1974)
10	Key Largo, Florida	Shinn (1976)
7.1	U.S. Virgin Islands	Gladfelter et al. (1978)
3 to 4	Exuma, Bahamas	Becker and Muller (2001)

Gladfelter (1982, 1983a) used a scanning electron microscope to describe the growth process in *A. cervicornis*. She reported that crystals are initially deposited randomly on the distal margin of the axial corallite. Subsequently, needle-like crystals attach and grow outward from the surface of the crystals. The needle-like crystals in contact with the calicoblastic epithelial cells grow and fuse together generating the skeletal foundation or septotheca. During daylight, calcium carbonate accretion occurs on all of the skeletal elements; at night the activity is limited to fusiform crystal formation. Gladfelter (1983b) reported daily tissue growth of 300 μm in the region of the axial polyp. "*A. cervicornis* exhibits a daily rhythm in calcification capacity, with daily maxima at sunrise and sunset. Daily minima occur shortly after sunrise and sunset" (Chalker 1977; Chalker and Taylor 1978; Gladfelter 1983b). Contrasting growth of in situ and laboratory-reared specimens revealed differences in the basal extension; however, other measurements (e.g., $CaCO_3$ accretion and vertical extension) were equivalent (Becker and Mueller 2001).

Growth in *A. cervicornis* is also expressed in expansion, occurring as a result of fragmenting and forming new centers of growth (Bak and Criens 1982; Tunnicliffe 1981). A broken off branch may be carried by waves and currents to a distant location or may land in close proximity to the original colony. If the location is favorable, branches grow into a new colony, expanding and occupying additional area. Fragmenting and expansion, coupled with a relatively fast growth rate, facilitates potential spatial competitive superiority for *A. cervicornis* relative to other corals and other benthic organisms (Shinn 1976; Neigel and Advise 1983; Jaap et al. 1989). Fragments that contained the axial corallite were found to have lower mortality than fragments that came from the inner portions of a colony and did not have axial corallites (Bowden-Kerby 2001a). There was up to a six-fold difference in growth rate over 12 months based on the fragment's origin (Bowden-Kerby 2001b).

Elkhorn Coral
The growth rate of *A. palmata*, expressed as the linear extension of branches, is reported to range from 4 to 11 cm annually (Table 4.3-7) (Vaughan 1915, Jaap 1974). The 4-cm annual growth rate cited by Vaughan (1915) undoubtedly underestimates growth. Annual linear extension was estimated to be 8.8 cm; basal extension was 2.3 mm/month, and tissue growth was 200 cm^2 per month at Quintana Roo, Puerto Morelos, Mexico (Padilla and Lara 1996). A colony two meters in height could theoretically be 20 to 29 years old based on a 7- to 10-cm annual growth rate. The theoretical age of a much larger colony(4 m) is 40 to 57 years old. Linear extension and tissue growth were dependent on the size of the colony; however, basal extension was independent of colony size (Padilla and Lara 1996). Colonies of *A. palmata* in the field had a greater calcification rate and rate of extension relative to specimens grown in an experimental tank (Becker and Mueller 2001). Wells (1933) reported from observations in 1932 that colonies of *A. palmata* were eight feet high (2.4 m) and 15 feet (4.5 m) in diameter at Bird Key Reef, Dry Tortugas; this is probably the maximum size that this species can attain.

Settled larvae typically create a small crust or patch with tubular corallites oriented at approximately 90 degrees from the plane of attachment. One or more protuberances develop and grow outward to form proto-branches.

Table 4.3-7. *Acropora palmata* growth rates reported from several sources.

Growth rate (cm/yr)	Location	Record
4	Dry Tortugas, Florida	Vaughan (1915)
10	Florida Keys	Jaap (1974)
4.7 to 9.9	U.S. Virgin Islands	Gladfelter, et al. (1978)
5.2	Colombia	Garcia et al. (1996)
2 to 11	Exuma, Bahamas	Becker and Mueller (2001)

The range of growth forms in *A. palmata* includes the iconic broad frond, with symmetrical colonies that are two or more meters across. Branches are up to 50 cm across and range in thickness from 4 to 5 cm, tapering toward the branch terminal; these colonies are most typical of the spur and groove formations where water circulation is omni-directional. In areas where wind and waves are predominantly from a single direction, the branches tend to grow in to the direction of the waves. The series of branches look like a medieval fortification (palisade); this growth form is typical of the barrier reef habitat. As depth increases, the branches are oriented in a more vertical orientation (Wainwright 1976; Graus et al. 1977). This compensates for hydraulic bending forces, but the thickening of the base also helps to counteract the hydrodynamic forces (Schumacher and Plewka 1981). *Acropora palmata* porosity ranges from approximately 35 to 45% by volume (Schumacher and Plewka 1981).

Acropora palmata can rapidly monopolize large areas by fragment propagation. A branch of *A. palmata* may be carried by waves and currents away from the mother colony to distances that range from 0.1 to 100 m, but usually less than 30 m (Baums et al., unpublished data). Fragments cleaved from the colony may grow into new colonies (Highsmith et al. 1980; Bak and Criens 1982; Highsmith 1982; Rogers et al. 1982).

Fragmentation during storm events is a significant means of generating new colonies, as documented during several storms: Hurricanes Hattie (Stoddart 1962, 1969), Edith (Glynn et al. 1964), Gerta (Highsmith et al. 1980), Allen (Woodley et al. 1981), David and Frederic (Rogers et al. 1982), Hugo (Bythell et al. 1991), Joan (Geister 1992, Zea et al. 1998), Gilbert (Kobluk and Lysenko 1992; Jordan-Dahlgren and Rodriguez-Martinez 1998), Andrew (Lirman and Fong 1996, 1997, Jaap pers. observ.), Georges and Charley (2004) (Jaap pers. observ.), as well as after Storms Bret (Van Veghel and Hoetjes 1995) and Gordon (Lirman and Fong 1997). Lirman and Fong (1997) reported that *A. palmata* fragment wounds healed rapidly (1.59 cm of linear growth/month). Nine months after Tropical Storm Gordon, 157 of 218 fragments had fused to the sea floor, and protobranches on the fragments grew rapidly.

Population dynamics

Atlantic *Acropora* spp. are generally considered intermediate along the continuum from r-selected (rapid colonizers, fast growth, early maturation, but small maximum size and thus limited contribution to reef growth; generally brooding corals) to k-selected (slow growing, generally spawning, but attaining large colony size via indeterminate growth) life history strategies. *Acropora palmata* and *A. cervicornis* tend to be fast growing, have rapid wound healing, high rates of survival of asexually produced fragments, and the ability of broken branches to grow into new colonies (Gladfelter et al. 1978; Bak and Criens 1982; Highsmith 1982). Their level of aggression (i.e., ability to extend their mesenterial digestive filaments onto neighboring species and digest away living tissue) is relatively low compared to many other Caribbean corals (Lang 1973). However, Atlantic *Acropora* spp. have superior overgrowth capabilities. These life history characteristics, supported by documentation of recent trends in populations across the Caribbean, illustrate that once *Acropora* spp. experience local (reef-scale) reductions in colony numbers and size, recovery may not occur for decades.

There are several implications of the current low population sizes of *Acropora* spp. throughout much of the Caribbean. First, the number of sexual recruits to a population will be most influenced by larval availability, recruitment, and early juvenile mortality. Because corals cannot move and are dependent upon external fertilization in order to produce larvae, fertilization success declines greatly as adult density declines; this is termed an Allee effect (Levitan 1991). To compound the impact, *Acropora* spp., although hermaphroditic, do not effectively self-fertilize; gametes must be outcrossed with a different genotype to form viable offspring. Thus, in populations where fragmentation is prevalent, the effective density (of genetically distinct

adults) will be even lower than colony density. It is highly likely that this type of recruitment limitation
(Allee effect) is occurring in some local *A. palmata* and *A. cervicornis* populations, given their state of drastically reduced abundance/density. Simultaneously, when adult abundances of *A. palmata* and *A. cervicornis* are reduced, the source for fragments (to provide for asexual recruitment) is also compromised. These conditions imply that once a threshold level of population decline has been reached (i.e., a density where fertilization success becomes negligible) the chances for recovery are low.

Population Genetics
Understanding the population structure of *A. cervicornis* and *A. palmata* is complicated by the fact that both corals undergo both sexual and asexual (clonal) reproduction (see Reproduction section above) and the relative contribution of each is not readily discernable in the field (Miller et al. in review). Two aspects of population structure are of critical importance in assessing extinction risk in widespread clonal species: (1) The degree of genotypic diversity (within populations and overall); and (2) the degree of genetic exchange between populations. The levels of genotypic diversity in *A. palmata* and *A. cervicornis* are of particular concern given their presumed dominant asexual reproductive mode (Highsmith 1982) and rapid range-wide decline (see Description and Distribution section above). That is, while quantitative field surveys may provide abundance estimates based on number of colonies or percent cover, it is conceivable that the genotypic diversity in either species might be drastically lower. The degree of genetic connectivity among populations is important in understanding the potential adaptation of local populations to specific environmental conditions and the potential for re-colonization from neighboring or distant reefs in areas of extirpation.

Immunological self-recognition (fusion versus rejection response when two individuals are placed in contact) was used in an early study to investigate clonal structure in *A. cervicornis* (Neigel and Avise 1983). This approach indicated that ramets of individual genets occurred at up to 20 m distance and individual genets occupied up to 10 m^2 in Jamaica and St. Croix, U.S.V.I. (Neigel and Avise 1983). However, there has been subsequent questioning of the genetic basis of the self-recognition response, as electrophoretically distinct individuals have been shown to fuse (e.g., Heyward and Stoddart 1985). Molecular genetic analysis seems to be necessary to reliably evaluate clonal structure.

Common molecular approaches to study genetic population structure such as mitochondrial DNA markers have yielded low levels of intraspecific variation in anthozoans in general and corals in particular and, hence, are of limited use in coral population genetic studies (Shearer et al. 2002). The presence of intracellular symbionts in coral tissue greatly complicates the application of highly polymorphic, anonymous DNA markers since it is difficult to distinguish between coral and symbiont DNA.

Previous efforts at developing coral-specific microsatellite markers for *Acropora* spp. also met with little success (Marquez et al. 2000). Nonetheless, molecular genetic tools have recently become available to address questions of population genetic structure and gene flow in *A. cervicornis* (Vollmer and Palumbi in prep) and *A. palmata* (Baums et al. in press a). These tools are summarized below, based upon manuscripts in development or under scientific review.

A recent study examined genetic exchange and clonal population structure in *A. palmata* by sampling and genotyping colonies from eleven locations throughout its geographic range using microsatellite markers (Baums et al. in press a). Results (Baums et al. in press b) indicate that populations in the eastern Caribbean (St. Vincent and the Grenadines, U.S.V.I., Curaçao, and Bonaire) have experienced little or no genetic exchange with populations in the western Caribbean (Bahamas, Florida, Mexico,Panama, Navassa, and Mona Island). Puerto Rico is an area of mixing where populations show genetic contribution from both regions, though it is more closely connected with the western Caribbean. Within these regions, the degree of larval exchange appears to be asymmetrical with some locations being entirely self-recruiting and some receiving immigrants from other locations within their region (Baums et al. in press b).

The clonal structure of individual *A. palmata* populations was found to be highly variable, ranging from completely sexual where each colony represents a different genet to completely asexual, where all colonies comprise a single genet (Baums et al. in prep). The overall range-wide average, expressed as Ng/N (the number of genotypes found divided by the total number of colonies sampled) was about 0.5. Interestingly, clonal structure appeared to vary between the eastern and western Caribbean, with eastern populations being denser and more genotypically diverse (i.e., greater contribution by sexual recruitment) than western populations (Baums et al. in prep). In fact, four out of five populations sampled in the Florida Keys were monoclonal, indicating they were derived from fragmentation of a single larval recruit (Baums et al. in press (a) and unpublished data). This lack of genotypic diversity in several *A. palmata* populations implies that sexual reproduction may be completely lost and is thus a basis for concern for the long-term persistence of this species. Measures of genetic diversity such as heterozygosity are unknown for either species and are not likely to be revealed from the current genetic approaches.

Vollmer and Palumbi (in prep.) used DNA sequences of specific nuclear and mitochondrial genes, to analyze connectivity of *A. cervicornis* populations on a Caribbean-wide scale. Their results indicate a much finer scale of geographic differentiation (i.e., less connectivity across large areas) than the microsatellite results for *A. palmata* (Baums et al. in press b). They report that larval exchange between *A. cervicornis* populations as close as 2 to 15 km is extremely limited, implying that larval sources need to be conserved on a very small spatial scale. Little is known regarding clonal structure of *A. cervicornis* populations throughout their geographic range, although Vollmer and Palumbi (in prep.) indicate that approximately 60% of the colonies they sampled (purposely sampling colonies distant from each other) from areas throughout the Caribbean represented distinct genotypes. As in *A. palmata*, populations of *A. cervicornis* in southeast Florida (Broward County, probably the most abundant extant stands anywhere) appear to have low genotypic diversity as each of the large thickets sampled to date is monoclonal (Baums and Vargas unpubl. data).

Ecological relationships

Coral reefs serve a number of functional roles in subtropical and tropical environments of the Caribbean, including, but not limited to primary production, recycling of nutrients in relatively oligotrophic seas, calcium carbonate deposition yielding reef construction, refuge and foraging base for other organisms, and modification of near-field or local water circulation patterns (De Freese 1991). Coral reefs also protect shorelines, serving to buffer inshore subtidal (e.g., seagrass) and intertidal (e.g., mangroves) communities from otherwise high wave energy conditions in certain localities. Coral reefs are host to a multitude of species of algae, invertebrates, and fishes. Reef environments are characterized by an incredible diversity of species packed into a relatively small spatial dimension (m^2 to km^2) defined by high benthic diversity (Connell 1978; Richards and Lindeman 1987). Organisms essential in the construction of tropical reefs are hermatypic (reef-building) corals and coralline algae. Through reef construction, these organisms provide habitat for sedentary and mobile species (Lewis 1981).

The functional roles discussed below are presented for *Acropora* spp. where information specific to acroporids are available, and otherwise for coral reefs in general. This generalization to function in coral reef systems as a whole is appropriate in evaluating the role of *Acropora* spp. given their status as constructional or "foundation" species in Caribbean coral reef ecosystems as described below.

Acropora spp. were important shallow and mid-depth reef builders in the wider Caribbean

Acropora palmata and *A. cervicornis* are two of the major reef-building corals in the wider Caribbean. Historically, both of these species formed dense thickets at shallow (<5 m) and intermediate (10 to 15 m) depths in many reef systems, including some locations in the Florida Keys, western Caribbean (e.g., Jamaica, Cayman Islands, Caribbean Mexico, Belize), and eastern Caribbean. In the Florida Keys, for example, *A. palmata* was the primary builder of constructional spur and groove reefs along much of the Florida reef tract, with coralline spurs up to several meters in height and up to 15 m in length (Shinn 1963; Shinn et al. 1981). Early descriptions of Florida Keys reefs referred to reef zones, of which the elkhorn (*A. palmata*) zone was described for many shallow-water reefs (Figure 4.3-8) (Jaap 1984; Dustan 1985; Dustan and Halas 1987).

Interestingly, Shinn et al. (1977) noted that in southeastern Florida, some reefs were able to form and keep pace with sea level rise without the "help" of reef construction of *A. palmata*. As summarized in Bruckner (2002), however, the structural and ecological roles of Atlantic *Acropora* spp. in the Caribbean are unique and cannot be filled by other reef-building corals in terms of accretion rates and the formation of structurally complex reefs.

Coral reefs influence water circulation patterns

An important characteristic of coral reefs is their ability to modify the surrounding physicalchemical environment (Ginsburg and Lowenstam 1958). The reef framework controls the accumulation of sediments on and adjacent to the reef, as well as local circulation patterns (Jaap 1984). Barrier reefs are the best example of the ability of organic communities to affect circulation patterns that in turn influence benthic community distribution and sedimentation. Barrier reefs provide shelter for the back reef lagoon, allowing for benthic communities adapted to low-wave energy conditions, such as seagrass beds, to persist and flourish. Several studies have noted the differences in sediment and habitat characteristics between inshore and offshore environments (Enos 1977; Szmant and Forrester 1996) and associated differences in sediment nutrient characteristics. Sediments in the back reef (inner shelf margin) consist of finer grain particles with greater nutrient pools relative to sediments directly associated with reefs, such as large skeletal fragments. Benthic community distribution also differs considerably between nearshore and offshore. Seagrasses and other soft-sediment communities dominate the inner shelf margin, while reefs and bare sand slope areas dominate the outer shelf margin.

Coral reefs serve important refuge and foraging functions

Coral reefs, including hard substrate and associated sediments, afford organisms an incredible array of refuges (Jaap 1984). Epifauna are organisms living on the reef surface, and include mobile epifauna (crustaceans, echinoderms, mollusks, and fishes) and sessile epifauna (e.g., sponges, corals, gorgonians, and bryozoans). Infauna are those animals which burrow into hard substrate, such as polychaete and sipunculid worms, sponges, and mollusks, while minute meiofauna are associated with reef sediments. Holes and crevices in the reef structure provide shelter for echinoderms, mollusks, polychaetes, crustaceans, other invertebrate groups, and fishes. In a single coral colony, for example, Grassle (1973) counted 1,441 polychaetes representing 103 species. In several coral colonies, McClosky (1970) counted 1,517 individuals representing 37 different invertebrate species. Gastropods, crustaceans, echinoderms, and fishes consume benthic algae associated with the reef structure (i.e., coral-produced substrate); these herbivores, in turn, fuel the production of higher trophic levels such as invertivores and carnivores.

While no comprehensive quantitative inventories have been made of all of the flora and fauna associated with coral reefs (Lewis 1981), probably the best information illustrating the diversity associated with these structures is for fishes. In western Atlantic reef environments, the number of fish species directly or indirectly associated with the reef system can exceed 400 species (Starck and Davis 1967; Jones and Thompson 1978; Bohnsack et al. 1987). The high taxonomic diversity of reef fishes indicates that many species are highly evolved, with several families entirely restricted to the reef environment, among them: Chaetodontidae (butterflyfishes), Scaridae (parrotfishes), Acanthuridae (surgeonfishes), Labridae (wrasses), Holocentridae (squirrelfishes), Balistidae (triggerfishes), and Pomacentridae (damselfishes) (Sale 1977; Longhurst and Pauly 1987). Many reef fishes are highly sedentary, with some species (e.g., damselfishes) actively defending territories. Even the spatial distribution of larger predatory species tends to be very reef-specific, with individuals rarely traveling more than 5 km from a home site after post-settlement, except for spawning purposes (Longhurst and Pauly 1987).

In addition to the important functions of reef building and reef maintenance provided by Atlantic *Acropora* spp., these species serve as fish habitat (Ogden and Ehrlich 1977; Appeldoorn et al. 1996), including essential fish habitat (CFMC 1998), for species of economic and ecologic importance. Loss of *Acropora* spp. from the Caribbean would have substantial impacts on many coral reef species and by extension on the composition of reef communities.

Assessments of reef fish abundances and diversity have been conducted in the Caribbean and the Florida Keys over the last four to five decades. Invariably, these studies have quantified fish populations relative to geomorphic strata or reef zonation (Ehrlich 1975; Sale 1980; McGehee 1994; Lindeman 1997; Kendall at al. 2003), or relative to substrate characteristics such as rugosity (Luckhurst and Luckhurst 1978), complexity (Nunez Lara and Arias Gonzalez 1998), or refuge (hole) size (Hixon and Beets 1989, 1993). A number of long-term sampling efforts may have data that can be used to infer habitat use or value, but these analyses have either not been published or are limited in spatial scope.

However in St. Croix, U.S.V.I., heterotypic schools of juvenile French and white grunts (*Haemulon flavolineatum* and *H. plumieri*) were found to transfer substantial amounts of nitrogen and phosphorous in the nutrient-poor waters of a coral reef; water nearby *A. palmata* with grunts had ammonia (NH^{4+}) concentrations up to 0.7 µM (micromolar) greater compared to a nearby colony without fish (Meyer et al. 1983). While direct connections between reef fishes and Atlantic *Acropora* spp. have not been well reported (with the exceptions below), several studies have found a positive relationship between substrate complexity and fish densities and diversity. Unfortunately, few of these studies provide data on the use of certain coral species or growth forms by particular fish species.

One exception to this pattern is the study by Lirman (1999) who reported significantly higher abundances of grunts (Haemulidae), snappers (Lutjanidae), and sweepers (Pempheridae) in high-topography areas with coverage by *A. palmata* compared to lower topography or lower coral cover sites. Comparisons between sites where *A. palmata* was absent and present suggested that fish schools, comprised primarily of grunts and snappers, use *A. palmata* colonies preferentially.

Settlement habitats of the white grunt, *Haemulon plumieri*, in another study were examined in southwest Puerto Rico in a *Thalassia*-*Acropora cervicornis* back-reef lagoon (Hill 2001). Although this site might nominally be classed as a seagrass bed, *A. cervicornis* was the primary focus of newly settling grunts. Neither the *Thalassia* (seagrass) nor other available coral sites (boulder or brain corals, gorgonians, algal covered corals) attracted or maintained significant numbers of juveniles during the study.

Hill (2001) indicated that *A. cervicornis* thickets were the preferred settlement habitat for grunts that became saturated during high recruitment seasons, yielding greater usage of supposed sub-optimal habitats nearby (e.g., seagrass or gorgonians). Numerous reef studies have described the relationship between increased habitat complexity, and increased species richness, abundance and diversity of fishes. Habitat selection is viewed as a trade-off between refuge from predation and access to feeding resources (Werner and Gillliam 1984). Settlement and juvenile habitats typically are thought to reduce exposure to predators (Shulman 1984). Hixon and Beets (1989, 1993) showed that appropriately sized refuges could moderate predation effects and thus alter reef fish distribution patterns. At a larger scale, complete absence of particular habitats has been shown to affect fish assemblage composition if species are not able to use alternate habitats (Nagelkerken et al. 2000). Loss of the complex habitats provided by *A. cervicornis* and *A. palmata* could result in increased rates of predation on juvenile snappers and grunts, with likely reductions of habitat-specifics like *H. plumieri*. It is important to note that *A. palmata* and *A. cervicornis* are the only large, branching coral species in Caribbean reef systems capable of creating large amounts of complex reef habitat. Though "standing dead" coral skeletons (especially *A. palmata*, as *A. cervicornis* tends to crumble into rubble) can still serve as habitat for fishes, subsequent storms and bioerosion will eventually destroy this habitat if none is being constructed to replace it.

In the current situation, with low abundance of *Acropora* spp. on most Caribbean reefs, very little new complex reef habitat is being created and, hence, its availability to ecologically and economically important reef fishes is likely to continue to decline in the coming years.

Competition

Coral reefs are described as space-limited systems and thus it is believed that competition for space is an important structuring factor. Because of their fast growth rates and canopy-forming morphology, *A. palmata* and *A. cervicornis* are known to be competitive dominants within coral communities, in terms of their ability to overgrow other stony and soft corals. However, other types of reef benthic organisms (i.e., algae) have higher growth rates and, hence, expected greater competitive ability than *Acropora* spp. Since the 1980s, many Caribbean reef areas have undergone a shift in benthic community structure involving reduced cover by stony corals and increased coverage by macroalgae. This shift is generally attributed to the greater persistence of macroalgae under reduced grazing regimes due to human overexploitation of herbivorous fishes (Hughes 1994) and the regional mass mortality of the long-spined sea urchin in 1983-84. Impacts to water quality (principally nutrient input) are also believed to enhance macroalgal productivity.

Aronson and Precht (2001) emphasize, however, that these Caribbean-wide changes in benthic assemblages were precipitated by massive coral mortality events (namely the loss of *Acropora* spp. from White Band Disease) as macroalgae are generally unable to actively overgrow and kill live corals. In other words, the coral-dominated Caribbean reef system was resistant to reduced herbivory regimes for a period of time as long as corals maintained their occupation of space. However, when coral mortality occurred, macroalgae were able to pre-empt that space (especially following the loss of grazing by *Diadema*) and were subsequently resistant to coral re-colonization (Hughes and Connell 1999). Thus the described shifts have been persistent on a decadal scale. The noted exception is in areas where the grazing sea urchins (*Diadema antillarum*) have recently recovered and removed the macroalgal dominants, thereby clearing space to allow enhanced coral recruitment (Edmunds and Carpenter 2001).

In summary, macroalgae are now the major space-occupiers on many Caribbean reefs. Their dominant occupation of reef surfaces impedes the recruitment of new corals (McCook et al. 2001) and hence, recovery by sexual recruits of *Acropora* spp. It is unlikely, however, that macroalgae have major impacts as direct competitors with healthy adult colonies. Other encrusting invertebrates may also pose a direct overgrowth threat to small colonies or bases of *Acropora* spp., but the extent of such interactions is not well documented.

Predation

Acropora spp. are subject to invertebrate (e.g., polychaete, mollusk, echinoderm) and vertebrate (fish) predation, but “plagues” of coral predators such as the Indo-Pacific crown-of-thorns outbreaks (*Acanthaster planci*) have not been described in the Atlantic.
Predation may directly cause mortality or injuries that lead to invasion of other biota (e.g., algae, boring sponges).

The most important predators on Atlantic *Acropora* spp. are the fireworm, *Hermodice carunculata*, and the muricid snail, *Coralliophila abbreviata*. Both these predators will feed on a wide range of cnidarian prey, but may prefer *Acropora* spp. *Hermodice* are commonly found enveloping the long branch tips of *A. cervicornis* that are subsequently left devoid of tissue (Marsden 1962; Lizama and Blanquet 1975; Dustan 1977). *Hermodice* also feeds on branch tips or protuberances of *A. palmata*, where the predation scars appear as white patches (Porter 1987). Vargas-Angel et al. (2003) report a density between 86 and ~618 *Hermodice* ha^{-1} in *A. cervicornis* thickets in southeast Florida with predation scars affecting <0.2% of the *A. cervicornis* cover. There are few other data on the prevalence or impact of *Hermodice* on *Acropora* spp. populations.

Although these predators rarely kill entire colonies, there are several possible mechanisms of indirect impact. Because they prey on the growing tips (including the apical polyps), especially of *A. cervicornis*, growth of the colony may be arrested for prolonged periods of time. Additionally, *Hermodice carunculata* from the Mediterranean
Sea has been shown to serve as a vector for a bacterial bleaching pathogen in laboratory experiments (Sussman et al. 2003).

The other important predator of Atlantic *Acropora* spp. is the gastropod, *Coralliophila abbreviata*. This predator also feeds on a wide range of corals, but seems to be particularly damaging to *Acropora* spp. (Baums et al. 2003b). Prevalence data from throughout the Caribbean indicates that approximately 10% to 20% of *Acropora* spp. colonies harbor snails (Baums et al. 2003a). The rate of consumption by *Coralliophila* is highly variable, but may reach 6.5 cm^2 of coral tissue per snail per day (Bruckner et al. 1997) and probably averages ~1.5 cm^2 of coral tissue per snail per day (Baums et al. 2003b). Given that the mean snail density on infested *A. palmata* colonies is reported at over three snails per colony (Bruckner et al. 1997; Baums et al. 2003a) with a maximum of at least 23 snails per colony (Baums et al. 2003a), snail predation clearly represents a significant potential source of tissue loss. There is evidence that these predators concentrate on remnant *Acropora* populations following host coral decline (Knowlton et al. 1990; Baums et al. 2003a). For example, after Hurricane Allen struck the north coast of Jamaica in 1980 and greatly reduced the acroporid population, *C. abbreviata* continued to feed on remnant *A. cervicornis* colonies, reducing the population further (Knowlton et al. 1981). It should be noted, however, that *Coralliophila* seem to be extremely rare or absent on *Acropora* spp. in certain areas (e.g., Bocas del Toro, Panama, Baums pers. comm.; Dry Tortugas, Miller pers. observ.).

The three-spot damselfish (*Pomacentrus planifrons*) and other species in the genus establish algal nursery gardens within branching *Acropora* spp. when available and on other coral species when acroporids are rare (Thresher 1976; Brawley and Adey 1977; Kaufman 1977; Itzkowitz 1978; Williams 1978; Sammarco and Carleton 1982). Although not predators in the strict sense, the damselfishes nip off living coral tissue, thus denuding the skeleton to make a place for their algal gardens. Again, it is likely that *P. planifrons* impacts are proportionally greater when the abundance of *Acropora* is reduced. Observations in several areas (e.g., Dry Tortugas, Navassa) suggest that isolated small colonies, particularly of *A. cervicornis*, have a very high prevalence of damselfish occupation.

Other predators also consume *Acropora* tissue to a lesser degree. Although not widely documented, the Caribbean long-spined sea urchin (*Diadema antillarum*) is known to feed upon live *Acropora* coral tissue (Bak and van Eys 1975, Sammarco 1980). Laboratory experiments confirmed that this sea urchin will feed on coral tissue when starved, but may also do so when feeding on turf algae when sea urchin population numbers are relatively high (e.g., >4 individuals/m^2) (Porter 1987). More recent studies indicate that besides damselfishes, parrotfishes, such as the stoplight parrotfish (*Sparisoma viride*), may also incidentally feed upon *Acropora* tissue. Very little is known concerning the extent of parrotfish grazing on Atlantic *Acropora* spp., but monitoring in the Florida Keys indicates that these scars usually heal in a matter of weeks to months (Williams pers. comm.).

Overall, predators can have important direct and indirect impacts on *A. palmata* and *A. cervicornis*. Predation impacts are greater in the current scenario of low coral abundance as coral predators have not been subject to the same degrees of disturbance mortality and their broad diet breadth has allowed them to persist at high levels despite decreases in acroporid prey. However, predation impacts on *Acropora* spp. appear to be much lower in certain geographic areas.

4.4 State Comprehensive Wildlife Conservation Strategies

(excerpted from the State Wildlife Action Plans Summary Report (August 2006): http://www.teaming.com/pdf/StateWildlifeActionPlansReportwithStateSummaries.pdf)

The wildlife action plans represent a collective vision for the future of conservation. For the first time, states have had the opportunity to assess the full range of challenges and actions that are vital to keeping wildlife from becoming endangered.

The impetus for the historic planning effort comes from the Teaming with Wildlife coalition, representing more than 3,500 agencies, conservation groups, and businesses who for more than a decade have tirelessly championed the cause for funding to keep wildlife from becoming endangered. The coalition's work led to passage of the Wildlife Conservation and Restoration Program and the State Wildlife Grants Program in 2000. As a requirement of these programs, Congress asked each state wildlife agency to develop a "comprehensive wildlife conservation strategy"—a wildlife action plan—that evaluates wildlife conservation needs and outlines the necessary action steps.

While the wildlife action plans share a common framework of the eight required elements, they are tailored to reflect each state's unique wildlife, habitat, and conservation needs. States worked closely through the Association of Fish and Wildlife Agencies and the U.S. Fish and Wildlife Service on the development of the wildlife action plans. By combining the best scientific information available with extensive public participation, states developed effective action plans that will work for wildlife and for people.

The wildlife action plans focus on practical, proactive measures to conserve and restore important lands and waters, curb establishment of invasive species and address other pressing conservation needs. The tools for conservation employed in the action plans emphasize incentives, partnerships and collaborative management, rather than top-down regulations. The action plans also stress the importance of gaining the knowledge necessary to effectively conserve a broad range of wildlife species. In addition, every state wildlife action plan incorporates continued monitoring and evaluation in order to measure the success of the proposed actions in conserving wildlife.

Taken as a whole, the wildlife action plans present a national action agenda for the conservation of wildlife species that is focused on those that have not benefited from conservation attention due to lack of dedicated funding. The results are already apparent in improved relationships at all levels—across public and private ownerships, across state boundaries, and in the growing list of new groups and individuals working together for wildlife. Taking the timely next steps to adequately fund these wildlife action plans is crucial in order to achieve the goal of preventing wildlife from becoming endangered.

Below are the Executive Summaries for each of the South Atlantic states' Comprehensive Wildlife Conservation Strategies. For detailed information contained in each Plan, please refer to each document. The documents can be downloaded in pdf format at http://www.teaming.com/state_pages.htm.

North Carolina

For more than fifty years, state fish and wildlife agencies have benefited from funds accumulated through the Federal Aid in Wildlife Restoration Act (Pittman-Robertson), the Federal Aid in Sport Fisheries Restoration Act (Dingell-Johnson), and the Aquatic Resources Trust Fund (Wallop- Breaux), to support the conservation and management of game fish and wildlife species. These funds have been critical to the establishment of long-term state agency planning related to game species. Yet conservation efforts for the majority of fish and wildlife species, those that are not hunted or fished, have in large part been opportunistic and crisis-driven, limited by the availability of funding, and by a lack of strategic approaches to species and habitat conservation. With more than 1,000 species now listed on the Federal Endangered and Threatened species list, the need has never been greater for funding and planning to support the conservation, protection, and restoration of the full array of wildlife species, especially those not covered under traditional funding sources.

In 2001 Congress, recognizing this need, began providing annual funding allocations to supplement existing state fish and wildlife conservation programs. Along with this new funding came the responsibility of each state and territory to develop a Wildlife Action Plan. The North Carolina Wildlife Action Plan was submitted to meet that obligation, and in the process, provide a conservation blueprint for agencies, organizations, industries, and academics across the state to advance the sound management of our fish and wildlife resources into the future. Within the document, we identify critical fish and wildlife resources and priority conservation needs associated with those resources. Our Plan is strengthened by all of the local, state, and regional conservation planning efforts that have preceded it; these efforts provided us a foundation upon which to build.
Our Plan promotes proactive conservation measures to ensure cost-effective solutions ("keeping common species common") instead of reactive measures enacted in the face of imminent losses.

Five goals form the core of the Plan: 1) to improve understanding of the species diversity in North Carolina and enhance our ability to make conservation or management decisions for all species, 2) to conserve and enhance habitats and the communities they support, 3) to foster partnerships and cooperative efforts among natural resource agencies, organizations, academia and private industry, 4) to support educational efforts to improve understanding of wildlife resources among the general public and conservation stakeholders, and 5) to support and improve existing regulations and programs aimed at conserving habitats and communities.

In order to meet these goals, we engaged hundreds of people across a broad spectrum of agencies and organizations. We continue to seek the feedback and input of conservation stakeholders.

Key themes that are perpetuated through the document include:

- The need to strengthen partnerships among natural resource agencies, organizations, academics, and individuals in order to meet shared goals and visions,
- The need to impact the landscape in a large-scale fashion, and to consider all components of a sustainable community of plants and animals,
- The need to gather additional information and fill knowledge gaps in order to advance our understanding of species and their habitats,
- The need to work cooperatively with private landowners to influence the conservation of natural resources across the majority of the state, and
- The need to educate and engage local governments, planning commissions, and urban public about the importance of fish and wildlife conservation as a key component of successful land use planning.

The sections of the Plan build on one another in similar fashion to its development. Within the **Approach** section are summaries of key processes and exercises that were carried out in order to develop the Plan, including organizational frameworks, partnerships and stakeholder involvement, and the species prioritization process. Next, in the **State of the State** we provide an overview of the condition of the state's natural resources, threats affecting species and habitats in the state, key conservation partners, and challenges faced in program administration and efficacy. In **Statewide Conservation Strategies** we address four broad-scale conservation issues, including strategies on urban wildlife issues, private lands wildlife management, land conservation priorities, and education and outreach. Following is the most detailed chapter of the report, entitled **Species and Habitat Assessments & Conservation Strategies**. In this chapter, we feature the conservation needs of terrestrial resources within habitats across the three ecoregions of the state (the Southern Blue Ridge, Piedmont, and Mid-Atlantic Coastal Plain), aquatic resources within the 17 river basins in the state, and marine resources at our coast (this section is largely based on the North Carolina Division of Marine Fisheries Coastal Habitat Protection Plan). Next, we address cross-cutting conservation needs among habitats and basins within **Synthesis of Conservation Priorities**. In **Status and Trends Monitoring** we discuss species and habitat monitoring needs. We outline ways to monitor the implementation of conservation activities, adapt to new information, and revise future iterations of the Plan in our final chapter, **Implementation Monitoring, Adaptive Management, & Review and Revision Procedures**. Last, we present **Acknowledgements**, a comprehensive **Glossary**, a **Key to Abbreviations and Acronyms**, and multiple **Appendices**.

This document was developed at the strategic level, meaning that the implementation of activities identified in the Plan must go one step farther to consider the operational details of involving partners, setting explicit objectives and targets, detailing monitoring protocols, etc. We have organized the format and content of the Plan to provide maximum utility as a resource to set conservation priorities. The Plan is designed to flow from beginning to end, but individual chapters and sections can also be used independently, as stand-alone documents. For example, users may turn to a particular habitat or basin section to review priority needs and recommendations pertaining specifically to their region or expertise area (e.g., the Catawba River basin, maritime forest habitat).

We hope that the information provided within each chapter and section translates into clear and objective conservation planning at that level.

Our Plan has been nearly three years in development. The development process was strengthened by the input, feedback, and participation of hundreds of stakeholders across the state (stakeholder representation extended across more than 15 state and federal agencies, 12 non-governmental organizations, five universities, and four private companies). But the completion of this first edition is just the beginning. The Plan is a work in progress, and will continue to evolve during implementation and through future revisions. Though the funding that initiated development of the state Plan continues to be allocated on an annual basis (making long-term planning difficult), there is hope across the nation that our state Strategies will clearly demonstrate to Congress the need for increased and permanent Federal fish and wildlife conservation funding in the future. Regardless of funding sources, the partnerships and collaborative efforts that this Plan fosters should lead to significant accomplishments in the conservation of North Carolina's wildlife resources.

South Carolina

In May of 2002, the South Carolina Department of Natural Resources (SCDNR) began a process to develop the Comprehensive Wildlife Conservation Strategy (CWCS) that was funded through the State Wildlife Grants (SWG) program. The SCDNR committed to developing the Strategy and begin implementing the conservation actions by October 1, 2005. The goal of the Strategy is to emphasize a cooperative, proactive approach to conservation while working with federal, state and local governments; local businesses; and conservation-minded individuals to join in the effort of maintaining the fish and wildlife resources of South Carolina.

In order to sustain South Carolina's diverse wildlife resources in the future, the following actions are critical: (1) increase baseline biological inventories with emphasis on natural history, distribution and status of native species; (2) increase commitment by natural resource agencies, conservation organizations and academia toward establishing effective conservation strategies; (3) increase financial support and technological resources for planning and implementation of these strategies; and (4) create public-private partnerships and educational outreach programs for broad-scale conservation efforts. South Carolina's CWCS is a first step toward instituting these actions.

The diversity of animals in South Carolina is vast. Habitats in this state range from the mountains to the ocean and include many different taxonomic animal groups. SCDNR wanted to address as many of those groups as possible for inclusion in the list of priority species for the CWCS; as such, twelve taxonomic groups are included in the Strategy: mammals, birds, reptiles, amphibians, freshwater fishes, diadromous fishes, marine fishes, marine invertebrates, crayfish, freshwater mussels, freshwater snails, and insects (both freshwater and terrestrial).

The SCDNR identified 1,240 species to include on the state's Priority Species List. Reports were prepared for each species, guild or indicator; in these reports, authors described the species, their status, population and abundance, habitat needs, challenges, conservation accomplishments and conservation actions. This approach allows for identification of both general conservation strategies for wildlife and habitats in South Carolina, as well as development of species-based conservation strategies. The latter allows for management of particular species within a given habitat. A separate volume, **Supplemental Volume: Species and Habitat Accounts**, contains these reports in their entirety. The SCDNR also identified habitats critical for the priority species considered in the CWCS. Both terrestrial and aquatic habitats were considered and reports were prepared for 38 habitats (terrestrial and marine) organized within five ecoregions, as well as 13 ecobasins, which characterize the freshwater aquatic habitats of the state. These reports are also presented in the Supplemental Volume.

As conservation strategies were developed for each species, it became evident that they could be separated into eight categories, which we have designated as Conservation Action Areas (CAAs). These eight CAAs are: Education and Outreach; Habitat Protection; Invasive and Nonnative Species; Private Land Cooperation; Public Land Management; Regulatory Actions; Survey and Research Needs; and Urban and Developing Lands. Within each CAA, conservation actions were condensed from the recommendations prepared for each animal on South Carolina's Priority Species List. Some of the actions identified will affect all species included in the CWCS; others may affect only a few species. Each of these actions was prioritized and measures that indicate success of implementing the action were identified.

It is also critical that we monitor priority species, their habitats and the effectiveness of the actions that are implemented to conserve them. With the information gathered in this program, project leaders will be required to produce annual progress reports for review by a steering committee and the CWCS coordination team. These reports will be evaluated for insight into adaptive management needs and reassessments of the CWCS.

From the beginning of the CWCS effort, SCDNR and the planning team sought to realize successful partnerships and public involvement in the development of the strategy. It is understood that successful conservation is furthered by the existence of a strong collaborative involvement between all resource stakeholders, private or public, governmental or nongovernmental. Task forces were convened to assist in determining important natural resource issues in South Carolina. Taxa teams were assembled to determine challenges to species and conservation actions to address those challenges. Public meetings were held to gather input from the citizens of the state. Prior to submission of the CWCS, the SCDNR began creating Conservation Action Committees around the CAAs identified above; two of these committees have convened and have begun working toward identifying statewide strategies for species and habitat conservation. Partnerships will continue to be critical in implementing the actions identified in South Carolina's CWCS.

Georgia

In December 2002 the Wildlife Resources Division (WRD) of the Georgia Department of Natural Resources (DNR) began a process to develop a comprehensive wildlife conservation strategy. Through the Wildlife Conservation and Reinvestment Program, WRD made a commitment to develop and begin implementation of this comprehensive wildlife conservation strategy (CWCS) by October 1, 2005. Funding for this planning effort came from a federal grant to WRD through the State Wildlife Grant program; matching funds were provided through Georgia's Nongame Wildlife Conservation Fund.

The goal of the strategy is to conserve Georgia's animals, plants, and natural habitats through proactive measures emphasizing voluntary and incentive-based programs on private lands, habitat restoration and management by public agencies and private conservation organizations, rare species survey and recovery efforts, and environmental education and public outreach activities.

The best available wildlife data were used to develop this CWCS. The strategy included an assessment of habitats required by these species, as well as problems affecting these habitats. Further, this strategy addressed research and survey needs, habitat restoration needs, and monitoring needs. It also included an evaluation of existing programs and policies for wildlife conservation in Georgia and recommendations for improvements in these areas. Coordination with other organizations that manage land or administer conservation programs in Georgia was a key component of this effort.

The planning process involved staff within DNR, representatives of private and public conservation organizations and land managers and owners in Georgia. A Steering Committee composed of representatives of various agencies, organizations, and land management groups provided project oversight. Technical teams addressed specific components of the conservation strategy; these teams included WRD staff and representatives of other agencies and organizations. Input from the Steering Committee, stakeholders, representatives of other conservation organizations, consulting biologists, academic researchers, and the public was used in the development of the conservation strategy. Educational materials were developed to inform the public about the project's goals and milestones; these materials were posted on a website developed specifically for this project and distributed at public meetings.

Components of this planning effort included: 1) development of databases on rare species and natural communities; 2) identification of high priority species and habitats; 3) identification of high priority research and biological inventory needs; 4) surveys for rare species on public and private lands; 5) development of databases of conservation lands and high priority watersheds and landscapes; 6) prioritization of conservation, education, and habitat protection needs; 7) collaboration with state and federal agencies on habitat protection/restoration plans; 8) technical assistance to private conservation organizations and local governments; 9) review of existing conservation laws, rules, and policies; and 10) public input and educational outreach.

Three technical teams focused on biodiversity database development and use, GIS/mapping support and land cover assessments, and environmental education, respectively. The GIS support team developed and distributed a survey to WRD staff to determine priority needs for geographically based dataset needs. Team members also reviewed the land cover database produced by the Georgia Gap Analysis Program, continued development of a statewide conservation lands database, and produced land cover and vegetation maps. The database support/enhancements team discussed uses of biological diversity data. This team developed specific recommendations for exchange and application of biodiversity information, including improved Web-based access to rare species/natural community information, region-specific rare species datasets for WRD law enforcement personnel, and watershed-based datasets. The environmental education team developed recommendations for improvements in wildlife-related education programs, and was assisted by the Environmental Education Alliance of Georgia.

Six technical teams focused on the following groups of species: birds, amphibians and reptiles, mammals, fishes and aquatic invertebrates, terrestrial invertebrates, and plants.
Although conservation efforts for plants could not be addressed under this grant, a parallel conservation planning process was undertaken, funded in part through a federal grant to the Wildlife Resources Division, with matching funds provided from the Nongame Wildlife Conservation Fund. These technical teams consulted numerous data sources and used a variety of criteria to identify high priority species for Georgia; these included critically imperiled species, habitat indicator species known to be in decline, species endemic to Georgia, and rare or uncommon species in need of further research to determine conservation objectives.

Results of the various biological and ecological assessments undertaken in this planning effort are presented in this document. Many of the details of these analyses can be found in the appendices that follow the main report. Ranges of distribution, habitat associations, conservation needs, and research priorities for 296 species of high priority animals and 323 species of high priority plants are outlined in Section IV and in appendices A and B. Similarly, high priority habitats are defined for each ecoregion and management needs for these habitats are discussed in Section IV and Appendix C.

In this document, conservation goals are defined broadly, while discussions of strategies and partnerships more specifically address the objectives that must be met to achieve these goals. Conservation goals, strategies and partnerships are identified for each of the five ecological regions of the state in Section IV of this report. In addition, statewide wildlife conservation themes and strategies are addressed in Section V. Lists of specific high priority conservation actions were also developed. These conservation actions were first identified by the technical teams, Steering Committee, and other stakeholders and included specific programs for improvements in habitat protection, conservation of high priority habitats and species, research and surveys, and environmental education and public outreach. These identified conservation actions were then evaluated by the Steering Committee using a set of seven ranking criteria. The complete set of 78 prioritized conservation actions can be found in Appendix L of this report. Summaries of existing programs and resources for habitat protection and recommendations to increase capacity for wildlife conservation in Georgia are provided in Section V of this document.

The following goals represent important conservation themes in this document:

- Maintain known viable populations of all high-priority species and functional examples of all high priority habitats through voluntary land protection and incentive-based habitat management programs on private lands and habitat restoration and management on public lands.
- Increase public awareness of high priority species and habitats by developing educational messages and lesson plans for use in environmental education facilities, local schools, and other facilities.
- Facilitate restoration of important wildlife habitats through reintroduction of prescribed fire, hydrologic enhancements, and vegetation restoration.
- Conduct statewide assessments of rare natural communities and habitats that support species of conservation concern.
- Improve efforts to protect vulnerable and ecologically important habitats such as isolated wetlands, headwater streams, and caves.
- Combat the spread of invasive/noxious species in high priority natural habitats by identifying problem areas, providing technical and financial assistance, developing specific educational messages, and managing exotic species populations on public lands.
- Minimize impacts from development and other activities on high-priority species and habitats by improving environmental review procedures and facilitating training for and compliance with best management practices.
- Update the state protected species list and work with conservation partners to improve management of these species and their habitats.
- Conduct targeted field inventories of neglected taxonomic groups, including invertebrates and nonvascular plants.
- Continue efforts to recover federally listed species through implementation of recovery plans, and restore populations of other high priority species.
- Establish a consistent source of state funding for land protection to support wildlife conservation, and increase availability and use of federal funds for land acquisition and management.
- Continue efforts to monitor land use changes statewide and in each ecoregion, and use predictive models to assess impacts to high priority species and habitats.

Monitoring needs for species, habitats, and conservation programs are also addressed in Sections IV and V of this document. Monitoring programs are acknowledged as critical components of adaptive management efforts in wildlife conservation, and specific recommendations are provided to improve existing monitoring programs. In addition, partnerships with other organizations involved in monitoring efforts are recommended.
Specific high priority monitoring projects are mentioned in the body of the report and in Appendix L. The approach taken in this planning effort was to identify the types of data to be collected and relevant performance indicators for every high priority conservation action as a first step to development of monitoring programs.

Several projects undertaken as components of this planning project represent efforts to develop new analytical tools and methods that can inform future conservation plans at various geographic scales. A pilot project to develop historic vegetation maps was completed by researchers at the University of Georgia. Using land lot survey data from the 1800s, researchers developed historic vegetation maps for three state-owned wildlife management areas. This pilot project produced analytical tools and data that will facilitate development of habitat management plans for public lands. A second pilot project utilized land cover data from the Georgia Gap Analysis Program and occurrence data for rare and declining species to identify regions of the state that may represent important areas for conservation work in the future. These two projects are described in appendices J and K, respectively.

Project staff began development of a new natural community classification system that will serve as a standard for habitat mapping on public lands. The new classification system is based on ecosystems and vegetation alliances described by NatureServe and the Natural Heritage Network. WRD staff also collaborated with a group of volunteers working on a detailed guide to Georgia's natural environments. This document will be based on the NatureServe ecosystem classification and written for a broad audience including teachers, science students, and practicing biologists. Development of this document will facilitate mapping and tracking of natural communities consistently across the state and increase public awareness of Georgia's ecosystems.

Public involvement in the development, review and revision of this document was facilitated by a series of fourteen public meetings undertaken over the project period.
These included regional stakeholder meetings as well as traditional public meetings. In addition, public input was solicited through materials posted on the CWCS website, news releases, brochures, fact sheets, and presentations given to various groups and organizations around the state. These public outreach efforts will continue as we begin to implement the conservation strategy.

The CWCS reflects an assessment of wildlife conservation needs and programs to address those needs based on data available in 2003-2005. Our understanding of the conservation needs of Georgia's species and habitats is likely to change based on the result of additional surveys, results of monitoring efforts associated with management efforts, or new trends in land uses. In addition, the development of new analytical techniques, funding programs, or legislative mandates may result in a need to reassess some of the conservation priorities described in this document.

The intent of the Wildlife Resources Division is to begin a formal process of reviewing the current wildlife conservation strategy within the next five years and to adopt revisions to the strategy as deemed necessary based on this review. In order to do this, we propose to reconvene the technical teams and Steering Committee and hold public meetings to assess and address changing conservation needs for species and habitats in Georgia. The proposed procedure for this review is outlined in Section VI of this document.

The first piece of legislation to be approved by the 2005 session of Georgia General Assembly was the Georgia Land Conservation Act and on April 14, 2005, Governor Perdue signed into law this important piece of legislation. The bill enjoyed overwhelming public and legislative support and was generally lauded throughout the state. The intent of the Act is to provide funding options and a flexible administrative framework to conserve land resources, recognize the values of the State's natural and cultural resources, and promote land conservation partnerships.

The Wildlife Resources Division of the Georgia Department of Natural Resources views this new state land conservation program as an important and timely component of the Comprehensive Wildlife Conservation Strategy that will aid significantly in its implementation. This Act directs some $100 million for land conservation efforts in the state of Georgia and makes available $45 million in state and private funding that can and will be used to match and leverage various federal wildlife conservation grants consistent with the strategies and priorities included in this document.

The changes that are occurring in the Georgia landscape as a result of population growth and increasing development pressures present daunting challenges to those involved in wildlife conservation. The trend of increasing fragmentation and degradation of natural habitats is likely to continue in the coming decades, driven by local, national, and global economic and demographic factors. Many scientists believe that the next fifty years will be a critical period in the struggle to protect our remaining biological resources.

The following elements are critical for conservation of Georgia's natural heritage: (1) increased emphasis on field research focused on the identification and assessment of species, biotic communities, and ecosystems; (2) greater commitment of resources to identify and protect those habitats that contribute most significantly to biodiversity; (3) further development and funding of conservation programs that emphasize public-private partnerships for broad-scale conservation of "working landscapes"; (4) greater emphasis on land use planning to minimize impacts of future developments on natural habitats; and (5) increased collaboration between researchers and educators to heighten public awareness of the magnitude and significance of biodiversity decline in the state. The Department of Natural Resources will continue to work with a wide array of public agencies, private conservation organizations, research institutions, sportsmen's groups, educators, local governments, and landowners in the coming years to address these critical elements of wildlife conservation.

Florida

The primary support and focus for wildlife conservation and management within the United States historically has come from state hunting and fishing interests and Federal Assistance programs for game species under the Pittman–Robertson, Dingle–Johnson, and Wallop–Breaux Acts. Additionally, the Endangered Species Act has provided support to recover federally threatened and endangered species. Although these programs have been successful, the majority of wildlife species have unmet conservation needs and many are at risk of becoming imperiled.

Waiting until a species is on the verge of extinction and then trying to recover it is costly and results in the inevitable loss of some species. To encourage a new conservation paradigm and work towards managing species before they become imperiled, the U. S. Congress created the State Wildlife Grants Program. This program is dedicated to a holistic approach that includes all species, but is centered on conservation of species that have not fallen under historical efforts.

As a requirement of participating in the State Wildlife Grants Program, the Florida Fish and Wildlife Conservation Commission (FWC) has joined the other 55 states, territories, and district by committing to develop a Comprehensive Wildlife Conservation Strategy (Strategy) for the state.

To meet the intent of the State Wildlife Grants Program, the FWC has created Florida's Wildlife Legacy Initiative (Initiative). The goal of the Initiative is to develop a strategic vision for conserving all of Florida's wildlife. The three main objectives of the Initiative are: (1) to create partnerships for wildlife conservation across the State of Florida; (2) to support partnership building and use of the Strategy by making funding available through Florida's State Wildlife Grants Program; and (3) to develop and implement Florida's Strategy. Thousands of experts and stakeholders have participated and provided input to meet these objectives. These partners, including representatives from other state and federal agencies, organizations, businesses, and individuals, have been integral throughout the Strategy development process.

As discussions and work have progressed on planning, development, and implementation of Florida's Wildlife Legacy Initiative, several major premises have been employed and incorporated throughout the Strategy:

- The goal of Florida's Strategy is to build a blueprint and action plan for conserving the vast array of wildlife that makes Florida such a unique place to live and visit. This blueprint should be compatible with human needs and not preclude recreational or other use of wildlife resources and landscapes.
- Florida already has developed and implemented significant wildlife resource management tools and programs. The Strategy has been designed to build upon these efforts in a cumulative manner, identify gaps and further needs, and create a comprehensive vision for coordinating efforts across the state.
- Florida's Strategy uses a habitat category approach to arrange wildlife species and habitats, and the conservation threats and actions needed to conserve them, into meaningful and manageable categories. By taking actions that sustain the health and integrity of the habitat categories, the broad array of wildlife that lives within each will be conserved and maintained.
- The Strategy encompasses the entire state and therefore is too broad for any one individual, group, or agency to develop and implement. Coordination and cooperation among federal and state agencies, local governments, Native American tribes, non-governmental organizations, private entities, and individuals is essential.
- A non-regulatory approach is paramount to create partnerships for implementation of actions needed to conserve wildlife. The Strategy focuses on voluntary and cooperative efforts providing a starting point to develop non-regulatory mechanisms. The Strategy is not regulatory in nature and is not intended to be used in a regulatory manner.
- Meeting the needs of wildlife will mean a healthier environment for future generations of Floridians. Florida faces a huge challenge to meet the needs of an expanding human population while conserving wildlife resources.
- Education has played a vital role in conservation of Florida's wildlife and other natural resources. Support for conservation education is needed to promote awareness, responsible action and behavior.

- The Strategy should clearly meet or exceed the eight elements required under the State Wildlife Grants Program and federal guidance.

The Strategy is organized in chapters, which follow a progression of thought and content development. The **Introduction**, **Approach**, and **State of the State** form the beginning section of the Strategy. The **Introduction** briefly outlines what the effort is and provides context for how it has been undertaken in Florida. The **Approach** summarizes the processes that were carried out in order to develop the Strategy, including organizational structure and methods specific to each Strategy requirement. The **State of the State** provides a discussion of Florida's natural resources, including economics, wildlife species, and conservation resources.

Florida's Strategic Vision forms the central section of the Strategy and synthesizes a strategic view for wildlife conservation at the statewide-level. Priority conservation issues are addressed in this chapter, including species, habitats, threats, actions, data gaps, monitoring tools, and conservation challenges. Species form the basis for Florida's entire endeavor and focus should continually be placed back upon them as the Strategy is implemented and reviewed. Several habitats have been highlighted for their importance and generally were associated with coastal, wetland, upland pine, reef, and submerged aquatic vegetation areas. Major statewide threats identified include: habitat loss and fragmentation, degradation of water resources, incompatible fire management, invasive plants and animals, and management of the physical environment (e.g., dams, shoreline hardening, dredging, etc.). Major statewide actions developed to abate these threats include: development of incentive-based programs for conservation, acquisition of important lands and waters, coordination of conservation efforts, public education, and development of a cooperative conservation effort. Priority data gaps to be filled focus on improved habitat mapping capability, filling species information needs, improving understanding and methodology for marine systems, and initiation of more efforts related to genetic diversity issues. Monitoring and adaptive management are focused on species, habitat, threat, and overall Strategy levels and will be critical to documenting success and refining efforts. Lastly, key conservation challenges such as partnership development, information management, and public awareness must be met and overcome for efforts to be successful.

The chapters on **Species of Greatest Conservation Need** (SGCN), **Habitats**, and **Multiple Habitat Threats and Conservation Actions** form the final and most extensive section of the Strategy. The SGCN chapter identifies 974 species of interest and lists their status and trends. The Habitats chapter describes 45 terrestrial, freshwater, and marine habitat categories that comprise the state of Florida. These habitat category descriptions include information on their status and trends, associated SGCN, related threats, and conservation measures needed. Additionally, the chapter **Multiple Habitat Threats and Conservation Actions** lists threats that apply to greater than five habitats and the suite of actions to abate each threat. Last, the Strategy contains **Acknowledgements**, **References/Literature Cited**, a **Glossary of Acronyms**, a **Glossary of Terms**, and four **Appendices**.

Florida's Strategy is a strategic vision of the integrated conservation efforts needed to sustain the broad array of wildlife in the state. More detailed operation-level plans will be needed to complete many of the actions identified in the Strategy. Such plans should be developed by the appropriate entities whose interest, authority, or responsibility encompass each action. Although the Strategy is not intended to be a work or management plan for the FWC or any other organization, support provided by the State Wildlife Grants Program will enable coordination and implementation of many projects through Florida's Wildlife Legacy Initiative. The Strategy is a work in progress that will continually be updated, revised, and improved based on the input and deliberations of all those interested in wildlife conservation. Working together, Floridians can shape a future that is filled with the wonderful wildlife resources that define this great state and provide for the enjoyment, recreation, sustenance, and livelihood of its citizens and visitors.

Acropora Status

(Source: http://www.nmfs.noaa.gov/pr/species/invertebrates/elkhorncoral.htm)

ESA Threatened - throughout its range

Taxonomy
Kingdom: Animalia
Phylum: Cnidaria
Class: Anthozoa
Order: Scleractinia
Family: Acroporidae
Genus: *Acropora*
Species: *palmata*

Species Description
Elkhorn coral is a large, branching coral with thick and sturdy antler-like branches.

The dominant mode of reproduction for elkhorn coral is asexual, with new colonies forming when branches break off of a colony and reattach to the substrate. Sexual reproduction occurs via broadcast spawning of gametes into the water column once each year in August or September. Individual colonies are both male and female (simultaneous hermaphrodites) and will typically release millions of "gametes".

The coral larvae (planula) live in the plankton for several days until finding a suitable area to settle, but very few larvae survive to settle and metamorphose into new colonies. The preponderance of asexual reproduction in this species raises the possibility that genetic diversity may be very low in the remnant populations.

Colonies are fast growing: branches increase in length by 2-4 inches (5-10 cm) per year, with colonies reaching their maximum size in approximately 10-12 years. Over the last 10,000 years, elkhorn coral has been one of the three most important Caribbean corals contributing to reef growth and development and providing essential fish habitat.

Habitat
Elkhorn coral was formerly the dominant species in shallow water (3 ft-16 ft (1-5 m) deep) throughout the Caribbean and on the Florida Reef Tract, forming extensive, densely aggregated thickets (stands) in areas of heavy surf. Coral colonies prefer exposed reef crest and fore reef environments in depths of less than 20 feet (6 m), although isolated corals may occur to 65 feet (20 m).

Elkhorn Coral Critical Habitat

NMFS designated critical habitat for elkhorn and staghorn corals in November 2008 in four areas: Florida, Puerto Rico, St. John/St. Thomas, and St. Croix.

Distribution

Elkhorn coral is found on coral reefs in southern Florida, the Bahamas, and throughout the Caribbean. Its northern limit is Biscayne National Park, Florida, and it extends south to Venezuela; it is not found in Bermuda. Once found in continuous stands that extended along the front side of most coral reefs, the characteristic "*Acropora palmata* zone" supported a diverse assemblage of other invertebrates and fish. These zones have been largely transformed into rubble fields with few, isolated living colonies.

Population Trends

In areas where loss has been quantified, estimates are in the range of 90-95% reduction in abundance since 1980. Additional drastic reductions (e.g., 75-90%) were recently observed in some areas such as the Florida Keys in 1998 due to bleaching and hurricane damage.

Threats

Since 1980, populations have collapsed throughout their range from disease outbreaks with losses compounded locally by hurricanes, increased predation, bleaching, elevated temperatures, and other factors. This species is also particularly susceptible to damage from sedimentation.

The dominant mode of reproduction for elkhorn coral is asexual fragmentation; this life history trait allows rapid population recovery from physical disturbances such as storms. However, this mode of reproduction makes recovery from disease or bleaching episodes (in which entire colonies or even entire stands are killed) very difficult. The large role of asexual reproduction for this species increases the likelihood that genetic diversity in the remnant populations may be very low. Scientists are becoming increasingly concerned for this species based on its demographic paramaters; specifically, how species recruitment and genetic diversity affect recovery potential.

Conservation Efforts

Florida Keys National Marine Sanctuary (FKNMS), the largest coral reef management entity in the region, has developed a management plan for the Sanctuary's corals that includes protective activities, such as zoning, channel markings, and restoration efforts.

Restoration activities have included efforts to re-attach *Acropora* fragments generated by ship groundings and hurricane events; these efforts have had mixed success. Similar efforts to re-attach coral fragments have also been made in Puerto Rico and the U.S. Virgin Islands.

Other restoration efforts have included attempts to culture and settle coral larvae with very limited success. New techniques for restoring *Acropora* are currently being pursued. Such new techniques involve enhancing sexual recruitment, reestablishing ecological roles within reef systems (e.g. herbivorous urchins), and other methods for controlling predators and disease.

In 1998, the United States Coral Reef Task Force was established by Presidential Executive Order 13089 to coordinate and strengthen efforts for protecting coral reef ecosystems. The Task Force is co-chaired by the Departments of Commerce and Interior, and includes leaders of 12 federal agencies, seven U.S. states and territories, and three freely associated states. In 2002, the Task Force adopted a resolution calling for the development of Local Action Strategies, which are locally-driven plans for collaborative and cooperative action among federal, state, territory, and non-governmental partners to reduce key threats on valuable coral reef resources. Three Local Action Strategies have been developed within the range of elkhorn coral for Florida, Puerto Rico, and the U.S. Virgin Islands. These strategies are underway and will be implemented over a three-year period (FY2005-2007).

Regulatory Overview

On March 4, 2004, the Center for Biological Diversity petitioned NOAA's National Marine Fisheries Service (NMFS) to list elkhorn (*Acropora palmata*), staghorn (*A. cervicornis*), and fused-staghorn (*A. prolifera*) coral under the Endangered Species Act (ESA). On June 23, 2004, NMFS found that listing these species may be warranted [pdf] and initiated a formal review of their biological status. NMFS convened the Atlantic *Acropora* Biological Review Team (BRT) to summarize the best available scientific and commercial data available for these species in the status review report.

The BRT completed the status review [pdf] [4.9 MB] on March 3, 2005. On March 18, 2005, NMFS determined that elkhorn and staghorn corals warrant listing [pdf] as "threatened" species under the ESA. However, NMFS also concluded that listing fused-staghorn coral is not warranted, as it is a hybrid and does not constitute a species as defined under the ESA. On May 9, 2005, NMFS proposed adding elkhorn and staghorn coral to the Endangered Species list [pdf].

NMFS finalized the ESA listing of elkhorn and staghorn coral on May 4, 2006 (71 FR 26852 [pdf]). More information can be found in the press release [pdf] of the final listing.

NMFS designated critical habitat for elkhorn and staghorn corals in November 2008..

NOAA Fisheries

General fact sheet
Atlantic *Acropora* corals

What is a coral?

Staghorn coral (*A. cervicornis*)

Corals are colonial invertebrates that excrete a calcium carbonate skeleton. There are two main types of corals: hermatypic, which produce reefs and are only found in tropical regions, and ahermatypic, which do not produce reefs and are found worldwide.

Most hermatypic corals host symbiotic (living together) algae, which live inside their tissue. The algae are called zooxanthellae. Zooxanthellae give corals their color and need sunlight for photosynthesis. They provide food to the coral and remove some of the corals waste products. In return the coral provides protection and access to light.

What do corals do?

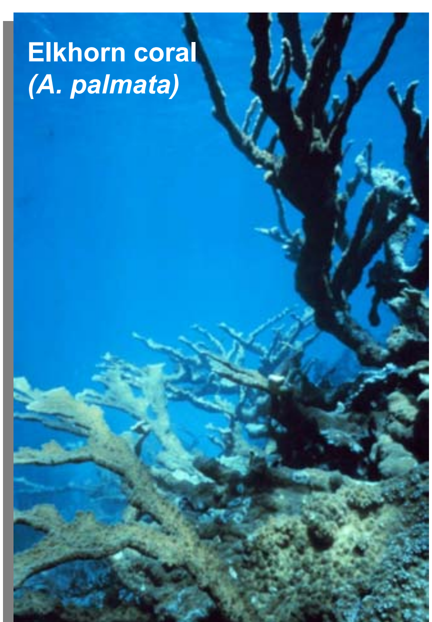
Corals provide habitat for reef fish and invertebrates. They also increase biological diversity. Corals reefs form a barrier along coasts and around islands offering shoreline protection from storms. Coral reefs support fishing, scuba diving, boating, and other recreational activities, as well as subsistence and commercial extraction that generate billions of dollars per year worldwide.

What is *Acropora*?

The *Acropora* genus is the most abundant and species-rich group of corals in the world. Only three species exist in the Atlantic/Caribbean region, Staghorn coral (*Acropora cervicornis)*, Elkhorn coral (*A. palmata)*, and Fused staghorn (*A. prolifera)*, a hybrid of the two. Acroporids are branching corals. These three coral species were the dominant reef building species throughout Florida and Caribbean.

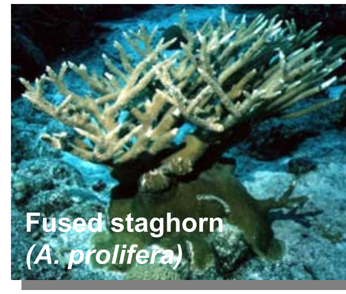
Where are the Atlantic Acroporids found?

Atlantic acroporids are found typically in shallow water on reefs throughout the Bahamas, Florida and the Caribbean. Acroporids live in high-energy zones, with a lot of wave action. Too much wave action (major storms) can cause branching corals to break. However, fragmentation via branch breakage is one method of reproduction for acroporids.



Elkhorn coral (*A. palmata*)

NOAA Fisheries



Fused staghorn (*A. prolifera*)

What salinity do *Acroporids* require?

Although some corals can tolerate extremes, most acroporids require normal marine salinity (33-37‰).

What temperatures do *Acroporids* need to survive?

Acroporids are typically found in water temperatures from 66°F to 86°F. Some degree of stress is experienced at water temperatures greater than 2-3°F cooler or warmer than normal for an extended period.

Do *Acroporids* need sunlight?

Corals depend on the symbiotic zooxanthellae for food. Zooxanthellae need sunlight to photosynthesize. Runoff from land deposits nutrients, which trigger algal blooms, and sediments onto the reef that cloud water. Without sufficient light, the photosynthetic rate is reduced and with it the amount of nutrition produced by the zooxanthellae and the ability of corals to secrete calcium carbonate and build reefs. For branching corals, the optimum range is 60-100 percent of tropical sunlight. Corals grow best in clear water free from excess nutrients, runoff, or algal blooms. Acroporids are particularly sensitive to sediment, as they are among the least effective of the reef-building corals at trapping and removing sediment from their surface. On the other hand, excessive ultraviolet (UV) light may lead to bleaching.

What is coral bleaching and what causes it?

Bleaching is the temporary or permanent loss of zooxanthellae (symbiotic algae) from the coral. Many types of physiological stress can cause coral bleaching (e.g., UV, excessively warm or cold water temperatures, in some cases bacterial infection, etc.). However, the recent mass bleaching events are caused by warm water temperatures and have caused widespread coral mortality on coral reefs throughout the world,

What things negatively affect *Acroporids*?

There are many stresses affecting acroporids, both natural and human-induced. Land based sources of pollution, such as runoff, sewage discharge, dredging and coastal development can increase nutrient levels, sediment loading and turbidity. Runoff can also reduce oxygen levels and possibly introduce pathogens. Excess nutrients allow large fleshy algae (macroalgae) to proliferate and overgrow corals. Pathogens may cause diseases in corals such as white-band disease and white pox/patchy necrosis, which are thought to be two of the most significant causes of mortality to Atlantic acroporids. Climate change, associated with increased water temperature and elevated light levels, may cause bleaching, reduced coral growth rates and deposition rate of their calcium carbonate skeleton. Overfishing and disease have caused a reduction in number of important predatory fishes such as groupers and herbivores (plant eaters) such as parrotfish. Reduction in number to predatory fishes can possibly lead to an increase in organisms that prey on acroporids, such as the short coral snail, fireworm, and damselfish. Furthermore, without a healthy herbivorous fish population, macroalgae growth limits the recovery of stressed corals and the settlement of new baby corals to replace those that have been lost from disease, bleaching, predation and overgrowth.

5.0 The Human Environment in the South Atlantic

5.1 Coastal Communities in the South Atlantic

This description of potential fishing communities for the U.S. South Atlantic coast includes a compilation of various social indicators that are relevant to fishing, fishermen and fishing communities. These indicators provide baseline information from which assumptions about social impacts might be made regarding future regulatory actions. A number of data sources were used to assemble community profiles, including: the U.S. Census Bureau Decennial census and zip code business patterns; the federal permit system and state permit system. These profiles were bolstered by field visits in many of these communities to confirm the presence of fishing related activity and to interview key informants about the interconnectedness of that activity to the larger economy and culture of the community. This was accomplished using what is called rapid assessment. While this methodology is no substitute for the more in-depth ethnographic methods commonly used by anthropologists in community studies, it was all that was possible under the budgetary constraints of this research. In addition, these data were compiled into a Geographic Information System (GIS) to facilitate data mapping and amalgamation with other GIS data.

5.1.1 Methodology for Defining Fishing Communities

Previous descriptions of fishing communities tied to particular management actions have provided an indication of the difficulties in defining community and a community's relation to fishing dependence (Aguirre International 1996; Impact Assessment, Inc. 1991; NPFMC 1994; Johnson and Orbach 1996). Griffith and Dyer (Aguirre International 1996) developed a typology of fishing community dependence for the Northeast Multi-species Groundfish Fishery (MGF). In that typology, the authors identified indicators of dependence which included specific physical-cultural and general social-geographic indicators, i.e., number of repair/supply facilities; number of fish dealers/ processors; presence of religious art/architecture dedicated to fishing; presence of secular art/architecture to fishing; number of MGF permits; and the number of MGF vessels. Using previous results and rapid appraisal they developed a fishery dependence index score for the five primary ports in the MGF. As a result they were able to document five variables that best predicted dependence upon the MGF: (1) relative isolation or integration of fishers into alternative economic sectors, including political participation; (2) vessel types within the port's fishery; (3) degree of specialization; (4) percentage of population involved in fishery or fishery-related industries; and (5) competition and conflict within the port, between different components of the MGF (Aguirre International 1996).

McCay and Cieri (2000) recently compiled a social and economic profile of the fishing ports and coastal counties of the Mid-Atlantic region. In their study they used a variety of sources for information: (1) federal census and employment data, analyzed for the counties associated with the commercial fisheries of each state; (2) NMFS weigh-out data on 1998 landings, by species, gear-type, and port, together with similar data, by county, from the state of North Carolina; and (3) field visits and interviews. Their approach was to identify fishing communities recognized as "ports" by the port agents of the NMFS.

Detailed community profiles have been conducted in Alaska to understand the impacts of harvest allocation on communities and on fisheries (Impact Assessment, Inc. 1991; NPFMC 1994). These profiles utilized census data, permit data, and other available reports supplemented by ethnographic data collection for each community. The profiles provided baseline data to facilitate social impact assessment for license limitation management of the ground fish and crab fisheries.

Johnson and Orbach (1996) combined several counties into management areas, which reflected many sociological, ecological and environmental differences and the types of fishing found in the various fishing communities. Although they did not attempt to define dependence or specify specific fishing communities, they did contend that management of fisheries would be enhanced if it were to take into consideration the broader social and ecological realities of fishermen's behavior.

More recent research to identify fishing communities has been undertaken in both the Northeast and the Southeast. Hall-Arber et al. (2002) used several approaches in assessing a community's dependence upon fishing. One was a regional model of fishing-related employment compared to alternative employment. Another focused on fishing structure complexity and the degrees of individual communities' gentrification and the third approach used community profiles with detailed port characteristics and stakeholder views on community, way of life, institutions and fisheries management. They conclude that a regional analysis reflects the incorporation of a fishing component into economy of contemporary coastal communities.

In their study of Florida fishing communities, Jacob et al. (2001) used a protocol based on central place theory which combined federal and state fishing permit data and census employment data aggregated at the zip code level to sort population centers and their surrounding hinterlands into central places for the entire state of Florida. Zip code was used for the basic unit of aggregation because it is a geographic identifier for many forms of commercial and recreational fishing data, it is also a relatively small unit of measure, and its boundaries form a service delivery area. To account for the embedded nature of economic linkages in fishing communities, regional economic multipliers for employment were used to estimate the number of jobs that were directly and indirectly related to fishing in each community. Based upon their measure of dependency a small number of coastal communities were determined to be dependent upon fishing. However, using such a dependency measure is not without its drawbacks as concerns about the undercounting of certain occupations within the census data and the inability to satisfactorily measure the recreational sector in terms of its contribution to the local economy are noted.

Because there has been little or no research to document fishing communities in the South Atlantic, this description of communities will use a modified approach similar to that used by Jacob et al. (2002). Although a regional approach is sometimes warranted, it is apparent that in their Florida research (Jacob et al. 2002) some fishing communities became subsumed within the larger service sector economy of Florida's coastal regions, which have been fueled by the rapidly growing tourism and recreation sectors. While it is true that most Floridians do participate in an economy that extends beyond their community, it is likely that the majority of their needs are met within the confines of that place they consider their home or what we are referring to as a community. It is improbable that the same boundary serves as community for all individuals. Therefore we have to assume that based upon certain criteria a pre-determined boundary will encompass an area that captures a sense of community for most of those who live within that boundary. Without extensive ethnographic research into social networks and sense of place, it is impractical to assume that we know the exact boundary around a fishing community. For that reason, in this description there will be no definite boundary assumed, however the fishing community will be understood to exist within a range of boundaries.

Data at the census designated place level (CDP) are used for describing the demographic character of most communities. Where zip code level data only are available (permits, NAIC employment figures), data are compiled for the all zip codes associated with the area identified. A map, which shows the zip code boundary for each CDP, is provided along with the outline of the CDP.

One of the difficulties in using CDP data is that it has been shown that fishermen will often live outside the boundaries of the CDP where their vessel is home ported (Jacob et al. 2001). Data at the CDP level will not always have a direct one to one correspondence with other data such as the fisherman's home zip code or zip code business patterns for fishing employment locations. Therefore data that correspond to one level of place may not correspond to another. Consequently, it is important to understand these differences when undertaking any assessment of impacts to a community. Furthermore, it has been noted that census data often underreport certain groups of people. Recent research (Kitner 2001) has identified coastal communities and fishing communities as being part of those groups who may not be fully represented by census data.

Because at this time there are no standard guidelines for delineating the boundaries of a fishing community, this description will combine data from different levels and concepts of place (zip code, homeport and Census Designated Place). Each, in its own way, may represent some part of a fishing community, but none will represent the community in its entirety. Such boundaries cannot be determined without extensive research, as mentioned before. The data presented here will highlight the differences in the types of data used in determining the boundaries of a community and any such impacts that might ensue.

5.1.2 Census Demographic and Employment Data Caveats

When using census data it is important that certain caveats be made clear. As mentioned previously, census data has been notorious for underreporting certain groups of people who are difficult to locate and therefore are often not reported in the census. Commercial fishermen are part of that group as outlined in recent research by Kitner (2001). For that reason, it must be assumed that census data as it relates to fishing communities underreports employment and participation in work related to commercial fishing. As was pointed out in earlier research (Jacob et. al. 2001) any attempt at quantifying employment or income from commercial or recreational fishing becomes problematic. Data may be suppressed or grossly underreported and therefore any description will miss important economic and social contributions of fishing related businesses.

At the same time, census data is the only demographic data that can be applied over large geographic areas and population ranges. It is easily available and represents the most affordable alternative for describing any community at this time. Although these data are suspect, it can only be assumed that any underreporting is consistent across geographic area and population range. Although this situation is not ideal, by combining several different data from various sources, a general description of community and the fishing activity associated with it may be attained. Until more detailed ethnographic research that can examine the social and economic networks that exist in fishing communities can be undertaken, this general and often broad description of community will have to suffice.

Census demographic data were collected for communities and appear under each community description. Those data include the following variables for each community: total population by age; educational attainment; race; industry; occupation; average wage or salary; poverty status. These data were collected for census years 1970, 1980, 1990, and 2000. Census data for the first three decades were compiled using the MARFIN Socioeconomic Database created by the Louisiana Population Data Center. The census data for the year 2000 were compiled from the U.S. Census Bureau's American Factfinder Webpage. In using data from the 2000 census there are several caveats that must be noted. The 2000 census was the first year that individuals were allowed more than one choice when deciding race. Therefore, when comparing the category race to the previous three decades, the association will not be consistent. In order to lessen misunderstanding for this description only those categories where one race alone was chosen were used. In other words, those who chose more than one race were not included. This will result in some underreporting for the year 2000 in the tables presented.

Other significant changes in the 2000 census were made to the industry and occupation categories. This was the first decennial census to use the North American Industry Classification Code (NAIC) in replacement of the Standard Industry Code (SIC). In the transition from SIC to the NAIC, many industry and occupation categories were reclassified making it difficult to compare any previous census and the most recent. For the purposes of comparison here, certain industry categories were reclassified and compiled to reflect the best representation of the previous classification used in the preceding census (See Appendix 1 in Jepson et al. 2006). This recoding was done after comparing certain industry classifications which were moved into other categories with the switch to the NAIC from SIC. While admittedly not perfect, this reclassification was necessary to make comparisons of industry changes over time. The task of reclassifying the occupation category was deemed too onerous and therefore the only category reported for 2000 is the Farm, Fish and Forestry category, which did not change and most likely contains the majority of fishing related employment.

Employment data collected by the Census Bureau were also used at the zip code level for the community descriptions. Again, it must be assumed for reasons stated earlier that these data are likely to underreport actual fishing employment. In addition, the category of fishing that is reported in the economic census does not include those individuals who report themselves as self-employed, of which most commercial fishermen consider themselves to be. Therefore, employment figures again grossly distort the actual employment from commercial and recreational fishing. In addition, like Jacob et al. (2001), employment for the recreational sector was difficult to quantify and the marinas sector is once again used to provide some indication of community employment for the recreational sector. It is recognized that this measure is inadequate and is one component of a much larger employment sector.

At the end of each state's community profiles, two tables have been provided to categorize both the attendant fishing infrastructure in those communities, but to also begin a process of determining which of the following communities might warrant further consideration as a fishing community. The information provided in these tables is considered highly subjective based upon the presence or absence of certain criteria and an assessment of other information provided through interviews or historical data. It is therefore suggested that any future determination of fishing community status use these tables cautiously and be judicious in attempting to incorporate any other information that might be available to categorize any of the communities included in this document. It must also be noted that during field research and as part of the management process, other communities have been mentioned for inclusion to be considered as fishing communities and therefore those communities included in this document do not constitute an exhaustive listing of potential fishing communities.

5.1.3 North Carolina Communities with Substantial Fishing Activity

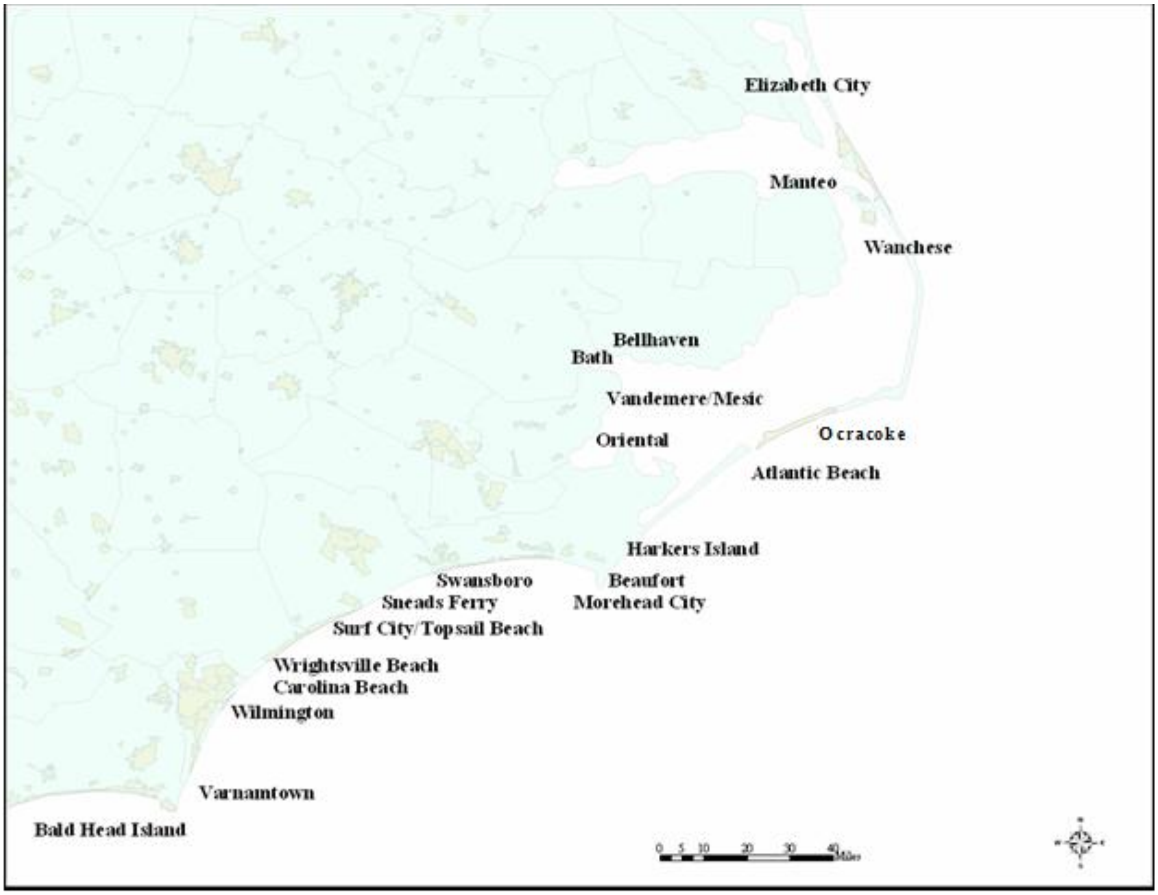

Figure 5.1.3-1. North Carolina Potential Fishing Communities.

According to the National Marine Fisheries Service, North Carolina has landed close to 140 and 160 million pounds of seafood in 2001 and 2002 respectively. Two ports, Wanchese-Stumpy Point, and Beaufort-Morehead City, both rank within the top 50 ports in terms of landings and value for those same years. In 2008, North Carolina vessels with federal permits predominantly held Atlantic dolphin/wahoo commercial (452) , Atlantic dolphin/wahoo charter (330), Atlantic king mackerel (313) or Spanish mackerel (202), or snapper grouper charter/headboat for snapper grouper (287) permits. Figure 5.1.3-1 shows potential fishing communities in North Carolina.

Table 5.1.3-1. Numbers of Federal Permits (October 2008) by Type for North Carolina (Source: NMFS 2008)

Type	Permits
ATLANTIC DOLPHIN/WAHOO COMMERCIAL	452
ATLANTIC DOLPHIN/WAHOO CHARTER/ HEADBOAT	330
S. ATLANTIC CHARTER/HEADBOAT FOR PELAGIC FISH	314
KING MACKEREL	313
SPINY LOBSTER & TAILING	15,23

S. ATLANTIC SNAPPER-GROUPER (225)	10
SPANISH MACKEREL	202
SOUTH ATLANTIC SHRIMP	168
DEALER	91

There were over 8,600 state licenses sold with capability of sale and over 3,900 reported sales in 2006 (Table 5.1.3-2). The overall number of licenses sold has been decreasing since 2001. The number of licenses reporting sales has been decreasing while the number of licenses without sales has been increasing.

Table 5.1.3-2. Number of licenses sold by the North Carolina Division each license year. The number of licenses with selling privileges that potentially can report catch on trip tickets by license year, and the number of licenses actually used to report catches. Individuals may hold more than one license with selling privileges (**Data Source: NCDMF 2007 Annual Report (Big Book), pp. II-89.)**

License Year	Number of licenses sold*	Number of licenses reporting sales	Number of licenses sold, but did not report sales
1994	6,779	4,820	1959
1994/1995	7,534	6,545	989
1995/1996	7,801	7,148	653
1996/1997	8,175	6,716	1459
1997/1998	8,317	7,009	1308
1998/1999	8,438	6,528	1910
1999/2000	9,711	5,892	3819
2000/2001	9,677	5,802	3875

*Licenses from 1994 to June 1999 are Endorsement to Sell licenses. Licenses from 1999 to the present include number of SCFL, RSCFL, Shellfish, Menhaden License for Non-Residents without SCFL, Recreational Fishing Tournament License to Sell Fish, and Land or Sell licenses. License year is July to June. Source: 1994-1997/98 license year sales were derived from historical reports. 1998/99-2001/2002 from FIN license sales reports.
**1998/99 was a transition year and not all dBase licenses were migrated to FIN. The numbers provided were from FIN.
***1999/00 to 2001/02 include licenses sold that were subsequently surrendered without a refund.
+1999/2000 license counts were stated as much higher in other documents. This was due to the grace period when switching from ETS to SCFL. The number above is correct.

The majority of license sales are for commercial fishing vessels, with over 8,846permits or 37.5 percent in 2008 (Table 5.1.3-3). Standard commercial fishing license is the next most frequent with 25.2 and recreational commercial gear third at 21.7 percent. There were 737 dealer licenses sold for the year 2008 in North Carolina.

Table 5.1.3-3. Number of State Permits by Type for North Carolina (Source: NCDMF 2008).

Type	Permits	Percent
Commercial Fishing Vessel Registration	8,846	37.5
Fish Dealer License	737	3.1

Spotter Plane License	9	0
Retired Standard Commercial Fishing License	912	3.9
Standard Commercial Fishing License	5,948	25.2
Total	23,581	100.0

There has been considerable research conducted with North Carolina fishermen and their communities over time. Johnson and Orbach's research (1996) combined several counties into management areas which reflected many sociological, ecological and environmental differences. Those differences were related to the different types of fishing found in the various communities. Although they did not attempt to specify specific fishing communities, they did contend that management of fisheries would be enhanced if it were to take into consideration the broader social and ecological realities of fishermen's behavior. Griffith (1999) has written extensively about North Carolina fishermen and their communities and Garrity-Blake (1994) has also provided an in-depth look at the menhaden fishery. Numerous journal articles and gray papers have also contributed to an understanding of North Carolina and its fisheries. But to date there has been no systematic attempt to identify fishing communities and begin baseline data collection. The communities described here were selected from a list of fishing communities identified by various advisory panel members who are knowledgeable about North Carolina fisheries and their communities. The list was modified after conducting rapid assessment in some of those communities. These descriptions are not a definitive list of fishing communities in North Carolina, but represent the first phase of assembling both the data and descriptions to begin identifying those communities which may indeed be classified as a "fishing community."

A map for each community is provided which displays federal dealers and a symbol indicating the number of federal permits by zip code. The zip code area name is displayed in light blue while the CDP name is in black. The symbol for permits is centered within the zip code area and does not represent the precise location of any permit holder. Dealer permits are displayed near their physical location.

5.1.3.1 Varnamtown

Varnamtown (Figure 5.1.3-2) has seen a slight population increase from 1990 to 2000. The majority of housing is owner occupied (Table 5.1.3-5) and residence is fairly stable with most living in the same house within the last five years for both the 1990 and 2000 census (Table 5.1.3-6). Just over fifty percent of the population is in the labor force for the last two decennial censuses, but the percent unemployed has declined from 8.2 percent in 1990 to 5.1 percent in 2000. The population is almost entirely White with a few Latinos according to Table 5.1.3-8. The poverty rate has declined from 17.2 percent in 1990 to 11.2 percent in 2000 (Table 5.1.3-10). Employment in the retail and wholesale industry leads with construction and transportation next (Table 5.1.3-11). There has been a slight decline in both the categories of Agriculture, Fishing and Mining (Table 5.1.3-11) and Farm, Fish, Forest (Table 5.1.3-12) from 1990 to 2000.

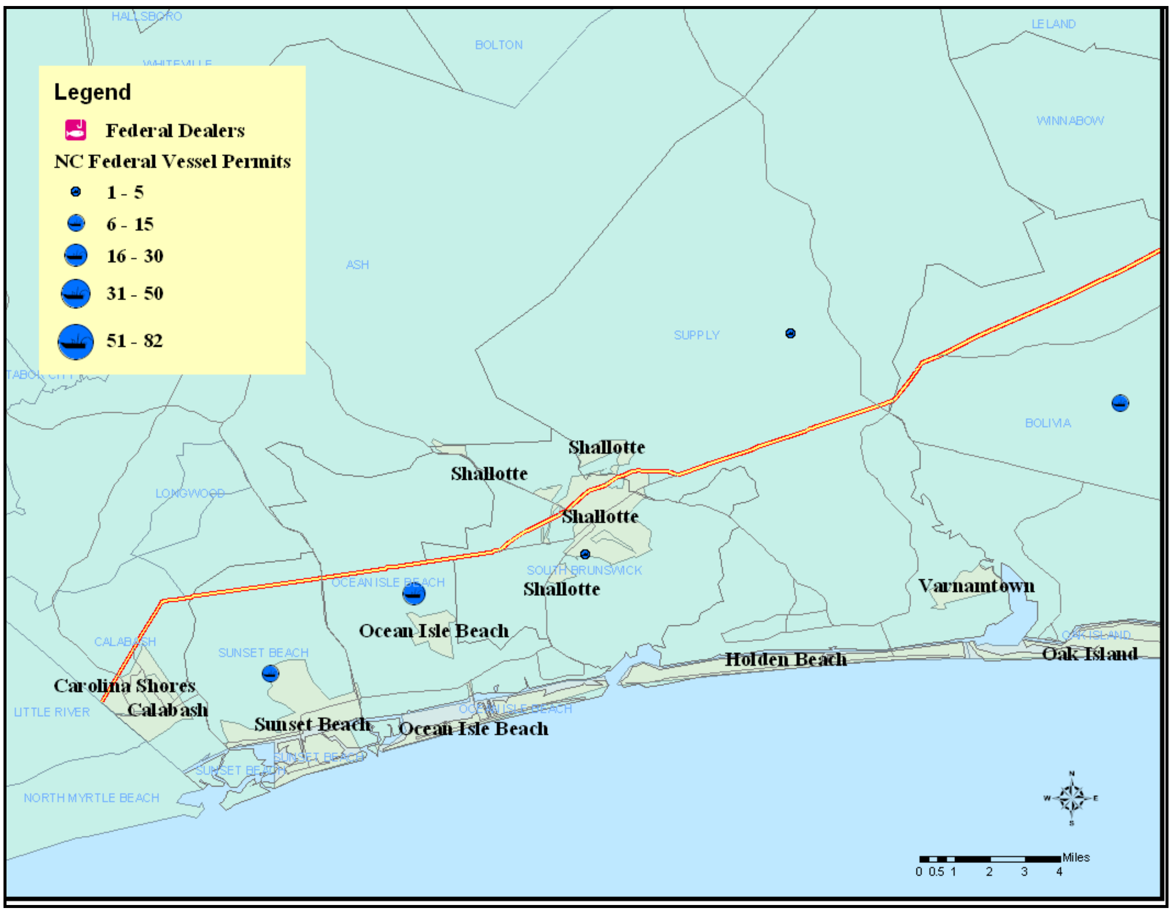

Figure 5.1.3-2. Varnamtown, NC.

Varnamtown is supposedly the fishing hub for this region, although as evidenced by the above map (Figure 5.1.3-2) and Tables 5.1.3-4 and 5.1.3-5, many fishermen list Supply as their residence for some reason, which may be where the post office is located. A sign at the town entrance prominently displays a shrimp trawler welcoming you to the community. Varnamtown is relatively rural and surrounded by farmland. There are at least five fish houses and a marina which services non-commercial boats. One of the fish houses does have charter operations and a jet-ski business that operate under the same roof.

One fish house owner commented that they struggle with their seafood business because shrimpers are having difficulty making ends meet. Most fishermen who dock and sell at local fish houses live near the town itself. A large percentage of locals make some kind of a living off the water – harvesting fish, clams, or oysters according to those interviewed. Some fish year-round, but many have other jobs such as carpentry and work on dredge boats. Development has changed the community; outsiders are a more common sight now, according to one individual, whereas in the past it was primarily locals living in the community.

Sunset Beach / Seaside

Sunset Beach is really two communities – one on the creek side and the other on the ocean side. The creek side with its strip malls and mobile homes is where the locals live year-round. It appears to be much more working-class than its ocean side counterpart. The beach side is developed with expensive homes, gift shops, and beach wear stores. On the creek side and a little more inland is the town of Seaside, where there is limited fishing. The Pelican Point Marina in nearby Shallotte is primarily a recreational marina with no commercial boats. A few small trawlers dock at a seafood restaurant near a steel and aluminum welding shop that caters to the fishing population.

Holden Beach, North Carolina

Developed much like Sunset Beach, Holden Beach has one marina but no charter operations. It is tourist centered, with beach wear marts and a couple of seafood restaurants.

Supply, North Carolina

Supply is an unincorporated area, yet the zip code area is named after this small community. Viewing the permit tables and the zip code related employment table it is obvious there is considerable fishing activity within the zip code area that does not appear in federal permit tables (Table 5.1.3-13) nor the state permit table (Table 5.1.3-15) for Varnamtown. Supply has over 600 licenses issued in 2002 with 167 shellfishing licenses and over 130 standard commercial fishing licenses. There are 22 dealers licensed in Supply and over 260 commercial vessels according to Table 5.1.3-16. In 2008 only 2 federal permits were issued, those being for south Atlantic shrimp (Table 5.1.3-13).

5.1.3.2 Southport/ Bald Head Island (28461)

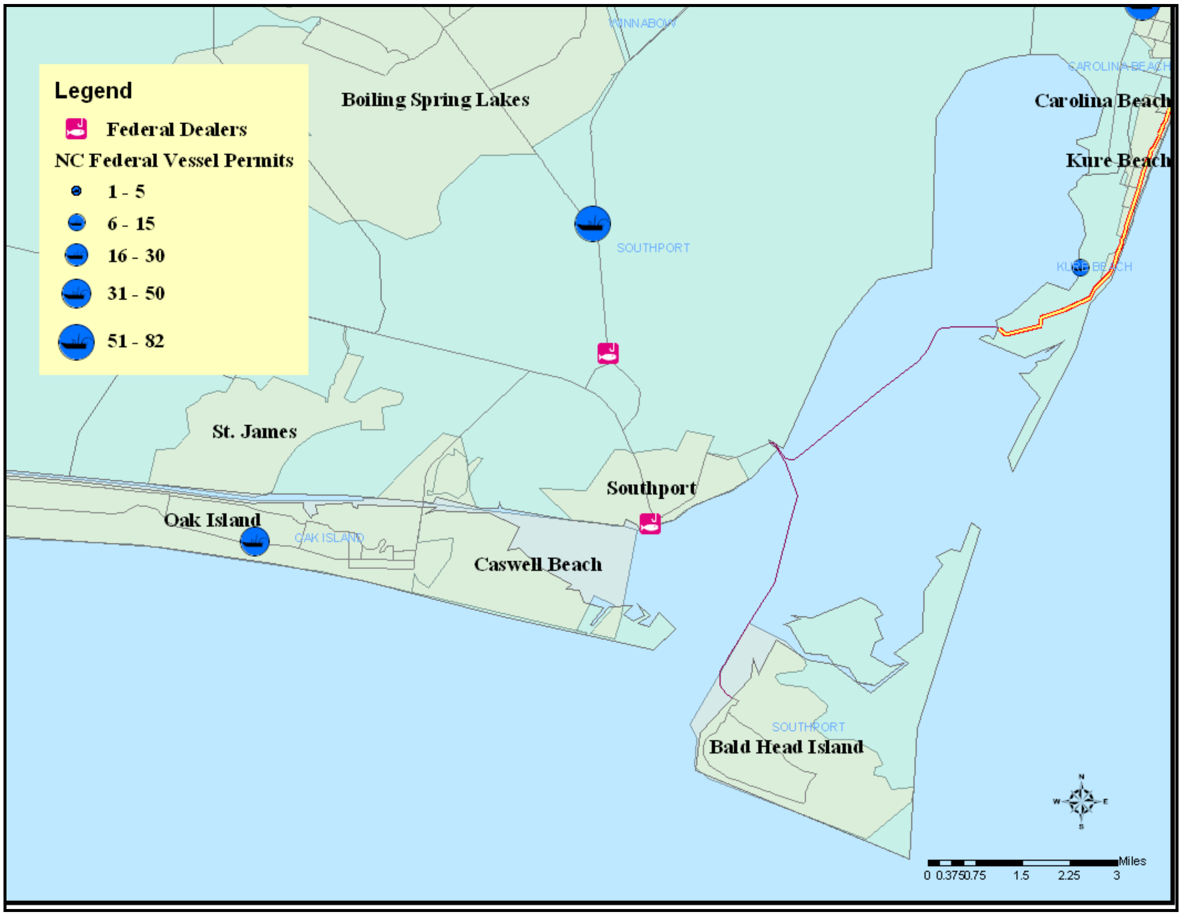

Figure 5.1.3-3. Southport/Bald Head Island, North Carolina.

Southport

Southport (Figure 5.1.3-3) is a quaint fishing community located at the mouth of the Cape Fear River, originally incorporated in 1792; this community caters to both tourists and locals. The downtown marina has restaurants, gift shops and several inns. There are at least three marinas in the area, with several seafood restaurants nearby. There is a dredging company and a nearby boat yard and a welding company that provide marine repairs. The North Carolina State Ports Authority has a small boat harbor located here and the NC Maritime Museum has a branch in Southport.

There are several recreational fishing tournaments held in Southport including the US Open King Mackerel Fishing Tournament held in October which attracts more than 500 boats annually. Other tournaments include the Lady Anglers King Mackerel Tournament in August and the Wildlife Bait and Tackle Flounder Tournament held in September.

Southport has some seafood employment with most in seafood processing and fish and seafoods as shown in Table 5.1.3-37. There are over 200 state permits with the majority being commercial vessel registrations and the next being standard commercial fishing licenses at 76. There were 14 dealer permits listed also.

Southport has seen a decrease in its population since 1980 from 2835 to 2386 in 2000. Approximately 70 percent of the housing was owner occupied in 1990 and 2000 and a large majority of the population has remained stable, living in the same home as five years before for both censuses. The percentage of people in the work force has increased while the percentage of unemployed has dropped according to Table 5.1.3-20. The majority of the population is White (76%) with 22% Black and less than 2% Latino (Table 5.1.3-21). The poverty rate in 2000 was 12.5 percent which is up from 10 percent in 1980 (Table 5.1.3-23). There has been a decline in both the Agriculture, Fishing and Mining industry category and the Farm, Fish, and Forestry occupation category since 1990 (Tables 5.1.3-24 and 5.1.3-25).

Bald Head Island

Bald Head Island is an exclusive community with a private ferry operated by the island. Many Southport residents work on the island or for the ferry system. There are a few restaurants, an inn, and gift shops located around a marina on the island. The marina is a full service marina with electrical service which will accommodate vessels up to 90 feet in length. There is a charter fishing operation at the marina, but no commercial vessels dock there. People can fish from shore and there is an annual fishing rodeo in May.

The population on Bald Head Island has doubled since 1990 to 165 persons. Housing tenure has shifted somewhat with the percent renter occupied growing from 8.3 percent in 1990 to 37.9 percent in 2000 (Table 5.1.3-27). Residence is beginning to show some stability with the percentage of people living in the same house as five years ago in 2000 more than in 1990 according to Table 5.1.3-28. A greater percentage of people are now in the labor force and unemployment has risen also as shown in Table 5.1.3-29. The population is predominately White according to Table 5.1.3-30, but there has been a recent increase in the category for Blacks although relatively slight in terms of overall population. According to Table 5.1.3-23 the average wage or salary has dropped considerably since 1990 and the number of persons in poverty has also risen. These dramatic changes reflect the total persons identified in the census for this island which has a relatively small population.

5.1.3.3 Carolina Beach (28428)

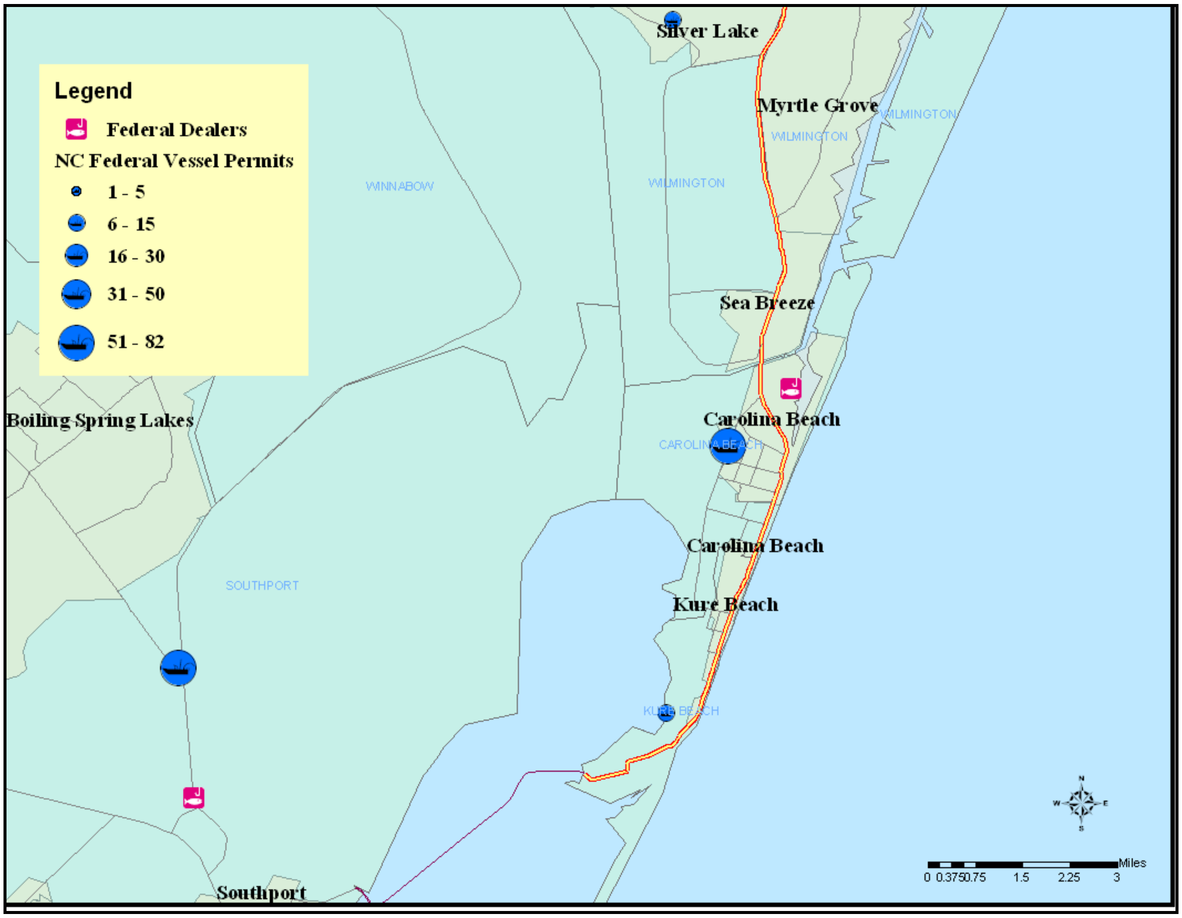

Figure 5.1.3-4. Carolina Beach, North Carolina.

Carolina Beach is situated along what is referred to as the Crystal Coast and has a storied history from Colonial times to the Civil War. Close to Wrightsville Beach, this community is not nearly as crowded or developed, but is still a major tourist destination that relies heavily on the charterboat industry. The municipal marina is where the charter and head boats are docked. Three head boats and three party/cruise boats and approximately 22 charters utilize the municipal marina. There are several bait & tackle shops nearby and there remains one commercial fish house in the community; out of at least five in the past. Five commercial vessels dock at the municipal marina. There are about eight seafood restaurants in the community and most of the hotels are independently owned rather than national chains. The area hosts three fishing tournaments each year: the Atlantic Anglers' Spring Classic Surf Fishing Tournament in May, the East Coast Got-Em-On-Live-Bait Classic King Mackerel Tournament in July, and the Carolina Beach Surf Fishing Tournament in October. The community also hosts the annual Seafood, Blues and Jazz Festival.

Carolina Beach's population has grown steadily since 1980 to over 4,700 people in 2000 (Table 5.1.3-40). Housing tenure has grown in the area of owner occupied since 1990 (Table 5.1.3-41) and more people seem to be living in the same house as they did five years ago (Table 5.1.3-42). The number of persons in the labor force has not changed much while unemployment has dropped from 1990 to 2000 (Table 5.1.3-43). Racial percentages for the population have remained relatively stable with a predominantly White population according to Table 5.1.3-44.

Carolina Beach has over twenty vessels with federal permits and by far the majority of those vessels hold charter permits for both snapper grouper and coastal pelagics (Table 5.1.3-49). Most of the employment for the zip code area is in fish and seafood (Table 5.1.3-50) while the majority of the 131 state permits are for commercial fishing vessels at 84 Table 5.1.3-51. There are another 35 standard commercial fishing licenses and 19 shellfish licenses in Carolina Beach.

5.1.3.4 Wilmington (28401, 28403, 28405, 28411, 28412)

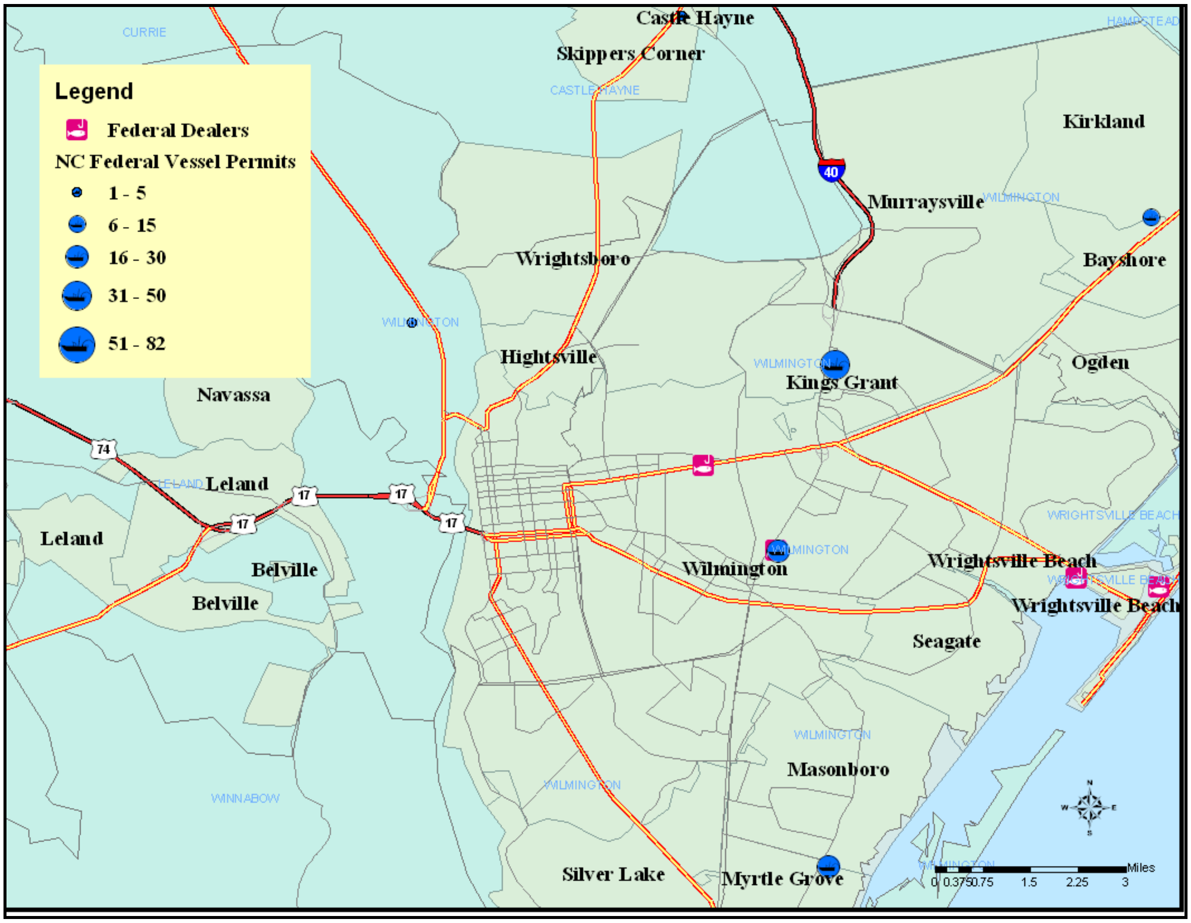

Figure 5.1.3-5. Wilmington, North Carolina.

Wilmington was previously known as New Liverpool, New Town and Newton, and founded by a group of Englishmen, many of whom were maritime businessmen. Located on the Cape Fear River, the town became an important port, but growth was originally slow following the Revolutionary War because of a lack of decent roads and the long distance of the port from the mouth of the river. However, in the mid-1800s, the port began to develop into a center for exports with rice, peanuts, flax, cotton, and naval stores being shipped all over the world. With the advent of the Civil War the export trade in Wilmington halted, however, the town gained prominence as "the lifeline of the Confederacy," involving itself in the blockade running/profiteering business. After the war, cotton exports were still an important commodity shipped from the port, but World War II brought a shift in the economy with more of an emphasis upon ship building. Today, Wilmington continues to be an important port with the State's Port Authority located there.

The total number of persons living in Wilmington has grown steadily since the 1970s according to Table 5.1.3-52. Housing tenure has not changed much with an almost even split between owner and renter occupied housing (Table 5.1.3-53). Residence has changed to some degree with more people living in a different house outside the county, so a new migration from outside the county and state must be taking place (Table 5.1.3-54). The percentage of people in the labor force has not changed much but unemployment has risen since 1990 from 3.8 to 8.6 in the year 2000 (Table 5.1.3-55). The population is still predominantly White, yet there is a substantial Black population that has historically been there (Table 5.1.3-56). The poverty rate has dropped since 1970 when it was 25.2, but still remains at 18.8 percent for the year 2000 ((Table 5.1.3-58). As with most communities there has been a substantial drop in the number of those persons employed in the agriculture, fishing and mining category of industry as well as the category of Farm, Fish and Forestry under occupation for Wilmington (Tables 5.1.3-59 and 5.1.3-60).

Wilmington has had between 30 to 40 vessels with federal permits since 1998 and most of those have had permits to fish coastal pelagics and snapper grouper (Table 5.1.3-61). There is considerable employment in the realm of fish and seafood and seafood markets, but the majority is in marinas and some also in boat building as reported in Table 5.1.3-62. In 2008, there were 970 state permits issued for Wilmington with the majority of those issued for commercial vessels. There were almost 285 standard commercial fishing licenses and 117 shellfish licenses sold for Wilmington residents. Over 42 dealer licenses were issued as were 3 to recreational fishing tournaments in order to sell licenses (Table 5.1.3-63).

5.1.3.5 Wrightsville Beach (28480)

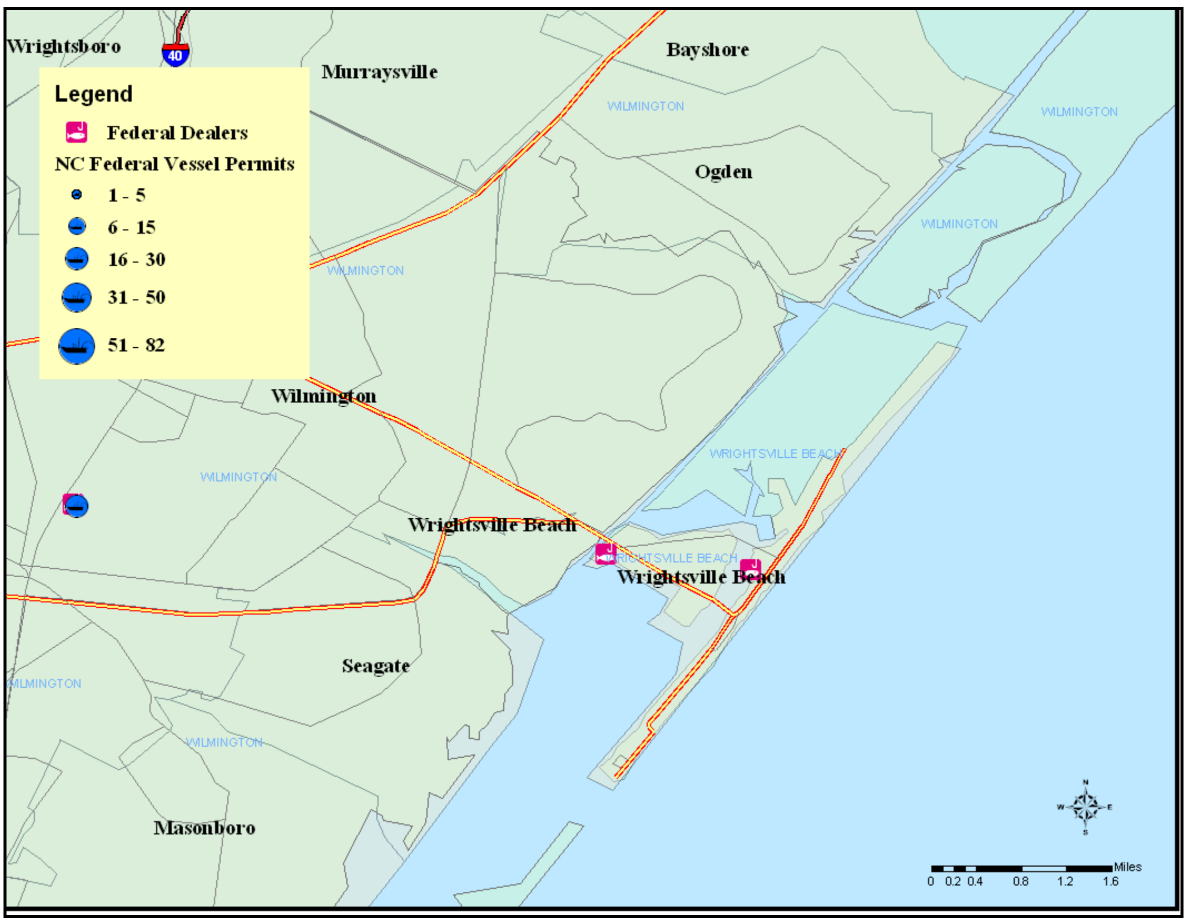

Figure 5.1.3-5. Wrightsville Beach, North Carolina.

The town of Wrightsville Beach occupies one of the barrier islands along North Carolina's southeastern coast. Today, the island is 1,000 to 5,000 feet in width and stretches almost four miles from Masonboro Inlet on the south to Mason Inlet on the north. Originally the island was called New Hanover Banks, a sandy barrier island cut by the shallow Moor's Inlet. The northern part of the island was called Shell Island. Development of the island was slow due to the distance and lack of transportation other than by boat. The island was once owned by the State of North Carolina until it was transferred into private hands in three separate grants between 1791 and 1881. One of the families who owned land was the Wright family, for which the island is named. For a century following, there were no residents on the island. However, hunters and fishermen were drawn to the area for the Spanish mackerel and bluefish. Sailing also became popular around the area and frequent races led to the establishment of the Carolina Yacht Club in 1853. Members of the Carolina Yacht Club erected a clubhouse, which was the first structure built on what would be called Wrightsville Beach. The Club is recognized as the third oldest yacht club in the United States.

A turnpike was completed in 1887, which connected Wilmington to Wrightsville Sound, and increased development and growth on the island. Also, the Wilmington Seacoast Railroad Company extended its track from Wilmington to the island. More yacht clubs were established, along with beach cottages, hotels and local stores, leading the area to become a popular summer vacation spot. On March 6, 1889, the town of Wrightsville Beach was incorporated. A public pavilion was created in 1905 on the end of the rail line. This pavilion included a bowling alley, shooting gallery, movie theatre and snack bar. In 1935, a large two-lane bridge across the Intracoastal Waterway to Harbor Island, then over Bank's Channel to Wrightsville Beach. A population of about 110 year-round residents in 1930 grew to about 1500 in 1945.

There has been a slight decline in the total population for Wrightsville Beach since 1980 (Table 5.1.3-64). Housing tenure has remained approximately the same with a slight increase in the number of owner occupied housing (Table 5.1.3-65). There seems to be increased stability residence with more people living in the same house in 2000 than there were in 1990 in terms of percentage (Table 5.1.3-66). The percentage of individuals in the labor force has remained about the same with a slight decrease and unemployment is relatively unchanged at 2.0 percent since 1990 (Table 5.1.3-67). The majority of the population remains White with slight increases in the number of Latinos and Blacks (Table 5.1.3-68). Average wage or salary saw a significant increase from 1980 to 1990 but a much smaller increase in 2000. The poverty rate has remained around 9.0 percent throughout the last three decades (Table 5.1.3-70).

In 2008, vessels with federal permits predominantly held Atlantic dolphin/wahoo commercial (9), Atlantic dolphin/wahoo charter (10), south Atlantic charter/headboat for pelagic fish(10), or snapper grouper charter/headboat for snapper grouper (7) permits (Table 5.1.3-73). In the community and most of the fishing related employment has been in the marina sector according to Table 5.1.3-74. There were 19 commercial vessels registered with the state and one dealer (Table 5.1.3-75).

5.1.3.6 Surf City/Topsail Beach (28445) and Hampstead (28443)

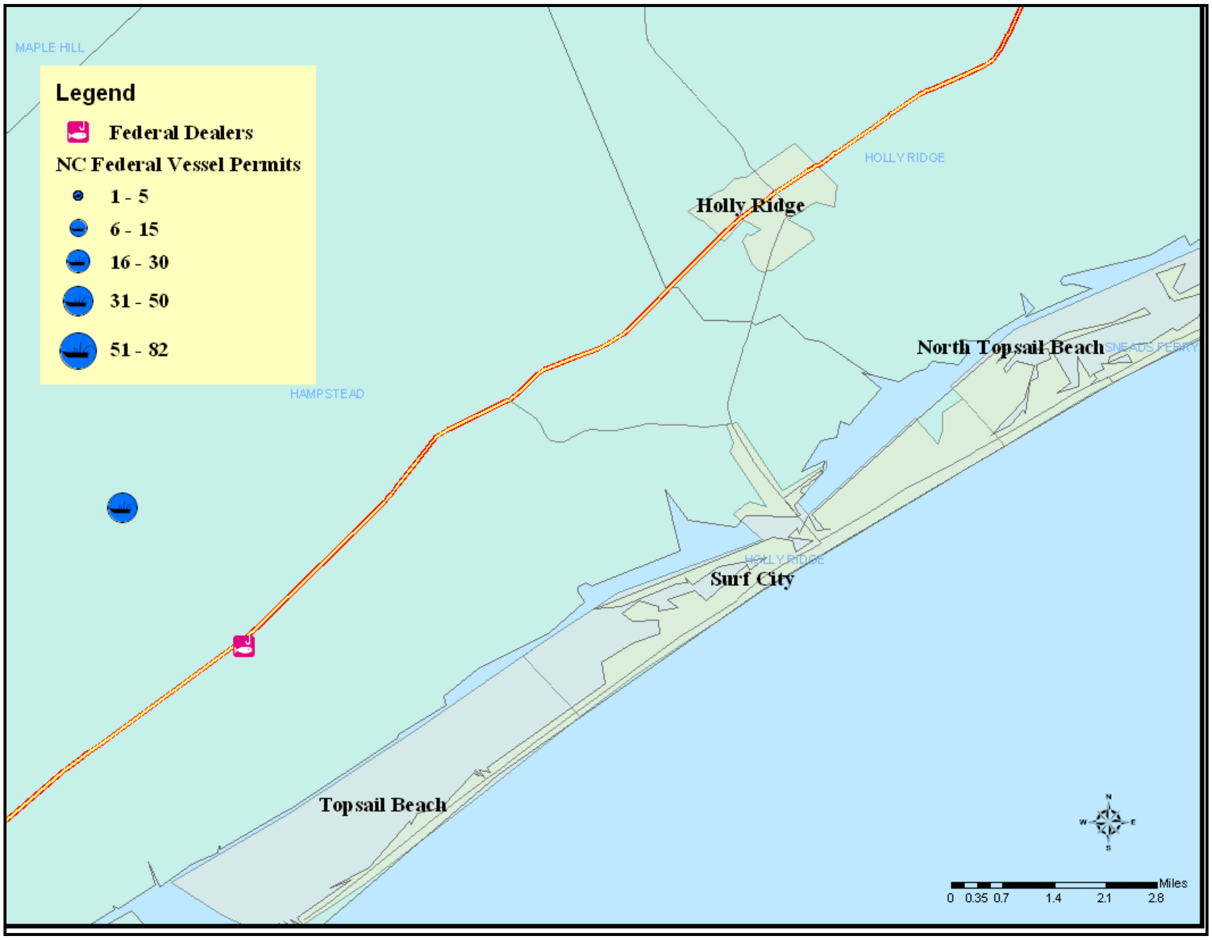

Figure 5.1.3-6. Surf City/Topsail Beach, North Carolina.

Surf City is located in Pender County and had at one time as many as seven long fishing piers. But, like Atlantic Beach and other places, hurricanes reduced that number to two. Fishing is still important but does not contribute as much to the economy as it once used to according to several key informants. There are still a few trawlers that dock here, but they are very small, inlet only trawlers. Most fishermen do not live on the island or in town, but live more inland in places like Hampstead and Holly Ridge. Several respondents commented that it is too expensive for anyone but "northerners" and tourists to live around the beach. Another factor that makes it hard to fish this area is because they are in the middle of the island, and it takes a long time to get out to the sound. It is 13 miles to the inlet from where they are located on the intracoastal waterway.

There is only one fish market in the town today. According to one informant, around 1940 to 1960 this place was a "fisherman's paradise" and there was so much business that the one fish house was open 24 hours a day. With the influx of outsiders, property values have increased making it difficult for fishermen to survive in this area. There are few commercial fishermen and few vessels in the area today that call this community home. Where it once was a commercial fishing village, it has now become more of a tourist/recreational community according to some.

Hampstead is changing from a small fishing village into one of the fastest growing areas in North Carolina. Fishing is still a major piece of the area's identity. There are two wholesale-only fresh fish dealers in the town. One donates approximately 5,000 pounds of fish to the yearly seafood festival which is held in October. The annual Spot Festival celebrates fishing and the fish for which it is named. .

Of the three communities listed, Topsail Beach is the only recognized Census Designated Place and therefore is the only one with census demographics reported. The population has seen a steady increase but remains relatively small with only 404 in the 2000 census (Table 5.1.3-76). Housing tenure has remained relatively the same with three quarters of the housing owner occupied (Table 5.1.3-77). Residence has changed little with slightly more people living in the same house as they did five years ago (Table 5.1.3-78). The percentage of people in the labor force has also remained the same as has the unemployment rate, which is very low at 0.5 percent (Table 5.1.3-79). The population is almost entirely White with a few Latinos appearing in the 2000 census as shown in Table 5.1.3-80.

While Topsail Beach shows few federal or state permits ((Tables 5.1.3-87 and 5.1.3-90, respectively), Hampstead does have more permits listed. Most federal permits that list Hampstead as homeport are either for dolphin/wahoo or snapper grouper (Table 5.1.3-85). The majority of fishing related employment listed for Hampstead is in fish and seafood while both Topsail and Hampstead each show relatively little employment in fishing (Tables 5.1.3-86 and 5.1.3-88). Hampstead has 459 state permits issued with 232 being for commercial vessels and another 121 being standard commercial fishing licenses. There were 58 shellfish licenses issued and 29 dealers in the area (Table 5.1.3-89).

5.1.3.7 Sneads Ferry (28460)

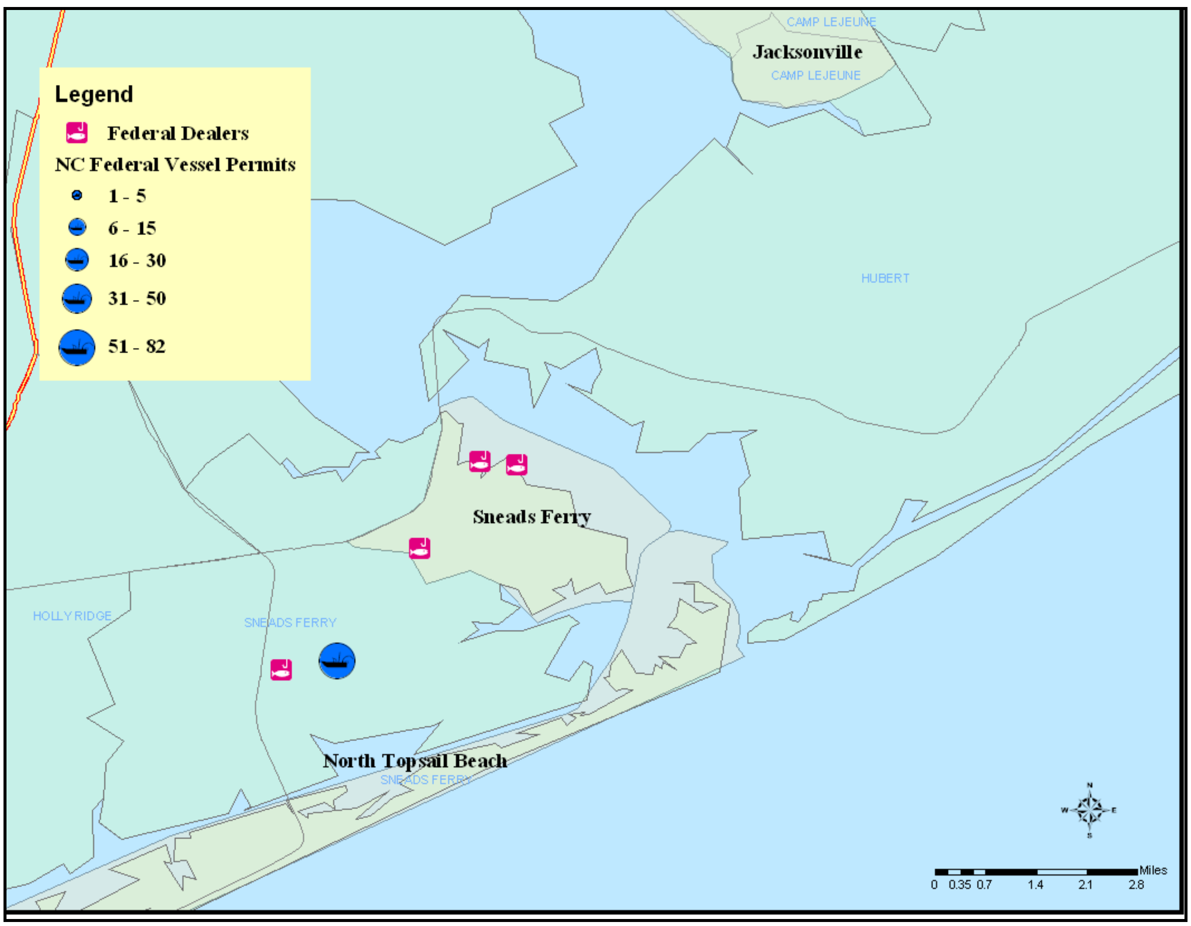

Figure 5.1.3-7. Sneads Ferry, North Carolina.

The white rubber boots worn by commercial fishermen in this community and many other parts of North Carolina are commonly referred to as "Snead's Ferry Sneakers."

With such an icon named after the community it suggests the importance of commercial fishing to the area.

Snead's Ferry is a small town with very little of the large-scale development that is evident elsewhere on the North Carolina coast. However, there are apparently more retirees moving here from places like Atlantic Beach because it is more affordable according to some individuals. Many houses in the community have fishing vessels docked in front of the house or on the lawn. Snead's Ferry's location is an advantage for fishermen, because the channel leads directly to the sound without having to travel through many creeks; this offers larger boats more accessibility. One respondent commented that at least half of the people in the community have something to do with the fishing industry. Others living in Surf City believe that Snead's Ferry is now made up of at least 20% of residents who are either servicemen or who work on the base. Some of these individuals also shrimp at night or on the weekends. This is a source of resentment, because these people are no longer full time fishermen, and have more disposable income with which to purchase better equipment or simply have better standards of living. The community celebrates the Shrimp Festival each second weekend in August.

One fish house owner who has been working in Snead's Ferry for 12 years has 15 boats that sell to him and dock at his place of business. These fishermen do everything, including net fishing, crabbing, clamming, and shrimping. He commented that he doesn't see much of a future in fishing because younger people are not getting involved. This same individual commented that a lot of new people are moving in from other places and he considers it only a matter of years before his place sells. The fish house next door is for sale and he is just waiting for the right price, and he will sell, too. Most of the captains and crew live within two miles of his fish house and there does not seem to be a problem finding crew; primarily because they have worked in the industry for so long and most have been with the same captains for quite some time. He also commented that most of the fishermen in town are shrimpers and net fishermen who go out daily which allows them to be home at night and have a more stable life.

In 2008, vessels with federal permits predominantly held south Atlantic shrimp (30), Atlantic dolphin/wahoo commercial (9), rock shrimp (17), or snapper grouper charter/headboat for snapper grouper (11) permits (Table 5.1.3-100). There were over 705 state commercial fishing vessel registrations for Snead's Ferry and, among those, there were 192 standard commercial fishing licenses (Table 5.1.3-102). The community also had 1 recreational sell license (Table 5.1.3-102). According to Table 5.1.3-101 there was some seafood employment in other areas with 16 persons employed in fish and seafood and 2 in marinas.

5.1.3.8 Swansboro (28584)

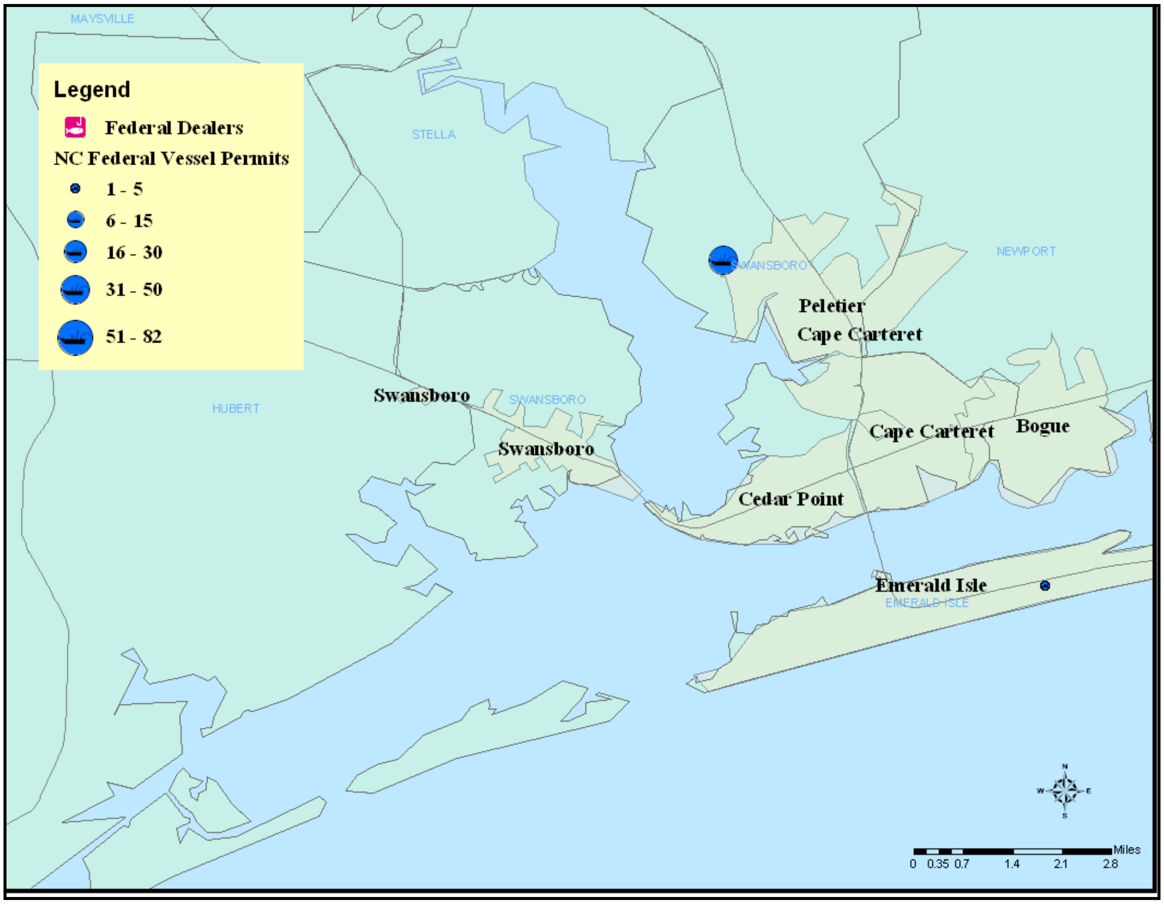

Figure 5.1.3-8. Swansboro, North Carolina.

Swansboro is supposedly the second oldest town in North Carolina. Settlement of the surrounding lands by English colonists probably was influenced by its proximity to Bogue Inlet and the White Oak River. Shipbuilding and the export of naval stores were the mainstays of the local economy. The town was a major port in the late eighteenth century, and relied mainly on ship building. The end of the Civil War brought a close to that prosperity and fishing became important socially and economically.

The community has a small historic section that has been well preserved with many old buildings still intact and restored, now used mostly for tourist shops. There are two fish houses with some small trawlers docked nearby. There are at least five seafood restaurants and two seafood markets. Though Swansboro has all the trappings of a fishing community, according to some, it is more a tourist community now. According to one fisherman, from Swansboro, the community was much more of a fishing town around ten years ago when there was close to double the fleet. Shrimping has experienced a recent downturn because imports with lower prices have affected the market. Because of the costs involved, local shrimp are more expensive and they are not as big, therefore more and more people are buying imports according to one individual. There are two main docks in the community, one has three trawlers and the other has two. Almost all captains and crew live in town, although crew may come from other places, fishing has always been a family business in Swansboro. There are a few charter businesses in town with one in particular that has a seafood market, a head boat and one charter.

In 2008, vessels with federal permits predominantly held Atlantic dolphin/wahoo commercial (12), Atlantic dolphin/wahoo charter (10), south Atlantic charter/headboat for pelagic fish (10), or snapper grouper charter/headboat for snapper grouper (10) permits (Table 5.1.3-112). Much of the employment according to census zip code data is in marinas with a few employed in fish and seafood (Table 5.1.3-113). There were over 126 state-permitted vessels with 69 standard commercial licenses and over 53 shellfish licenses according to Table 5.1.3-114, and 3 recreational tournament sell licenses.

5.1.3.9 Atlantic Beach (28512)

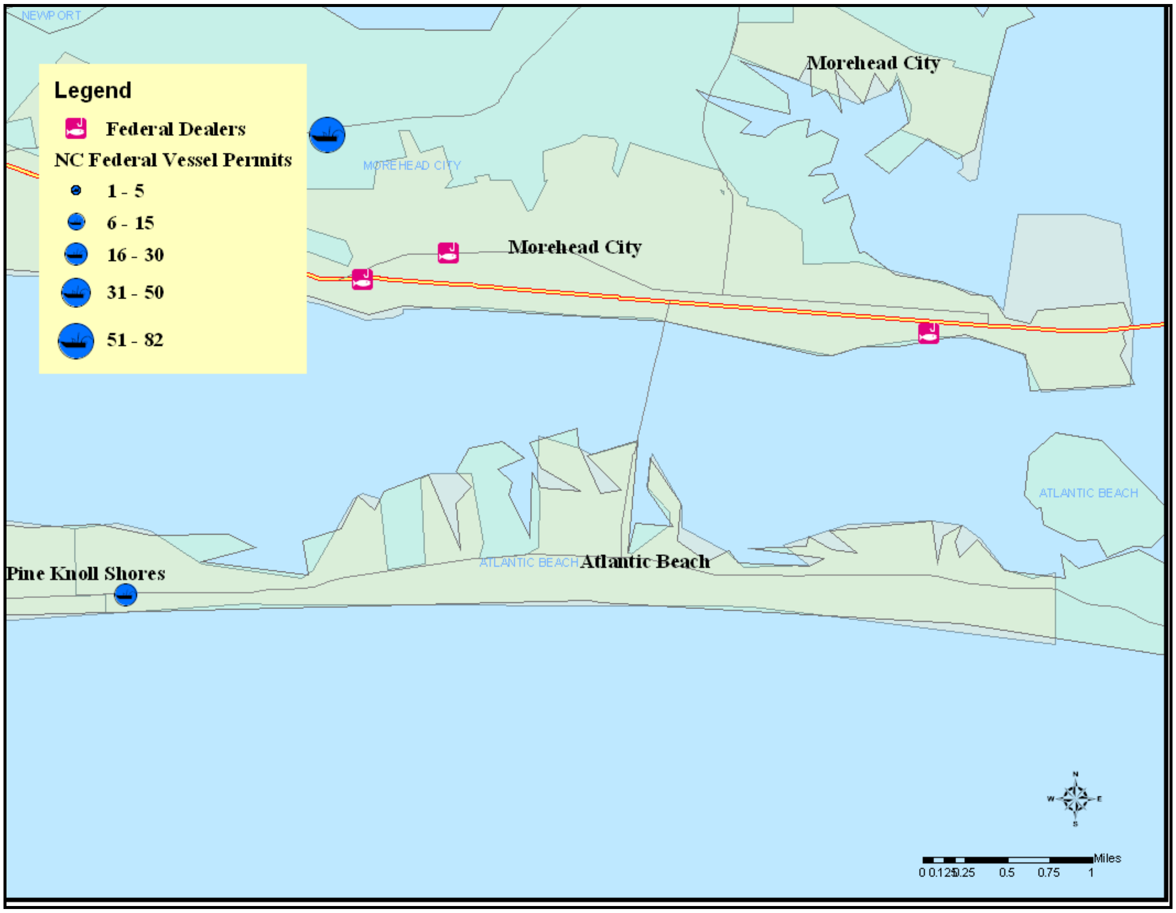

Figure 5.1.3-9. Atlantic Beach, North Carolina.

Atlantic Beach has been a popular resort town since the 1870s. The first bathing pavilion was built on Bogue Banks in 1887. Other resorts and tourism related development occurred over the next century and the area remains today a popular vacation destination. Today there is a boardwalk with rides, a video arcade, shops, restaurants, etc., along the waterfront. The beach is the primary attraction and there is a defined seasonal tourism during the summer months. There is a small marina in the community, with charterboats, but there is no commercial fishing out of Atlantic Beach. There are about 12-14 charterboats total, according to one respondent. Some boats that advertise as being from Atlantic Beach actually dock in Morehead. The charter business is also very seasonal, and there seems to be plenty of competition. During the off season, charter fishermen take on other jobs, like carpentry or anything they can find.

In 2008, vessels with federal permits predominantly held Atlantic dolphin/wahoo commercial (17), Atlantic dolphin/wahoo charter (19), south Atlantic charter/headboat for pelagic fish(15), or snapper grouper charter/headboat for snapper grouper (14) permits (Table 5.1.3-124). There are, however, over 55 state commercially registered vessels and 35 standard commercial fishing licenses (Table 5.1.3-126).

The Salter Path/Indian Beach area is south of Atlantic Beach and may have more fishing related businesses than Atlantic Beach. There are five or more seafood restaurants and several fish houses that sell retail and wholesale seafood. The community has many hotels and also a miniature golf course. A small area along the creek is where most of the fish houses and restaurants are located. One individual commented that most people make their living from seafood here, yet most fishermen have other jobs and their wives work because it is difficult to make a living solely from the fishing industry year round. Another commented that Salter Path used to be a fishing community with shrimp boats, net fishing, clam and scallop, but there is no offshore fishing from the area. Overall, this area has become more dependent upon tourism and the associated service economy.

Salter Path had 73 state registered commercial vessels and 54 standard commercial licenses issued for the year 2002. There were also 9 dealer licenses for the community (Table 5.1.3-127).

5.1.3.10 Morehead City (28557)

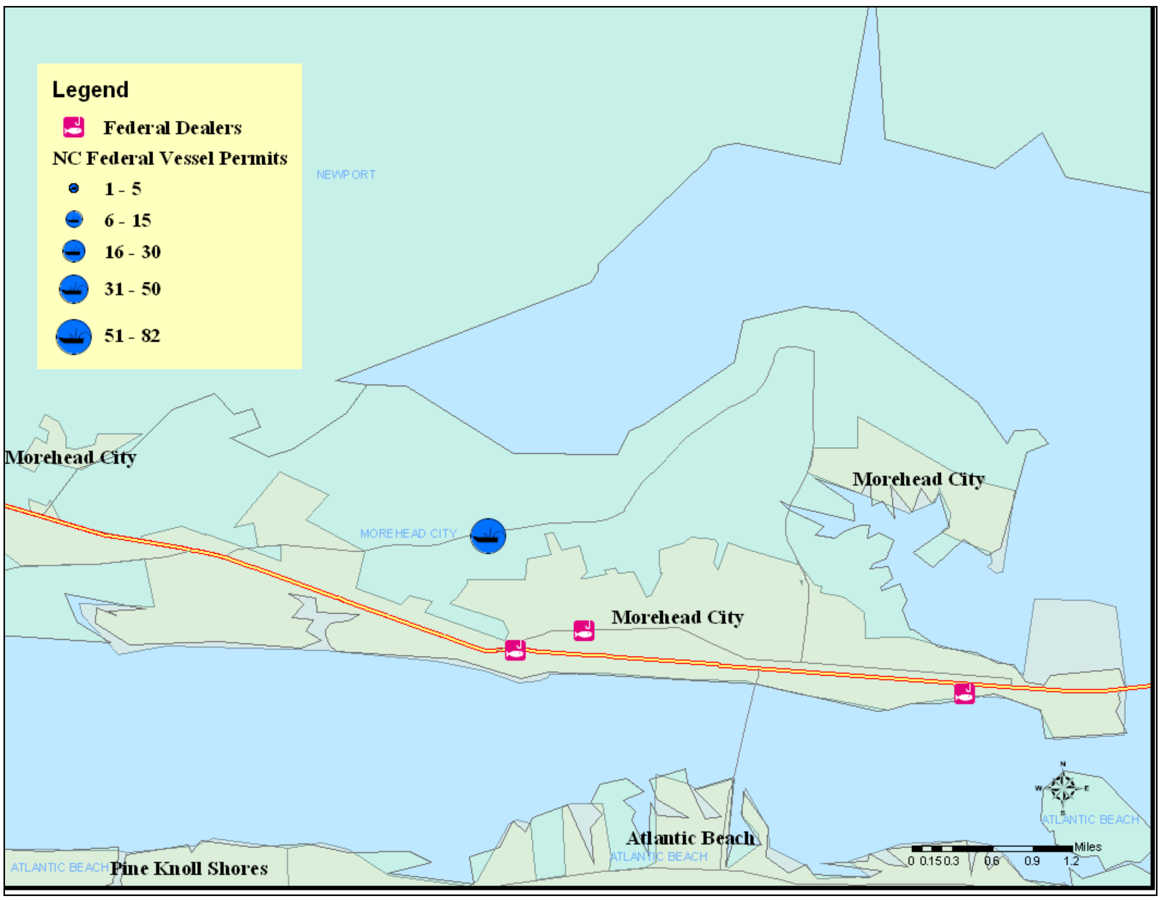

Figure 5.1.3-10. Morehead City, North Carolina.

Morehead City was founded in the 1840s and soon had a railroad line that connected its deep-water harbor with inland markets. Following several severe hurricanes during the 1880s and 1890s, fishermen who had lived on Shackleford Banks moved their houses by boat onto the mainland in the areas between 10th and 15th Streets. They called this area the Promise Land and it became the nucleus of the fishing industry that continues to be an important part of the economy of Morehead City. In recent years, a large charter-fishing fleet has developed, and Morehead City has become widely known as a center for sport and tournament fishing, drawing fishermen from all over the eastern United States. It is the location of one of the major, annual international Blue Marlin tournaments, as well as other fishing tournaments.

Today Morehead City has a community college, several strip malls and commercial enterprises. There is a coastal theme to many of the businesses and art galleries, with a focus on tourism. The waterfront is small but crowded with several tourist attractions and numerous charterboats. According to one captain of a charterboat, the best fishing area on the NC coast is 50-100 miles offshore of here. The Big Rock Blue Marlin tournament held the second week in June is the biggest paying tournament on the East Coast. The tournament brings approximately 200 boats to the area. With an estimated four people per boat plus families, the tournament generates considerable economic benefit to the community. Many of the local charterboats are chartered for this tournament, which has an entry fee of $12,000 per person. There are also several small tournaments held in the community during the mackerel and marlin season. While there are no local fishing clubs, the Raleigh Sport Fishing Alliance is a regional fishing club with many of its members fishing out of Morehead City. One charter crew member said that he commercial fished for 21 years, but tired of weather problems and the “feast or famine” economy of commercial fishing. He said he had seen some commercial fishermen go out by themselves in any kind of weather because they couldn’t find crew members, just to survive. He also mentioned that there are good crews around that migrate up and down the coast according to work.

In 2008, vessels with federal permits predominantly held Atlantic dolphin/wahoo commercial (45), Atlantic dolphin/wahoo charter (26), south Atlantic charter/headboat for pelagic fish(22), or snapper grouper charter/headboat for snapper grouper 22) permits (Table 5.1.3-137). About half held charter permits for both species groups. There are about 100 people employed in fishing related business according to census business figures in Table 5.1.3-138. About half of those are in marinas and 36 are employed in fish and seafood business. 398 state commercial vessel licenses were issued for Morehead City and 124 standard commercial fishing permits. There were 40 shellfish licenses and 18 dealer licenses issued by the state (Table 5.1.3-139).

5.1.3.11 Beaufort (28516)

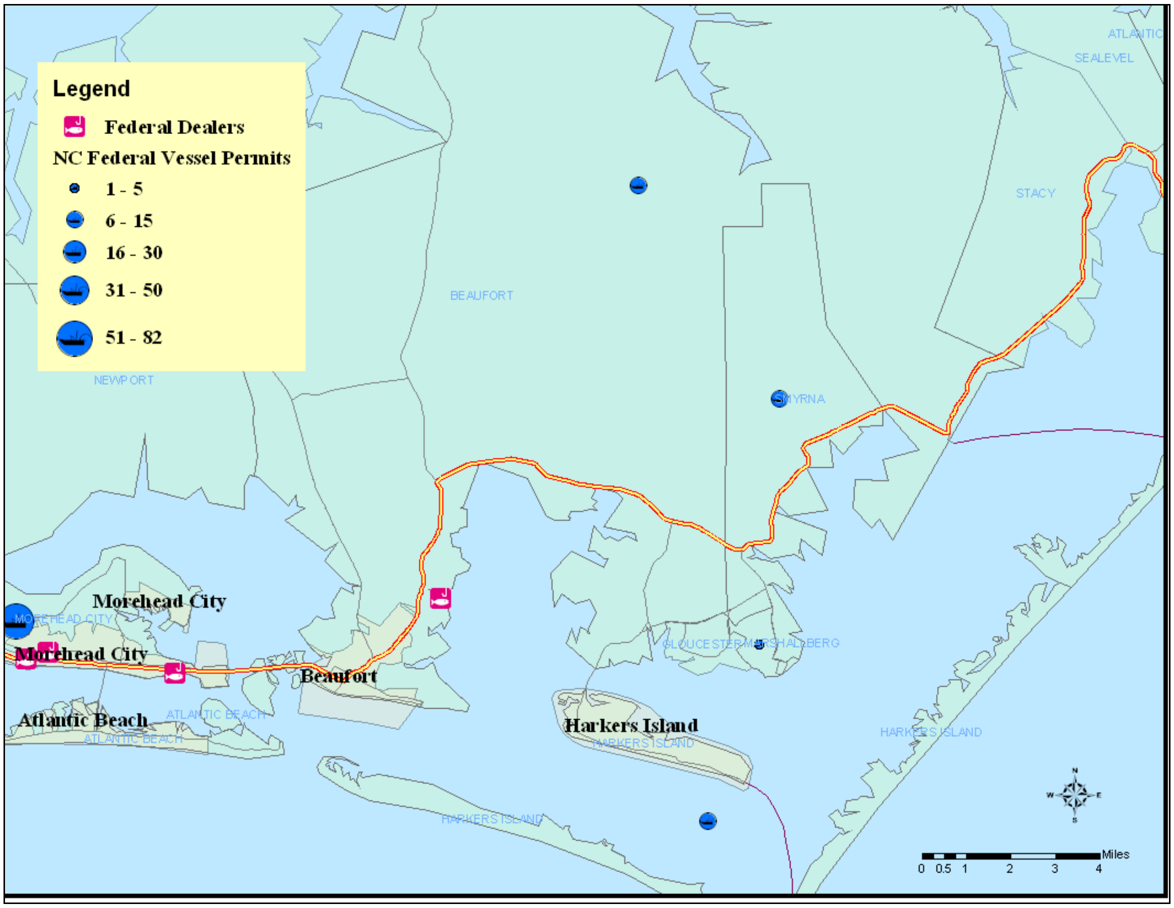

Figure 5.1.3-11. Beaufort, North Carolina.

Beaufort was built on a former Native American village, called Warelock which means "fish town" or "fishing village," near Cape Lookout and borders the southern portion of the Outer Banks. Its deep water harbor is home to vessels of all sizes and its marinas are a favorite stop-over for transient boaters. Originally a fishing village and port of safety, it was known as "Fishtowne" until incorporated in 1722. A whaling community, Diamond City, was located on Shackleford Banks, six miles to the southeast by boat during the eighteenth and nineteenth centuries. Lumber, barrel staves, rum, and molasses comprised some of Beaufort's main exports. However, when the port declined as a trade center, commercial fishing gained greater importance and became the primary economic activity of the town. Beaufort served as home port for a large menhaden fishing fleet and had numerous processing facilities for menhaden products.

Today, tourism, service industries, retail businesses and construction are important mainstays of the area, with many shops and restaurants catering to visitors from outside the area. The community has some exclusive homes along the waterfront but overall most housing is modest. It is home to both the NOAA Center for Coastal Fisheries and Habitat Research and Duke Marine Sciences Center. Directly across the bridge from Morehead city is Radio Island, which is the commercial fishing hub for Beaufort. There are a few private boats along the waterfront in downtown Beaufort, but the commercial enterprises are predominantly located on Radio Island. The waterfront does have two tour/party boats, in addition to private boats, some of which may be smaller charter vessels. There are several marinas in the community and several businesses that provide support services for both the recreational and commercial fishing industries.

According to one individual, Beaufort is a commercial fishing community, although less so now, than in the past. This seems to be largely due to fewer young people getting into the fishing business as it does not seem to pay well. This same individual has seven trawlers and four small snapper/grouper boats as part of his business. During the summer, three longline vessels travel from New York and dock at his facility. The majority of fish they purchase is marketed in Virginia and farther north. Shrimp is a large part of the seafood industry here, but, imports are having an impact on the domestic market lowering prices. His facility is a full service fish house, with processing, ice, fuel, and its own net repair. There was, at one time, an ice plant across the bridge, which has now become a condominium development. The last shad factory in the state is located on Front St. in Beaufort. At the time, there were only two shad vessels left in the state, and they were docked there, too. He said that shad built the fishing industry in Beaufort, but that people are trying to put them (the Shad Company) out of business because their property is valuable. He estimates that on Radio Island there are 20 trawlers that dock there permanently.

Another individual said that his fish house once processed year round, but now only operates seven months of the year due to closures. They had four employees, but now employ only two. He said that in 1987 Beaufort had its best year for shrimp. According to this individual most people involved in the fishery live in Beaufort or Morehead City. There are three fish houses in Beaufort, one of which deals primarily in bait. In 1987 there were about 25 larger commercial vessels (70-90’) in addition to a lot of smaller boats; now there are approximately 11 large commercial vessels in Beaufort.

In 2008, vessels with federal permits predominantly held Atlantic dolphin/wahoo commercial (15), Atlantic dolphin/wahoo charter (12), or south Atlantic shrimp (7) permits (Table 5.1.3-148). Most of the employment that is fishing related according to census business pattern data is related to boat building with 184 persons employed in that business. Others are employed in fish processing and fish and seafood according to Table 5.1.3-149. There are 391 commercial vessels registered with the state from Beaufort with almost 300 standard commercial fishing licenses. There are 119 shellfish licenses and 30 dealer license (Table 5.1.3-150).

5.1.3.12 Harker's Island (28531)

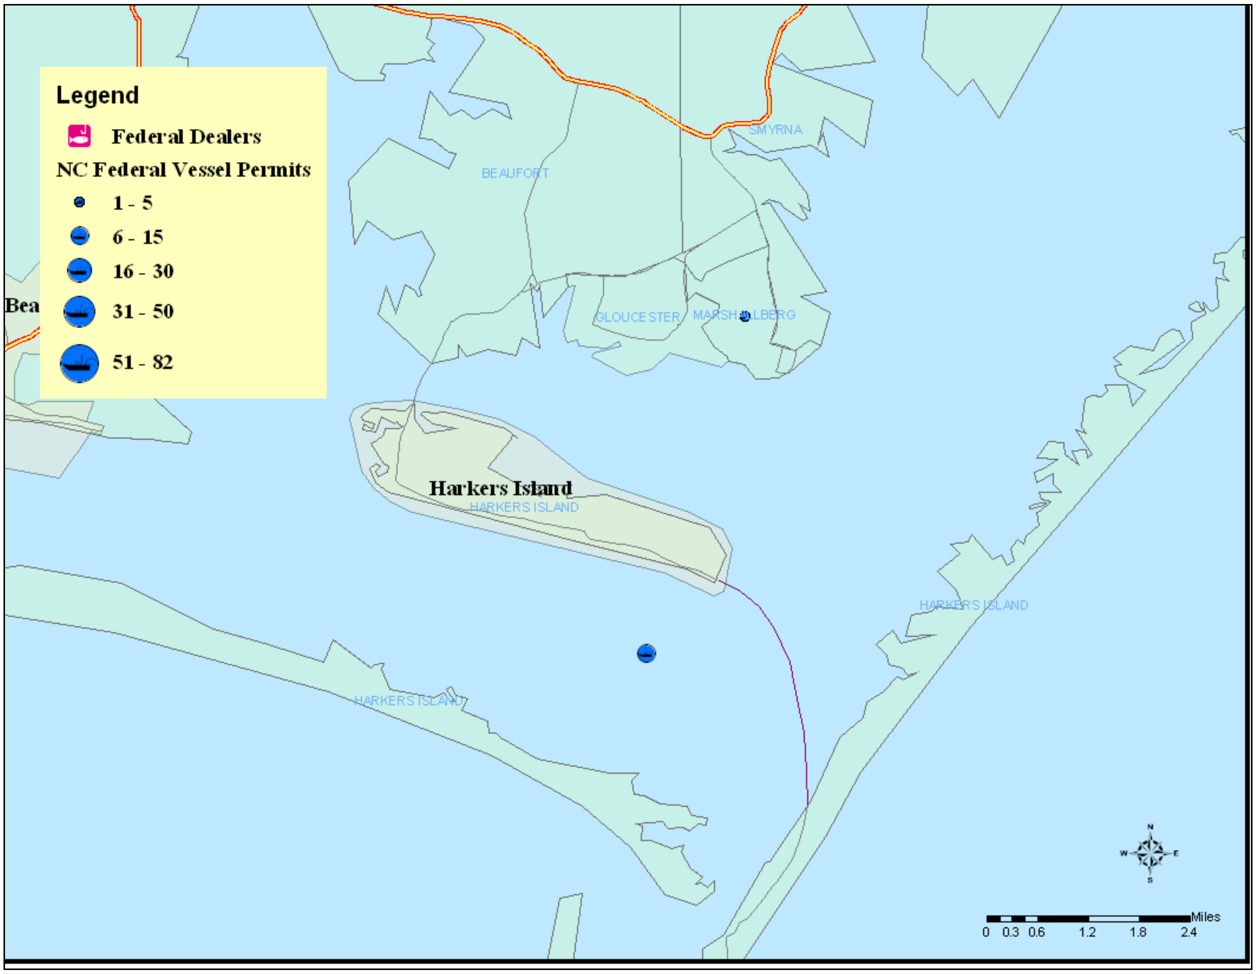

Figure 5.1.3-12. Harker's Island, North Carolina.

Harker's Island has a small marina at the entrance to the island where approximately nine small trawlers dock. The island does not seem to have seen the same residential development that many other coastal communities have, although it has reportedly been discovered by outsiders who are using it as a retirement destination. Fishermen on Cedar Island that were interviewed indicated that many of the locals from Harker's Island have moved to Gloucester because of high property taxes.

A few individuals consider Harker's Island a fishing community, even though landings are not nearly as high as in the past. Increasingly, there are more part-time fishermen, whereas in the past most were full-time. Accordingly, most have other jobs in order to make a living and fishing is to supplement income or solely more of a recreational endeavor. The hardcore old-timers who were the fishing mainstay on the island are too old and can't fish anymore or have passed away. Approximately one quarter of the island residents are full or part-time commercial fishermen according to several individuals. The island is also known for its boat building.

Ten years ago the island's economy was split evenly between fishing and tourism according to one individual, but more recently tourism has become the dominant industry. Rising property values have made it difficult for second and third generation islanders to remain. Recently, some undeveloped lots have been priced at or near $125,000; in addition property taxes seem to double every few years according to that individual. Locals are slowly being pushed from their heritage (commercial fishing), because they cannot afford the higher costs of living associated with the demographic shift when those of a higher socioeconomic class move to the area and are willing to pay higher prices for land and housing. Imports are also taking a toll on the fishing industry as the domestic seafood has to compete with cheaper imports. The majority of the boats built in the past were commercial and made of wood; today there are more, larger sport and head boats that are often built in Florida or other states. It is estimated that there are approximately 25 trawlers in the area today. There is some long hauling that is also done by some, where two boats pull a net with 5-8 men per boat.

In 2008, vessels with federal permits predominantly held Atlantic dolphin/wahoo commercial (7), Atlantic dolphin/wahoo charter (6), south Atlantic charter/headboat for pelagic fish (4), or snapper grouper charter/headboat for snapper grouper (4) permits (Table 5.1.3-160). There are over 156 commercial vessels with state licenses according to Table 5.1.3-162, with 77 standard commercial licenses and 68 shellfish licenses. Most of the fishing related employment according to census zip code business patterns in Table 5.1.3-161 is in the boat building sector.

5.1.3.13 Hatteras (27959)

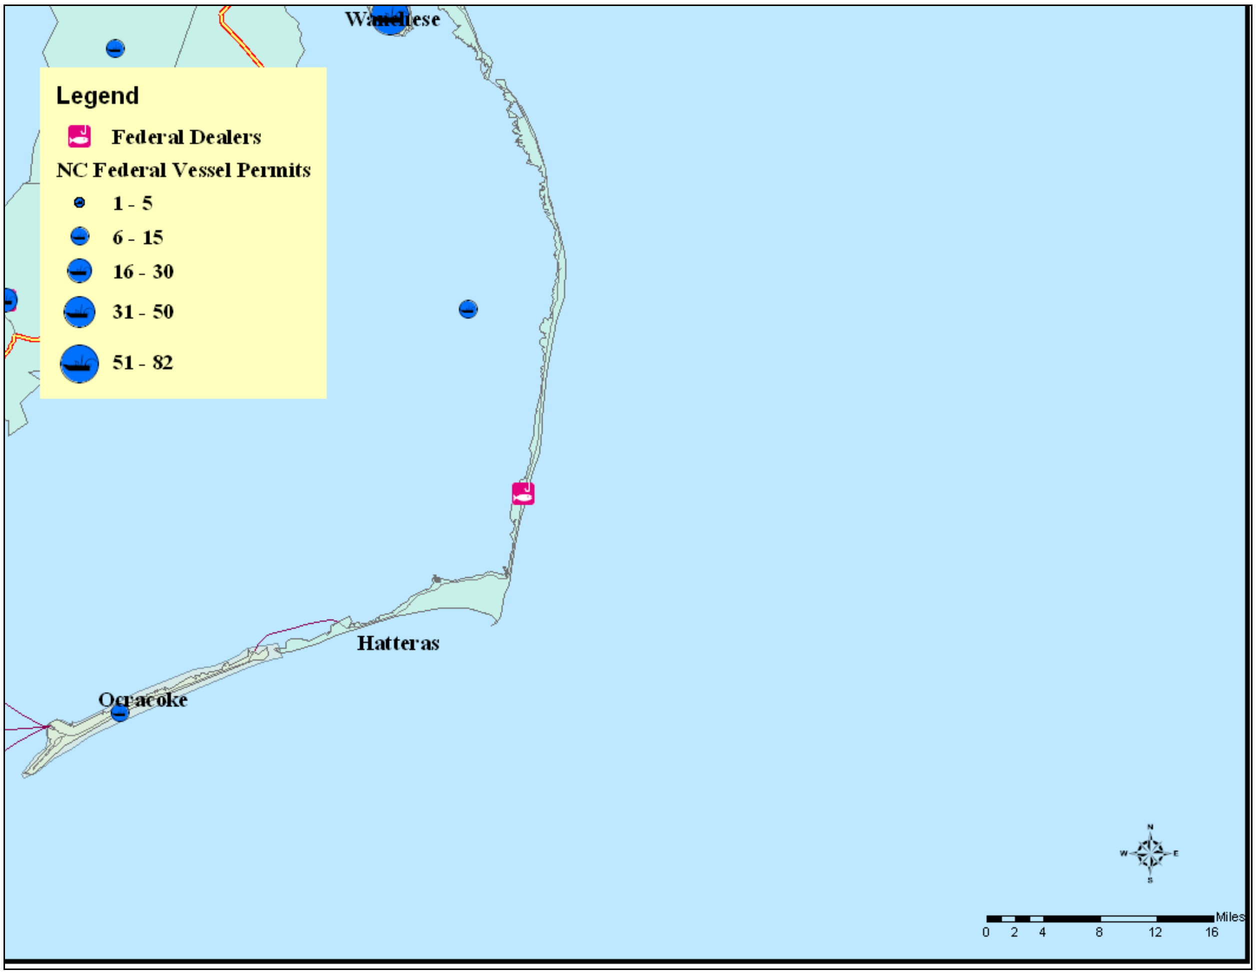

Figure 5.1.3-13. Hatteras, North Carolina.

Hatteras is located on the southern end of Hatteras Island on North Carolina's Outer Banks. The isolation of the community adds to the local character. Hatteras has historically been a seaport community with whaling an important part of the economy in its early history. Since World War II, the economy of the Hatteras community has depended on charter and commercial fishing. More recently, tourism has become an increasingly important economic activity (McCay and Cieri 2000).

The entire north end of Hatteras Island was once known as Chicamacomico, but in 1874, the postal service changed the name to Rodanthe. In earlier times, the Italian explorer Amerigo Vespucci landed in the area in the 16th Century. Centuries later, in 1858, the island became a popular fishing and shipping village and a post office was established. In 1861, Confederates troops landed on the northern end of the island to re-take Fort

Hatteras and Fort Clark, which had fallen to the Union's first naval invasion of the South. After the Civil War, development began to increase on the island and the Durant's lifesaving station was built in 1878. By the turn of the century, a U.S. weather station was established on the island and in the mid-1930s the Army Corps of Engineers had dredged a deep channel which allowed for better access from Pamlico Sound to Hatteras Inlet. Soon after, a sizable fishing fleet was established at Hatteras. During World War II, the area was known as "Torpedo Junction" due to more than 100 ships that were lost due to German submarines.

Hatteras Village is a small and quiet town surrounded by coast on either side. It is located next to a National Seashore with a historic lighthouse. Hatteras is host to several prestigious fishing tournaments and is homeport for the island's famous charter fishing fleet. In addition, there are numerous restaurants that offer fresh caught seafood.

There were as many as 10 or 12 fish houses once and most recently, the largest fish house was sold for condominium development; there are four working fish houses left now. According to one individual, many fishermen are leaving the fishing business as tourism is dominating the economy for the area. This same individual further commented that water quality has changed and that there used to be more shellfish on the shoreline; now it is all gone due to development. He further suggested that the bridges that have recently been built have changed the currents of the inlet and have affected the local ecosystem.

In 2008, vessels with federal permits predominantly held Atlantic dolphin/wahoo commercial (40), Atlantic dolphin/wahoo charter (45), south Atlantic charter/headboat for pelagic fish (39), or snapper grouper charter/headboat for snapper grouper (37) permits (Table 5.1.3-164). Most of the fishing related employment is in the marina sector (Table 5.1.3-165). There are 86 state registered commercial fishing vessels and 75 standard commercial fishing licenses in Hatteras. There are 12 dealer licenses and 10 shellfish licenses in the community (Table 5.1.3-166).

The census demographic table that follows was compiled using census block data for the area. Long term census data from 1970 and 1980 were not available for Hatteras.

Hatteras Census Demographics

Table 5.1.3-163. Hatteras Census Demographics.

5.1.3.14 Oriental (28571)

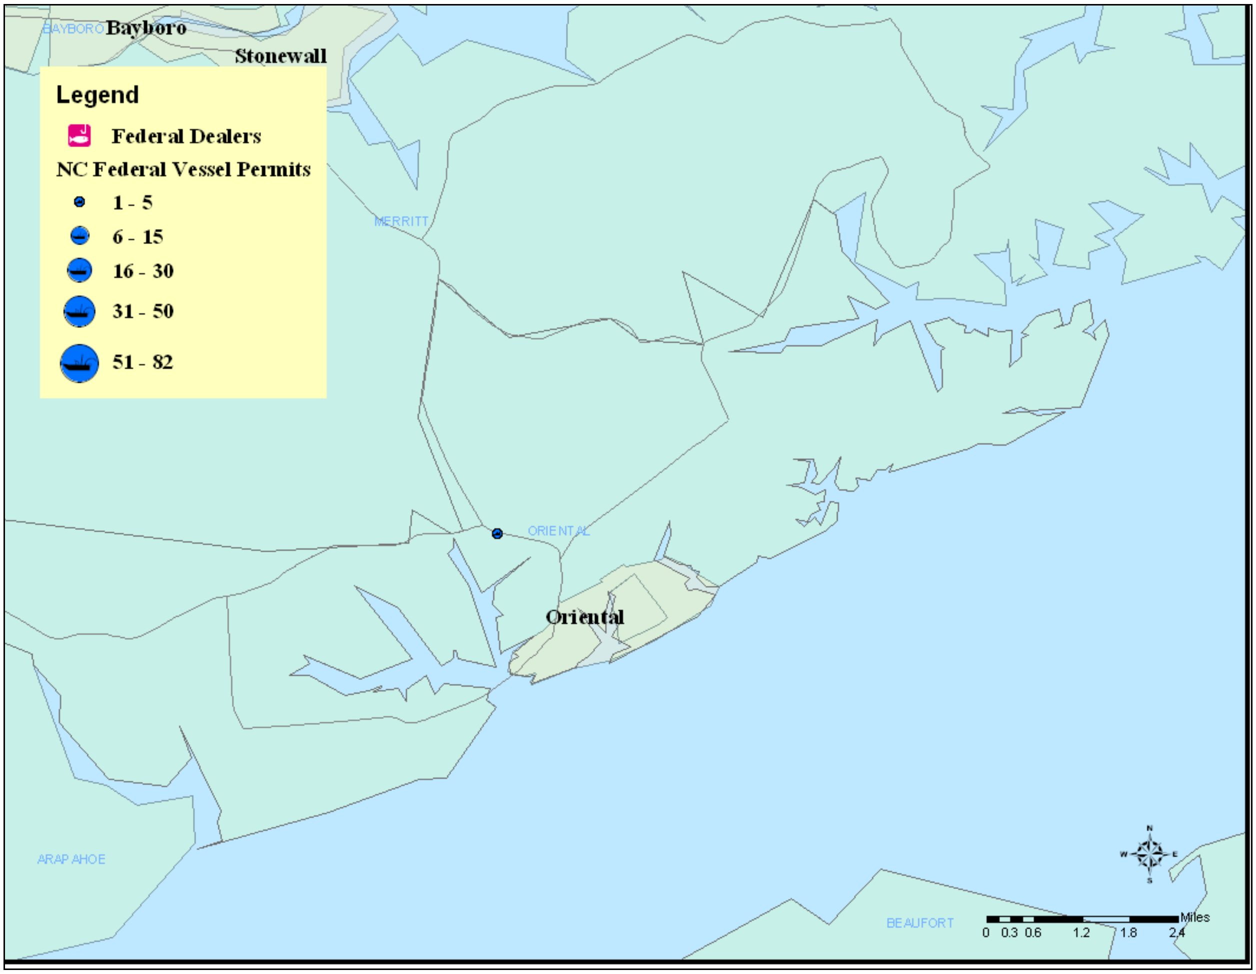

Figure 5.1.3-14. Oriental, North Carolina.

Oriental has seen little population growth over the past few decades and relatively little change in other census demographics. There has been a rise in unemployment from 1990 to 2000 but a drop in the number of individuals who are living below the poverty line for the same decade. There was little change in employment in farm, fish and forestry over that same time period. In fact, the number of federally permitted vessels has remained fairly constant (Table 5.1.3-176). There is considerable employment in fish and seafood with 72 people reported in that sector in Table 5.1.3-177. As far as state permits, there were 63 commercial vessels registered in Oriental and 53 standard commercial fishing licenses. There were also 8 dealer licenses issued within the community (Table 5.1.3-178).

5.1.3.15 Vandemere/Mesic (28587)

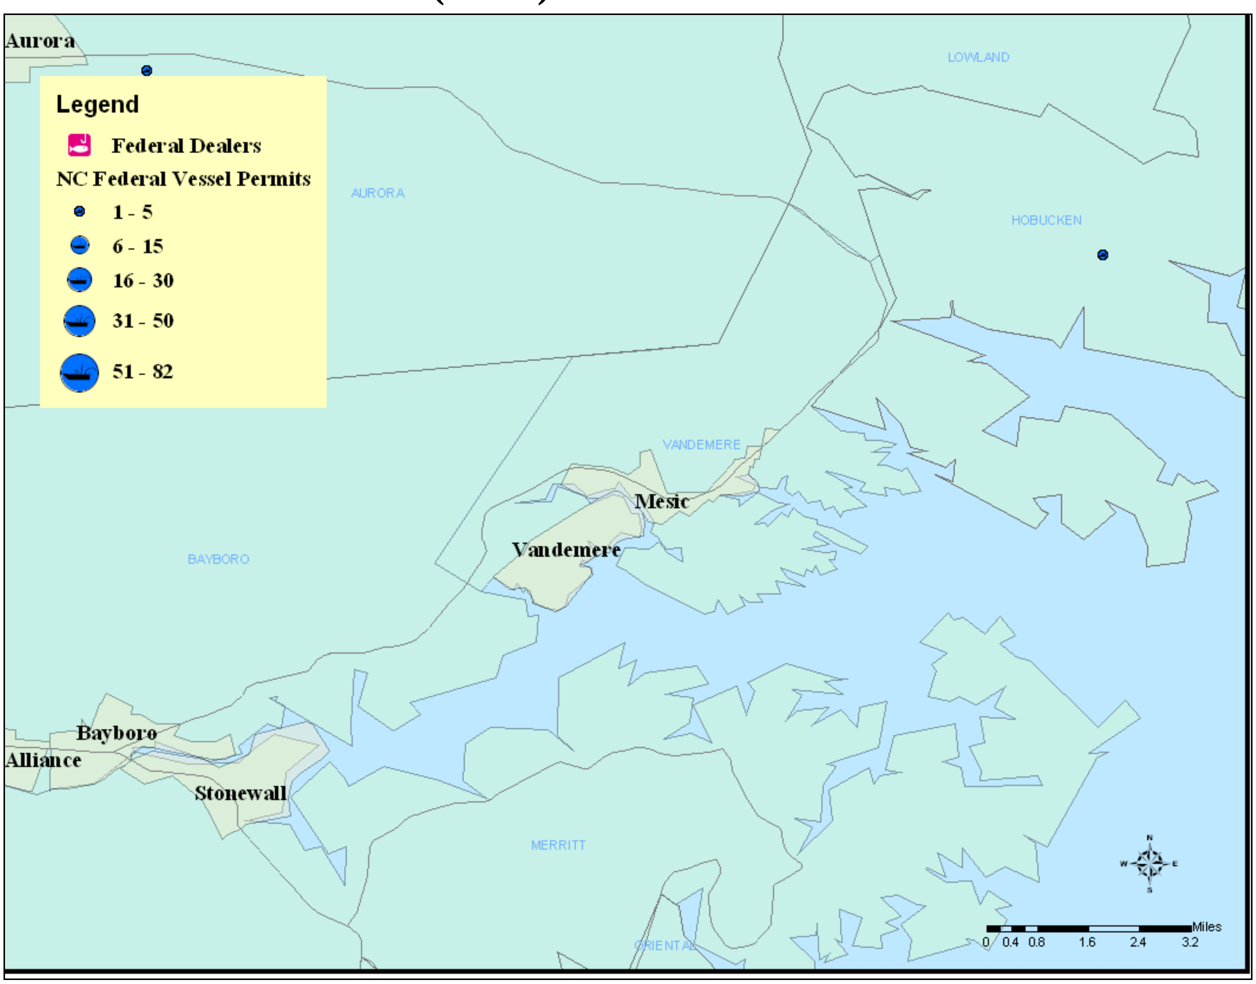

Figure 5.1.3-15. Vandemere/Mesic, North Carolina.

Vandemere and Mesic have both seen a slight population decline over the past decade. Both communities are predominately African-American. Vandemere has about 60% of the population in the labor force while Mesic has 45%. Vandemere has seen a decrease in the percentage of unemployed to 9.4 percent while Mesic has seen an increase to 5.6 percent. Both communities have seen a reduction in the number of people who live below the poverty line and an increase in the average wage or salary. Both communities have also seen a steady decline in the number of people who work in farm, fishing and forestry for both occupation and industry. There are very few federal permits in Vandemere (Table 5.1.3-197) and none listed for Mesic. There are 36 people employed in seafood processing according to Table 5.1.3-198 and 4 in fishing and fish and seafood. A total of 14 commercial vessels are registered with the state according to Table 5.1.3-199 and 12 standard commercial fishing licenses.

5.1.3.16 Bath (27808)

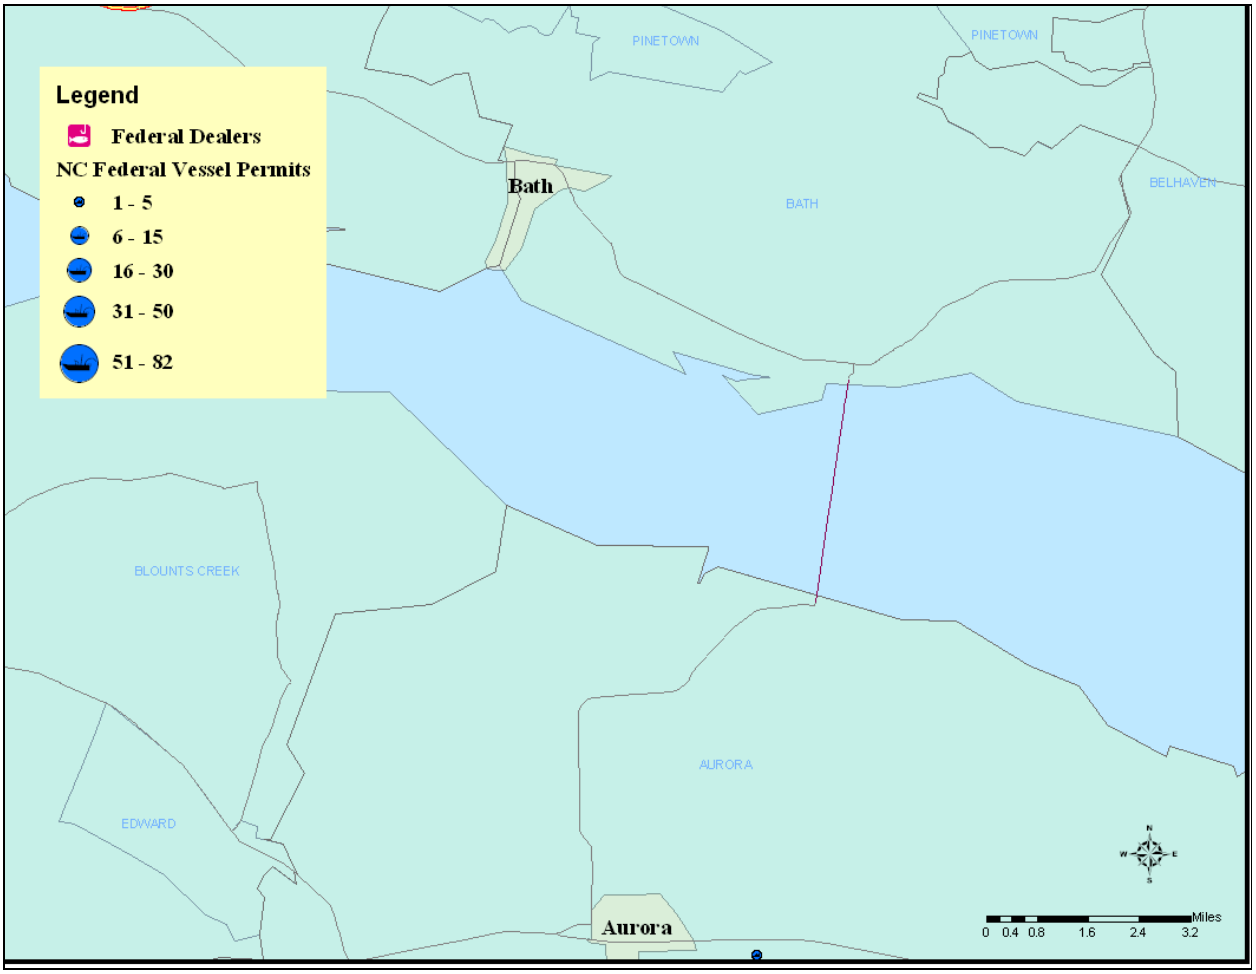

Figure 5.1.3-16. Bath, North Carolina.

There has been a slight population increase for Bath in the past ten years (Table 5.1.3-200) and an increase in the percentage of the population in the labor force (Table 5.1.3-203). Unemployment is 4.5% with a slight increase in the number of persons living below the poverty level (Table 5.1.3-206). There were very few people employed in the farm, fish and forestry category for either industry or occupation (Tables 5.1.3-207 and 5.1.3-208). According to Table 5.1.3-209 there were only 9 federal permits issued in 2008 and those were for south Atlantic shrimp. Employment in fishing related businesses reported in Table 5.1.3-210 shows only 4 people employed in fish and seafood. There are over 84 commercial vessels registered by the state in Bath and over 77 standard commercial fishing licenses according to Table 5.1.3-211.

5.1.3.17 Belhaven (2781

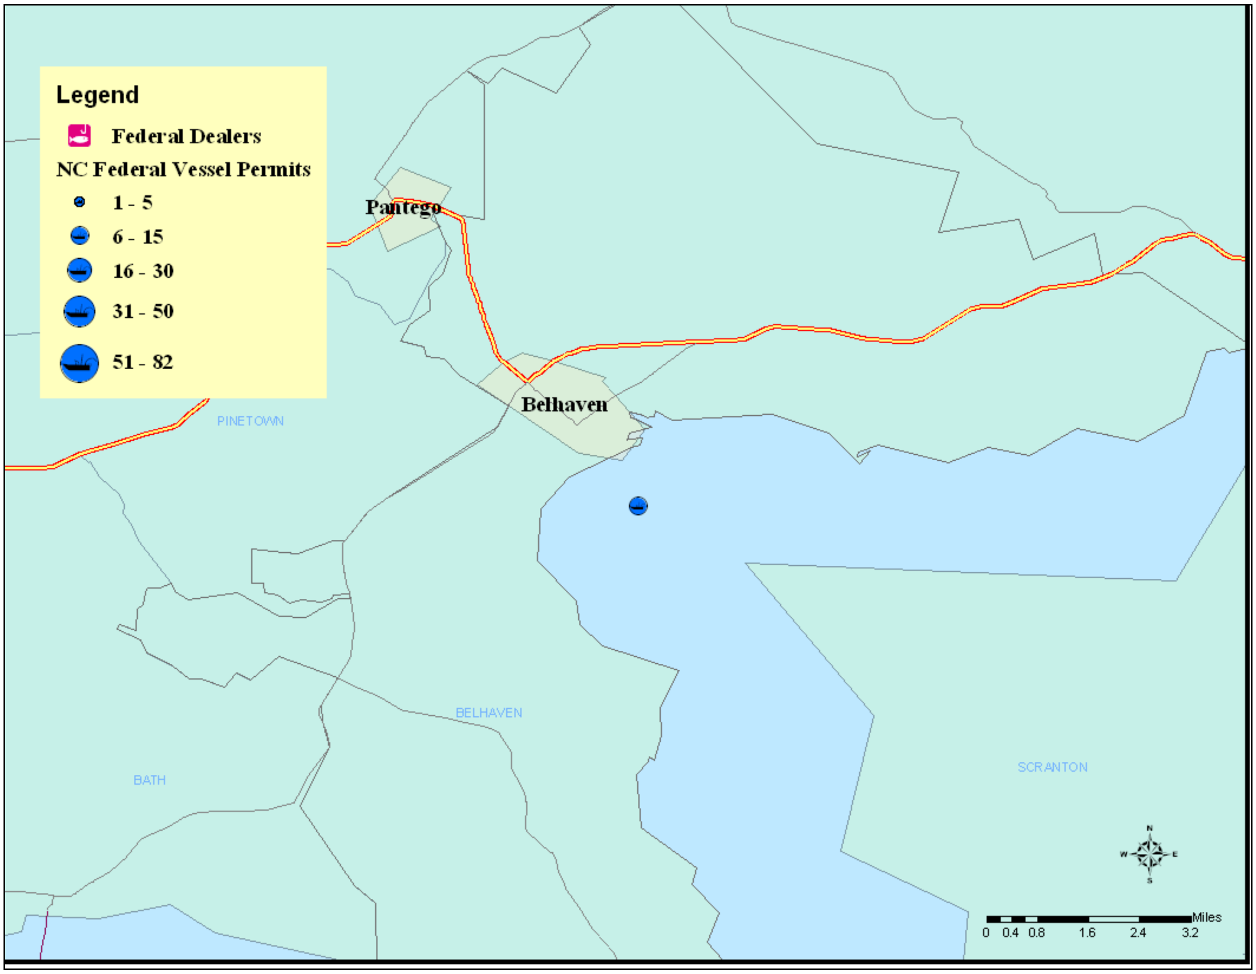

Figure 5.1.3-17. Bellhaven, North Carolina.

Belhaven is a predominantly African-American community (Table 5.1.3-216) which has seen a decline in population over the past decade (Table 5.1.3-212). The community has also experienced an increase in the unemployment rate and a decrease in the percentage of the population that is in the labor force (Table 5.1.3-215). Average household wage and salary has decreased while there has been a decline in the number of people who live below the poverty line (Table 5.1.3-218). There has been a decrease in the number of people who work in farm, fishing and forestry sector for both industry and occupation (Tables 5.1.3-219 and 5.1.3-220). While there are very few federally permitted vessels homeported in Belhaven (Table 5.1.3-221) there were over 100 people employed in fishing related businesses according to Table 5.1.3-222. There were over 188 commercial fishing vessels registered with the state from Belhaven and 163 standard commercial fishing licenses (Table 5.1.3-223).

5.1.3.18 Wanchese (27981)

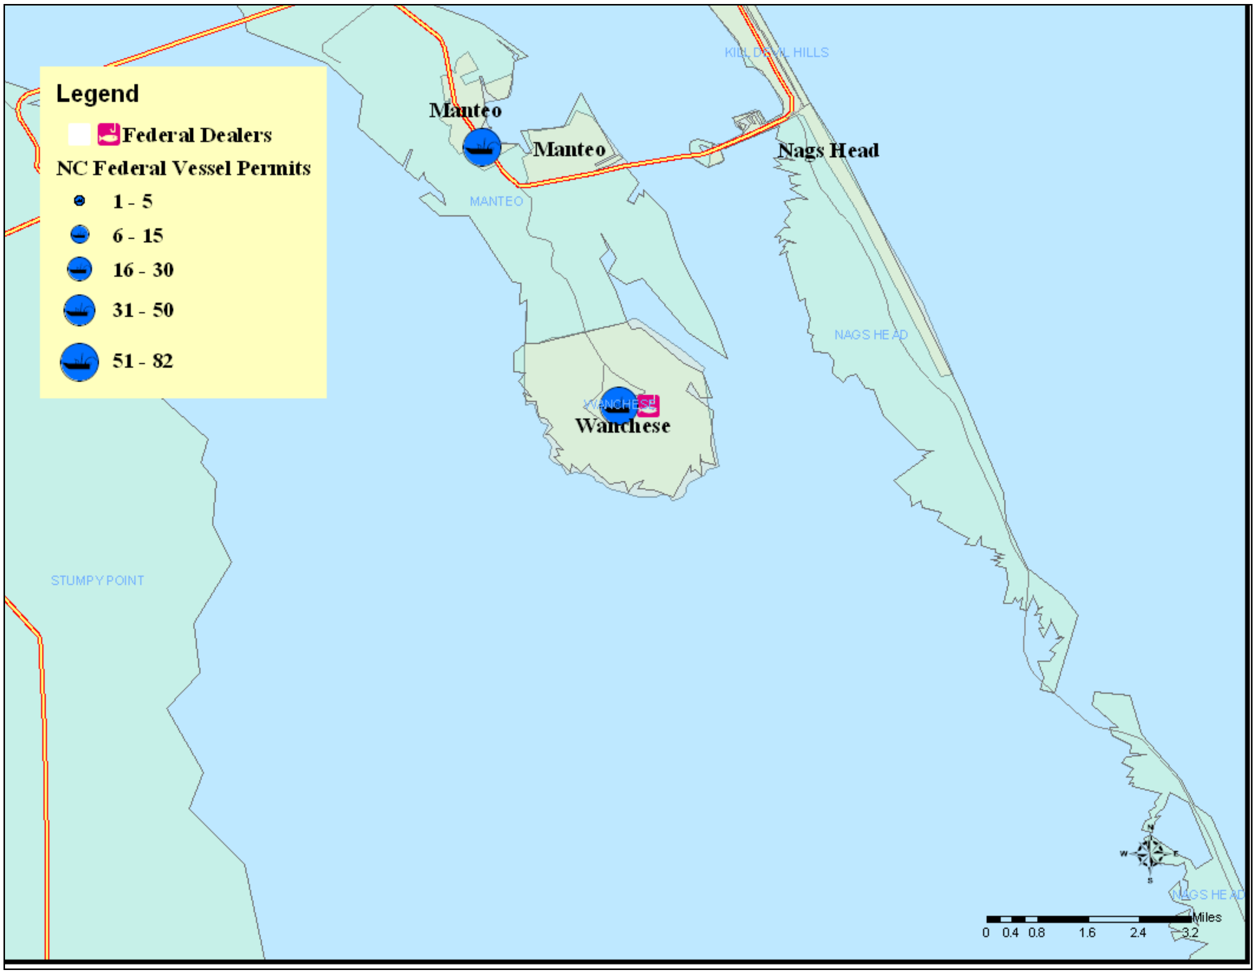

Figure 5.1.3-18. Wanchese, North Carolina.

Roanoke Island has a mix of tall, green, piney woods and miles of sheltered shoreline on the sound side providing a contrast to the open dunes of the outer islands. Wanchese, one of the island's two villages and is located at the southern end. It is a small, unincorporated fishing community with docks that provide services to many types of local and non-local commercial and recreational fishermen. Throughout the nineteenth century, the commercial industry was able to expanded owing in part to the first local postmaster, who owned or financed most of the commercial fishing boats in Wanchese. That individual established a system of credit for local fishermen at his store where debts were paid off when fishermen brought in their catches. It was said that at that time all residents were commercial fishermen (Wilson and McCay 1998).

Wanchese's first fish house was established in 1936 by ER (Zeke) Daniels, the grandfather of the current generation of two fish house owners. Zeke's son was the first to fish a trawler in Wanchese in the 1950s. He converted a 65' wooden boat which was primarily used to fish for species like flounder during the winter time. As mentioned most of their fishing occurred in the Pamlico and Albemarle Sounds, however there was a certain amount beach fishing that occurred, targeting species such as sea mollusks, trout, croaker, spots, striped bass (rock fish) and bluefish. The sounds provided croakers, butterfish, Spanish mackerel, spots and pig fishes. At that time, sea bass was the primary species targeted in the ocean during the winter months of the year. Later, a WWI subchaser was purchased and converted for scalloping (Wilson and McCay 1998).

The largest industrial area in Wanchese is centered round the Wanchese Seafood Industrial Park. The Park was built to enhance business opportunities in the seafood and marine trades. It encourages outside as well as local development in an effort to create a "new day for seafood and marine commerce." Between 1978 and 1985 it was reported that there were nine fish houses in operation in Wanchese. Today, there are six packing houses all operational and all dealing in many of the same species, with each house having a slightly different specialty. In the past all of the houses packed basically the same type of fish, with flounder being one of the most prominent species. However, over time this has changed as each house has had to specialize in order to remain in business.

Charterboat fishing has become increasing popular in Wanchese over the last 10 years. The number of charterboats has increased and facilities have been created to handle the increased presence of the for-hire industry. Currently, there are 27 charterboats and 2 head boats working out of Wanchese. Many of these individuals are from outside the Wanchese area; however, there are a few local fishermen who have decided to try recreational fishing instead of commercial.

Wanchese has seen an increase in its population over the past decade (Table 5.1.3-224) but a reduction in the percentage of people in the labor force (Table 5.1.3-227). Percent of unemployed has dropped from 8.9 in 1990 to 2.8 in 2000. While average wage and salary has increased, the number of people below the poverty level has remained constant (Table 5.1.3-230). However, the number of households with public assistance has gone from a high of 35 in 1990 to none in 2000 (Table 5.1.3-230). Employment in farm, fishing and forestry rose from 1980 to 1990 but has seen a decline in the year 2000 (Table 5.1.3-231 and 5.1.3-232). In 2008, vessels with federal permits predominantly held Atlantic dolphin/wahoo commercial (41),Spanish mackerel (29), king mackerel (25) Atlantic dolphin/wahoo charter (18), and south Atlantic charter/headboat for pelagic fish permits (Table 5.1.3-233). Employment in fishing related activities reported in Table 5.1.3-234 indicates 120 people employed in several categories with 56 in fish and seafood, 40 in boatbuilding, 16 in fishing and 8 in seafood processing. There were 247 commercial vessels registered and over 193 standard commercial fishing licenses in the community according to Table 5.1.3-235. There were also 12 dealer licenses and 20 flounder licenses for Wanchese (Table 5.1.3-235).

5.1.3.19 Manteo (27954)

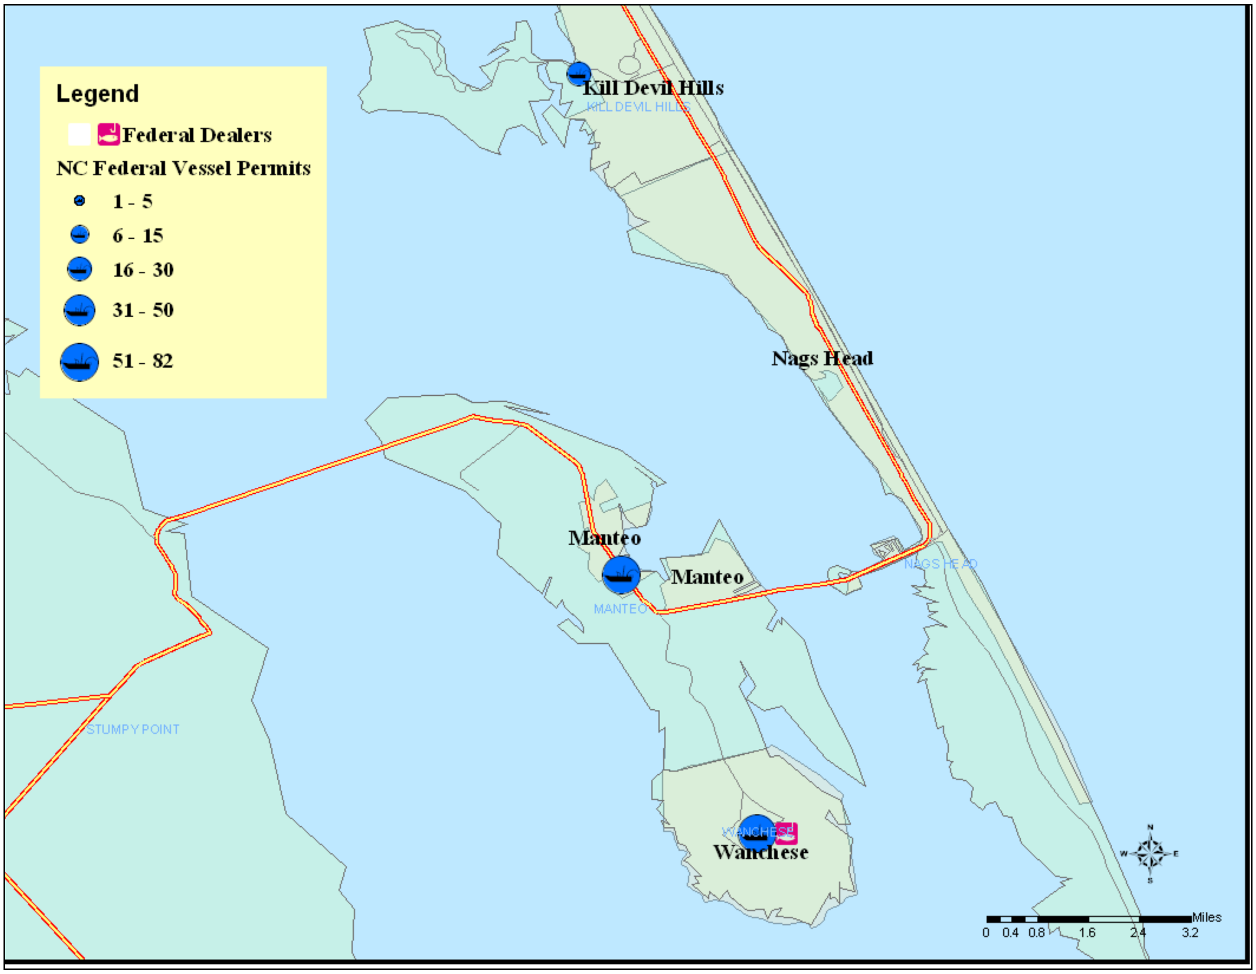

Figure 5.1.3-19. Manteo, North Carolina.

Manteo has seen steady population growth (Table 5.1.3- 236) with a decline in its African-American population (Table 5.1.3-240). The percent of the population that is unemployed has risen over the past ten years while the percent of people in the labor force has also declined slightly (Table 5.1.3-239). Average wage and salary has raised some but, the number of persons living below the poverty line has increased (Table 5.1.3-242). There has been a steady decline in the number of individuals working in the farm, fish and forestry sectors also over the past three decades (Tables 5.1.3-243 and 5.1.3-244). In 2008, vessels with federal permits predominantly held Atlantic dolphin/wahoo charter (37), south Atlantic charter/headboat for pelagic fish (35), or snapper grouper charter/headboat for snapper grouper (25), or Atlantic dolphin/wahoo commercial (14), permits (Table 5.1.3-245). Fishing related employment is highest among the fish and seafood sector according to Table 5.1.3-246 with 176 persons employed in that sector and 16 in marinas. The state reports over 170 commercially registered vessels and 142 standard commercial fishing licenses for Wanchese (Table 5.1.3-247).

5.1.3.20 Ocracoke (27960)

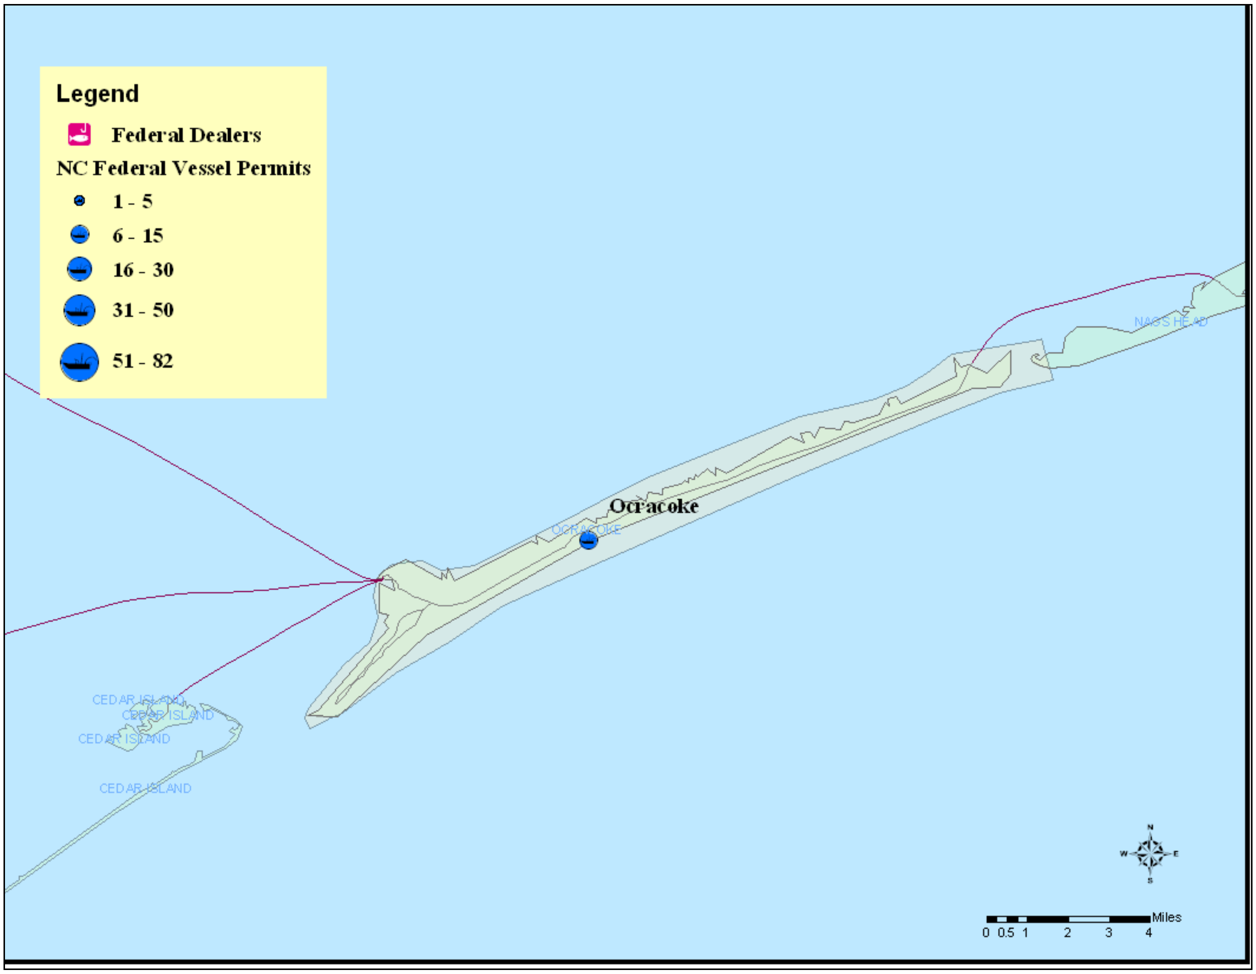

Figure 5.1.3-19. Ocracoke, North Carolina.

Ocracoke is the first island on the southern part of the outer banks. It is only accessible by ferry. Despite it being so isolated, it is rather progressive according to some, yet mostly undeveloped; much of the island consists of the National Park/Seashore. Most residents are year-round and there seems to be a strong sense of community among the locals. The commercial fishing industry has disappeared, though there is one small fish house with two inshore and one offshore fisherman working there. Tourism has been growing, as has the charter industry. There are three to four offshore charterboats, four or five inshore charters and one head boat. About three offshore commercial boats homeport there, with about 20 people claiming to be commercial fishermen on the island; although many of the fishermen have two or three different jobs. The major development boom started about six years ago and since then property values have skyrocketed. There are 12 to 15 seafood restaurants in and around the community.

Many individuals in this region and along the sound fish on the beach with nets or harvest shellfish; there is one shrimp trawler on the island. Ocracoke was never considered a full-fledged commercial fishing community according to some. There was no way to get the harvest off the island other than making the long trip to the mainland. The island has always been mostly tourist oriented.

Cedar Island has historically been a fishing community according those interviewed. There are three small fish houses in the community and most vessels are small as most fish inshore primarily for shrimp, crab and flounder. Pound netting is a historic method of fishing that is still practiced here. Territory now leased from the state was once claimed by local families who would fish specific locations. Today, many fishermen also work on the ferry or dredges to supplement their income.

Ocracoke was only recently designated a census place so comparison of previous census data cannot be made. There are few vessels that claim Ocracoke as homeport holding federal permits (Table 5.1.3-257). Fishing related employment is also very sparse as only 12 persons are reported as working in various sectors of fishing, fish and seafood, and marinas according to 5.1.3-258. There were however 81 commercial vessels registered by the state on the island and 61 standard commercial fishing licenses (Table 5.1.3-259).

5.1.3.21 Elizabeth City (27909)

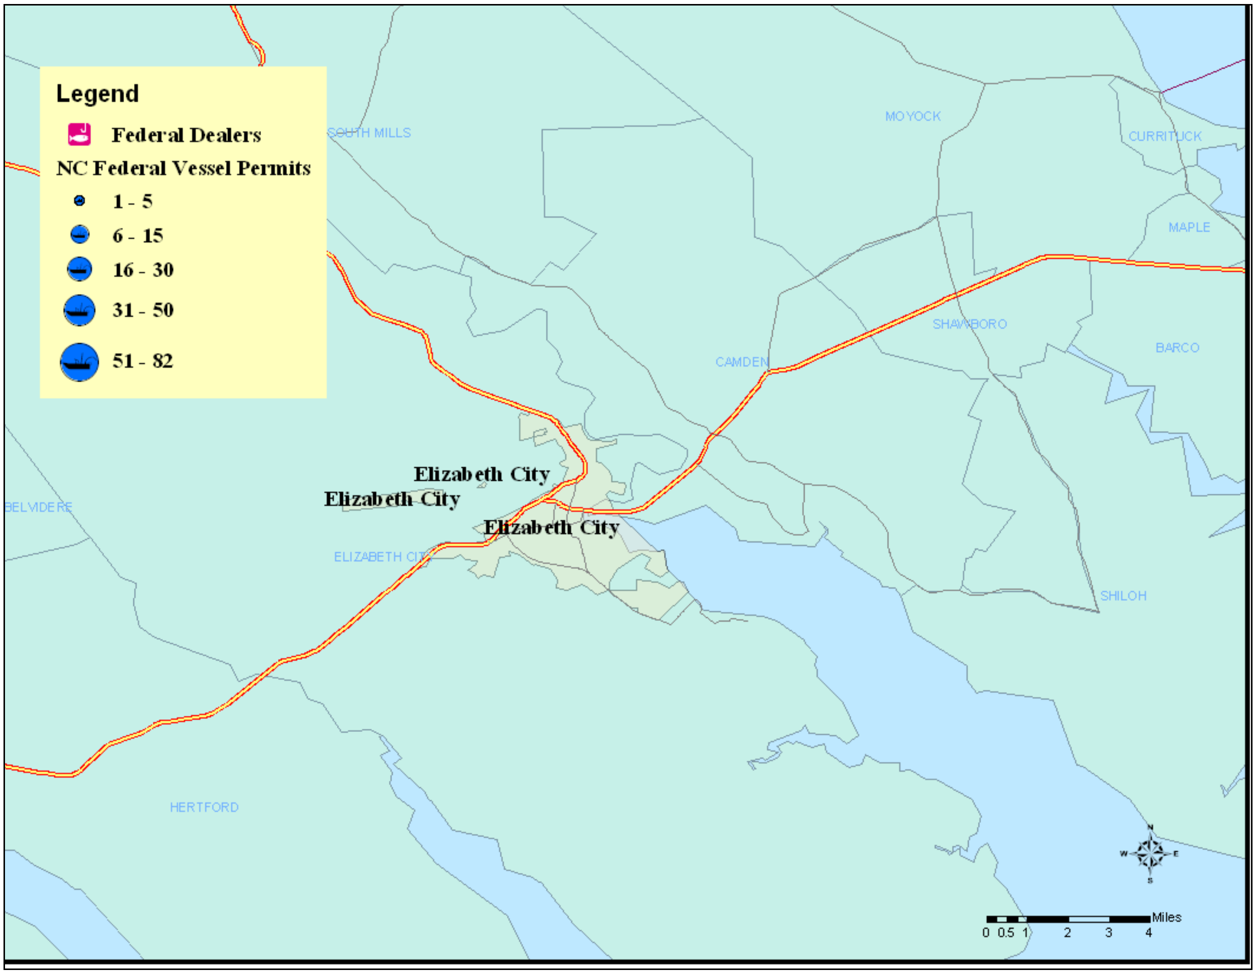

Figure 5.1.3-20. Elizabeth City, North Carolina.

Elizabeth City has seen substantial population growth in the past decade (Table 5.1.3-260) with most of the growth among African-Americans (Table 5.1.3-264), but has also experienced a significant rise in unemployment (Table 5.1.3-263). The percentage of population in the work force has risen slightly as has the number of people living below the poverty line (Table 5.1.3-266). In 2008, only 4 federal permits were issue to vessels that claim Elizabeth City as homeport (Table 5.1.3-269). However, there are 56 persons employed in the fish and seafood sector of fishing related employment reported in Table 5.1.3-270. There were 88 commercial vessels registered with the state and 193 standard commercial licenses reported in Table 5.1.3-271.

5.1.3.22 North Carolina Fishing Infrastructure and Community Characterization

The following tables provide a general view of the presence or absence of fishing infrastructure located within the coastal communities of North Carolina with substantial fishing activity. It should be noted that there are many other attributes that might have been included in this table, however, because of inconsistency in rapid appraisal for all communities, these items were selected as the most consistently reported or had secondary data available to determine presence or absence. It should also be noted that in some cases certain infrastructure may exist within a community but was not readily apparent or could not be ascertained through secondary data. Table 5.1.3-272 offers an overview of the presence of the selected infrastructure items and provides an overall total score which is merely the total of infrastructure present.

Table 5.1.3-272. Fishing Infrastructure Table for North Carolina Potential Fishing Communities.

Community	Federal Commercial Permits (5+)	State Commercial Licenses (10+)	Federal Charter Permits (5+)	Seafood Landings	Seafood retail markets	Fish processors, Wholesale fish house	Recreational docks / marinas	Recreational Fishing Tournaments	Total

In providing a preliminary characterization of potential fishing communities in Table 5.1.3-273 we have provided a grouping of communities that seem to have more involvement in various fishing enterprises and therefore are classified as primarily involved. These communities seem to have considerable fishing infrastructure, but also appear to have a history and culture surrounding both commercial and recreational fishing that contributes to an appearance and perception of being a fishing community in the mind of residents and others. The communities of Wilmington and Wrightsville Beach, which have considerable fishing infrastructure but are listed in secondarily involved are placed in that category largely because these two communities are located in a more metropolitan area that has a very diversified economy and while there seems to be an emphasis upon fishing, it is most likely that fishing has a small role in the overall economy and culture of the area. Others, like Elizabeth City, have a large processor located in the community, but may lack other components that are considered part of fishing culture or history. Many of these communities are in transition due to various social and demographic changes from coastal development, growing populations, changing regulations, etc. This preliminary characterization is just that and should not be considered a definite designation as fishing community, but a general guide for locating communities that may warrant consideration as a potential fishing community. Furthermore communities are not ranked in any particular order, this is merely a categorization.

Table 5.1.3-273. Preliminary Characterization of Potential Fishing Communities in North Carolina.

Primarily-Involved	Secondarily-Involved
Southport	Varnamtown
Carolina Beach	Bald Head Island
Sneads Ferry	Wilmington
Swansboro	Wrightsville Beach
Morehead City	Topsail Beach/Surf City
Beaufort	Atlantic Beach
Hatteras	Oriental
Wanchese	Vandemere/Mesic
Manteo	Bath
Harker's Island	Belhaven
	Ocracoke
	Elizabeth City

5.1.4 South Carolina Communities with Substantial Fishing Activity

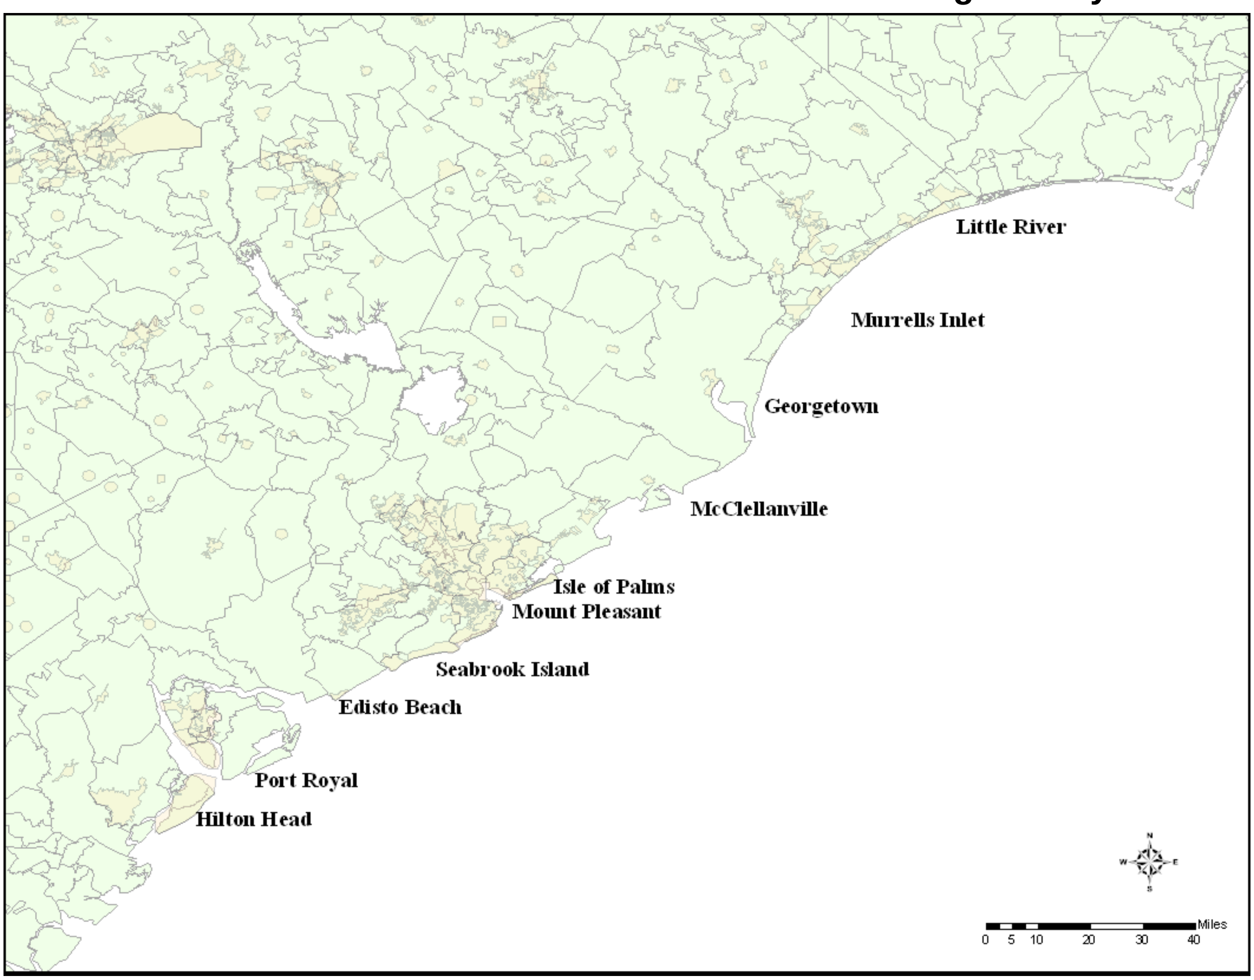

Figure 5.1.4-1. Potential Fishing Communities of South Carolina.

South Carolina landed over 14 million pounds of seafood in 2001 and over 13 million in 2002. The value of those landings was over 23 million dollars in 2001 and over 20 million dollars in 2002. No South Carolina port was listed in the top 50 U.S. ports in terms of pounds landed or in terms of value of landings. According to NMFS (2002) South Carolina recreational fishermen landed over 3 million pounds of finfish in 2001 and in 2002 that number dropped to just less than 2 million pounds. There were three processors in South Carolina during 2001 with a total of 28 employees. The number of wholesale dealers was not listed in the report under South Carolina, but was combined under Inland States. In the years 2001 and 2002, South Carolina had approximately 520 and 556 registered vessels respectively.

In 2008, South Carolina vessels with federal permits predominantly held south Atlantic charter/headboat pelagic, south Atlantic dolphin/wahoo charter, or South Atlantic shrimp permits.

South Carolina requires licenses for both recreational and commercial fishing, including the sale of seafood and other marine products. The table below lists commercial licenses only (Table 5.1.4-2). The majority of South Carolina state permits are saltwater licenses and trawler licenses. The next most common are crab pots, bait dealer and shellfish licenses.

Figure 5.1.4-1 shows potential fishing communities in South Carolina. A map for each community is provided which displays federal dealers and a symbol indicating the number of federal permits by zip code. The zip code area name is displayed in light blue while the CDP name is in black. The symbol for permits is centered within the zip code area and does not represent the precise location of any permit holder. Dealer permits are displayed near their physical location.

5.1.4.1 Hilton Head Island (29926, 29928)

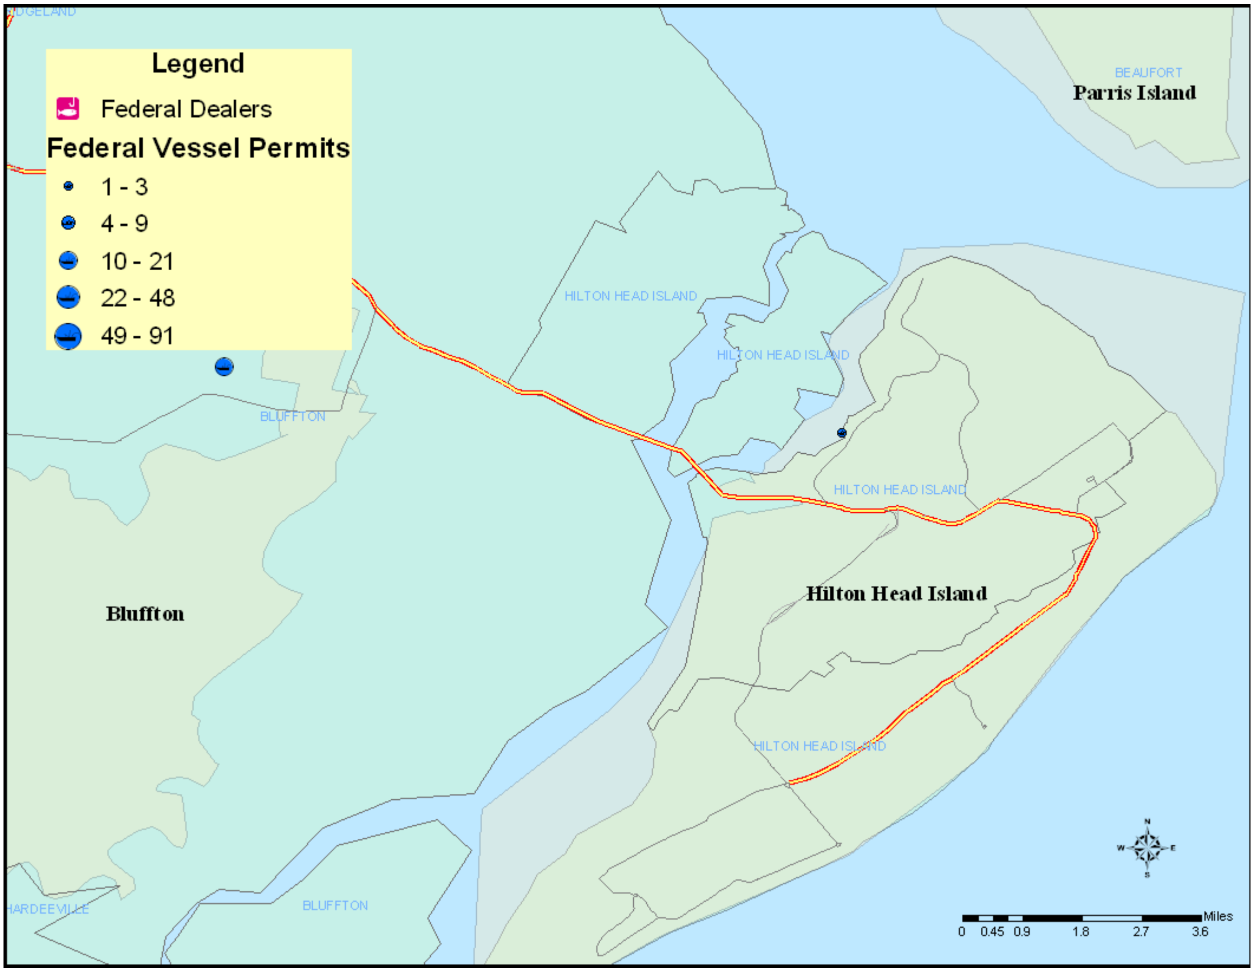

Figure 5.1.4-2. Hilton Head Island, South Carolina.

Hilton Head has seen steady population growth since 1980 and has tripled in size in 2000 (Table 5.1.4-3). While average wage and salary have also tripled over that time period and unemployment has remained low (Table 5.1.4-6), the number of people living under the poverty level has also risen noticeably (Table 5.1.4-9). There were at one time hundreds of persons employed in the farm, fish and forestry categories for occupation and industry. Recently, however, those numbers have dropped significantly (Tables 5.1.4-10 and 5.1.3-11). There are relatively few federally permitted vessels homeported at Hilton Head (Table 5.1.4-12) and most employment in fishing related business is in marinas sector according to Table 5.1.4-13. There were 108 total state permits for Hilton Head and 45 of those were Saltwater licenses and 11 trawler licenses (Table 5.1.4-13). Nearby Bluffton had 104 state permits with 44 of those being saltwater licenses and16 trawler licenses and 11 wholesale dealers (Table 5.1.4-15).

5.1.4.2 Beaufort/Port Royal (29935)

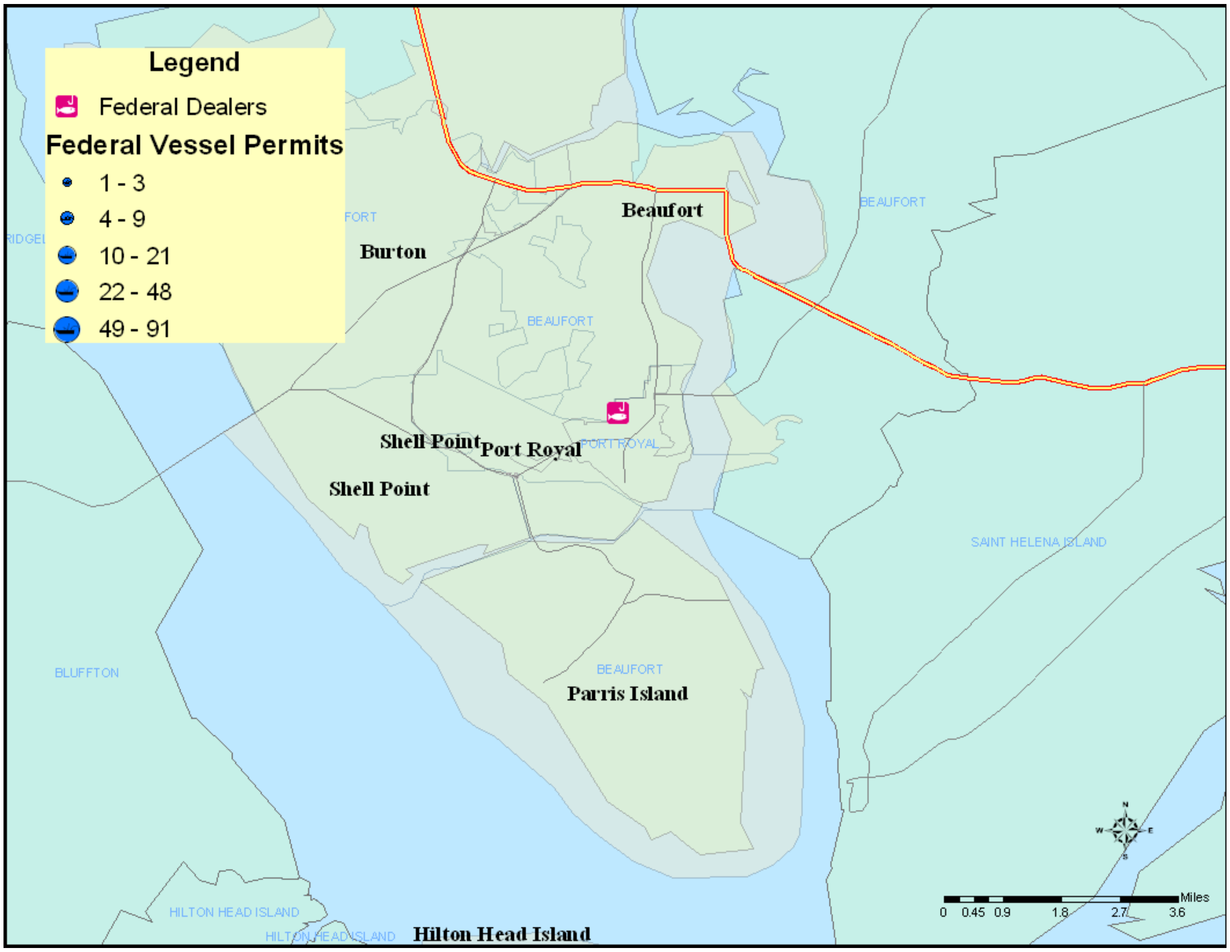

Figure 5.1.4-3. Beaufort/Port Royal, South Carolina.

Beaufort

The town of Beaufort was incorporated in 1711 and is the second oldest town in South Carolina. Both Beaufort County and the town of Beaufort were named for Henry Somerset, Duke of Beaufort (1684-1714), who was one of the Lords Proprietors of Carolina. Beaufort County was incorporated in 1785 and about 1800, it began to enter more prosperous times when rice, cotton and indigo plantations were abundant. Beaufort is the county seat and located on Port Royal Island. In 1874, the town of Port Royal was incorporated and is one of the large Sea Islands along the southeast Atlantic coast of the United States. The seaport of Beaufort is located at the head of one of the largest natural harbors on the Atlantic coast. Shrimping, fishing and crabbing are of major importance to these areas. They have been a part of their history since their settlement and the local economies continue to be dependent on them. Today, the entire area of downtown Beaufort is designated as a historic district. Every October in Port Royal there is an annual Shrimp Festival where the local maritime history is intertwined with the tourism industry. Local shrimpers share their history and recipes with tourists.

Port Royal

Port Royal has seen its population fluctuate over the past three decades and reached a high of 4,022 in 2000 (Table 5.1.4-16). The percent of unemployed persons had risen in the last decade to 9.0% (Table 5.1.4-19). Average wage and salary have also grown but persons below the poverty level has remained about the same (Table 5.1.4-22). Persons employed in farm, fish and forestry has also fluctuated over the years. Two federal permits were issued to vessels claiming it as homeport (Table 5.1.4-25). There are a 15 persons employed in the fish and seafood sector according to Table 5.1.4-26. There are only 13 state permits in Port Royal (Table 5.1.4-27), while in nearby St. Helena there are 197 with 73saltwater licenses, 25 trawler licenses and 14 wholesale dealers (Table 5.1.4-28). Beaufort which is also nearby had 198 total state licenses with 69 saltwater licenses and 23 trawler licenses (Table 5.1.5-29).

5.1.4.3 Edisto Beach (29438)

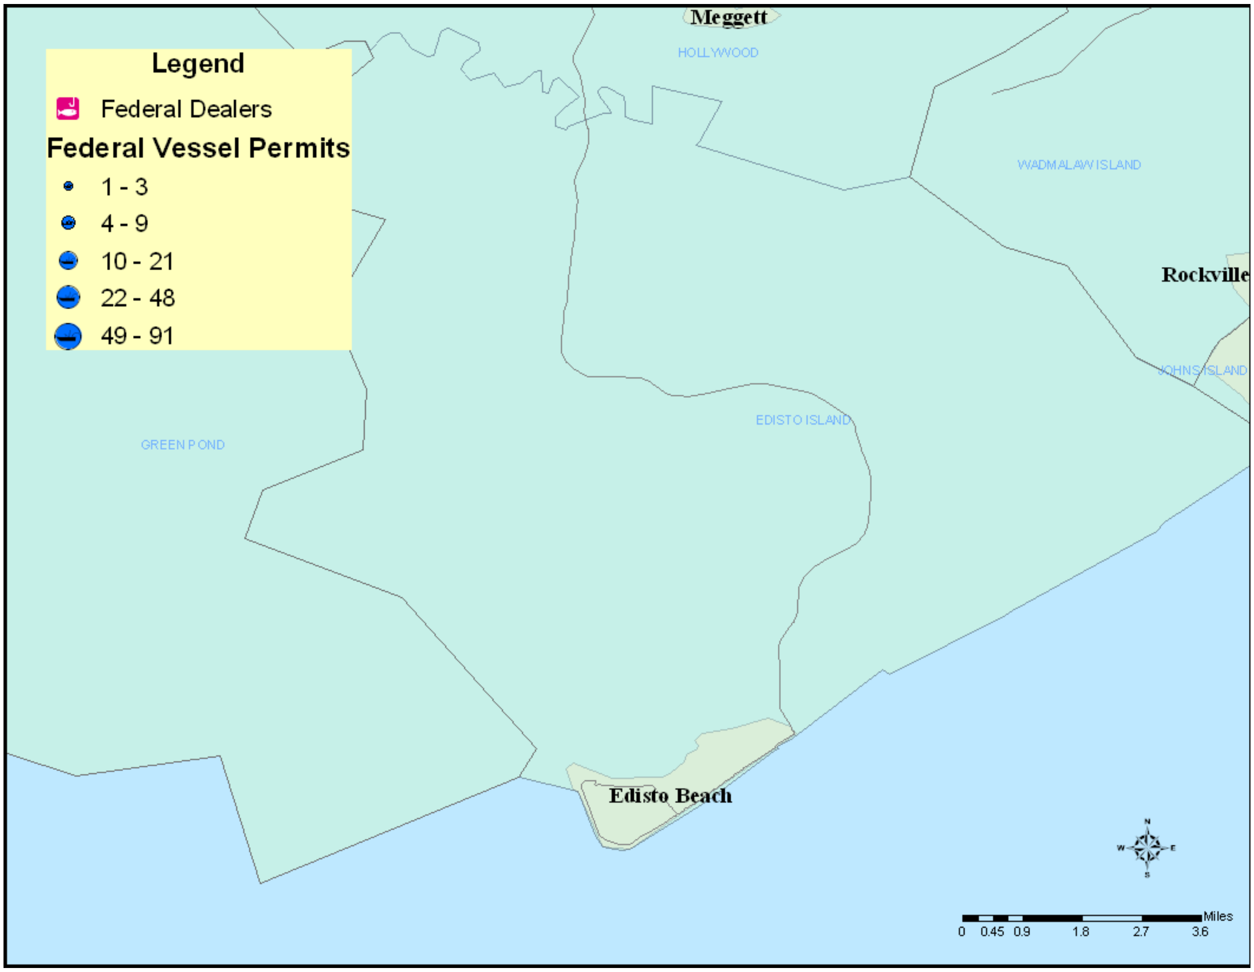

Figure 5.1.4-4. Edisto Beach, South Carolina.

Edisto Beach is a small beach community that has seen steady population growth over the past thirty years (Table 5.1.4-30). It has only about half of its population in the work force and unemployment has been and remains low (Table 5.1.4-33). Average wage and salary have jumped significantly in the last decade and the number of persons below the poverty level has risen only slightly. The number of persons employed in farm, fish and forestry has been few, but fluctuates over time. Two federal permits for south Atlantic shrimp were issued to vessels homeported in Edisto Beach (Table 5.1.4-39) and only 3 persons employed in fish and seafood according to Table 5.1.3-40. There are 44 state permits in the community with 20 of those being saltwater licenses and 8 trawler licenses (Table 5.1.4-51).

5.1.4.4 Seabrook Island

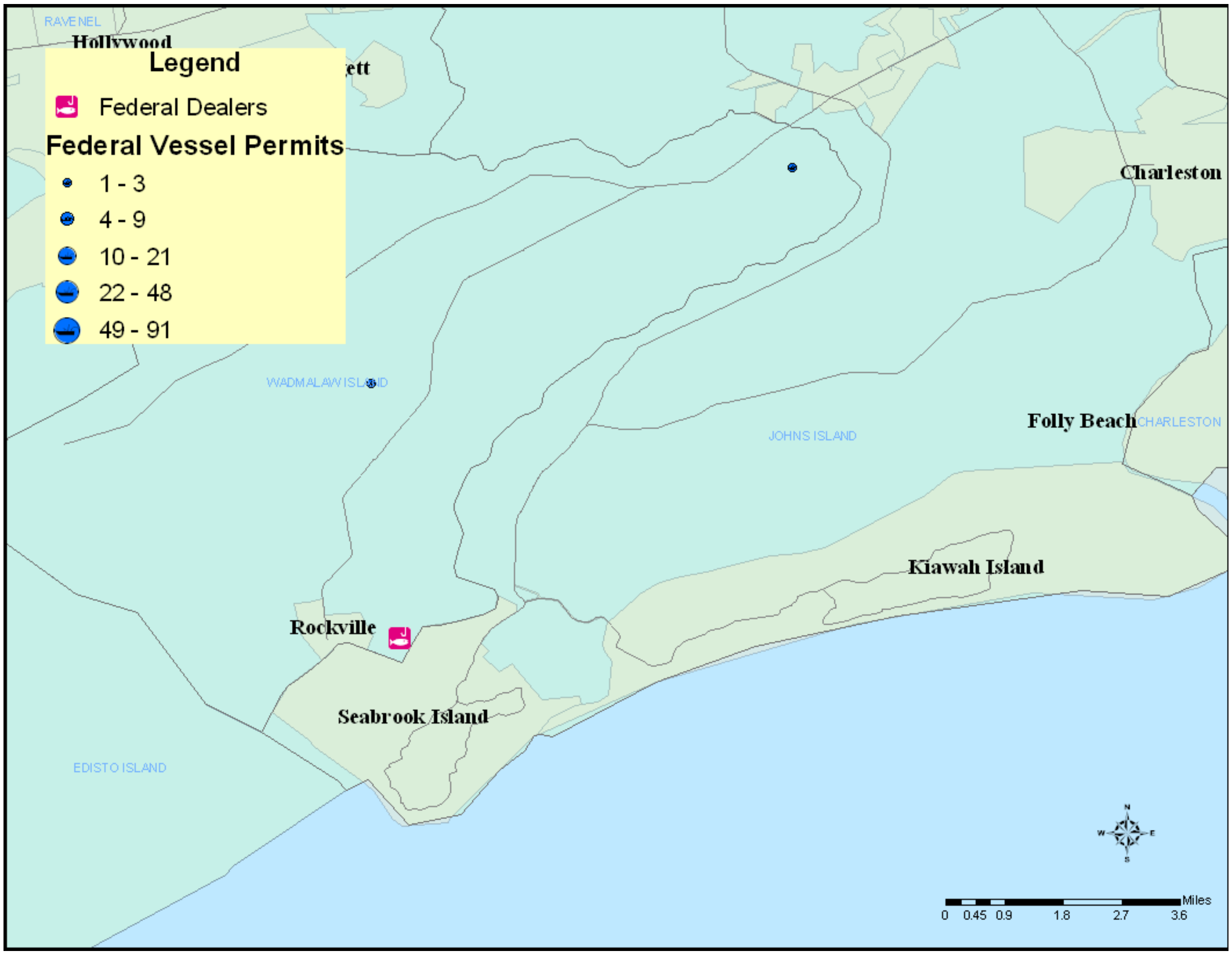

Figure 5.1.4-5. Seabrook Island, South Carolina.

Seabrook has seen some population growth since 1990 with a total population of 1203 in 2000. Most of households are owner occupied which has increased over the past ten years. Unemployment has decreased to 2.3 percent in 200 while the percent of the population in the labor force has dropped from 46.9 percent in 1990 to 40.6 percent in 2000. Average wage and salary has risen slightly while number of persons living under the poverty line has decreased. Employment in farm, fish and forestry occupation and industry has dropped over the past ten years to only 3 persons in the industry category. There is only five federal permits issued to vessels that claims Seabrook as a homeport (Table 5.1.4-51). All of the employment in fishing related sectors is in marinas according to (Table 5.1.4-52). There were 30 state permits for the community of Seabrook, but the nearby community of Wadmalaw Island did have 29 permits with 11 being saltwater licenses and 0 wholesale dealers (Table 5.1.4-53).

5.1.4.5 Mt. Pleasant (29464)

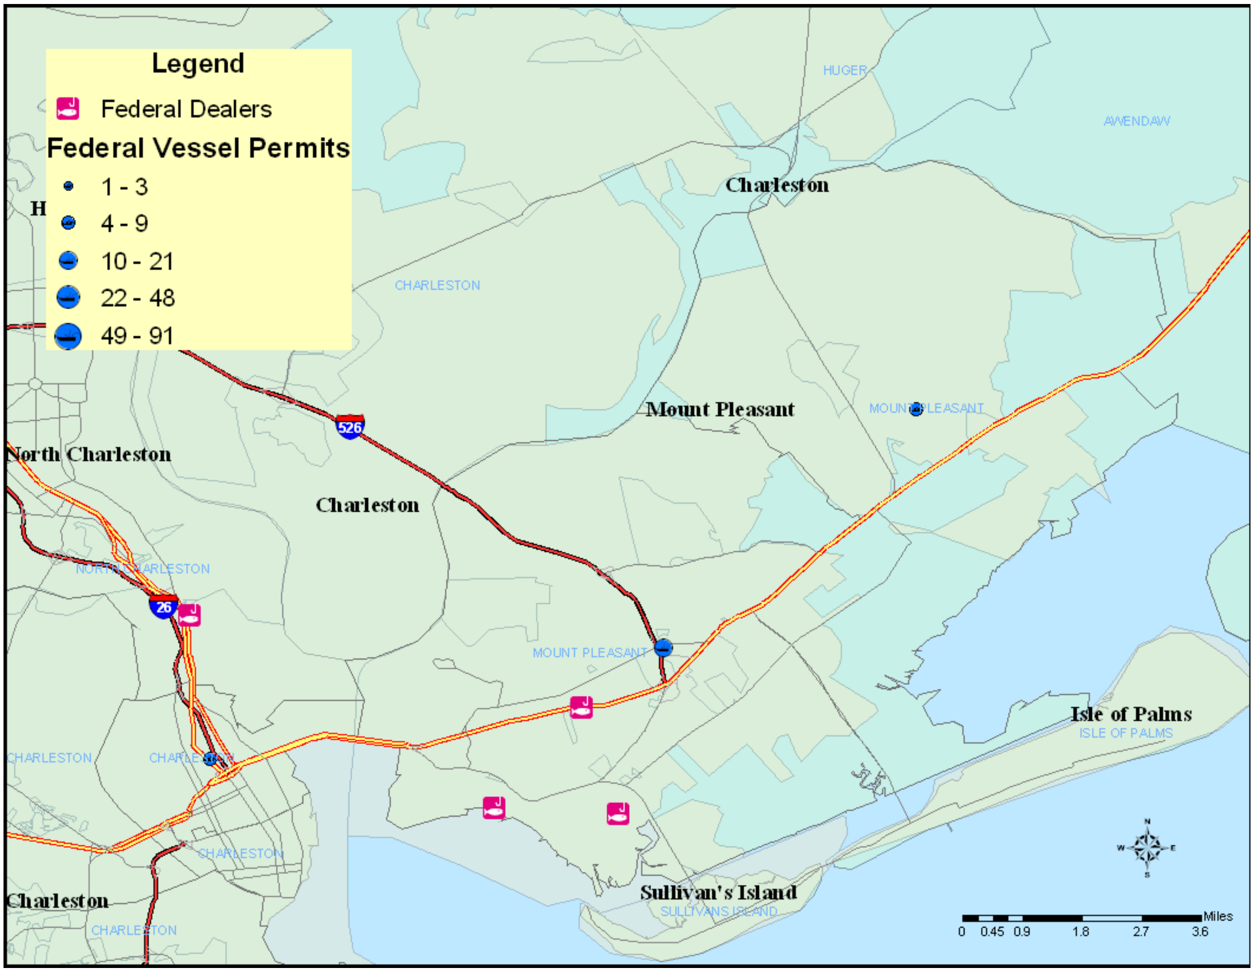

Figure 5.1.4-6. Mt. Pleasant, South Carolina.

The first inhabitants of the Mount Pleasant area were the Sewee Indians. The first English settlers arrived around 1680 under the leadership of Captain Florentia O' Sullivan. He had been granted 2,340 acres and each time a new family arrived, they were allotted several hundred acres. The first small settlement of the area was the village of Greenwich, which was adjacent to Jacob Motte's "Mount Pleasant" estate. Motte's estate was purchased in 1803 and divided into 35 large lots. In 1837, the village of Greenwich was merged with Mount Pleasant. Many of the families in this area had timber concerns and some maintained the ferries.

Mount Pleasant also played a leading role in the first major military engagement of the Revolutionary War in 1775. After the war, the area was known as a resort town with many stores and rentals available. The area is still widely known as a vacation area and "model town" in South Carolina.

Mount Pleasant has seen its population double every ten years from 1970 to 1990 and now has reached a high of 47,386 in 2000. The number of persons in the labor force has dropped slightly to 69.9 percent while percent unemployed has remained fairly low at 2.2

percent. Average wage and salary has risen substantially but so has the number of persons living below the poverty level. While there was a significant jump in the number of persons working in farm, fish and forestry in 1990, that number dropped significantly in 2000. While there are only 5 federal permits issued to vessels homeported in Mount Pleasant (Table 5.1.4-63), there are 12 persons listed as fishing and 28 persons employed in fish and seafood and markets (Table 5.1.4-64). There are 131 state permits in Mt. Pleasant with 53 saltwater licenses (Table 5.1.4-65). There were 10 trawler licenses and 14 wholesale dealer licenses.

5.1.4.6 Isle of Palms (29451)

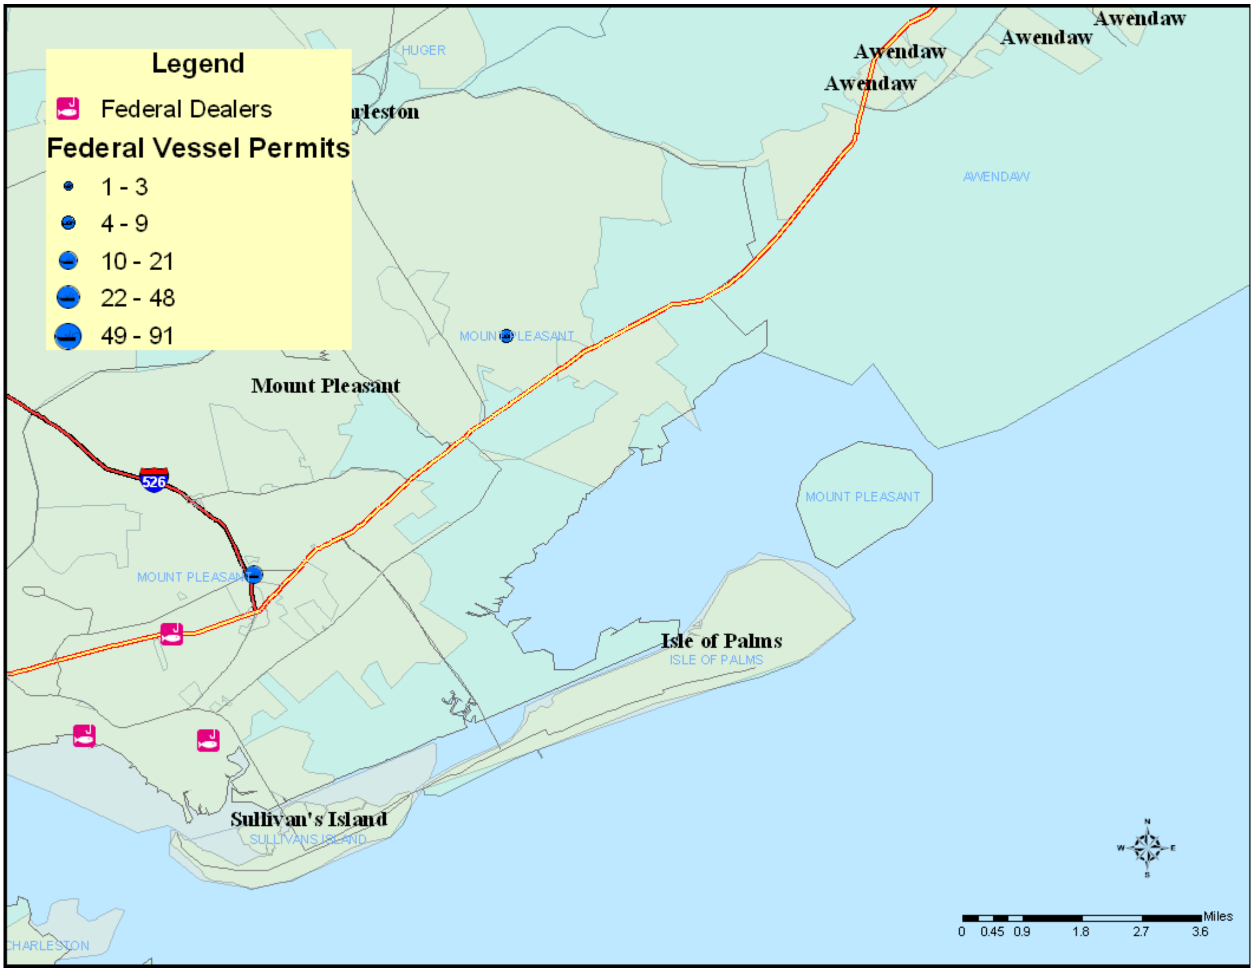

Figure 5.1.4-7. Isle of Palms, South Carolina.

Isle of Palms has seen little population growth over the past several decades. The percent of the population in the labor force has dropped slightly to 63.1 percent and unemployment is down to 1.3 percent in 2000. Average wage and salary has almost doubled every ten years since 1970 to a high of $76,170 in 2000. The number of persons below the poverty level dropped dramatically in 1990 but has since risen to 156. The number of persons in farm, fish, and forestry occupations and the industry has dropped steadily over the years. There are 6 federal permits issued to vessels that call Isle of Palms homeport (Table 5.1.4-75) most all employment in fishing related businesses is in marinas with 18 and 3 persons in fish and seafood markets. There were a total of 6 state permits according to (Table 5.1.4-77) and 3 of those were saltwater licenses and 0 were shellfish.

5.1.4.7 McClellanville (29458)

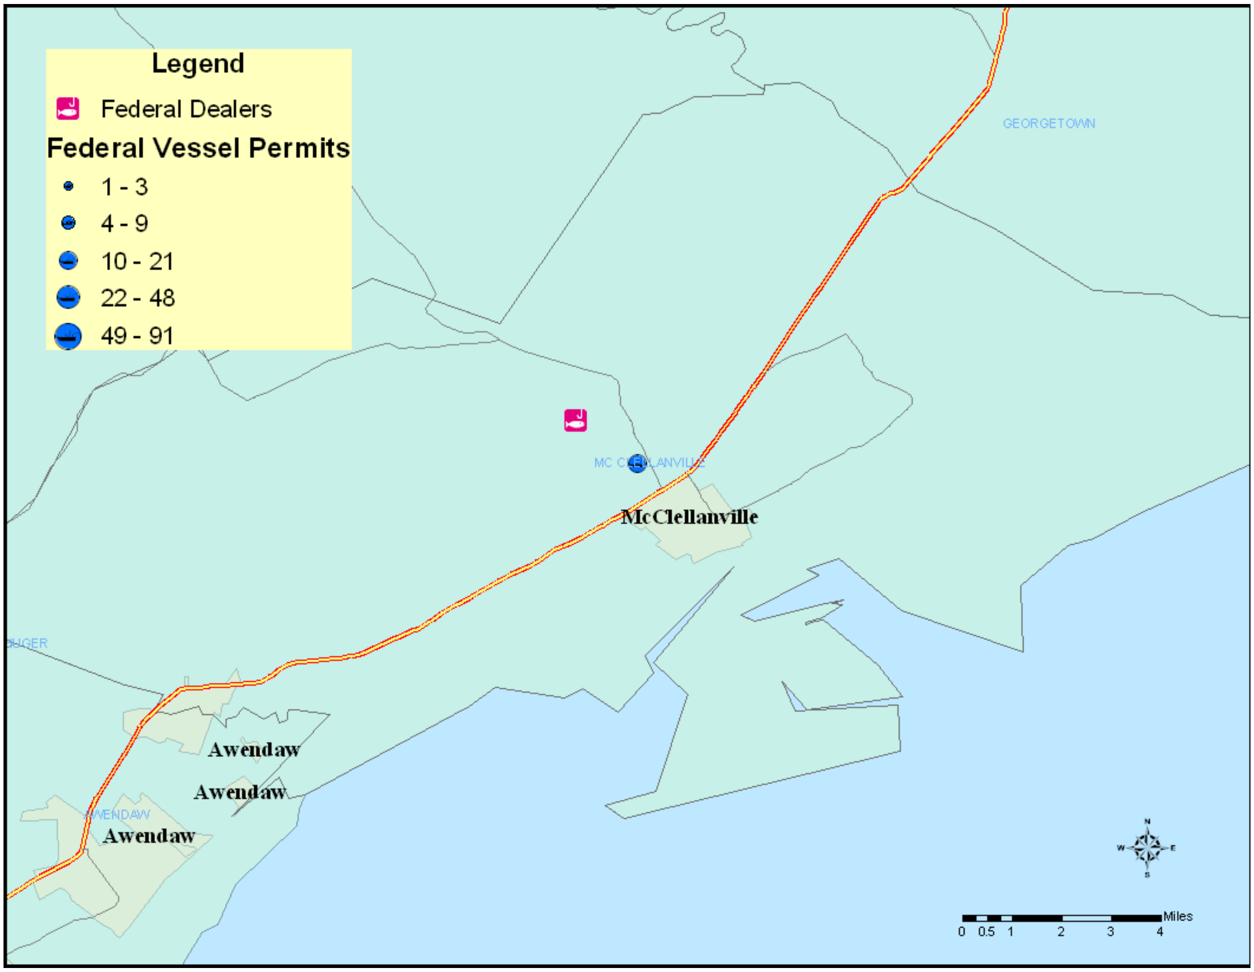

Figure 5.1.4-8. McClellanville, South Carolina.

The population of McClellanville dropped in the 1990 census but has since increased again in 2000 to 459. The percent of the population that is unemployed has remained very low while the percent of population in the work force has dropped from 64.3 percent to 56.9. Average wage and salary have grown, but so has the number of persons living below the poverty level. The number of persons employed in farm, fish, and forestry occupations has remained fairly constant over the past three decades. In 2008, there were 6 south Atlantic shrimp and 6 other federal permits issued to vessels homeported in McClellanville (Table 5.1.4-87). All employment in fishing related business is in fish and seafood (Table 5.1.4-88). There are 153 state permits in McClellanville, with 52 of those being saltwater licenses (Table 5.1.4-89). There are 16 trawler licenses, 23 handheld equipment licenses and 8 wholesale dealer licenses.

5.1.4.8 Georgetown (29440)

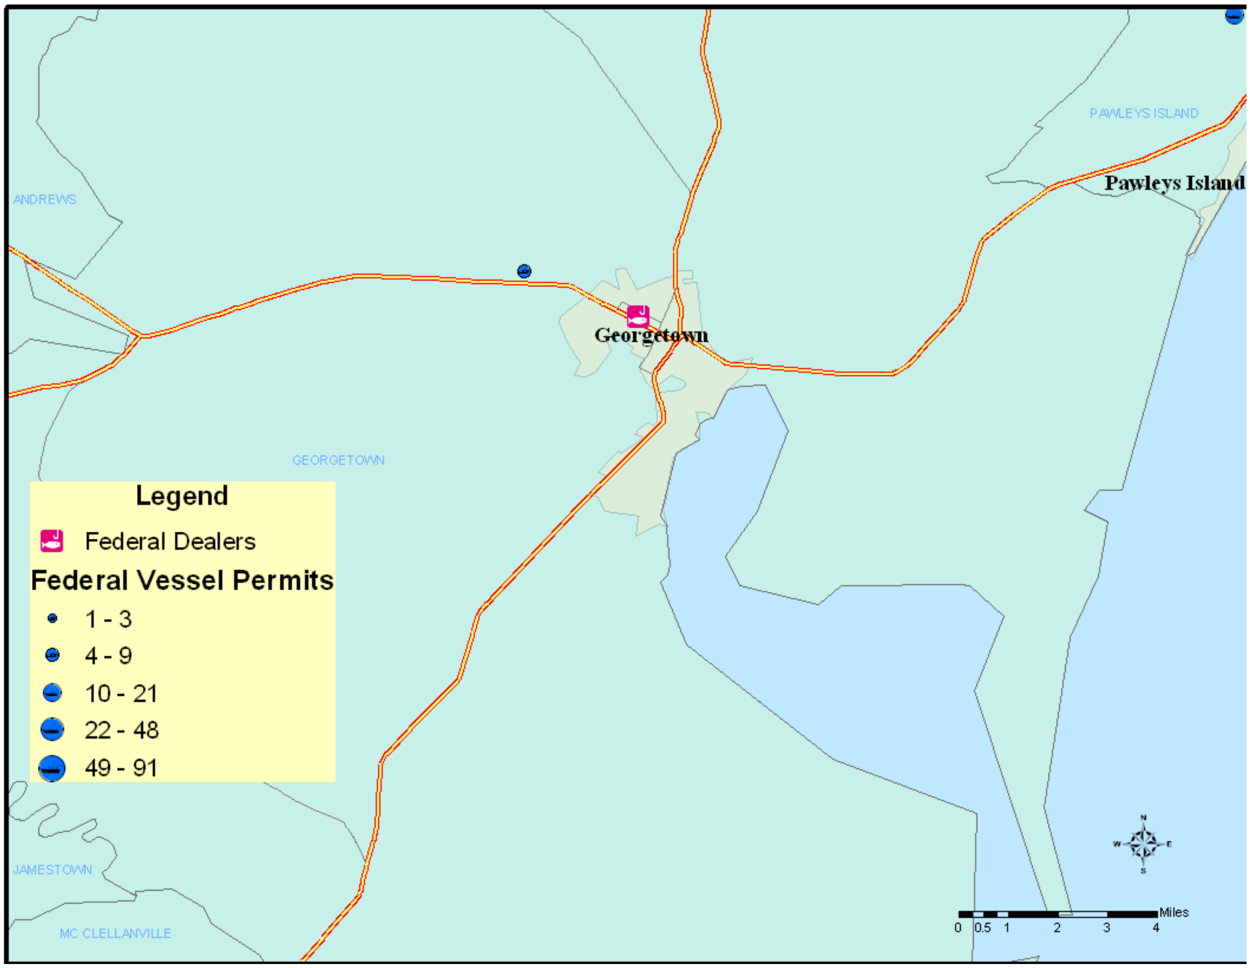

Figure 5.1.4-9. Georgetown, South Carolina.

Georgetown is South Carolina's third oldest city, following Charleston and Beaufort. The town became a busy seaport by 1729 as the import and export of cargo created wealth for the town, as well as targets for the pirates who were hiding out in the bays of the barrier islands. Many of the local stores in the area sold naval materials and uniforms. The indigo plant, of which the blue dye was derived from, grew along the coastal plains. An aristocratic society of plantation owners was established and they formed the "Winyah Indigo Society". However as the price of the dye fell from overseas markets, local planters began cultivating rice instead. The original rice seeds were brought in from Madagascar to the port of Charleston around 1680. Grocers in England were said to praise the "Carolina Gold" rice above all other rice. Rice even was used as a replacement for money, being accepted as payment for taxes. However with the Emancipation Proclamation and destructive hurricanes, the last commercial rice harvest in Georgetown County was in 1919. The area then turned to lumber production. In 1936, the International Paper Company built a plant in Georgetown. By 1942, this plant became the largest craft paper mill in the world. Commercial fishing and tourism are now significant industries in the area that contribute greatly to its economic well-being.

Georgetown's population has been declining from 1980 when it was 10,144 until 2000 where it dropped to 8,934. Georgetown's population is predominantly African-American and has approximately 56 percent of its population in the labor force. The unemployment rate has gone down since 1990 to 7.8 percent. Average wage and salary have grown slightly over the past 30 years, but the number of people living below the poverty level has dropped little. As is the case for most communities the number of persons employed in farm, fish and forestry has seen a steady decline. In 2008, vessels with federal permits predominantly held Atlantic dolphin/wahoo commercial (11), Atlantic dolphin/wahoo charter (10), or snapper grouper unlimited (9) permits (Table 5.1.4-99) and most fishing related employment is in boat building (Table 5.1.4-100). There are 8 persons reported as working in fish and seafood and markets also. With little fishing employment evident elsewhere, it is surprising to see over 502 state permits issued for Georgetown residents. Over 122 of those permits were for saltwater licenses and 22 were trawler permits. There are 19 wholesale dealer licenses in the community as well as 49 crab pot permits and 45 channel net (Table 5.1.4-101).

5.1.4.9 Murrells Inlet (29576)

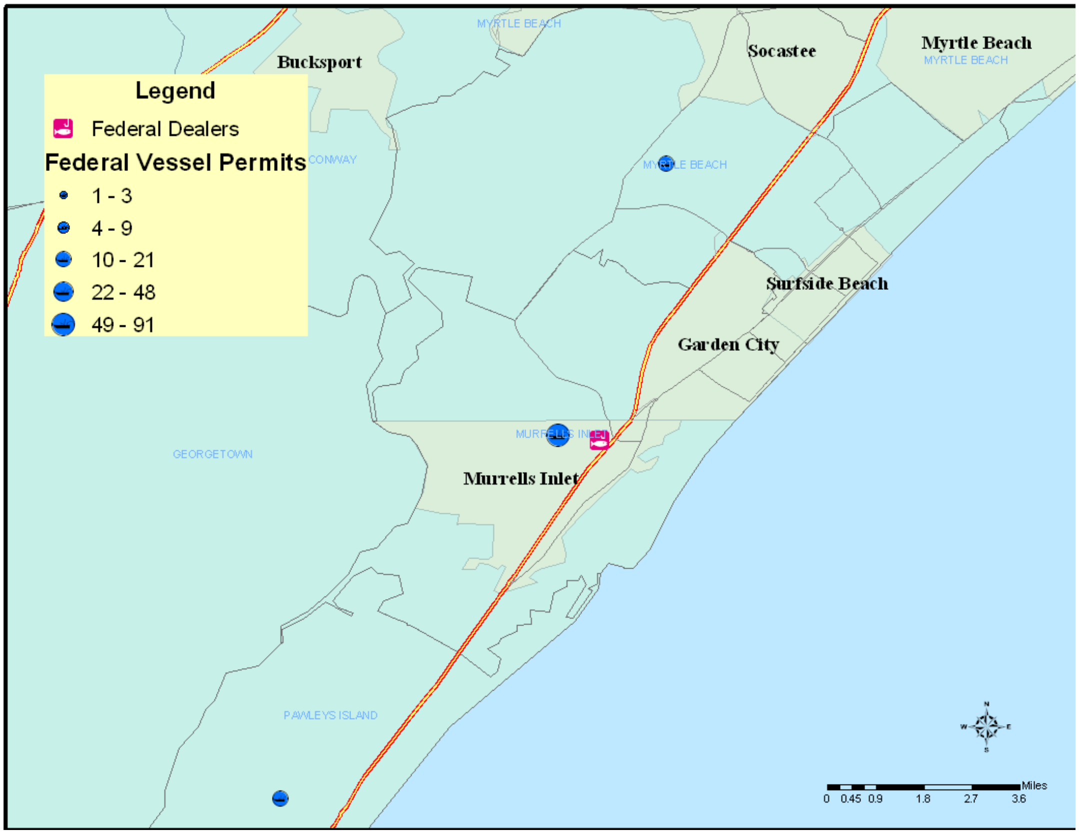

Figure 5.1.4-10. Murrells Inlet, South Carolina.

Murrells Inlet is known as the Seafood Capital of South Carolina. The origin of its name remains a mystery. However Murrells Inlet was officially named by the post office in 1913. The first settlers of the area were Native American Tribes. However beginning in the 16th and 17th centuries, Spanish and English colonists arrived in the area. Pirates also utilized the Inlet's winding creeks for refuge and a hiding place. Large tracts of land were cultivated into successful rice plantations. By 1850, almost 47 million pounds of rice were produced in this area. Murrells Inlet was used as a port during the Civil War to sneak cotton and other products to England in exchange for war supplies, such as food and medicine. The Civil War led to the decline of the rice culture and in 1916, the last remaining commercial rice grower was out of business.

By this time, commercial and recreational fishing became a popular industry. By 1914, captain-led fishing excursions cost $5 per person for a day trip out of the Inlet on a 20-foot skiff. Today, charter, recreational and commercial fishing are still popular in Murrells Inlet.

Murrells Inlet has seen its population increase to a high of 5,492 in 2000. The percentage of owner occupied housing has also increased to 85 percent. The percent of the population in the labor force has remained practically the same while unemployment has risen from 3 percent in 1990 to 5.2 percent in 2000. Average wage and salary has risen over the past few decades while the number of persons living below the poverty level has fluctuated and now is 435 in 2000. The number of persons working in farm, fish and forestry occupations has seen a decline like most communities.

In 2008, vessels with federal permits predominantly held south Atlantic charter/headboat for pelagic fish (29), Atlantic dolphin/wahoo commercial (22), Atlantic dolphin/wahoo charter/headboat (28), snapper grouper charter/headboat for snapper grouper (29), or snapper grouper unlimited (19) permits (Table 5.1.4-111). There are four federal dealers in the community. Most of the fishing employment is in fish and seafood markets with 10 persons employed in that sector out of the 16 total (Table 5.1.4-112). There are 135 state permits issued to residents of Murrells Inlet. Sixty-four of those permits are for saltwater licenses. Another 8 are for handheld equipment and 12 are for crab pots. There are 15 wholesale dealer licenses held by Murrells Inlet residents (Table 5.1.4-113).

5.1.4.10 Little River (29566)

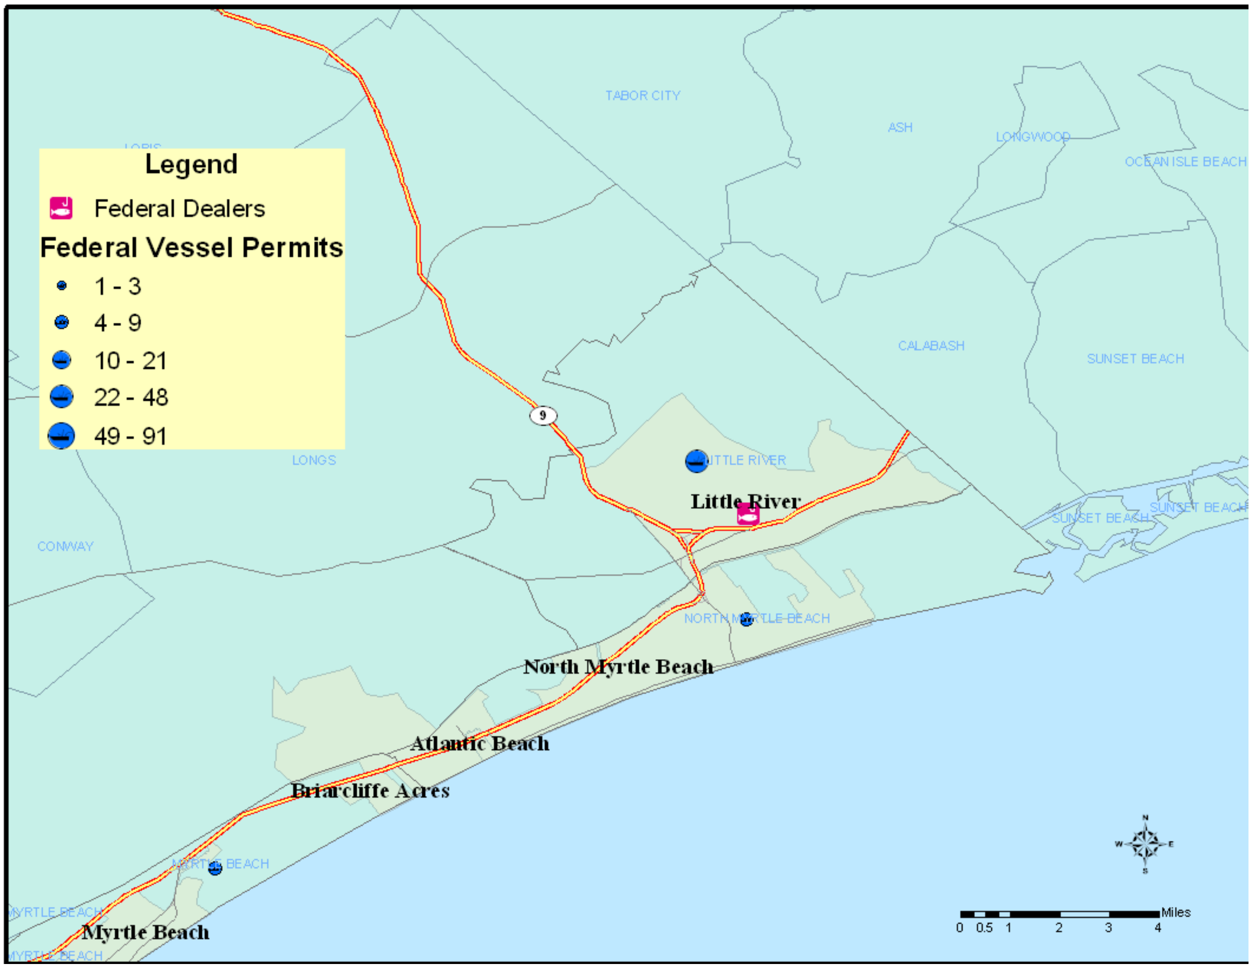

Figure 5.1.4-11. Little River, South Carolina.

Native American tribes who settled this area called the stream "Mineola," which means "Little River." Little River is one of the oldest settlements along the South Carolina coast. Fishermen and farmers began settling the area in the late 1600s and 1700s. The small, protected harbor was a refuge for shipwreck survivors and pirates, who needed a place to repair their boats and rest. It is still common to see treasure maps attempting to locate buried treasure on the placemats of the local restaurants.

For a time, Little River became known as "Yankee Town" by the rest of Horry County because of the settlers from New England. The area became a thriving port town in the 1850s. The shipments included fine lumber and naval supplies to Northern markets. The town had a few stores, sawmill, water house, school, churches and a bank. However the Civil War halted much of the town's developments. Today, Little River is widely known for its charterboats, deep-sea and commercial fishing.

Little River's population has nearly doubled in the last decade. The percent of owner occupied housing has risen from 61 percent in 1990 to over 80 percent in 2000. The percent of the population in the labor force has remained unchanged while unemployment has dropped. Average wage and salary have increased and so has the number of persons living below the poverty level. The number of persons working in the agriculture, fishing and mining sector has grown to 87 over the past ten years, while those in the occupation of farm, fishing and forestry has dropped. There are 17 vessels with federal permits homeported in Little River and the majority of them have either snapper grouper class 1 or snapper grouper charter permits (Table 5.1.4-123). Fishing related employment reported in Table 5.1.4-124 is mostly in the marinas sector with 31 persons and 7 more are in fish and seafood. Of the 87 state permits listed in Table 5.1.4-125, twenty-eight were for saltwater licenses.

5.1.4.11 South Carolina Fishing Infrastructure and Community Characterization

The following tables provide a general view of the presence or absence of fishing infrastructure located within the coastal communities of South Carolina with substantial fishing activity. It should be noted that there are many other attributes that might have been included in this table, however, because of inconsistency in rapid appraisal for all communities, these items were selected as the most consistently reported or had secondary data available to determine presence or absence. It should also be noted that in some cases certain infrastructure may exist within a community but was not readily apparent or could not be ascertained through secondary data. Table 5.1.4-126 offers an overview of the presence of the selected infrastructure items and provides an overall total score which is merely the total of infrastructure present.

Table 5.1.4-126. Fishing Infrastructure Table for South Carolina Potential Fishing Communities.

Community	Federal Commercial Permits (5+)	State Commercial Licenses (10+)	Federal Charter Permits (5+)	Seafood Landings	Fish processors, Wholesale fish house	Recreational docks / marinas	Recreational Fishing Tournaments	Total
Hilton Head Island	-	+	-	+	+	+	+	5
Port Royal	-	-	-	+	+	+	-	3
Edisto Beach	-	+	-	-	+	-	-	2
Seabrook Island	-	+	-	-	-	-	-	1
Mt. Pleasant	+	+	-	+	+	+	-	5
Isle of Palms	-	-	-	-	-	+	-	1
McClellanville	-	+	-	+	+	+	-	3
Georgetown	+	+	-	+	+	+	+	6
Murrells Inlet	+	+	+	+	+	+	-	6
Little River	+	+	+	+	+	+	-	6

In attempting a preliminary characterization of potential fishing communities in Table 5.1.4-127, we have provided a grouping of communities that appear to have more involvement in various fishing enterprises and therefore are classified as primarily involved. These communities have considerable fishing infrastructure, but also have a history and culture surrounding both commercial and recreational fishing that contributes to an appearance and perception of being a fishing community in the mind of residents and others. The communities are not ranked in any particular order, this is merely a categorization.

Table 5.1.4-127. Preliminary Characterization of Potential Fishing Communities in South Carolina.

Primarily-Involved	Secondarily-Involved
Mt. Pleasant	Edisto Beach
McClellanville	Seabrook Island
Georgetown	Isle of Palms
Murrells Inlet	
Little River	
Hilton Head Island	

Charleston, while having many commercial and charter permits is a large enough metropolitan area that fishing is rather small when compared to the larger economy and although historically may have played a role in the community culture is likely not a major focus historically or does it play a large role in the economy at this time. It is likely that the fishing community of Charleston has become ensconced in other parts of the metropolitan area, such as Shem Creek (Mt. Pleasant) and has become a component of that community's history and culture. Many of these communities are in transition due to various social and demographic changes from coastal development, growing populations, increasing tourism, changing regulations, etc. This preliminary characterization is just that and should not be considered a definite designation as fishing community, but a general guide for locating communities that may warrant consideration as a potential fishing community.

5.1.5 Georgia Communities with Substantial Fishing Activity

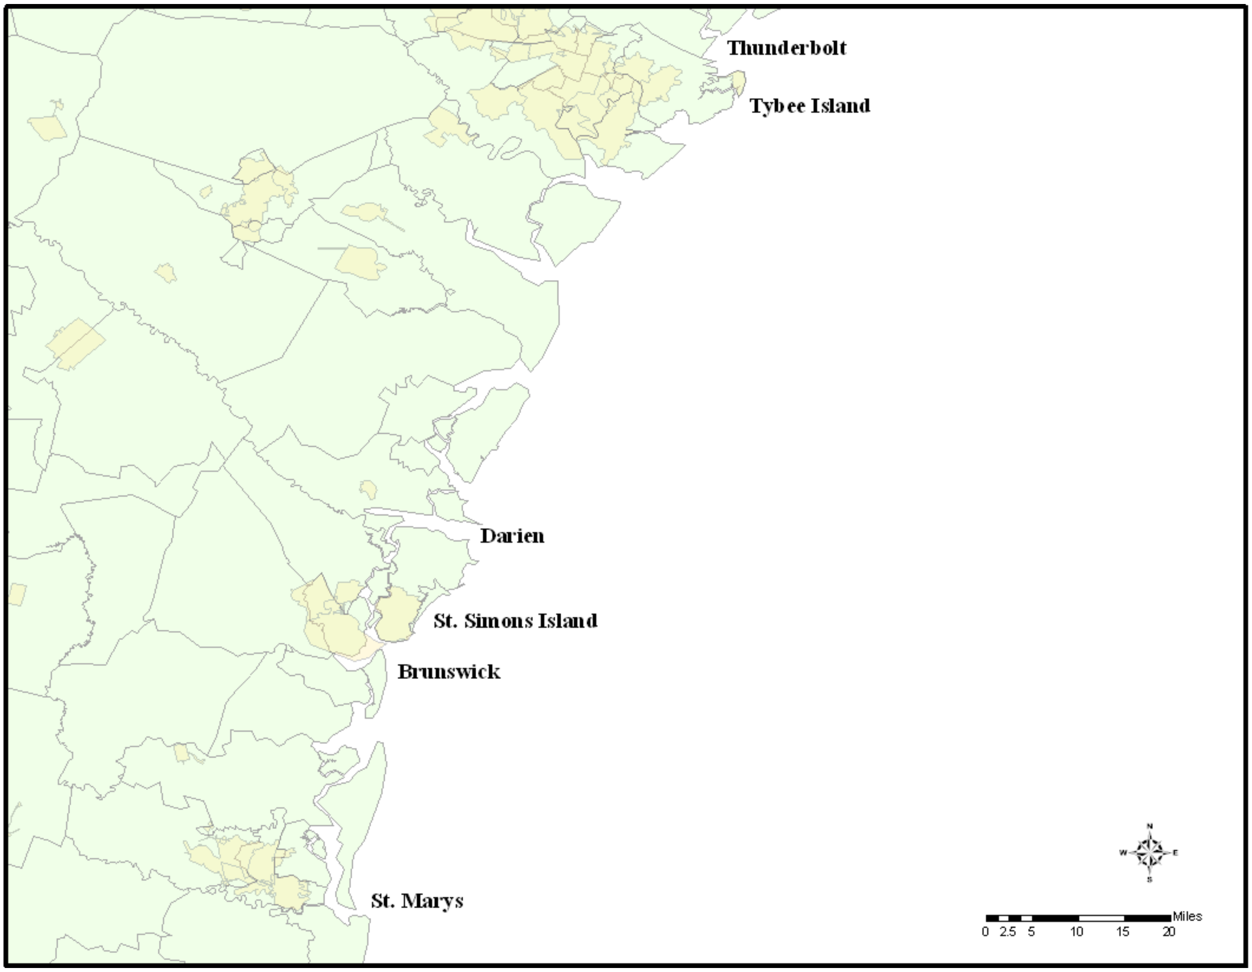

Figure 5.1.5-1. Potential Fishing Communities of Georgia.

Georgia landed over 9 million pounds of seafood in both 2001 and 2002. The value of those landings was over 14 million dollars in 2001 and over 15 million dollars in 2002. No Georgia port was listed in the top 50 U.S. ports in terms of pounds landed or in terms of value of landings. According to NMFS (2002) Georgia recreational fishermen landed over 2 million pounds of finfish in 2001 and in 2002 that number dropped to just over more than 1 million pounds. There were 5 processors in Georgia for 2001 with a total of 1,119 employees and 30 wholesale dealers employing 432 persons. In 2008, Georgia permitted 531 commercial vessels and 254 with trawl gear.

In 2008, Georgia vessels with federal permits held predominantly south Atlantic shrimp (102), Atlantic dolphin/wahoo charter (25), south Atlantic charter/headboat pelagic (28), south Atlantic charter/headboat for snapper grouper (28), and snapper grouper unlimited (23) permits. Figure 5.1.5-1 shows potential fishing communities in Georgia.

Georgia requires commercial fishermen to be licensed and also requires a license for commercial crabbing and commercial cast netting. A commercial trawling license is required to use power drawn nets in the state waters. In addition, the state requires a dealer license for retail and wholesale fish to be sold, soft-shell crab and bait dealers. Figure 5.1.5-1 shows potential fishing communities in Georgia.

5.1.5.1 Tybee Island (31328)

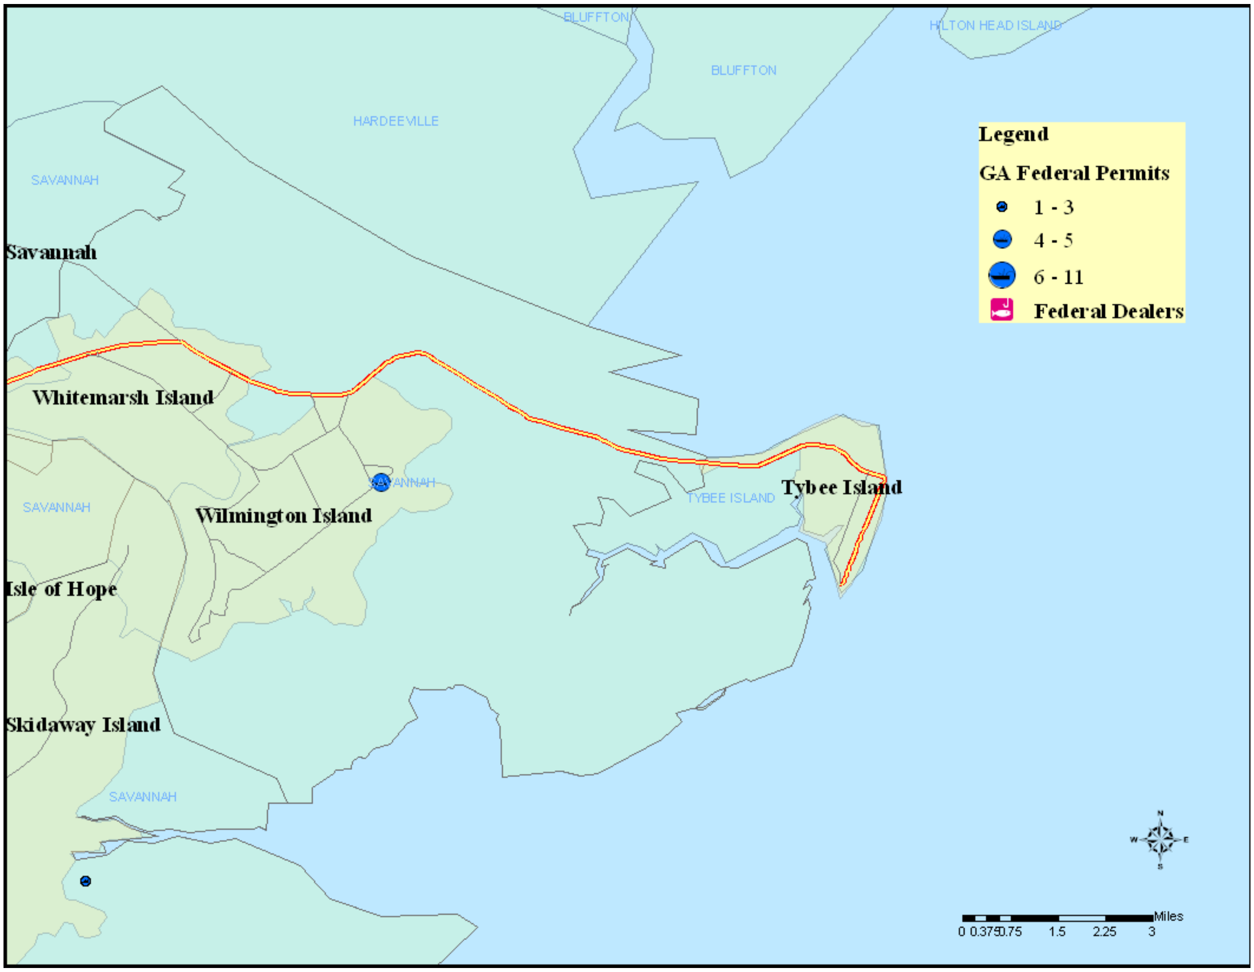

Figure 5.1.5-2. Tybee Island, Georgia.

Tybee Island stands at the mouth of the Savannah River. In 1736, a 90 foot lighthouse was built to help aid navigation in the area. At this time in America, this structure was the tallest. This lighthouse had to be rebuilt three times, lastly in 1773, due to storms. It currently stands at 154 feet tall and is Georgia's oldest lighthouse. After the Civil War, Tybee began to grow into a resort area. Before 1870 there were very few full time residents, but by the 1890s, there were over 400 beach cottages and local business for the summer residents. Tybee is still an attractive tourist destination with seven miles of beaches, with many options for both inshore and offshore fishing.

The population of Tybee Island has grown steadily over the past 20 years. The percent of the population in the labor force has also remained stable at around 61 percent and the percent of unemployed around 4.5 percent. Average wage and salary has increased to a high of $49,741 in 2000 while the number of persons living below the poverty level has remained around 330. The number of persons employed in the farm, fish, and forestry sectors of industry and occupation has slowly declined to where there were none reported in 2000. This is consistent with Table 5.1.5-12 where there are no vessels listed with federal permits for 2000 or 2001. Furthermore, Table 5.1.5-13 lists 3 persons employed in boat building as the only fishing related employment. There are however, 9 commercial vessels registered with the state from Tybee Island and all seven have full time fishermen as owners (Table 5.1.5-14).

5.1.5.2 Thunderbolt (31404, 31410)

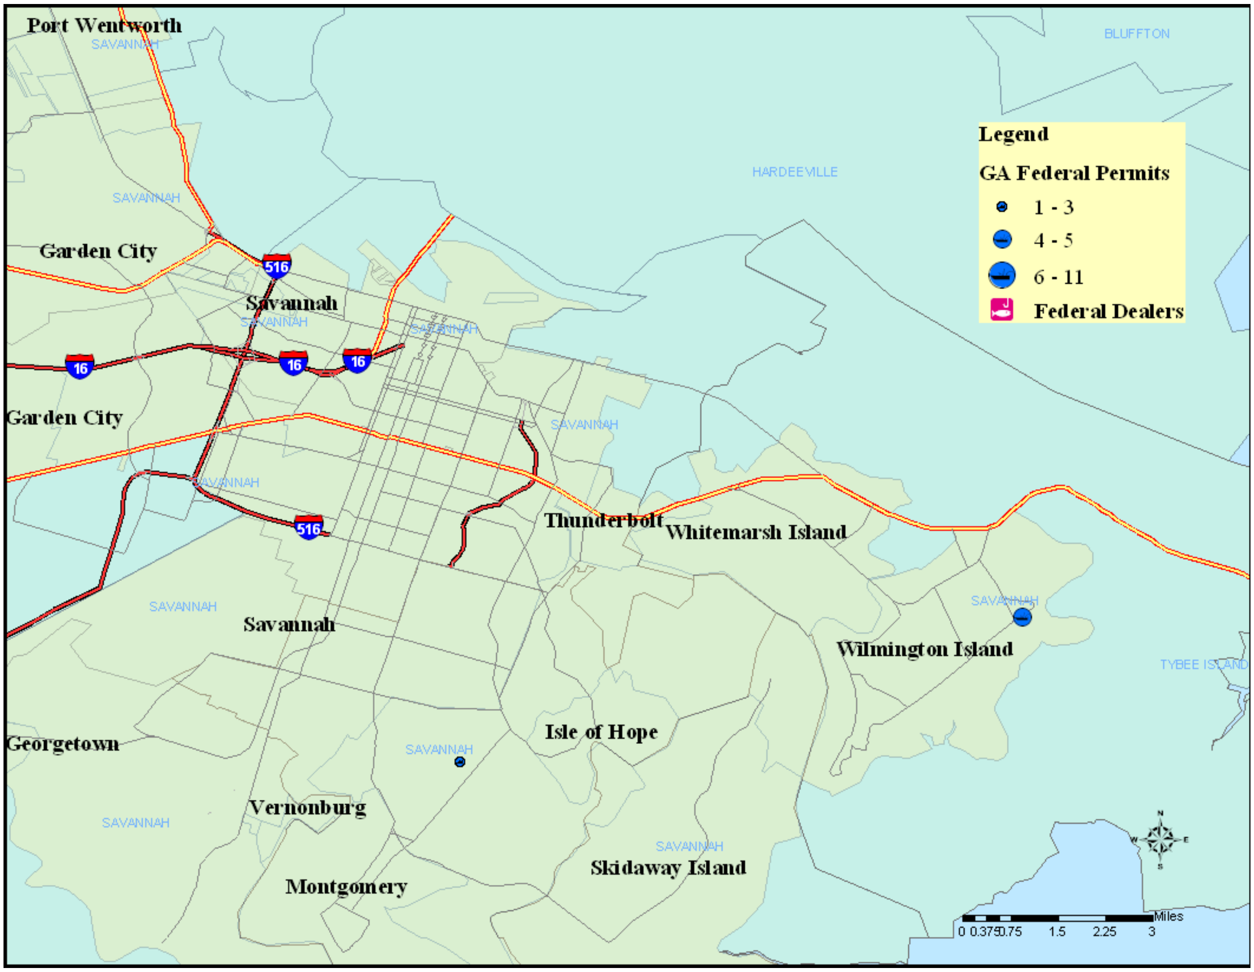

Figure 5.1.5-3. Thunderbolt, Georgia.

Thunderbolt's population has fluctuated over the past three decades and most recently declined during 1990 to 2000 where it stands at 2360. While the percent of population in the labor force has remained fairly stable, unemployment dropped significantly from a high of 17.2 in 1990 to 4.4 percent in 2000. Average wage and salary have risen slowly and the number of persons living below the poverty level has fluctuated some, but remains over 250. The number of persons employed in the farm, fish and forestry sectors under occupation and industry has dropped to zero over the past decade. This is consistent with fishing demographics as there are no vessels with federal permits listing Thunderbolt as homeport. There are at least three vessels registered with the state and three individuals who consider themselves to be full-time commercial fishermen according to Table 5.1.5-26.

5.1.5.3 Darien (31305)

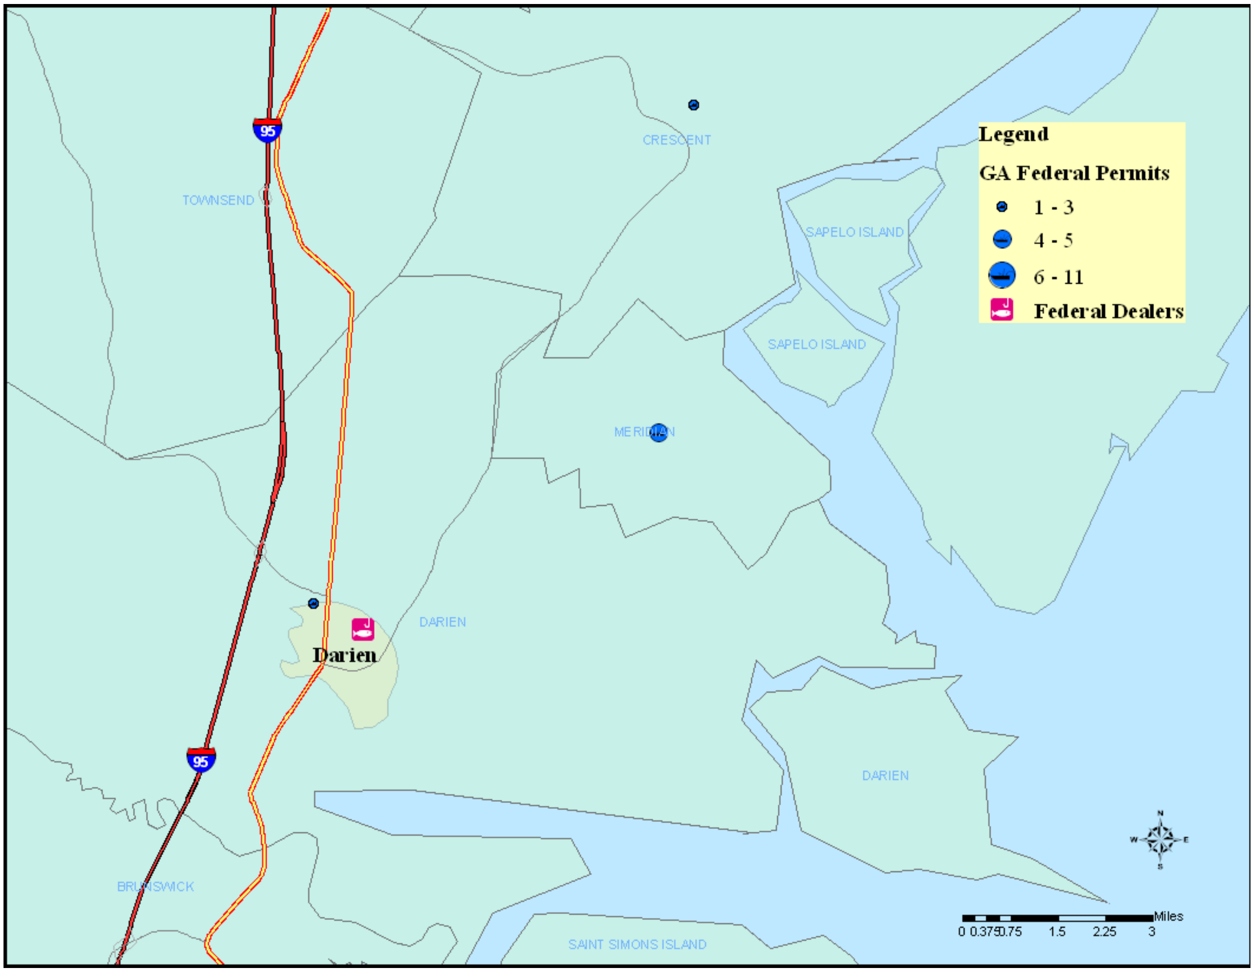

Figure 5.1.5-4. Darien, Georgia.

Darien was settled by Scottish Highlanders in the mid-1700s. During the 1800s, it was a leading seaport on the east coast. Even today, many shrimp fishing boats dock at the waterfront. Darien was named in honor of the unsuccessful colonization led by Darien Scots, at the Isthmus of Panama. After the American Revolution, Darien became an important port due to its position near the mouth of the Altamaha River. In 1816, the town of Darien was incorporated and it became the county seat in 1818.

The area became known as an international shipping port which was frequented by ships from Asia, Europe and South America. In 1900, more than 100 million linear board feet of timber and lumber were shipped from Darien. However, these shipments began to decline and in 1916, the last of Darien's sawmills went bankrupt. By the mid 1920s, the area experienced renewed growth with the commercial seafood industry. Many turned to the productive nearshore waters for their livelihood. By the early 1960s, McIntosh County had the largest shrimping fleet on the Georgia coast, with several oyster and shrimp packing houses along the banks of the Altamaha River. Even though today this area is economically dependent on tourism, commercial fishing is still the livelihood for many members of the community.

Over the past decade Darien's population has remained almost unchanged. Other demographic variables have also remained fairly stable as average wage and salary have also remained practically the same in 1990 and 2000. The number of persons living under the poverty level has also remained stable, while the percent of population in the labor force has gone up slightly; the unemployment percentage has gone down from 9.9 in 1990 to 2.4 in 2000. While there has been a decline in the number of persons reported in farm, fish and forestry occupations and industry there remain about 17 persons in those sectors. In 2008, 21 south Atlantic shrimp permits were issued Table 5.1.5-36 and fishing related employment shows 12 people employed in the sectors of fishing, seafood processing and fish and seafood (Table 5.1.5-37). The state has 56 commercial vessels registered in Darien including those having trawl gear.

5.1.5.4 Brunswick (31520, 31523, 31525)

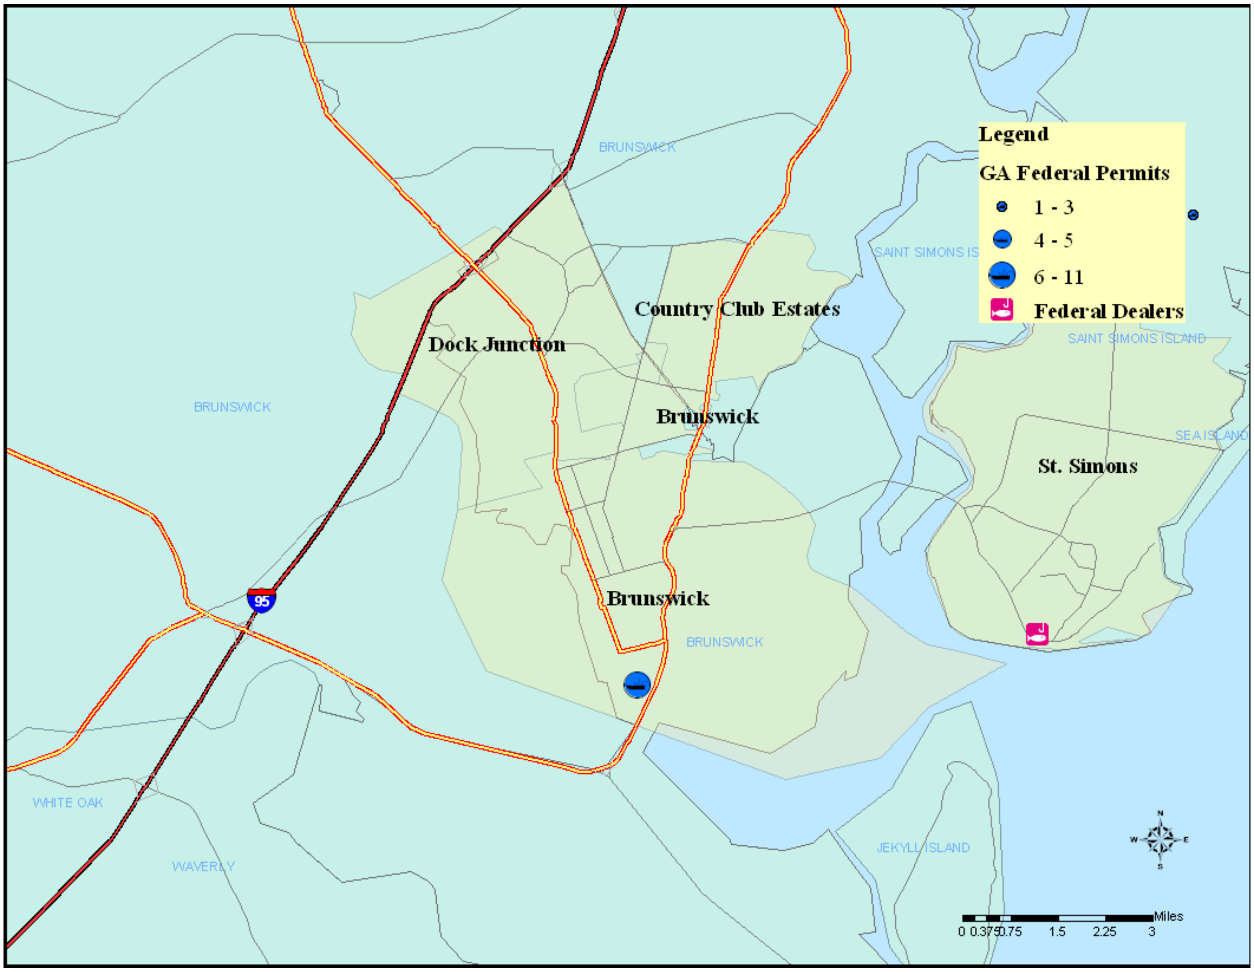

Figure 5.1.5-5. Brunswick, Georgia.

Brunswick's population has seen a steady decline over the past three decades in almost every age category. The percent of the population in the labor force has remained the same since 1990 but unemployment has risen to 10.4 percent in 2000. Average wage and salary has dropped since 1990 and the number of people living under the poverty level has increased. For those working in the sectors of farm, fish and forestry in occupation and industry there has also been a steady decline. Brunswick has 23 vessels holdings south Atlantic shrimp federal permits according to Table 5.1.5-48. There are a substantial number of persons working in fishing related businesses according to Table 5.1.5-49 with over 1500 persons working in the seafood processing sector. The state has 46 vessels registered including those with trawl gear (Table 5.1.5-50).

5.1.5.5 St. Simons Island (31522)

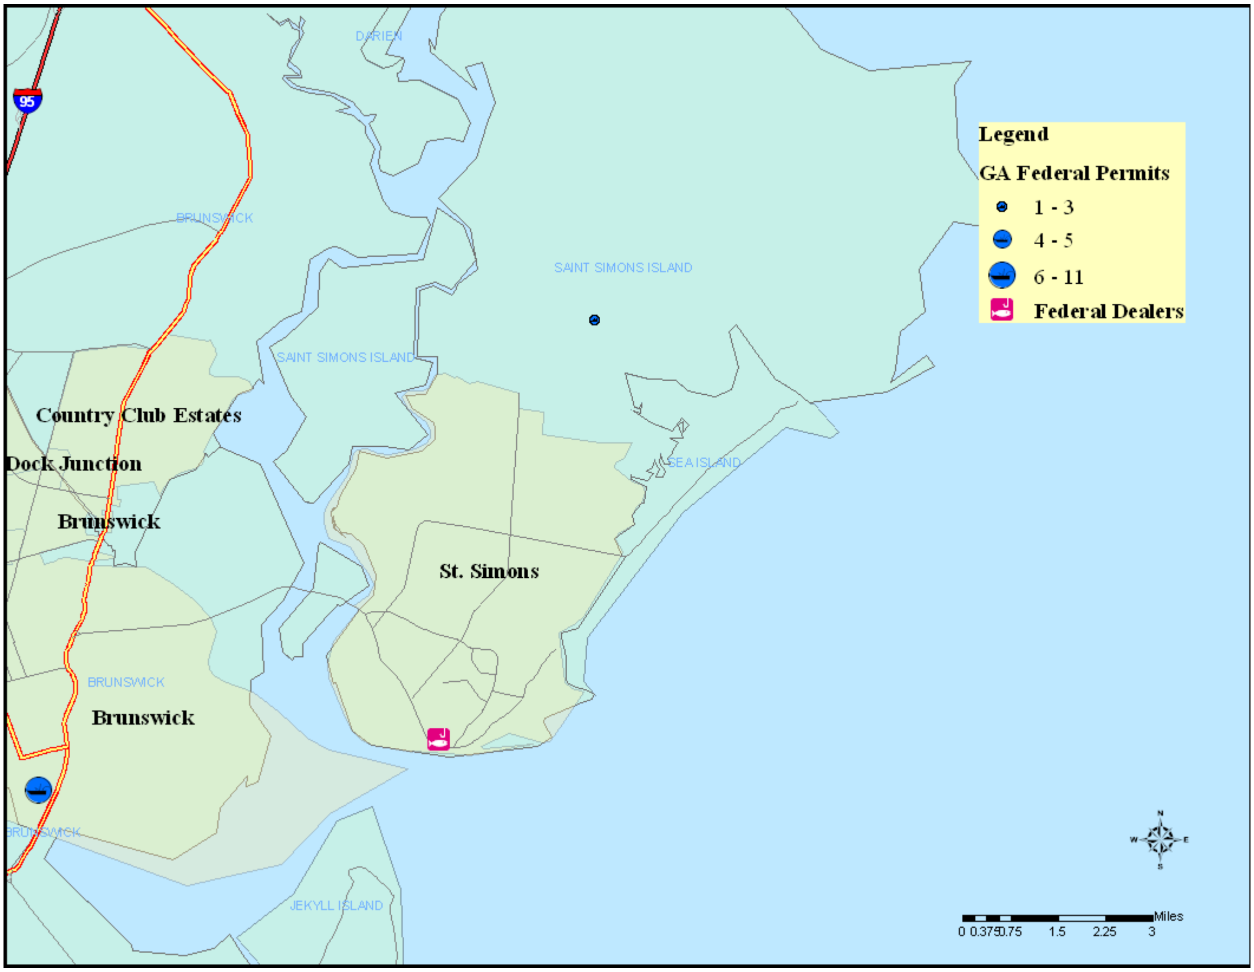

Figure 5.1.5-6. St. Simons Island, Georgia.

St. Simons Island has seen a fairly steady growth in its population. The percent of population in the labor force has remained fairly stable at just above 60 percent and unemployment has remained low at 3.4 percent. Average wage and salary have risen significantly while the number of persons living under the poverty level has remained about the same at over 600. As for most coastal communities, the number of persons employed in farm, fish, and forestry sectors under occupation and industry has declined steadily over the past 30 years for this community. St. Simons Island has little commercial fishing employment as there are no vessels registered with federal permits that homeport there (Table 5.1.5-60). Most all of the fishing related employment is in the marinas sector according to Table 5.1.5-61 and there are only 3 commercial vessels registered with the state (Table 5.1.5-62).

5.1.5.6 St. Mary's (31558)

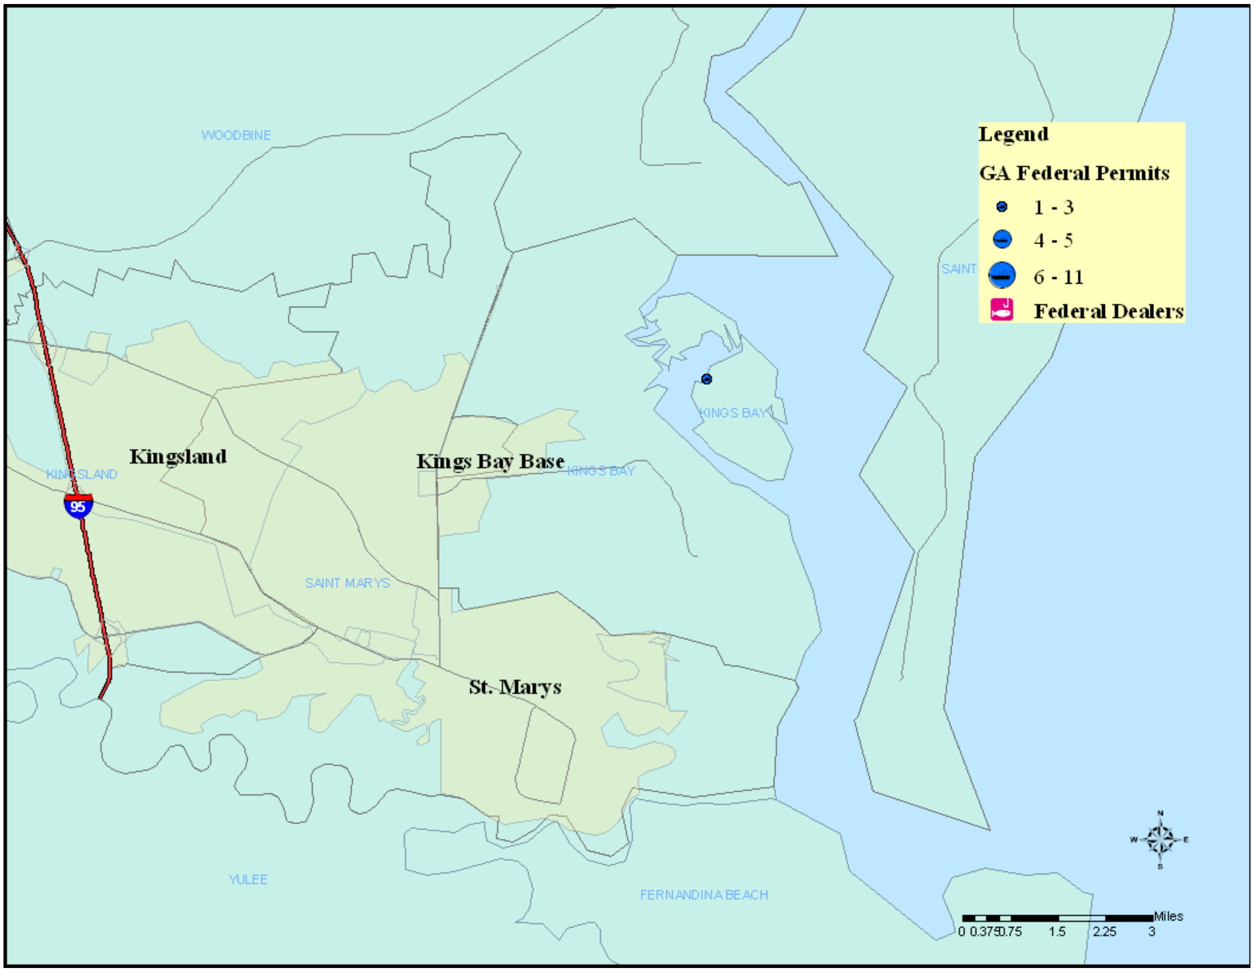

Figure 5.1.5-7. St. Mary's, Georgia.

St. Mary's has seen steady population growth since 1970. The percent of the population in the labor force has remained fairly constant while unemployment has risen to 6.4 percent. Average wage and salary has risen consistently over the years, but the number of persons living under the poverty level took a significant jump in 2000 to over 1400 persons in 2000 from 975 in 1990. Those employed in farm, fish and forestry sector have seen a steady decline in their numbers since 1970 also. There were only no vessels registered with federal permits from the community in Table 5.1.5-72, but there were 42 persons listed in the fishing sector in Table 5.1.5-73. The state has 14 vessels permitted including those having trawl gear (Table 5.1.5-74).

5.1.5.7 Georgia Fishing Infrastructure and Community Characterization

The following tables provide a general view of the presence or absence of fishing infrastructure located within the coastal communities of Georgia with substantial fishing activity. It should be noted that there are many other attributes that might have been included in this table, however, because of inconsistency in rapid appraisal for all communities, these items were selected as the most consistently reported or had secondary data available to determine presence or absence. It should also be noted that in some cases certain infrastructure may exist within a community but was not readily apparent or could not be ascertained through secondary data. Table 5.1.5-75 offers an overview of the presence of the selected infrastructure items and provides an overall total score which is merely the total of infrastructure present.

Table 5.1.5-75. Fishing Infrastructure Table for Georgia Potential Fishing Communities

St. Simons Island	-	-	-	-	+	+	+	+	4
St. Mary's	-	+	-	-	+	-	+	+	4

In attempting a preliminary characterization of potential fishing communities in Table 5.1.5-76, we have provided a grouping of communities that appear to have more involvement in various fishing enterprises and therefore are classified as primarily involved. These communities have considerable fishing infrastructure, but also have a history and culture surrounding both commercial and recreational fishing that contributes to an appearance and perception of being a fishing community in the mind of residents and others. The communities are not ranked in any particular order, this is merely a categorization.

Table 5.1.5-76. Preliminary Characterization of Potential Fishing Communities in Georgia

Primarily-Involved	Secondarily-Involved
Darien	Tybee Island
Brunswick	Thunderbolt
St. Mary's	
St. Simons Island	

Many of these communities are in transition due to various social and demographic changes from coastal development, growing populations, increasing tourism, changing regulations, etc. This preliminary characterization is just that and should not be considered a definite designation as fishing community, but a general guide for locating communities that may warrant consideration as a potential fishing community.

5.1.6 Florida Communities with Substantial Fishing Activity

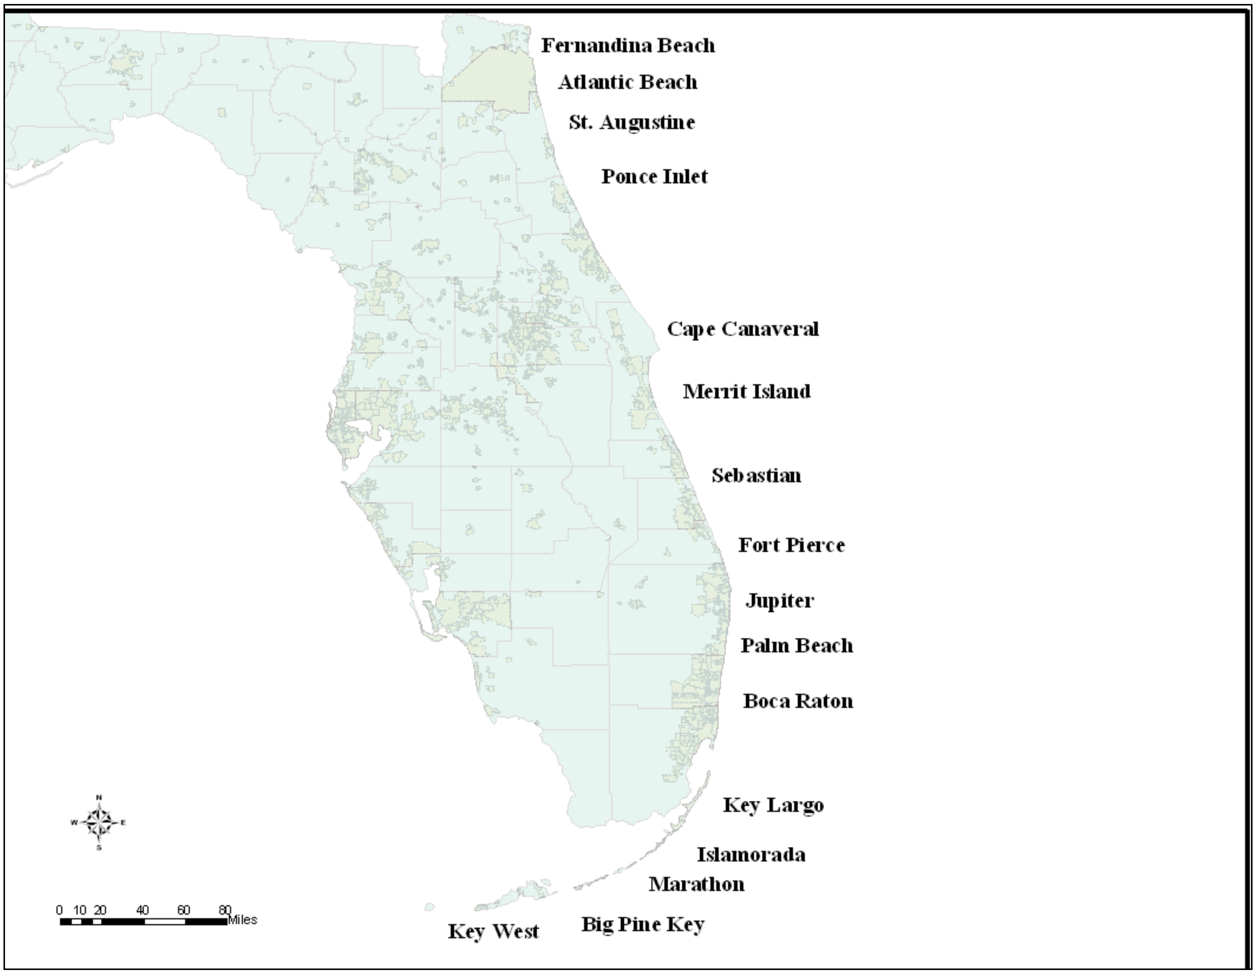

Figure 5.1.6-1. Florida Communities with Substantial Fishing Activity as Identified by South Atlantic Advisory Panels.

Figure 5.1.6-1 illustrates those communities which were identified originally by the advisory panels as communities that might be considered fishing communities. They are included below with brief profiles and census and fishing demographic tables used to describe the communities.

The East coast of Florida landed over 37 million pounds of seafood in 2001 and over 32 million in 2002. The value of those landings was over 48 million dollars in 2001 and over 38 million dollars in 2002. Florida had one port, Key West, listed in the top 50 U.S. ports in terms of pounds landed and in terms of value of landings there were three ports for Florida: Key West, St. Petersburg, and Ft. Myers. According to NMFS (2002) Florida recreational fishermen landed over 68 million pounds of finfish in 2001 and in 2002 that number dropped to just over 59 million pounds for the entire state. There were 93 processors in all of Florida for 2001 with a total of 2,654 employees and 284 wholesale dealers employing 2,485. In the years 2001 and 2002, Florida had approximately 2,136 and 1,934 registered vessels respectively. During those same years there were 5,502 boats registered in 2001 and in 2002 that number was 4,438.

In 2008, Florida vessels with federal permits predominantly held south Atlantic dolphin/wahoo commercial (1,196) , south Atlantic dolphin/wahoo charter (813), Atlantic king mackerel (1,008) or Spanish mackerel (1,101), or snapper grouper charter/headboat (919) permits. Figure 5.1.6-1 shows potential fishing communities in Florida.

5.1.6.1 Fernandina Beach (32034)

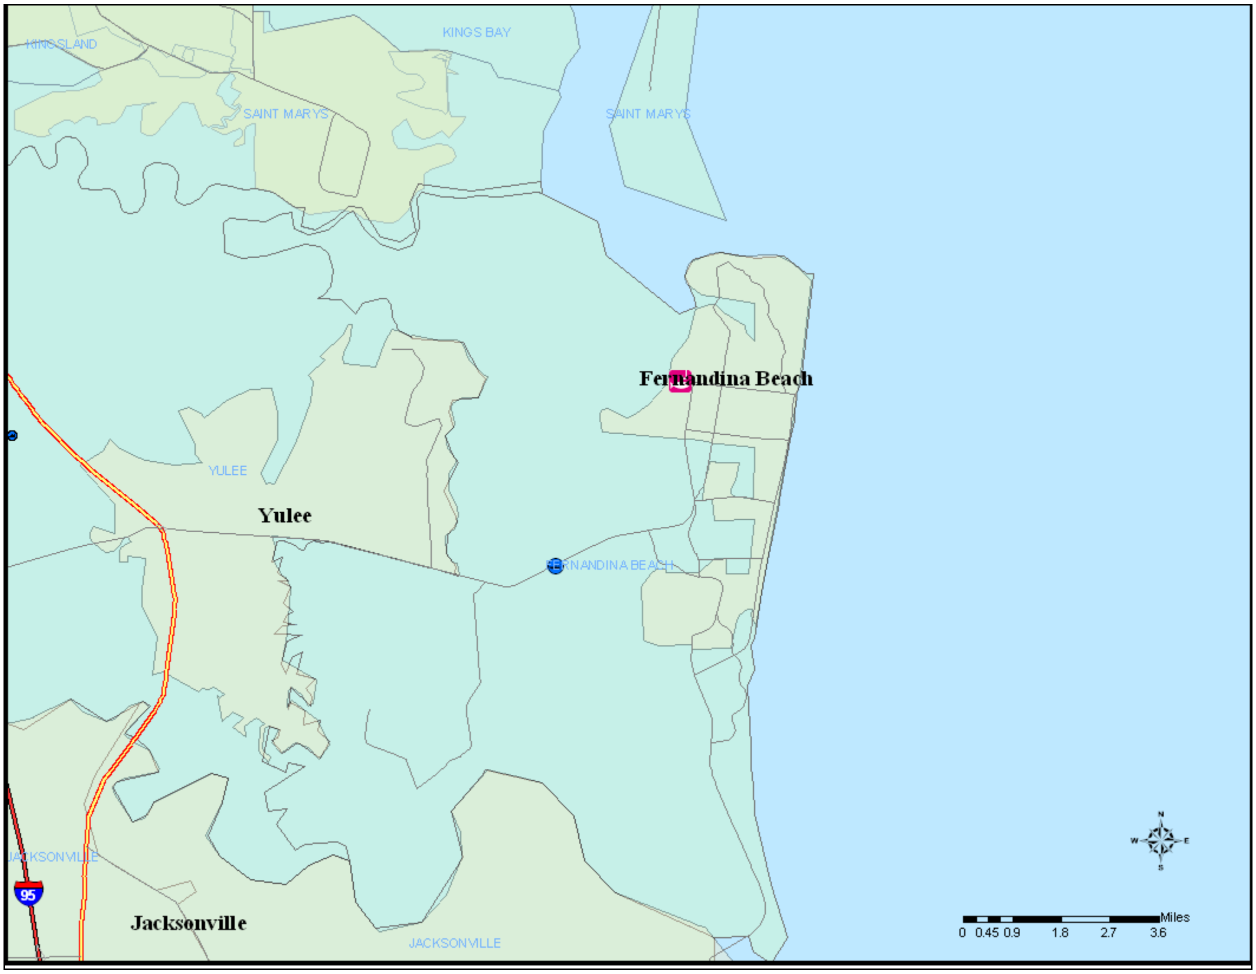

Figure 5.1.6-2. Fernandina Beach, Florida.

Fernandina Beach is located in Nassau County, Florida, on the northernmost barrier island (Amelia Island) of the state's east coast. The island extends from the mouth of the St. Mary's River southward to Nassau Sound and is just over thirteen miles long and two miles wide (Jacob et al. 2002).

Fishing has had a long history in the community as immigrants in the 1700s were net fishermen seeking mullet, sheepshead, crabs, trout, turtles, drum, oysters and "pogies" (menhaden). Agriculture, forestry, fishing, and tourism were the most prominent industries in the Fernandina Beach area during the early 1900's. Shrimp fishing was developed in 1902 by a Sicilian immigrant living in Fernandina Beach who fished with a small diesel engine on his boat to pull a shrimp seine net across the ocean floor. Commercial shrimp fishing grew substantially when a New England fisherman, who was searching the Florida peninsula for bluefish, began harvesting large quantities of shrimp. Shrimp processing and shipment facilities were soon developed in Fernandina Beach. That fishing heritage has been preserved in Old Town Fernandina Beach, which has been designated a National Historic District. Today, Fernandina's harbor is filled with commercial and charter fishing boats, shrimp boats and private vessels. Seafood restaurants contribute to the fishing village theme which continues to resonate throughout the community although tourism has become the primary source of economic revenue (Jacob et al. 2002).

5.1.6.2 Atlantic Beach (32233)

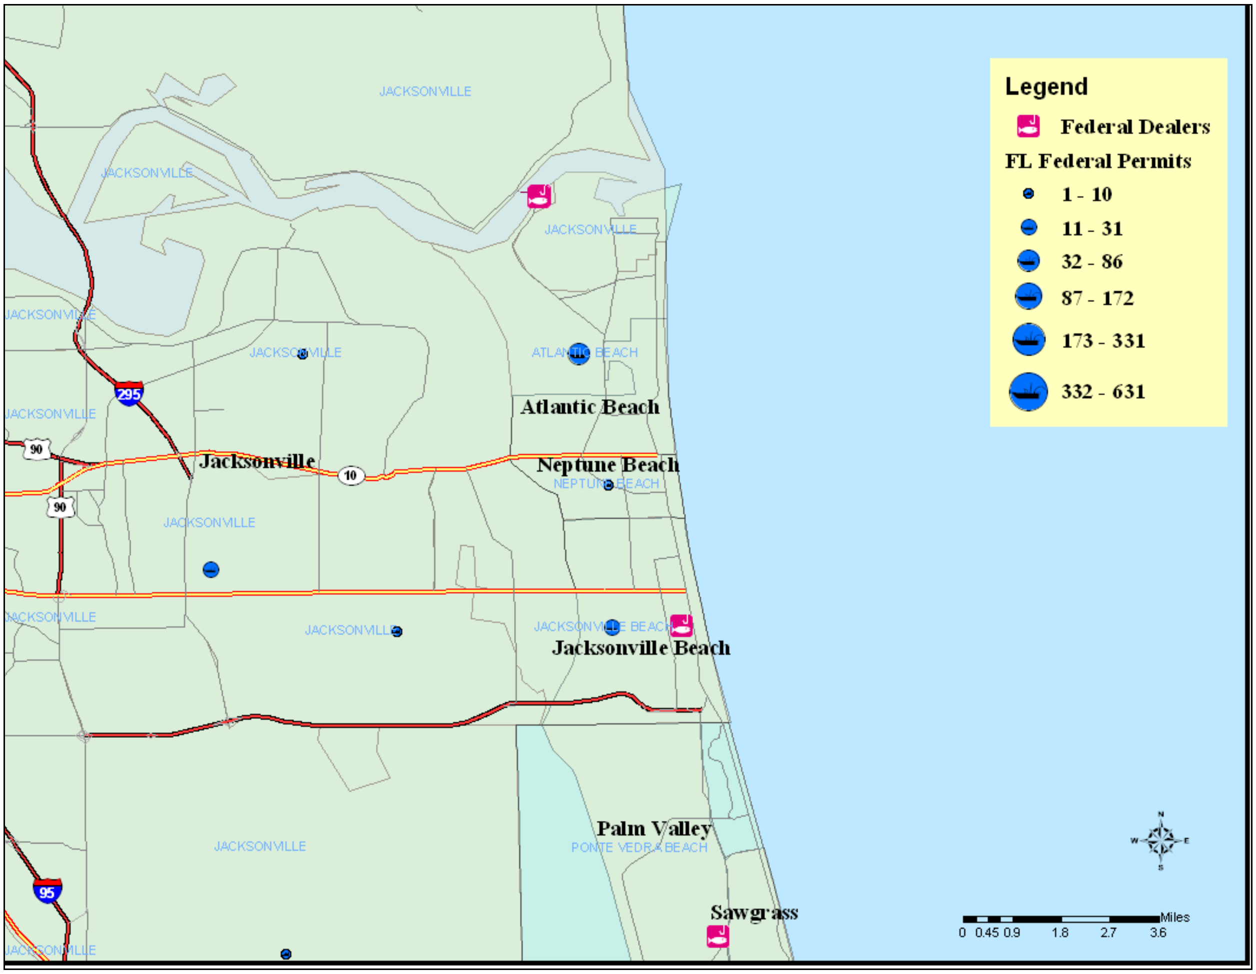

Figure 5.1.6-3. Atlantic Beach, Florida.

The community of Atlantic Beach has remained fairly small throughout its history. The arrival of Henry Flagler's Florida East Coast Railroad in 1900 helped spur development and prominence within this coastal community. However, it was not until the construction of the Mayport Naval Station in the 1940s and the completion of the Matthews Bridge in the 1950s that the area truly became ready for development. Beginning in the 1990s, the Atlantic Beach community embarked on environmental endeavors regarding their aquatic resources. They created the Tideviews Preserve and the Dutton Island Preserve. Among some of the many activities offered in the Dutton Island Preserve, fishing off the pier is a popular activity for park visitors.

Atlantic Beach has seen steady growth in its population. There has been a decline in the percent of the population in the labor force and unemployment has dropped to 3.3 percent in 2000. Average wage and salary rose significantly between 1980 and 1990, but only slightly in 2000. The number of persons living below the poverty level has dropped every decade but still is around 1100 person in 2000. Jobs in the sector of farm, fish and forestry have fluctuated over the past three decades, but dropped to low levels in 2000.

Although there no vessels with federal permits in Atlantic Beach (Table 5.1.6-22) there were 56 persons employed in the fish and seafood sector according to Table 5.1.6-23.

5.1.6.3 St. Augustine (32084, 32085, 32086, 32092)

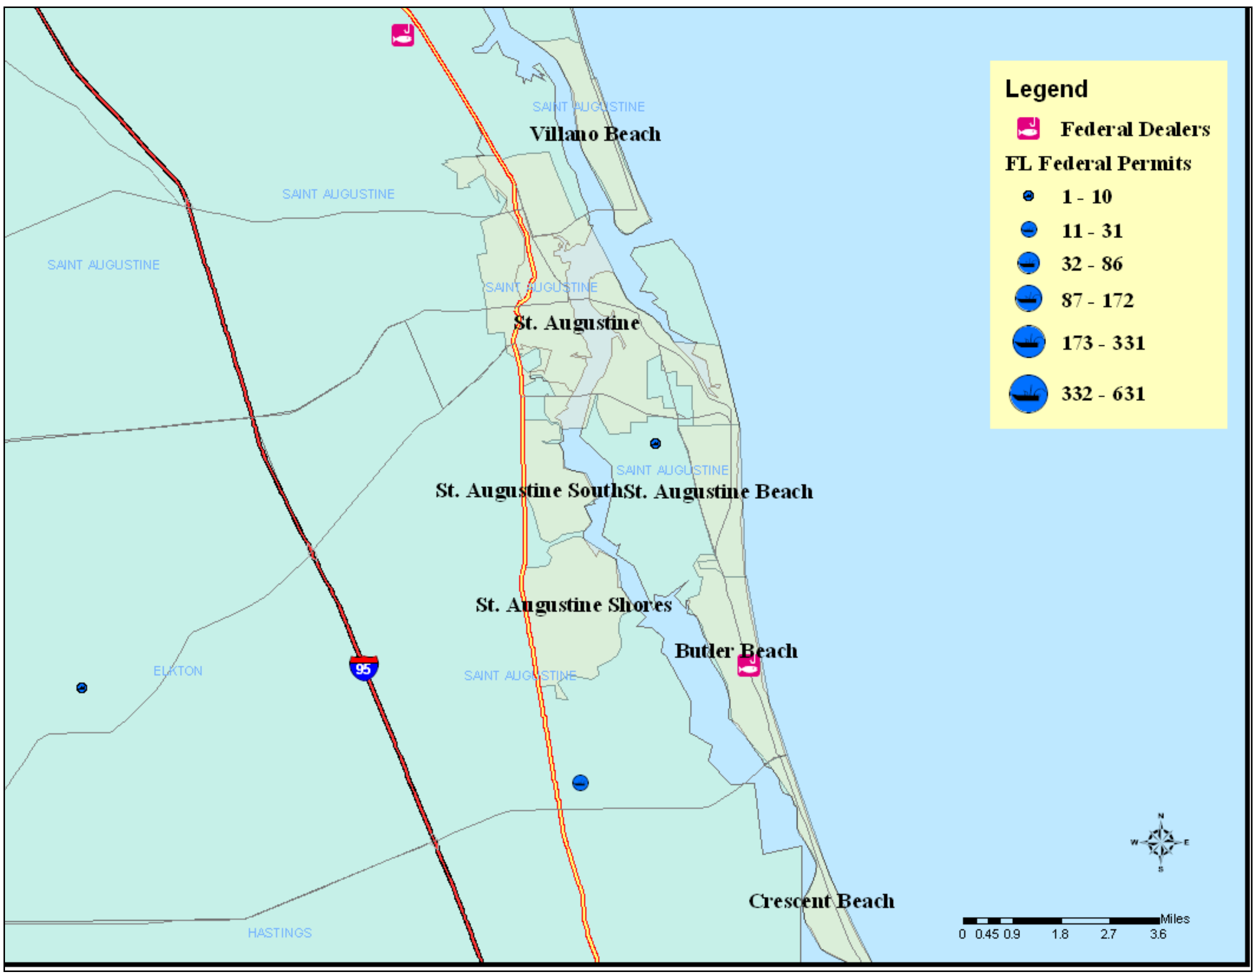

Figure 5.1.6-4. St. Augustine, Florida.

St. Augustine has the distinction of being the oldest European city in the United States. First sited by the Spanish explorer Don Juan Ponce de Leon in 1513, it was not settled until 1565 by Don Pedro Menendez de Aviles, a Spanish admiral, in the name of King Phillip II. The town's boom did not occur until the 1880s with the arrival of Henry M.

Flagler. His goal was to turn St. Augustine into a winter resort for wealthy Americans. It was this thinking that transformed the town. The construction of the railroad linked the city with much of the east coast. Flagler built three large hotels to help fulfill his dream of a tourist mecca. By the mid-1900s, St. Augustine's local economy was dominated by tourism.

The commercial fishing industry began in the St. Augustine/Fernandina area around 1900 with the arrival of a Sicilian immigrant named Sallecito Salvador. He placed an engine on his boat that allowed him to pull a shrimp seine across the ocean floor in 1902, and in 1906, he began his company, S. Salvador & Sons. Salvador moved his business to St. Augustine in 1922, where it thrived until 1929. Shrimp catch levels soared from about 1934 to 1940. These stories illustrate the longstanding culture of fishing in the St. Augustine area and the importance it holds for many of the fishing families there. Commercial fishing still continues at the port, the oldest continuously active port in the United States. Boat building, tourism, and recreational activities are also important to St. Augustine's port.

St. Augustine has seen a steady decline in its population since 1970. Both the percent of population in the labor force and unemployment have remained relatively stable over the years. Average wage and salary has grown steadily, while the number of persons living below the poverty level has dropped. The number of people employed in farm, fish and forestry has also dropped significantly over the past three decades, with the most pronounced decline from 1990 to 2000. In 2008, 3 federal charter/headboat permits were held (Table 5.1.6-33). There is significant employment in fishing related business as there are over 370 people employed in boat building according to Table 5.1.6-34 and another 75 in the seafood processing sector.

5.1.6.4 Ponce Inlet (32127)

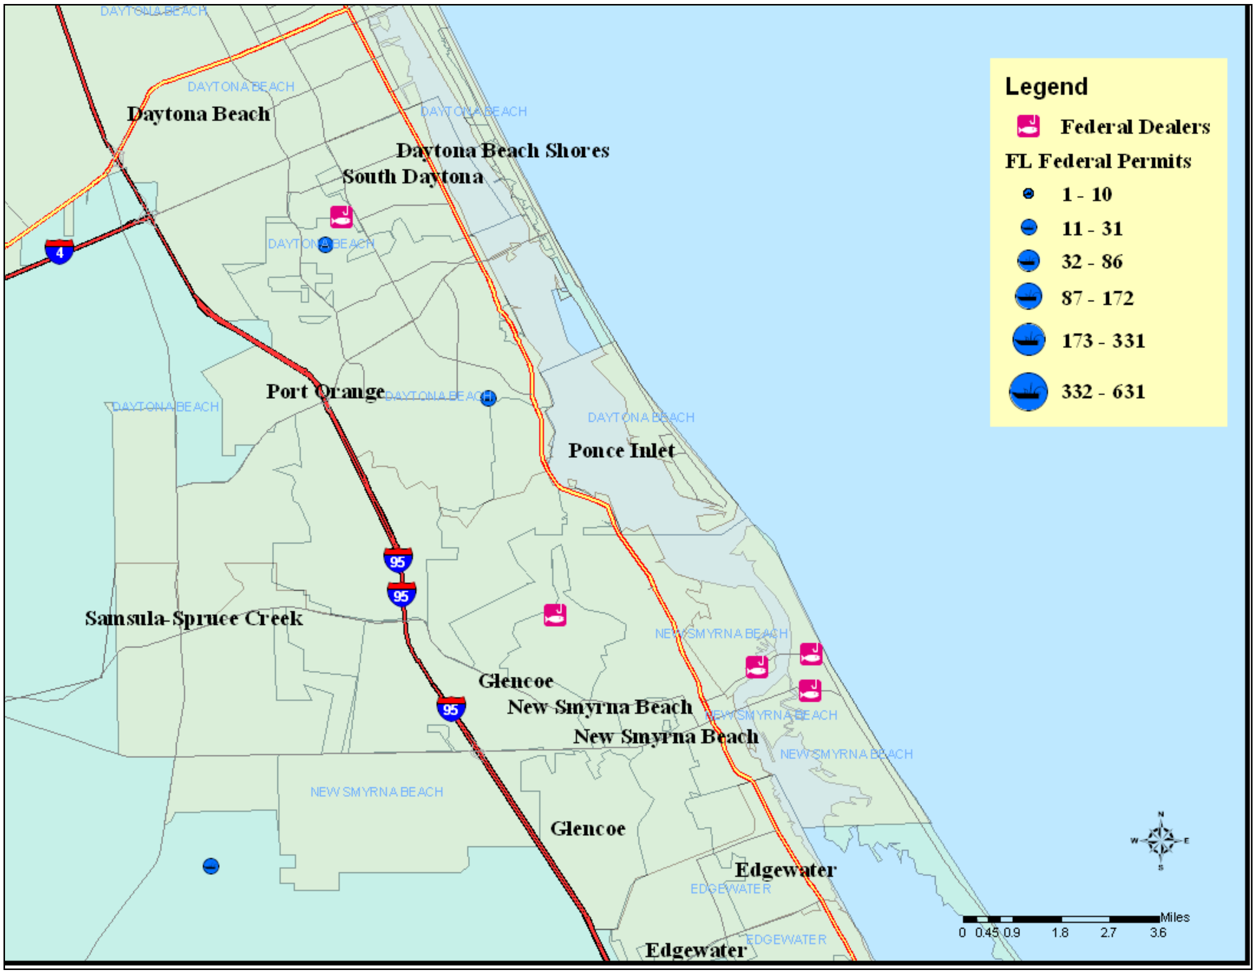

Figure 5.1.6-5. Ponce Inlet, Florida.

The town of Ponce Inlet was originally referred to as the port of mosquitoes until the early twentieth century and is located at the southern boundary of Ponce de Leon Inlet. There is some controversy as to whom actually first stepped foot on Ponce Inlet; perhaps it was Ponce de Leon in 1513 that went ashore to high ground to search for a lost vessel. Others believe it may have been Frenchman Jean Ribault in 1563 (Davies 1995).

Sport fishing became the mainstay for most residents of the Ponce Inlet area. The industry began to grow in the 1950s; however, many found that it was not very profitable. “In the winter the waters were so uncertain that sometimes the boats rocked at the dock for days while the tourist sought other recreation” (Davies 1995). However, when charter fishermen in the Florida Keys heard about the good conditions in the summer months in northern Florida, they would work out of the “growing number of docks from Daytona to the Inlet” (Davies 1995). The arrival of the head boat scared many of the original fishermen because they thought it would ruin the business. Eventually, the locals understood the economic opportunities associated with the head boat. By the 1960s, the sport fishing industry was quite successful for the fishermen of Ponce Inlet (Davies 1995).

The population of Ponce Inlet has grown over the years, but most of that growth came within the last decade. The percent of population in the labor force has remained around 45 percent and unemployment has dropped to a low of 1.9 in 2000 from 4.5 in 1990. Average wage and salary have risen significantly over the years, but so has the number of persons living below the poverty level. The number of people who work in farm, fish and forestry has dropped to fewer than 3 people according to census measures of occupation and industry. In 2008, vessels with federal permits predominantly held Atlantic dolphin/wahoo commercial (10), Atlantic dolphin/wahoo charter (19), south Atlantic charter/headboat for pelagic fish (20), or snapper grouper charter/headboat for snapper grouper (20) permits (Table 5.1.6-44). There is also some fishing related employment according to Table 5.1.6-45, which indicates over 180 people employed in the marinas sector.

5.1.6.5 Merritt Island (32952, 32953)

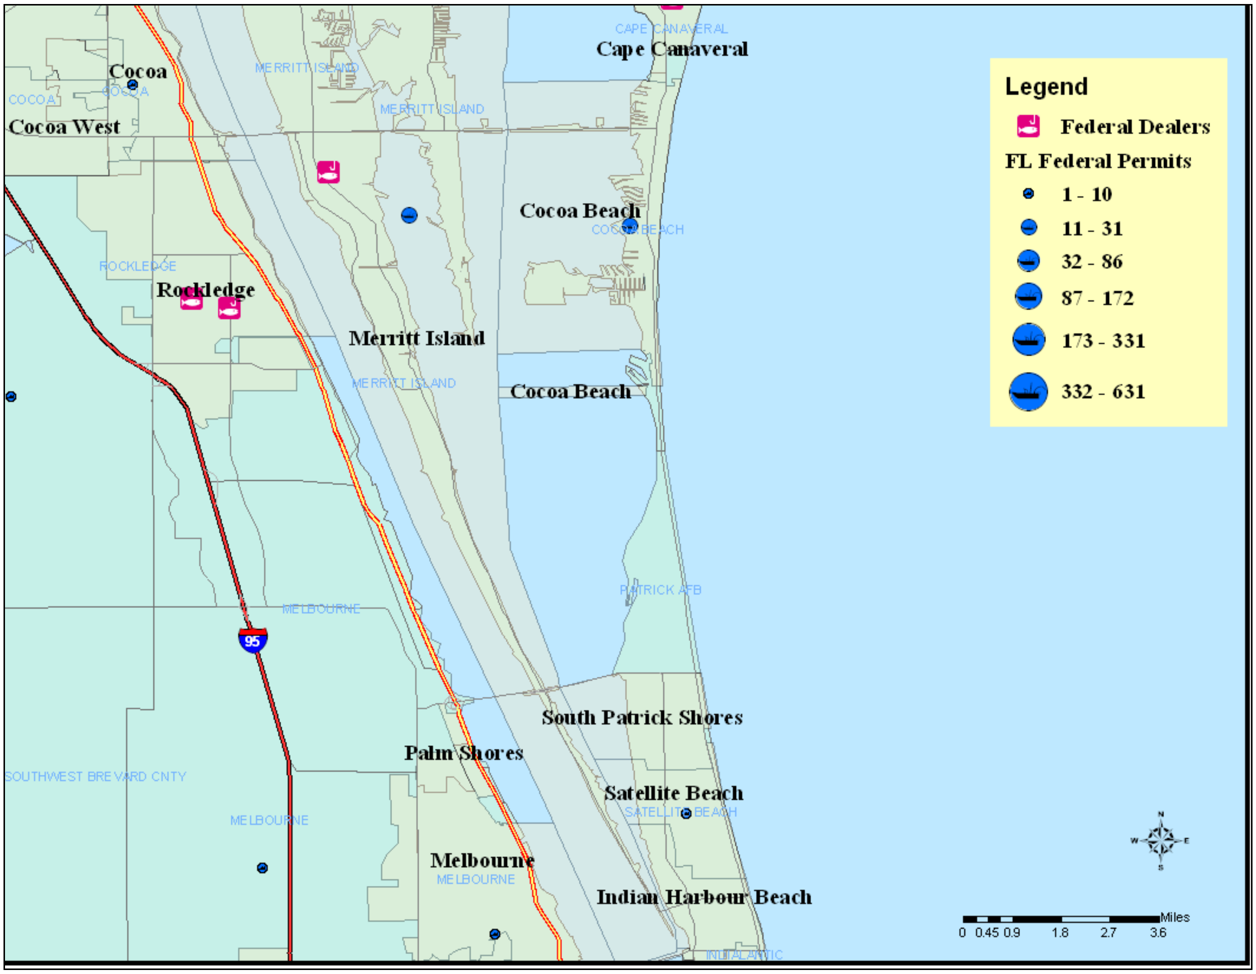

Figure 5.1.6-6. Merritt Island, Florida.

Merritt Island's population has grown slowly over the past three decades. The percent of the population in the labor force has dropped slightly over the past ten years, but unemployment has increased slightly. Average wage and salary have increased to over $40,000 for the year 2000, but the number of persons living under the poverty level has also grown considerably. As for most coastal communities the number of people working in the farm, fish and forestry sector of the economy has dropped significantly over the past decade but has shown a steady decline prior to the 2000 census. Merritt Island has only 26 federal permits issued of which 9 were for charter/headboats (Table 5.1.6-55). There is substantial employment represented in the fishing related sector of boat building with over 1100 persons employed in that sector according to Table 5.1.6-56.

5.1.6.6 Cape Canaveral (32920)

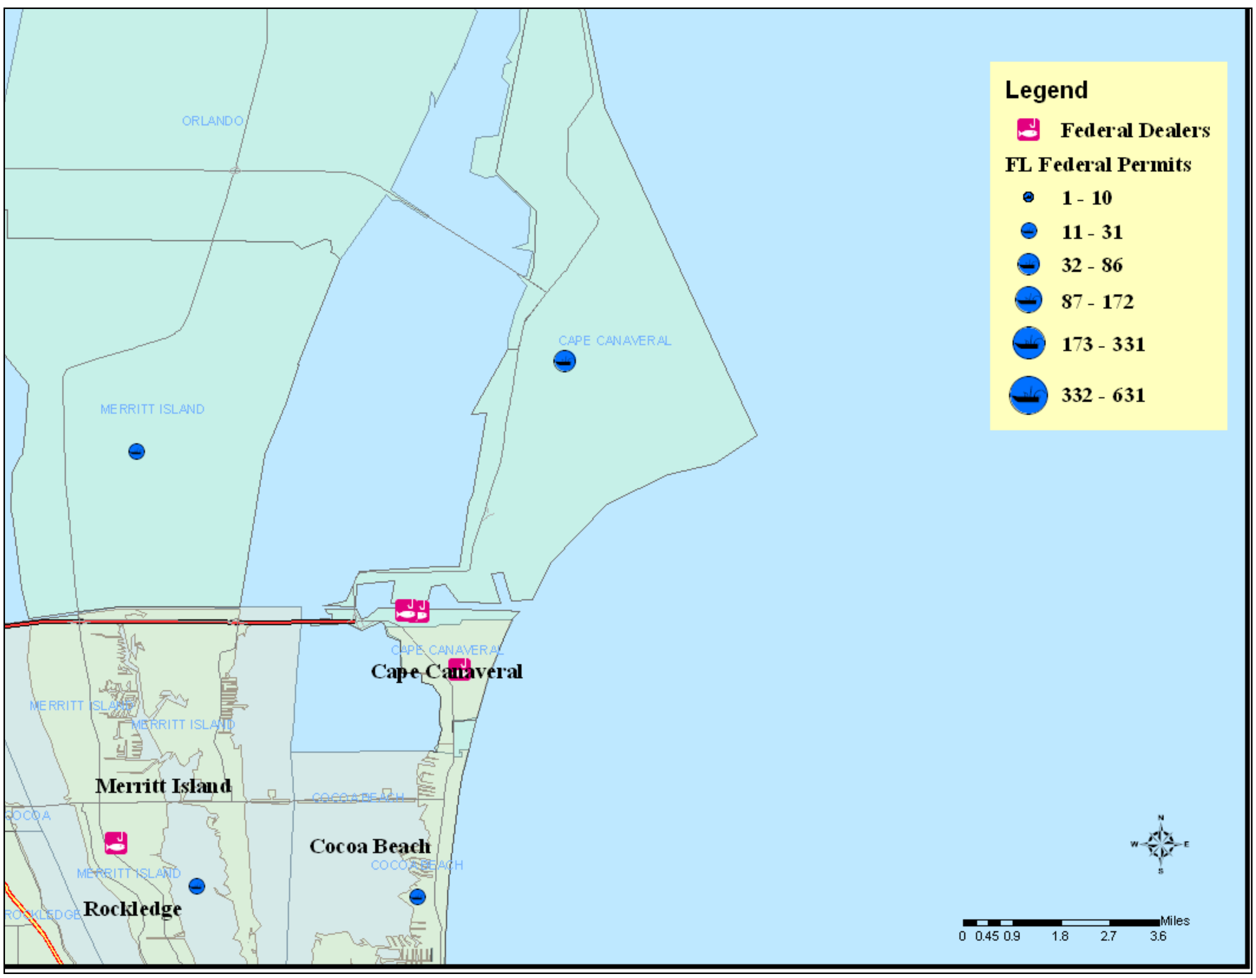

Figure 5.1.6-7. Cape Canaveral, Florida.

Cape Canaveral received its name from the Spanish explorers who found it in the early 1500s. The word "Cape" was used to describe the land formation, and the word "Canaveral" comes from the Spanish word for "canebreak." There is much debate over the exact translation and meaning of the name. A traveling exhibition for the Smithsonian Institute translates Cape Canaveral as “Place of the Cane Bearers,” so named by Spanish explorer Francisco Gordillo after he was shot by an Ais Indian arrow made of cane. Others believe it should be translated as “Point of Reeds” or “Point of Canes” because the Spanish mistook some of the indigenous plants for sugar cane. Whatever the exact translation of the name may be, all agree that it is of Spanish origin.

Even before the area of Cape Canaveral was settled, it was an important landmark for sailors. Once sighted, they would turn northeastward for the journey back to Europe. Douglas D. Dummitt arrived in the area in the 1820s, establishing Dummitt Grove on Merritt Island. He used the Indian River to ship his oranges northward, beginning in 1828. However, the actual geographic area known as Cape Canaveral was not settled until the 1840s. Cut off from the mainland, this small community remained self-reliant until the late 1800s.

The city of Cape Canaveral really began to expand in the early 1920s when a group of retired Orlando journalists were vacationing in the area and appraising its value. They invested over $150,000 in the surrounding beach areas, calling it Journalista, the area today known as Avon-by-the-Sea. Instead of the area becoming solely a beach resort for wealthy inland residents and northerners, many fishermen moved into the area as well. However, with the establishment and expansion of the space program in the United States in the late 1950s and early 1960s, Cape Canaveral, Titusville, Merritt Island, and the surrounding communities truly began to expand.

Today, the residents of Cape Canaveral and the rest of Brevard County rely on the surrounding waters. Port Canaveral, constructed in the 1950s, is the second busiest cruise port in the world and home to many charter fishing companies in the area. The more than three dozen charter fishing boats offer half-day, three-quarter-day, full-day, and gulf stream trips for dolphin, tuna, king and Spanish mackerel, wahoo, redfish, tarpon, snook, snapper, grouper, and many others. Both light tackle flats fishing on the Indian and Banana Rivers and Mosquito Lagoon as well as deep sea fishing are available. Most of the boat captains are second or third generation fishermen. The history of fishing in Brevard County dates back more than 100 years.

Cape Canaveral’s population has grown steadily over the years while the percent of the population in the labor force has dropped. Unemployment has also dropped but remains above 5 percent. Average wage and salary has grown while the number of persons living below the poverty level has dropped from a high in 1990 of 1282 to 1035 in 2000. The number of persons working in the fish, farm and forestry sector has dropped significantly to only 17 persons in 2000 for both occupation and industry. In 2008, vessels with federal permits predominantly held Atlantic dolphin/wahoo commercial (10), Atlantic dolphin/wahoo charter (13), south Atlantic charter/headboat for pelagic fish (11), or snapper grouper charter/headboat for snapper grouper (13) permits (Table 5.1.6-66) with a large portion of the employment in fishing related business in marinas with 125 according to Table 5.1.6-67 with 35 in boat building and 17 in fish and seafood.

5.1.6.7 Sebastian (32976, 32958)

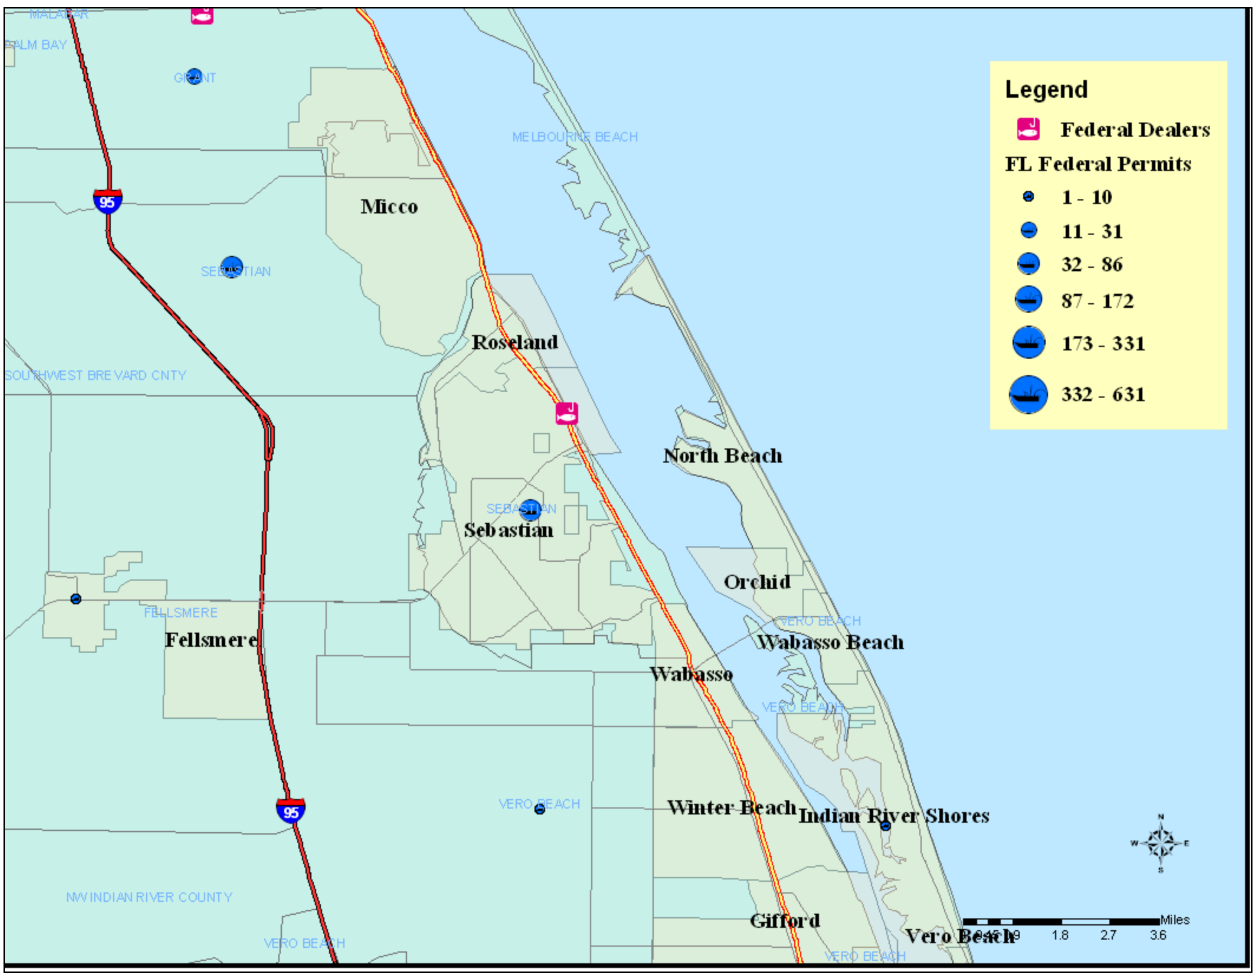

Figure 5.1.6-8. Sebastian, Florida.

Sebastian and Vero Beach are two of the five districts that comprise Indian River County. Both communities were first settled in the 1880s. Communication with the rest of the country and even other counties was difficult. Therefore, settlers had to hunt, trap, and fish for everything. The railroad was completed in time for the Spanish American War, bringing troops to Florida (Newman, 1953). The arrival of the railroad also increased the commercial fishing sector of Sebastian and Vero Beach. Icehouses developed to pack and store the fish around 1900, and the trains exported the products north. The original fish house of one of the very first commercial fishing families still operates today on Indian River Drive in Sebastian.

Today, recreational fishing, along with commercial fishing, is an important part of the Indian River County culture. The Indian River Lagoon is home to more than 700 species of fresh and saltwater fish. Saltwater anglers can fish the Sebastian Inlet and the Sebastian River for snook and red drum in the 20 to 30 pound class. Grouper, snapper, flounder, sheepshead, permit, whiting, blues, and shark can be caught off the Sebastian Inlet pier. Deep sea fishing charters also leave from Sebastian and Vero Beach, offering bottom fishing and blue water trolling for dolphin, sailfish, wahoo, grouper, and cobia.

Sebastian has seen moderate population growth since 1990 to 2000 after a large increase from 1980 to 1990. The percent of the population in the labor force has remained relatively stable while unemployment has dropped from 5.7 percent in 1990 to 3.2 in 2000. Average wage and salary have grown steadily over the past few decades, but the number of persons who live under the poverty level has increased dramatically. The number of persons working in the farm, fish and forestry sectors for occupation and industry has fluctuated since 1980, but has dropped in the most recent census. In 2008, vessels with federal permits predominantly held Atlantic dolphin/wahoo charter (13), south Atlantic charter/headboat for pelagic fish (6), snapper grouper charter/headboat for snapper grouper (13), or rock and south Atlantic shrimp (12) permits (Table 5.1.6-77). There is not much employment reported in the fishing related sectors of Table 5.1.6-78 with only15 in the marinas sector, 9 in fish and seafood and 3 in fishing.

5.1.6.8 Fort Pierce (34950)

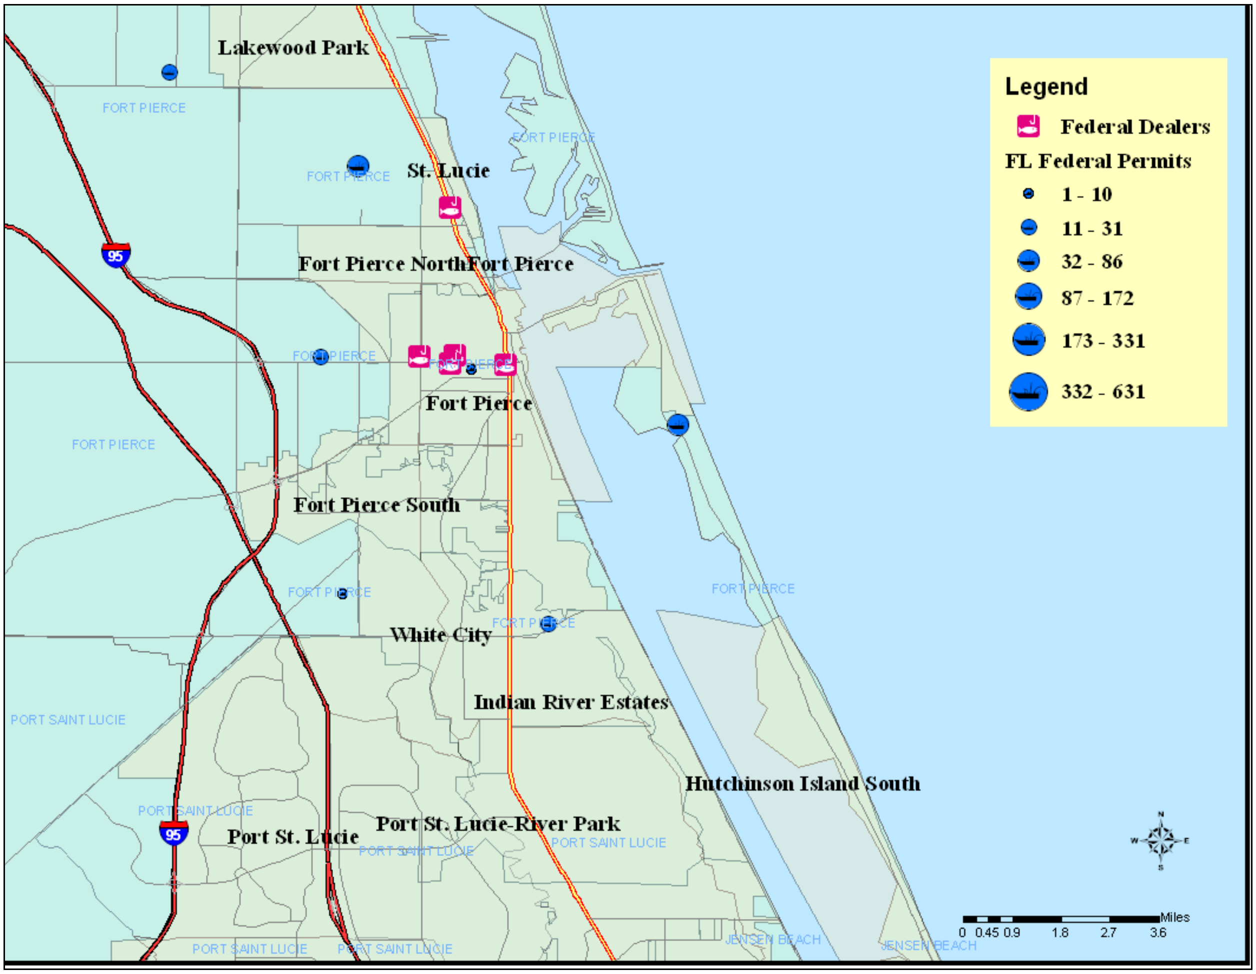

Figure 5.1.6-9. Fort Pierce, Florida.

The Spanish built Fort Santa Lucia on the Jupiter Inlet in 1565 from which the county now draws its name—St. Lucie County. Permanent U.S. inhabitance of Fort Pierce dates back to the Seminole Indian War. U.S. Army Lt. Col. Benjamin Kendrick Pierce, for whom the town is named, built a fort in 1837 to use as the army's headquarters. The war ended in the early 1840s, making way for settlement and development: "Water transportation, fishing and canning fish were key to the area's early economy." The arrival of Henry Flagler's railroad in the early 1900s opened Fort Pierce's economy to the rest of the east coast. Fort Pierce beach was used as a naval base during World War II.

The culture of fishing has been in the area since its inception. Anecdotes passed down from one generation to the next of Fort Pierce residents describe the abundance of fish in the area in the late 1800s and early 1900s. One such story, told by Newman (1953) in her book, *Early Life along the Beautiful Indian River*, tells of a man who bound his shirt at the sleeves and waist and cut a plunging neckline. He would then stand in the water until the shirt was full of fish and then empty it out into a bucket on the shore. In the late 1800s, a man from the nearby town of Titusville helped to create the commercial fishing sector in Fort Pierce. He would bring the fish to Titusville for shipping to the rest of the east coast. The first icehouse for packaging fish was built in 1900 (Newman 1953).

Recreational fishing has also become a popular pastime in Fort Pierce and the rest of St. Lucie County. This is due in part to the fleet of Spanish galleons that sunk off the St. Lucie and Martin Counties coastline. The sunken ships created artificial reefs that have resulted in excellent fishing and diving spots for locals and tourists. The reefs attract spiny lobsters, marlin, snook, flounder, and grouper. Some of the more popular fish in the St. Lucie River include channel bass, snook, ladyfish, jack crevalle, and trout. Black sea bass is another famous catch in the area. Most charter fishing boats in the area offer half, three-quarter, and full-day trips for dolphin, sailfish, wahoo, amberjack, tuna, kingfish, snapper and grouper.

Fort Pierce has seen moderate population growth over the past three decades while the percent of the population in the labor force has remained around 55 percent and unemployment dropped from 12.4 percent in 1990 to 8.8 percent in 2000. Average wage and salary has grown slowly over the past ten years while the number of persons living under the poverty level has risen significantly. The number of people working in farm, fish and forestry has remained relatively high for both occupation and industry over the years with both categories having over 1000 persons in each. In 2008, vessels with federal permits predominantly held Atlantic dolphin/wahoo commercial (49), Spanish mackerel (45), king mackerel (36), south Atlantic charter/headboat for pelagic fish (14), or snapper grouper charter/headboat for snapper grouper (14) permits (Table 5.1.6-88). There are over 260 persons employed in the boat building sector of fishing related employment according to Table 5.1.6-89.

5.1.6.9 Jupiter (33458, 33468, 33469, 33477, 33478)

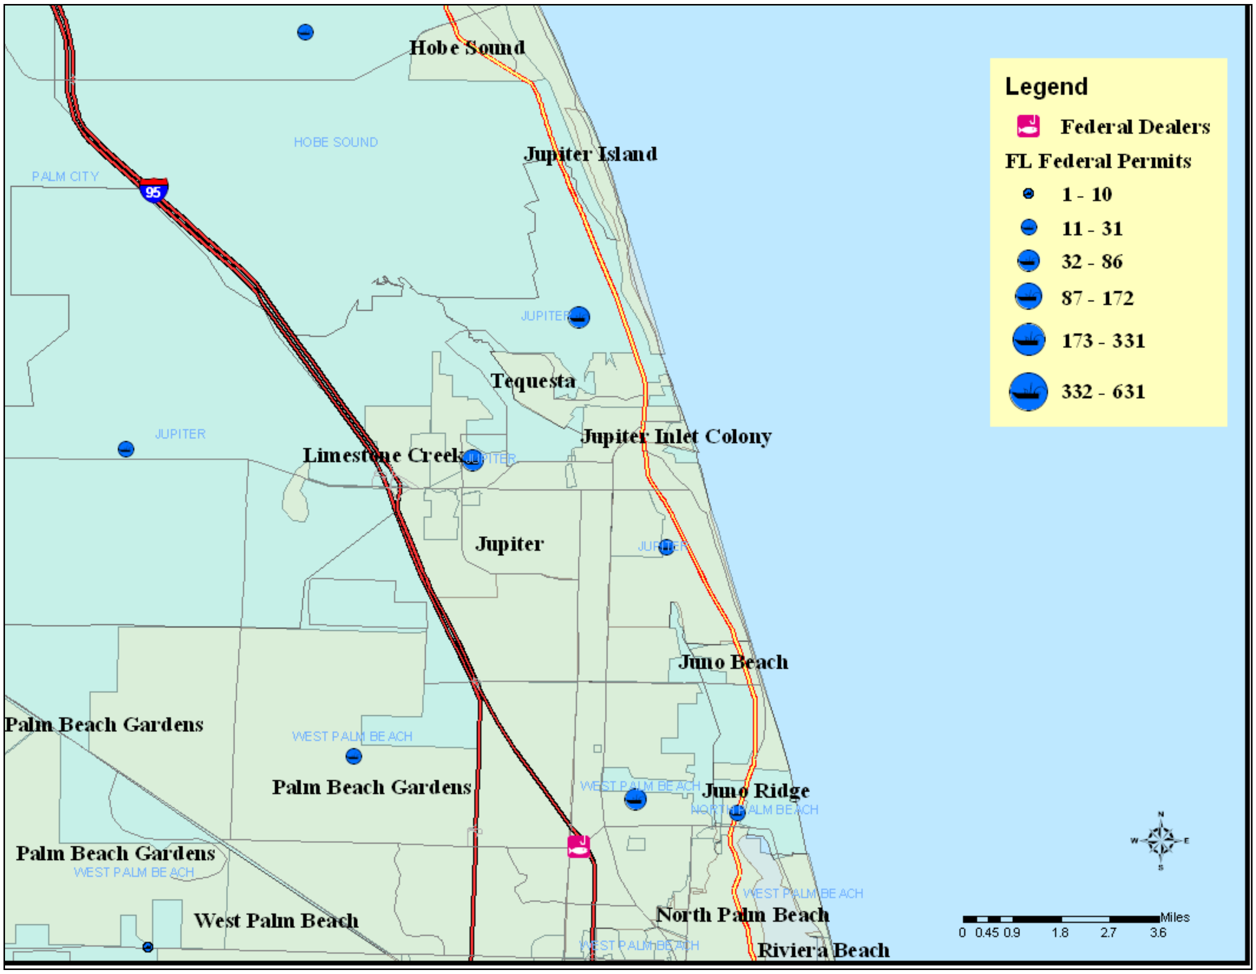

Figure 5.1.6-10. Jupiter, Florida.

The name Jupiter derives from the original inhabitants of the area, the Jeaga Indians. The Native Americans called themselves Jobe, so the Spanish explorers called the inlet the Jobe River. The English settlers who arrived in the 1760s thought the name was Jove, a mythological god also known as Jupiter. Jupiter first became famous when Jonathan Dickinson's boat the "Reformation" was shipwrecked along the coast in 1696. However, it was not until 1821 that real development of the area began. Eusebio Gomez was given 12,000 acres in a land grant in 1815. In 1821, he "started the real estate business on Jupiter Island by selling 8,000 of his acres for $8,000" (Reed 1955).

Sport fishermen have been present in the Jupiter Island region since the 1800s. Stanley (1988) lists numerous species of fish that were and still are popular in Jupiter Island. Snook, tarpon, mangrove snapper, and jack crevalle were some of the most desired fish. Later, with the advancement of boat technology, species in the Gulf Stream, such as sailfish, dolphin, wahoo, and King mackerel became popular catches of the local fishermen.

Two events of the late 1920s decreased some of the fishing in the area. A hurricane struck Lake Okeechobee in 1928. The devastation it caused led to the Okeechobee Flood Control Project. The project created high levels of silt and mud around Jupiter Island, causing a severe decline in the snapper and grouper populations, "two of the most sought after food fish" (Stanley 1988). However, this did not diminish the appeal of sport fishing. J.D. Bassett moved from Virginia to Palm Beach in 1925. He was one of the most avid fishermen in Jupiter. "He made the trip to and from Palm Beach so often that the captain of his boat said, 'Mr. Bassett, you come up here almost every day. Why don't you just move up here'" (Stanley 1988). Bassett was not the only person drawn to Jupiter's waters.

Many of the fishermen in Jupiter practice catch and release. "In February 1986, three Palm Beach-based sportfishing boats caught and released 72 sailfish in a span of five hours five miles east of the Jupiter Island Beach Club" (Stanley 1988). Many of those who enjoy fishing Jupiter Island today are said to be descended from those families that have been fishing the area for decades.

Jupiter has seen fairly steady population growth with its 2000 population reaching 39,314. The labor force has remained fairly constant with just over 60 percent of the population participating. Unemployment has also remained low at 3.3 percent for both 1990 and 2000. Average wage and salary have risen to a high of $54, 945 and the number of persons living under the poverty level has also climbed to a high of 1885 in 2000. The number of people working in farm, fish and forestry occupations and industry reached a peak in 1990 but has since declined dramatically in 2000. In 2008, vessels with federal permits predominantly held Atlantic dolphin/wahoo commercial (68), mackerel (69/66), or south Atlantic charter/headboat for pelagic fish (28) permits Table 5.9.3.1 and most of them have coastal pelagic permits with 20 holding snapper grouper class 1 permits. There is some fishing related employment according to Table 5.1.6-100 with 40 persons employed in the marinas sector and 16 in fish and seafood.

5.1.6.10 Palm Beach (33480)

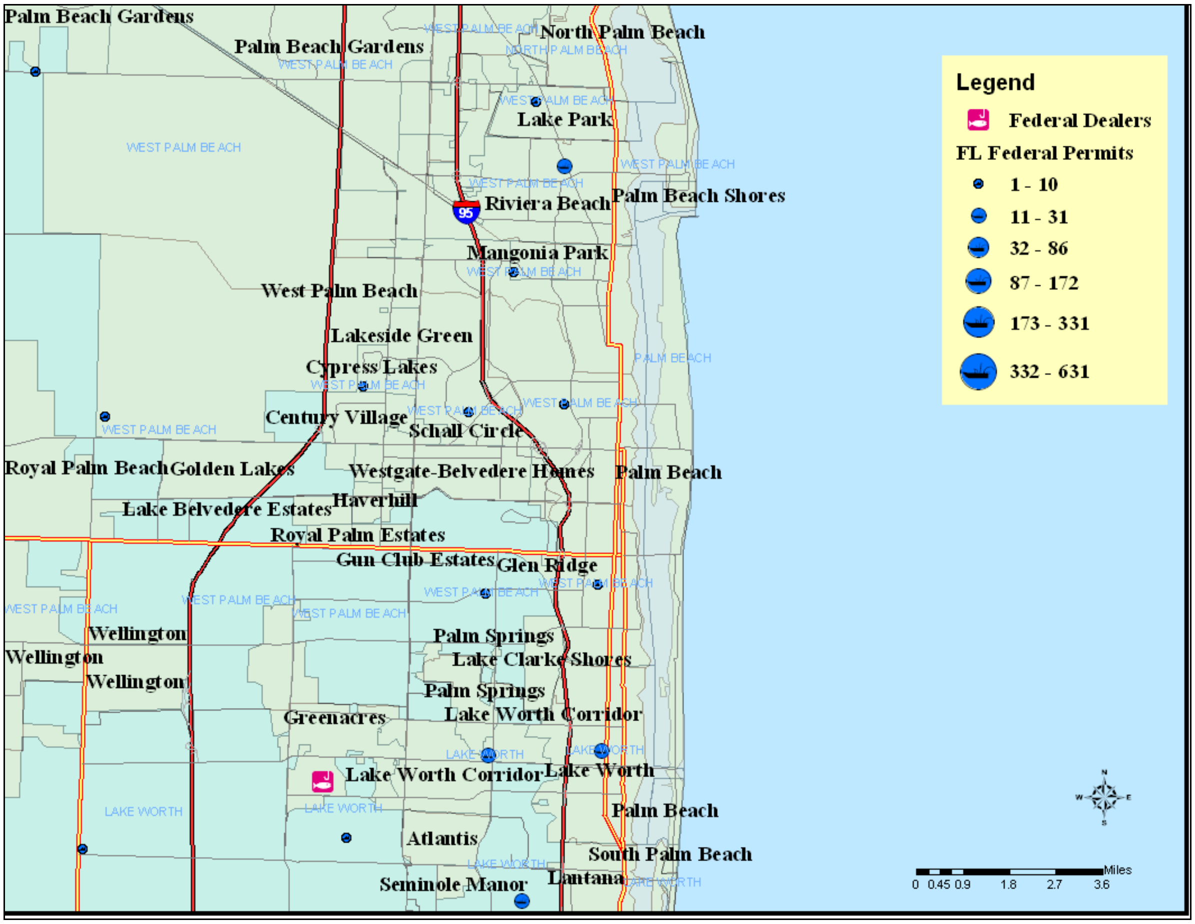

Figure 5.1.6-11. Palm Beach, Florida.

Palm Beach was originally known as Lake Worth. The name was changed to Palm Beach in the 1900s, when a man from Philadelphia noticed the coconut palm trees growing near the lake. In 1878, a ship named the “Providencia” was sailing from South America back to Barcelona with a shipment of coconuts. The ship wrecked on the beach and hundreds “of the coconuts washed ashore, embedded themselves in the sandy beaches, and sprouted into young trees” (Spencer 1975).

Life for the early settlers was difficult. The only lumber available to build their homes was from wood washed ashore from shipwrecks. Residents of Palm Beach had to sail north to Titusville for supplies, such as flour, meal, and other staples (Spencer 1975). Most of the original settlers, prior to 1900, were from Michigan, Illinois, Ohio, Iowa, and Wisconsin. A.O. Lang, a German horticulturist and one of the first residents of Palm Beach, planted numerous citrus fruit trees, such as limes, lemons, oranges, and pineapples (First Federal Savings and Loan Association of Lake Worth 1967).

Citrus groves were not the only source of food and income for the residents of Palm Beach. Fish were plentiful for the early settlers. The importance of fish dates back to the Native Americans who once inhabited the land. They partook in shark-fishing, using the teeth for cutting, the vertebrae as ornaments, and the rest for meat. Shellfish were an important part of the Indians diet as well (McGoun 1998).

The western part of Palm Beach County was known for its catfish industry. The arrival of Henry Flagler's Florida East Coast Railroad assisted in increasing the profitability of the catfish industry in Palm Beach, making it easier to ship the fish northward (McGoun 1998). However, during WWII, fishermen were not only retrieving fish from the waters. West Palm Beach was an embarkation point for the Air Force bomber crews. German submarines would sit offshore and sink US military vessels. "In the early days of the war, local fishermen would go out and pick up survivors from these ill-fated ships" (First Federal Savings and Loan Association of Lake Worth 1967).

The Frontier days of 1873 to 1893, pioneers called the area from Jupiter to Hypoluxo the "Lake Worth Region" and traveled by boat from one homestead to another. H.F. Hammon was the first to claim a homestead in the area that is now Palm Beach. E.N. "Cap" Dimick was the most influential settler by being the first hotelier in Palm Beach and the first Mayor. Most of his family had settled in the area by 1876 and his descendants still remain.

Palm Beach has seen relatively slight population growth over the past two decades. It has a low percentage of its population in the labor force with only 31 percent and unemployment is low at 3.3 percent. Average wage and salary is extremely high at $94,562 and the number of people living below the poverty line has remained fairly constant at 551. The number of persons working in farm, fish, and forestry occupation and industry has dropped considerably since 1990 as is the case for most coastal communities. Table 5.1.6-110 indicates there are 59 federal permits issued and about one third of them hold mackerel permits. There is relatively little fishing related employment according to Table 5.1.6-111 with only 3 in the fishing sector and 3 in marinas.

5.1.6.11 Boca Raton (33487, 33431, 33486, 33496, 33432, 33434)

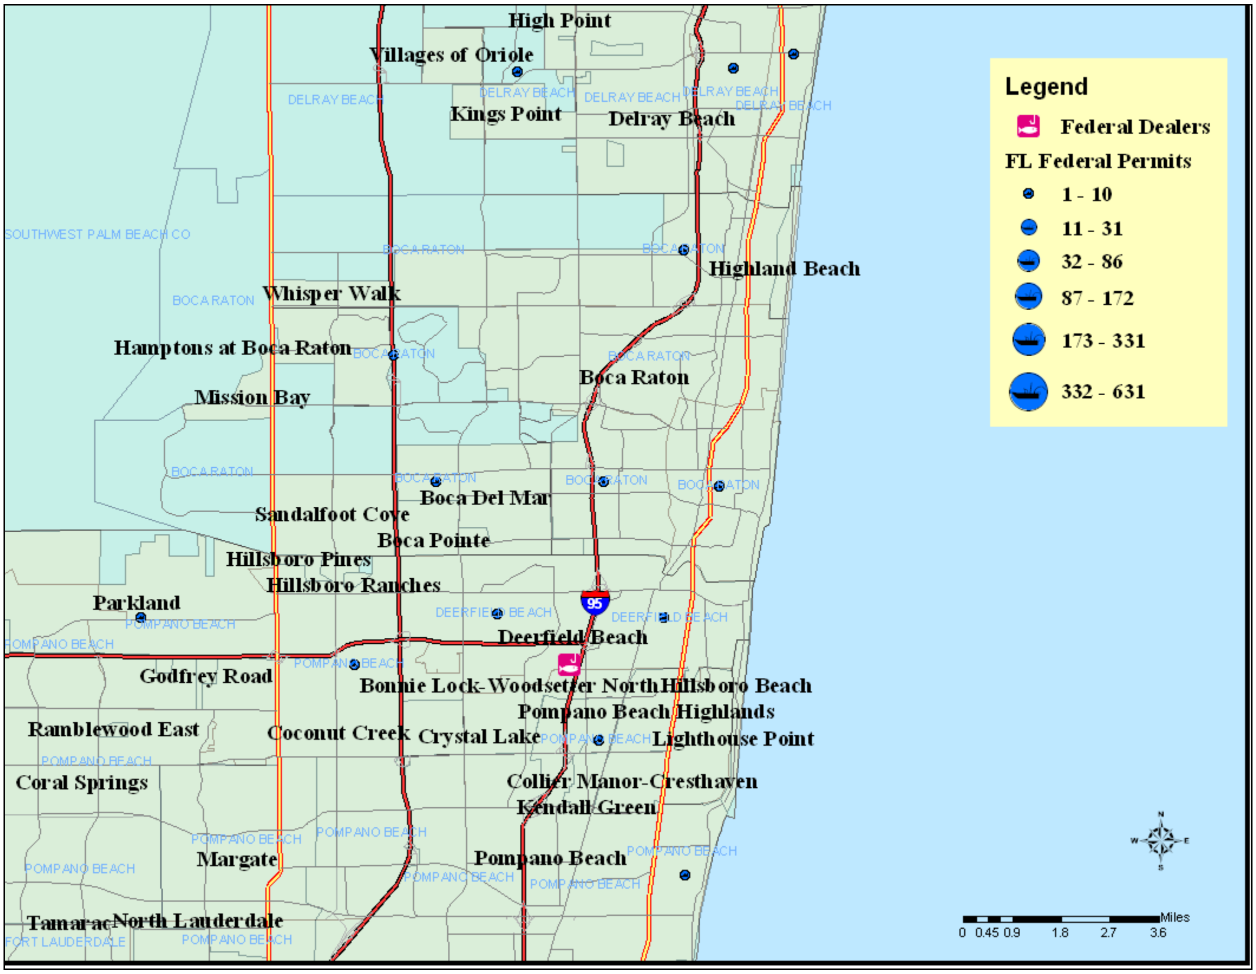

Figure 5.1.6-12. Boca Raton, Florida.

The area of current day Boca Raton was inhabited by Native Americans for nearly 1,000 years before the arrival of the Spanish. The original name given to the area by the Spanish explorers was “Boca de Ratones.” In nautical terms, “boca” denotes an inlet. Some of the translations include, “haulage inlet,” “inlet of mice,” “inlet of sharp-pointed rocks,” and “inlet of cowardly thieves.” “Rata,” not “raton” is the Spanish word for rat (Ashton 1984).

Captain Thomas Moore Rickards, Sr. of Missouri was one of the first people who wanted to settle the area of Boca Raton. He arrived in Florida in 1876 and became a citrus farmer in Candler. The freeze of 1894-5 forced him farther south to Lake Boca Raton. A year later, the tracks for Henry Flagler’s East Coast Railroad were laid in Boca Raton, allowing for easier, faster shipping and more convenient modes of transportation. By the beginning of the 1900s, Boca Raton “came into existence as a little agricultural center of orchards and farms” (Ashton 1984).

In 1904, a Japanese immigrant, Joseph Sakai, established a Japanese farming community of pineapple farmers in Boca Raton. He named the area Yamato.

The land boom of the 1920s and the arrival of famous architect Addison Mizner helped Boca Raton gain the image it still retains today as that of a luxurious resort town. He had already helped build up Palm Beach and was now aiding in the development of the areas to its south (Ashton 1984).

Boca Raton has experienced fairly steady population growth reaching 75,594 in 2000 (Table 5.1.6-112). Unemployment has risen slightly in 2000 from 1990 but the percentage of the population in the labor force has remained around 59 percent (Table 5.1.6-115). The average wage and salary is high being above $60,000 yet the number of persons living below the poverty level has grown steadily since 1970 (Table 5.1.6-118). The number of persons employed in farm, fish and forestry occupations and industry dropped dramatically in 2000 from a high in 1990. within 2008, there were 33 federal permits issued Table 5.1.6-121 but there are no federal dealers in Boca Raton. As far as fishing related employment there are 21 people listed in the fish and seafood sector according to Table 5.1.6-122.

5.1.6.12 Key Largo (33037)

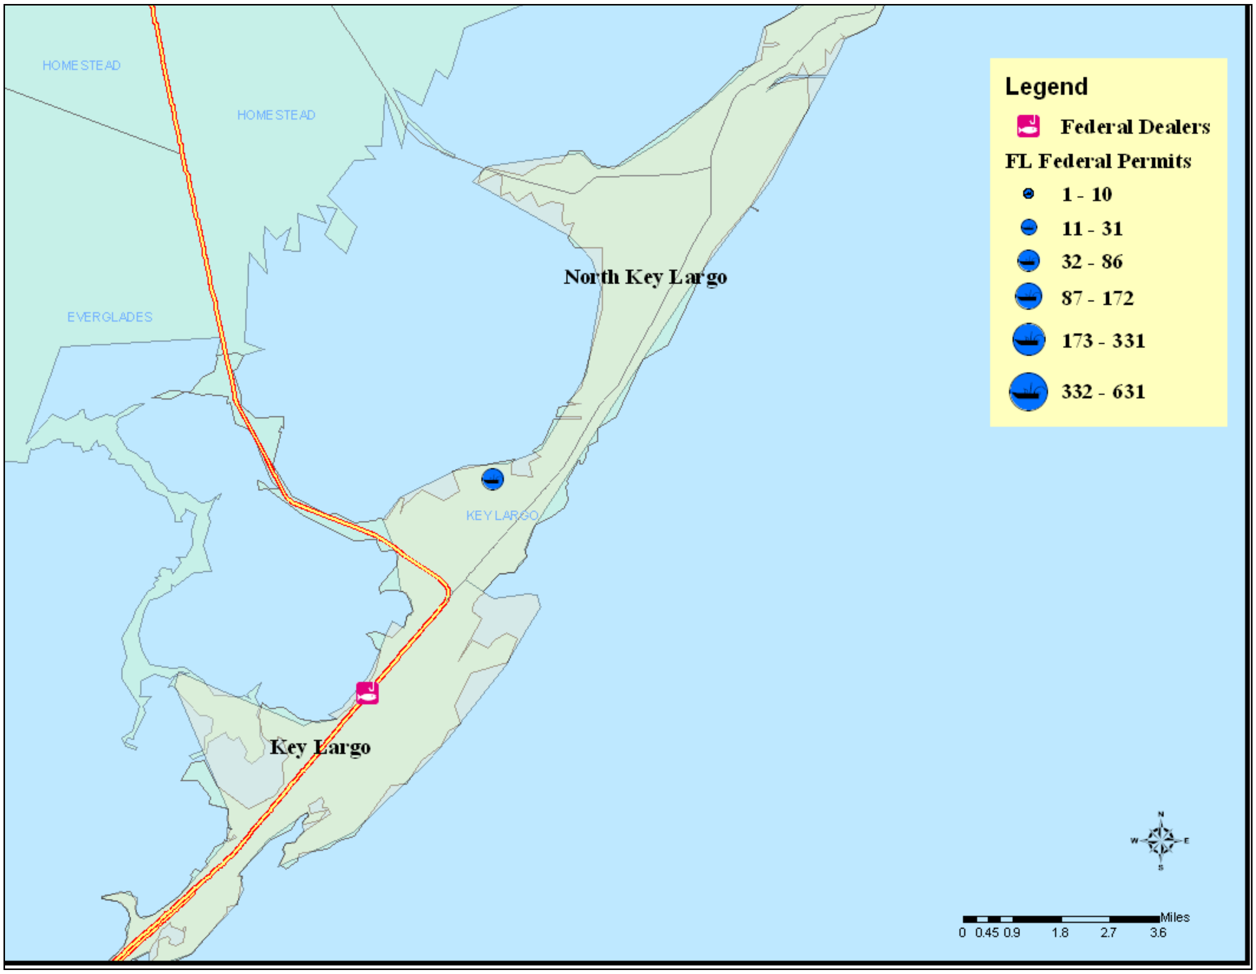

Figure 5.1.6-13. Key Largo, Florida.

The Florida Keys were first discovered by Juan Ponce de Leon in 1513. He named them Los Martires, the martyrs, "because they seemed twisted and tortured" (Williams 1991). The first permanent European settlement did not occur until the mid-1800s; however, the Keys were inhabited by the Calusa Indians for thousands of years. Williams (1991) notes that the first people to establish permanent homes in the Upper Keys—Key Largo and Islamorada—were Methodist fishermen and farmers. Ben Baker established pineapple farming in Key Largo, the longest Key and oldest named site in Florida, in 1866. He shipped his fruit on small boats to Key West, where the produce was loaded onto larger vessels for shipment to the northern states.

5.1.6.13 Islamorada (33070, 33036)

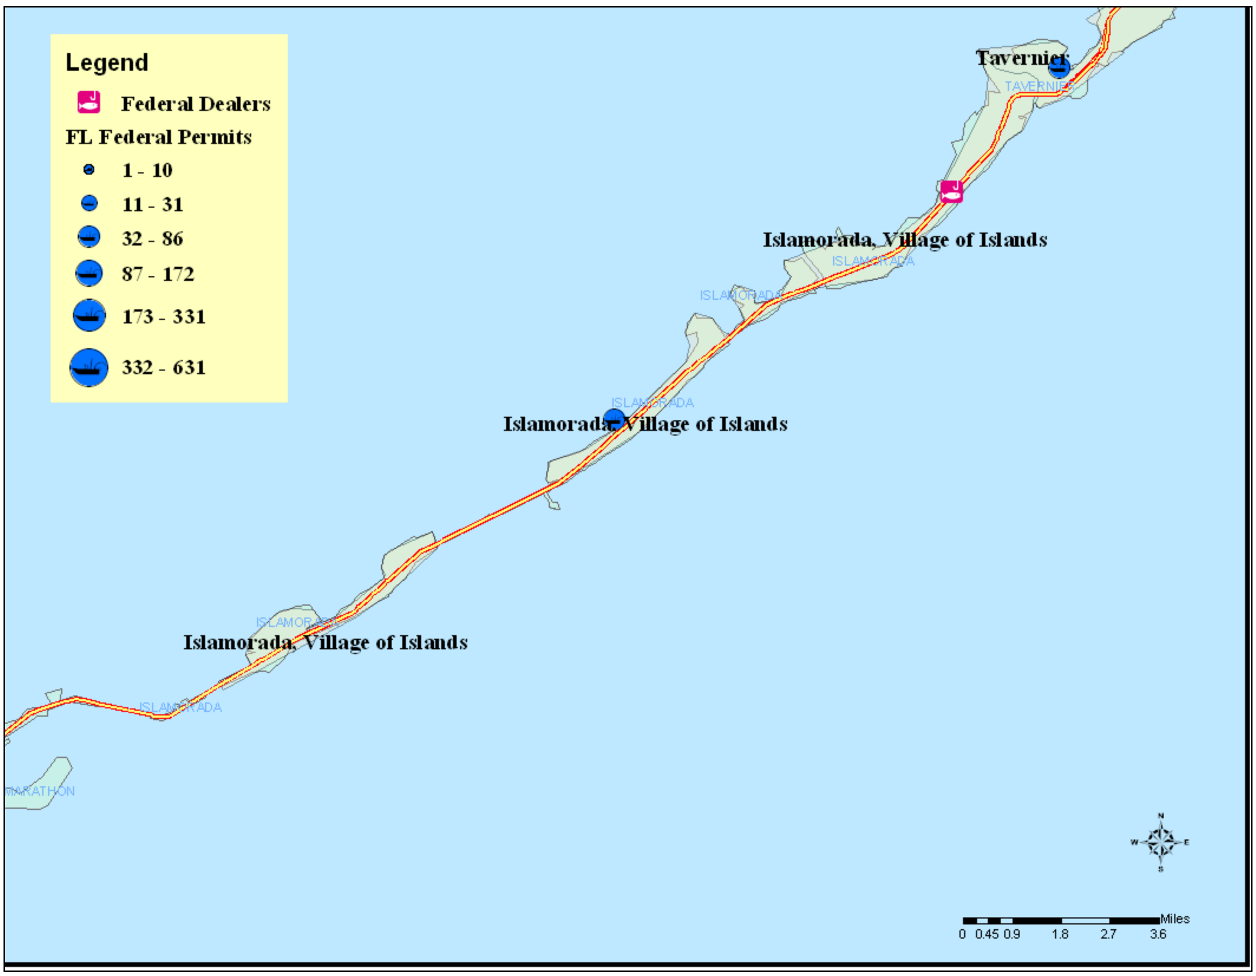

Figure 5.1.6-14. Islamorada, Florida.

Incorporated in 1997 and officially named Islamorada, Village of Islands, the community includes the islands of Upper and Lower Matecumba Keys, Plantation Key and Windley Key. The first settlers were Conchs who were of British descent by way of the Bahamas.

They fished and raised fruits and vegetables to survive. In the early 1930s wealthy Americans began to vacation in this area, particularly for the sport fishing. It has remained an important sport fishing center and self proclaimed "Sportfishing Capital of the World." It has been estimated that there are over 100 charter fishing vessels in Islamorada. In addition to offshore charters there are probably just as many guide boats that fish the nearshore and inshore waters. The community supports a large tourist economy that is centered on the charter fishing industry and has at least 24 marinas and approximately 45 hotels/motels to cater to fishermen. There are at least 6 air fill stations where divers can fill their tanks and several marinas offer dive trips. There are a few commercial operations in the community with most supporting a retail wholesale operation with a restaurant.

The community has seen substantial population growth because of its recent incorporation. Employment and unemployment have not changed dramatically. Average wage and salary have increased and so has the number of persons living below the poverty level. Both may be artifacts of the incorporation. This community is one of the few that has seen an increase in the number of persons working in farm, fish and forestry according to Table 5.1.6-141 and fishing related employment is spread out among marinas, fish and seafood and boat building (Table 5.1.6-144).

5.1.6.14 Marathon (33050)

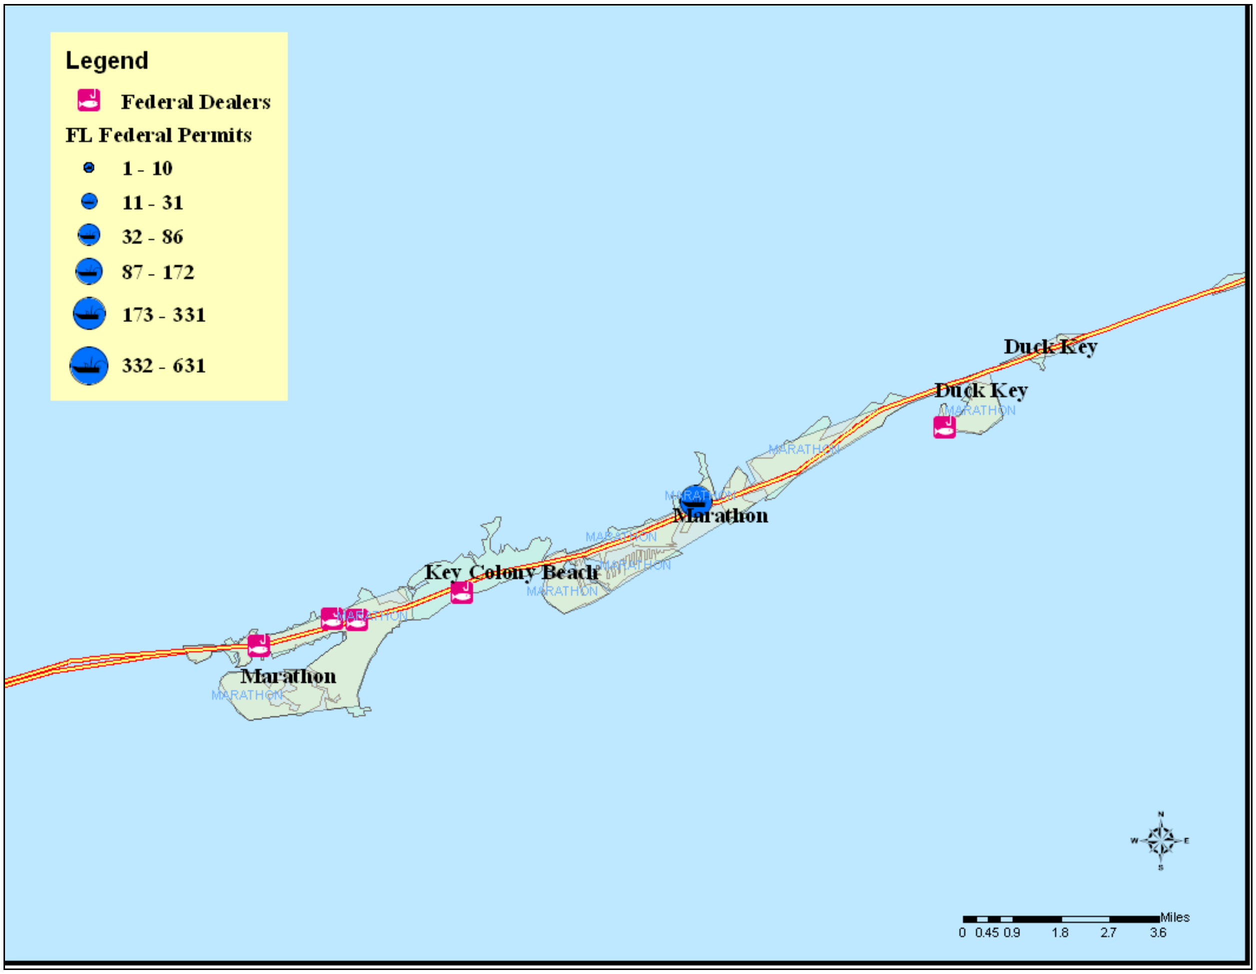

Figure 5.1.6-15. Marathon, Florida.

Marathon, or Key Vaca as it was called by the Spanish, was originally settled in the early 1800s by a group of Bahamians and numerous families from Mystic, Connecticut involved in fishing. Salvaging cargo from the Spanish Galleons in the area was also steeped in this key's history as well. Marathon has seen steady growth in its population since 1970. The percentage of the population employed in the labor force along with unemployment has remained constant over the past ten years. Average wage and salary have also slowly increased over the years, but the number of individuals living under the poverty level has also climbed to over 1400 persons. The number of persons working in occupations or industry sector of farm, fish and forestry has dropped since 1990 but still remains high at over 200 persons. In 2008, vessels with federal permits predominantly held Atlantic dolphin/wahoo commercial (72), Atlantic dolphin/wahoo charter (41), south Atlantic charter/headboat for pelagic fish (43), snapper grouper charter/headboat for snapper grouper (25), king and Spanish mackerel (27/63), or snapper grouper unlimited (25) permits (Table 5.1.6-154). According to Table 5.1.6-155 there are 92 persons employed in the fish and seafood sector of fishing related employment. There are 39 in the fishing sector and 47 in marinas.

5.1.6.15 Big Pine Key (33042, 33043)

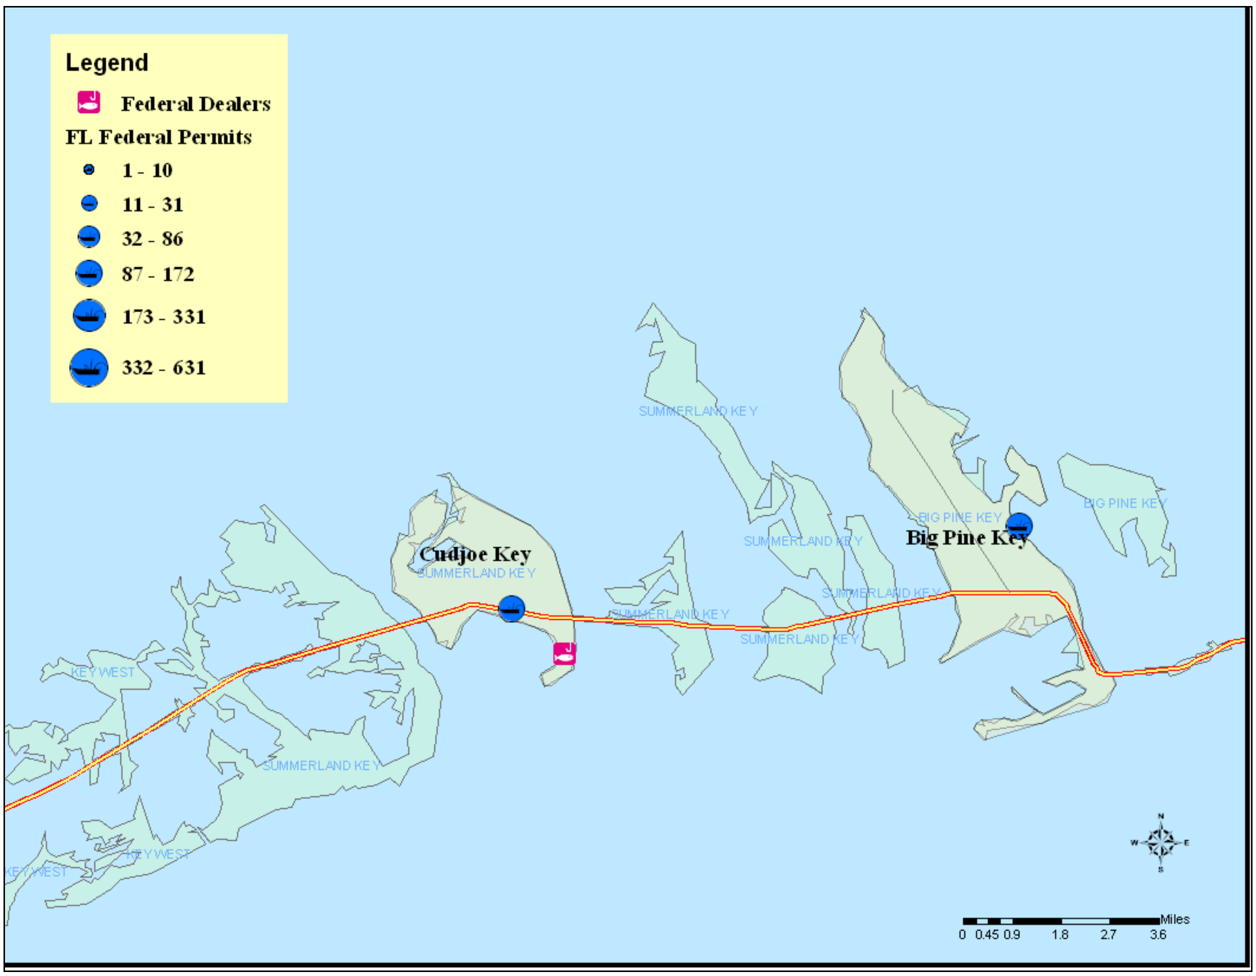

Figure 5.1.6-16. Big Pine Key, Florida.

Big Pine Key, located in the Lower Keys, does not have a true history of its own. Settlement was sparse well into the twentieth century. The 1870 census for Big Pine Key lists only one inhabitant, George Wilson. Wilson was a charcoal burner, providing his product for residents of Key West before the days of electricity. A shark processing plant was established on Big Pine in 1923 by Hydenoil Products. The sharks were harvested for their leather and liver oil. The company averaged 100 sharks a day in 1930. The fishermen caught mostly hammerhead, sand, nurse, dusky, leopard, sawfish sharks. Even with this seeming success, the plant was shut down in 1931 because of possible financial difficulty.

Big Pine Key and Cudjoe Key are included in tables for fishing demographics but the census demographics include only Big Pine Key. The population for this area has seen steady growth, while the percent of the population in the labor force and unemployment have remained fairly constant over the years with unemployment fairly low at 2.1 percent. Average wage and salary have increased steadily along with the number of persons living under the poverty level. The number of persons working in the farm, fish and forestry occupation has dropped since 1990 but still remains high compared to other coastal communities. In 2008, there were 124 federal permits issued and they are spread out among the different types with most holding permits for dolphin/wahoo, king and Spanish mackerel or snapper grouper (Table 5.1.6-165). According to Table 5.1.6-166 there are 50 people employed in the fishing sector and another 27 in the marinas sector.

5.1.6.16 Key West (33040, 33041, 33045)

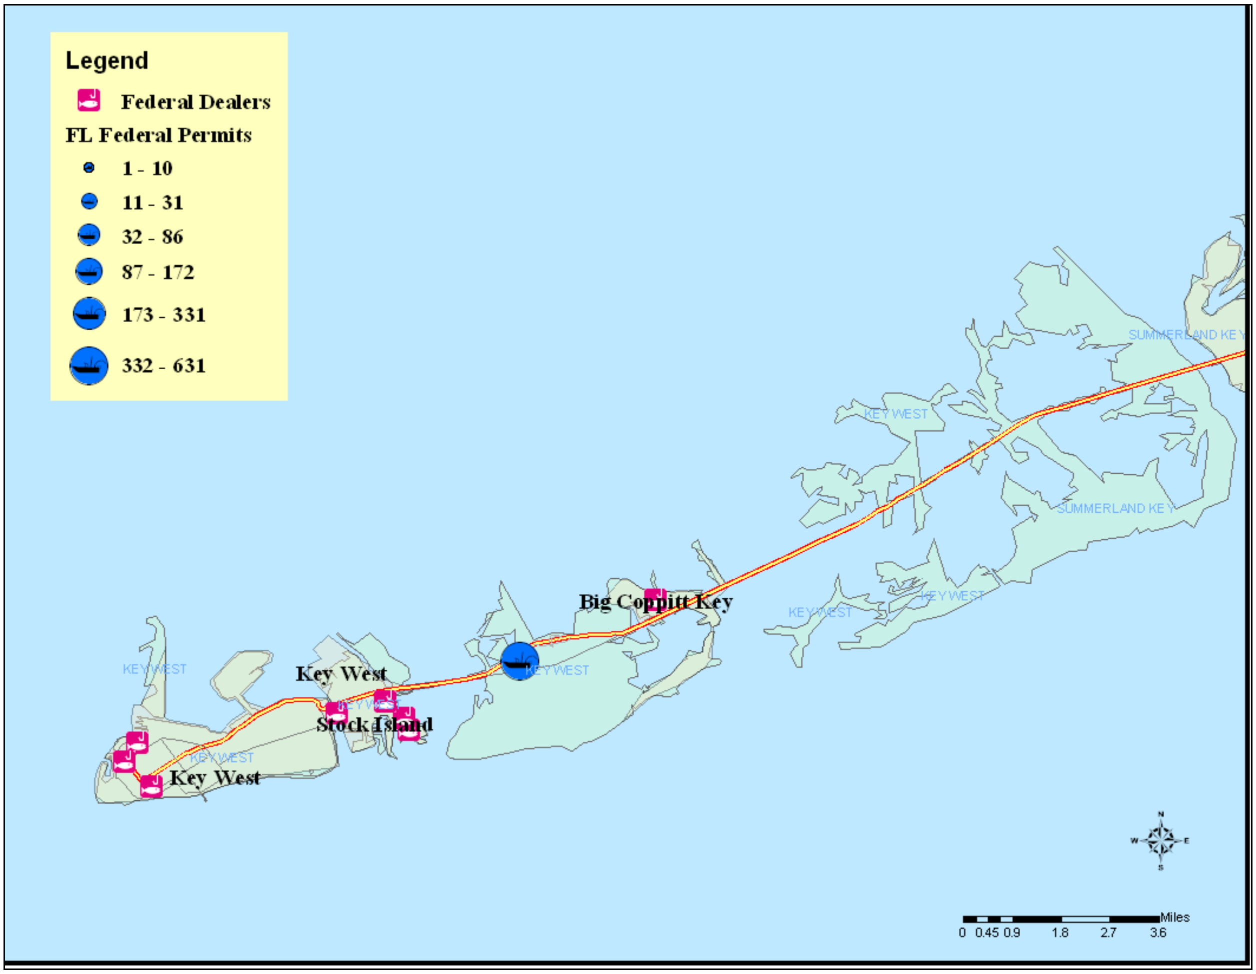

Figure 5.1.6-17. Key West, Florida.

Spanish explorer Juan Ponce de Leon and chronicler Antonio de Herrera were the first Europeans to set eyes upon Key West on May 15, 1513. It has the distinction of being the oldest city in south Florida (Williams 1991). They called the island Cayo Hueso (Isle of Bones) because of the numerous bones they found on what was either a Calusa Indian burial ground or battlefield. It is believed that the English thought the Spanish meant "oeste" (west) and changed the name to Key West. However, the first permanent occupancy of Key West did not occur until 1822. In 1822, Spaniard Juan Salas sold the city of Key West to a Mobile, Alabama businessman named John Simonton for $2,000. Naval Commodore David Porter was sent to establish a naval post to help rid the area of pirates in that same year. They also established a port in order to open the shipping lanes from the Gulf of Mexico, the Caribbean, and the Atlantic. A Customs House was established later that year. By 1830, the pirates were gone; however, hurricanes and the fear of running aground on the coral reefs still plagued boat captains. These boating difficulties gave way to one of the first profitable ventures in Key West—salvaging of shipwrecks (Williams 1991).

When salvaging was no longer profitable, sponging and Cuban cigar manufacturing became the mainstays of Key West's economy (Williams 1991). The people of Key West, or conchs as they are commonly known, began the sponge trade in Florida, and by the 1890s, they made Key West "the commercial sponging capital of the world." Nevertheless, fishing was a primary source of income and survival since the very beginning. Before permanent settlement of Key West, fishermen from New England and the Bahamas would come to take advantage of the species the waters of Key West had to offer. Similarly, in the early 1900s, fishermen from St. Augustine would fish in Key West and sell their catch in Havana. Since the beginning, grouper and spiny lobster have been the most profitable species of the Key West fishing industry.

Shrimp has been another important species for the Key West fishing community. John Salvador, a son of one of the original fishing families in St. Augustine, discovered rich shrimping grounds in the Dry Tortugas in 1950. The rush to harvest the shrimp has been related to the gold rush of 1849, naming the shrimp "pink gold." "Currently, Key West pink shrimp make up almost 50% of the total Monroe County shrimp landings." The marine resources have been the key to survival and income for conchs for nearly 200 years. Today, the port in Key West is famous for its scuba diving, sport fishing, and yachting opportunities.

The population of Key West has not grown much over the past three decades. The percent of the population in the labor force and unemployment have both remained fairly constant since 1990. Average wage and salary has grown over the years while the number of people living under the poverty level has decreased overall. Key West has the greatest number of persons working in the farm, fish and forestry categories of any coastal community with over 300 in both occupation and industry. In 2008, there were 1,010 federal permits issued and they are spread out among the different types with most holding permits for dolphin/wahoo, king and Spanish mackerel, spiny lobster or snapper grouper (Table 5.1.6-176). Given so many fishing vessels the number of persons employed in fishing related employment seems low with only 18 in the fishing sector and 49 in marinas.

The city of Key West boasts more than two dozen fishing charters in its area. Most of the boats can support between two and six anglers. Half and full-day trips seem to be the most popular, with many offering swordfish fishing excursions at night as well. Some of the most popular species for offshore sport fishing adventures in the waters off Key West include sailfish, tuna, wahoo, and dolphin. Many of the fishermen offer reef and wreck fishing trips, allowing anglers to catch various species of snapper and grouper. Some of the more popular targeted species include red snapper, yellowtail snapper, mutton snapper, black grouper, and mangrove snapper. There are about half a dozen headboats that fish the waters of Key West as well. These boats can accommodate far more fisherman. Trips usually last for about four hours. Some of these boats specifically target snappers and groupers.

Tournaments are also an important part of the recreational fishing sector in Key West. One of the largest tournaments in the area, The Key West Fishing Tournament, lasts from

April through November. Forty-four species of fish are fished, six of which are groupers and six species of snappers. Other longstanding tournaments in the area include the Mercury Redbone at Large Key West Classic and the Mercury S.L.A.M (Southernmost Light tackle Anglers Masters) held in April and September, respectively. These tournaments are an opportunity for the recreational fishing boat owners to make money as well as many of them rent their boats to tournament participants who do not have vessels of their own.

Marinas and bait and tackle shops are important to the recreational sector as well as the commercial industry. Key West has more than half a dozen marinas, many of which are full service marinas. For example, the Sunset and Oceanside Marinas offer boat repairs, fuel, storage, and repairs. Many of the recreational fishermen in the area are docked at either Garrison Bight Marina or at Amberjack Pier at the City Marina.

5.1.6.17 Florida Fishing Infrastructure and Community Characterization

The following tables provide a general view of the presence or absence of fishing infrastructure located within the coastal communities of Florida with substantial fishing activity. It should be noted that there are many other attributes that might have been included in this table, however, because of inconsistency in rapid appraisal for all communities, these items were selected as the most consistently reported or had secondary data available to determine presence or absence. It should also be noted that in some cases certain infrastructure may exist within a community but was not readily apparent or could not be ascertained through secondary data. Table 5.1.6-178 offers an overview of the presence of the selected infrastructure items and provides an overall total score which is merely the total of infrastructure present.

Table 5.1.6-178. Fishing Infrastructure Table for Florida Potential Fishing Communities.

Community	Federal Commercial Permits (5+)	State Commercial Licenses (10+)	Federal Charter Permits (5+)	Seafood Landings	Seafood retail markets	Fish processors, Wholesale fish house	Recreational docks / marinas	Recreational Fishing Tournaments	Total
Atlantic Beach	-	+	-	+	+	+	+	-	5
Big Pine Key	+	+	+	+	+	+	+	-	7
Boca Raton	+	+	-	-	+	-	+	-	4
Cape Canaveral	+	+	-	+	+	+	+	+	7
Fernandina Beach	+	+	+	+	+	+	+	+	8
Fort Pierce	+	+	+	+	+	+	+	+	8
Islamorada	+	+	+	+	+	+	+	+	8
Jupiter	+	+	+	+	+	+	+	+	8
Key Largo	+	+	+	+	+	+	+	+	8
Key West	+	+	+	+	+	+	+	+	8

Ponce Inlet	+	+	+	+	+	+	+	+	8
Sebastian	+	+	+	+	+	+	+	+	8
St. Augustine	+	+	+	+	+	+	+	+	8

In attempting a preliminary characterization of potential fishing communities in Table 5.1.6-179, we have provided a grouping of communities that appear to have more involvement in various fishing enterprises and therefore are classified as primarily involved. These communities have considerable fishing infrastructure, but also have a history and culture surrounding both commercial and recreational fishing that contributes to an appearance and perception of being a fishing community in the mind of residents and others. The communities are not ranked in any particular order, this is merely a categorization.

Table 5.1.6-179. Preliminary Characterization of Potential Fishing Communities in Florida.

Primarily-Involved	Secondarily-Involved
Fernandina Beach	Atlantic Beach
Fort Pierce	Boca Raton
Islamorada	Palm Beach
Jupiter	
Key Largo	
Key West	
Marathon	
Fernandina Beach	
Fort Pierce	
Islamorada	

Many of these communities are in transition due to various social and demographic changes from coastal development, growing populations, increasing tourism, changing regulations, etc. This preliminary characterization is just that and should not be considered a definite designation as fishing community, but a general guide for locating communities that may warrant consideration as a potential fishing community.

5.2 Fisheries under SAFMC Management

5.2.1 Shrimp Fishery

5.2.1.1 Description of fishing practices, vessels and gear

5.2.1.1.1 Commercial penaeid shrimp fishery

Otter trawl

The otter trawl is the most common gear used to harvest these shrimp species and consists of: (1) a cone-shaped bag in which the shrimp are gathered into the tail or cod end; (2) wings on each side of the net for herding shrimp into the bag; (3) trawl doors at the extreme end of each wing for holding the wings apart and holding the mouth of the net open; and (4) two lines attached to the trawl doors and fastened to the vessel. A ground line extends from door to door on the bottom of the wings and mouth of the net while a float line is similarly extended at the top of the wings and mouth of the net. A flat net is more often used when fishing for brown shrimp since they burrow into the bottom to escape the trawl. This net has a wider horizontal spread than other designs and is believed to be more effective at capturing brown and pink shrimp. In areas where white shrimp are the main target, trawls used in the fishery have been modified to increase the efficiency in the capture of white shrimp. The tongue trawl or high-rise trawl, was designed to fish higher in the water column making it more effective in catching the more active white shrimp (SAFMC 1996b). Most trawl vessels are rigged for towing two to four nets simultaneously. In Florida, this is only the case for vessels operating in offshore waters. In inland and nearshore waters, Florida trawlers are restricted to no more than two nets each having a maximum surface area not to exceed 500 square feet. The double-rigged shrimp trawler has two outrigger booms from whose ends, through a block, the cable from the winch drum is run to the two nets. Some vessels use twin trawls, which are essentially two trawls on a single set of doors, joined together at the head and foot ropes to a neutral door connected to a third bridle leg. Thus, instead of towing two 70 foot nets the vessel tows four 40 foot nets. This rig has some advantages in ease of handling and increased efficiency. The quad trawl net configuration allows faster towing speed and wider net spread compared to double-rigged trawls. In South Carolina, it is unlawful to have onboard a vessel or to trawl with any trawl or trawls having a total foot rope length of two hundred and twenty feet or greater, not including try nets or nets bundled below deck.

Trawlers operating in Georgia and South Carolina waters are restricted to a combined maximum length of 220 feet of foot rope, defined as the measure from brail line to brail line, first tie to last tie on the bottom line, but not to include a try net up to 16 feet in length. Trawling accounts for more than 95% of the food shrimp landed in Georgia. Georgia's fleet is comprised of large trawl vessels, with 66% in excess of 40 feet in length. Hand-retrieved trawls, those with no mechanical retrieval capabilities and typically less than 25 feet in length, account for approximately 28% of all vessels harvesting food shrimp. Their minimal size restricts their effective fishing range to shallow, near-shore areas close to the shoreline. In 1977, Georgia's sounds were closed to shrimp trawling. Since that time, the sounds have been opened only five times. Each opening lasted less than seven days. Most hand-retrieved trawl fishery participants do so for personal consumption or for supplemental income.

The duration of tows varies depending on many factors including amount of bycatch species and concentration of shrimp. Small boats fishing in inshore waters make much shorter drags than the larger, offshore vessels whose tows generally last several hours (SAFMC 1993).

Wing net

In Biscayne Bay, Florida, food production shrimp are harvested with wing nets. A wing net is a net in the form of an elongated bag kept open by a rigid frame that is attached to either side of a vessel and is not towed behind a vessel or dragged along the bottom. Vessels are equipped with two such nets each with a perimeter no greater than 28 feet and a surface area not exceeding 500 square feet. This is a top water fishery and shrimp are harvested as they leave the bay. Roller frame trawls are also allowed; however, these are not used in the food shrimp fishery on the Atlantic coast.

Cast net

In Georgia, cast netting is the second most popular means of commercially harvesting food shrimp. Like the hand-retrieval fishery, most individuals who are commercially licensed utilize this fishery recreationally or as a form of supplemental income. Operating under the same season as that of the trawl fisheries, but without area restrictions, participants typically target shrimp in waters within the estuary proper, frequently fishing near or adjacent to sounds and tidal river mouths. During the initial years of its existence, the commercial cast net fishery in Georgia operated under minimal restrictions; however, regulatory changes in 1998 created gear restrictions and catch limits. Currently, the commercial catch limit for the cast net fishery is 50 quarts of shrimp at any one time, no more than 10 percent of which may be dead. Cast nets must be constructed of uniform mesh and material from the thimble or horn, to the lead line, with a minimum of ¾ pound of lead per radius. Commercial nets must have a minimum mesh size of 5/8 inch and cannot exceed a radius of 12 feet.

Channel net

In some areas, primarily North and South Carolina, channel nets are also used for commercial shrimping. Channel nets are essentially anchored shrimp trawls that fish almost the entire water column as they are held open by currents. In South Carolina channel nets are required to have top-opening turtle excluder devices (TEDs).

Other gear

In North Carolina, skimmer trawls are used in shallow tributaries. This gear is attached to frames that can be raised and lowered into the water on either side of the vessel. The tailbag can be retrieved and dumped without stopping and "hauling back." Butterfly nets, rectangular nets held open by a frame and attached to the side of the vessel, are used in a few areas. Haul or beach seines are also used to a minor extent for commercial fishing in some areas. The use of non-trawl gear, especially in North Carolina inshore waters is on the increase. Landings from these methods of fishing (e.g., beam trawls and chopstick gear) have increased from 137,000 lb in 1993 to 827,000 lb in 2002. In Georgia, seines 12 feet or less, with a maximum depth of 4 feet and maximum stretched mesh of 1 inch may be used any time in state waters. Seines less than 100 feet in length, with minimum stretched mesh size of 1 ¼ in, may be used on any sand beach or on any barrier island in Georgia but are prohibited in inlets or tidal sloughs. Seines 100-300 feet in length are allowed only on the oceanfront sides of beaches and must have a minimum stretched mesh of 2 ½ in.

Fishing area

The commercial fishing area for penaeid shrimp (white, brown and pink) species in the South Atlantic is mainly concentrated from Pamlico Sound and Ocracoke Inlet, North Carolina to Fort Pierce, Florida. There is another fishery off the Florida Keys where the main target is pink shrimp. Commercial shrimp catches in all four states are taken from internal waters, state waters out to three miles and from the EEZ. Most of the shrimp in these states are caught by otter trawls (SAFMC 1996b).

In North Carolina, the important shrimping areas are Pamlico Sound, Core Sound, major rivers and off the southern coast, south of Ocracoke Inlet. The brown shrimp fishery is the most important fishery followed by the white shrimp fishery in the fall and the pink shrimp fishery in the spring. Vessels operate night and day in Pamlico Sound, Neuse River, Bay River, Core Sound, Newport River, North River, White Oak River, New River and the Intracoastal Waterway in the southern portion of the state as well as the ocean off the central and southern coasts. Daytime shrimping in North Carolina takes place along the southern coast and in the New River during the fall.

South Carolina's major food shrimp trawling area is continuous in the Atlantic Ocean from the entrance of Winyah Bay near Georgetown southwestward to the South Carolina - Georgia state line near Savannah, Georgia, including the mouths of three sounds. Effort occurs to a lesser extent in state waters northwest of the Winyah Bay entrance to the South Carolina-North Carolina state line at Little River. Trawling often occurs in the EEZ off South Carolina prior to the opening of the territorial sea and during the open state trawling season. The summer to winter white shrimp fishery is the most important shrimp fishery for South Carolina vessels. Trawling occurs in the daylight hours in response to activity of the primary target species, white shrimp. The season generally runs from mid-May through December. The channel net fishery is prosecuted in inshore waters of North Santee Bay near Cape Romain and in Winyah Bay near Georgetown generally from mid-September through November.

In Georgia, shrimping takes place along the entire coast. Shrimp are harvested in estuarine and nearshore waters of each coastal county. Georgia law allows for state waters to be opened for the harvest of food shrimp from May 15 until December 31. At the discretion of the Commissioner of the Department of Natural Resources, the season can be extended through the last day in February. All decisions regarding the opening and closing of the state's waters to the harvest of food shrimp are based on current, sound principles of wildlife research and management. On average, Georgia waters are open from Mid-June through January. In Georgia, white shrimp comprise the largest annual portion of the commercial catch, yielding approximately 80% of all harvested shrimp and is the most economically valuable. This species is primarily harvested in state waters during the late summer, fall, winter and spring months, though it may be caught year round in federal waters adjacent to Georgia. The brown shrimp comprises approximately 18% of the total annual catch. During the summer months, when it is most prevalent in state waters, brown shrimp may comprise upwards of 70% of the total harvested shrimp. Pink shrimp makes up less than 2% of the total and is rarely if ever targeted.

The most important fishing area along Florida's east coast is the northeastern part of the state, between Fernandina Beach and Melbourne, just south of Cape Canaveral. Along Florida's east coast, the shrimp fishery is characterized by brown shrimp dominating the summer fishery and white shrimp dominating the fall and winter fisheries. Pink shrimp are harvested in Biscayne Bay generally during the period November through May.

Commercial bait shrimp fishery

The commercial bait shrimp fishery is much larger in Florida than in the other South Atlantic states. Live shrimp for bait are caught in Dade County and in six counties around the St. Johns River. A variety of gear is used in this fishery, but otter trawls (St. Johns) and roller frame trawls (Biscayne Bay) are the most commonly used. Wing nets are used in Volusia County for live bait shrimp harvest. There is very little effort directed specifically for commercial bait shrimp in either North or South Carolina.

In Georgia, however, the commercial bait shrimp fishery is the state's fourth most valuable commercial fishery. Targeting smaller shrimp than the food shrimp industry, the commercial bait shrimp fishery is restricted to designated zones inside the estuary. Prior to 1978, bait shrimp fishermen had no restrictions on area; however, as a result of consecutive freezes in the winters of 1977 and 1978, and the subsequent depletion of overwintering stocks of white shrimp, experimental "bait zones" were developed in an effort to protect nursery grounds and facilitate law enforcement (Music, Georgia DNR, pers. comm. 2003). As a result, both recreational and commercial bait fishermen are restricted to fishing in these designated zones, which are located throughout coastal Georgia in tidal creeks and rivers. Commercial bait harvesters may possess up to 50 quarts of shrimp, no more than ten percent of which can be dead. Vessels participating in the commercial bait shrimp fishery in Georgia are generally 25 feet in length or less, are equipped with large live wells and are powered by outboard motors. Typically, these vessels employ either a mongoose or flat/box net, with the headrope not to exceed 20 feet in length.

5.2.1.1.2 Recreational penaeid shrimp fishery

Recreational shrimp harvest in the South Atlantic occurs almost exclusively in state waters and is comprised mostly of penaeid shrimp (white, brown and pink) species. A variety of gear types are employed for recreational food shrimp activities and recreational shrimping for bait.

Licensing requirements are not consistent across all states and not all recreational shrimp fishermen are required to obtain a state permit or license to fish for penaeid shrimp species. In North Carolina, a person must obtain a Recreational Commercial Gear License (RCGL) to shrimp trawl for recreational purposes (i.e., not sell). The license holder can only trawl in open areas and must use a shrimp trawl with a maximum headrope length of 26 ft. The shrimp trawl must be equipped with a bycatch reduction device (BRD) and the use of mechanical methods for retrieval is prohibited. According to the RCGL data, recreational shrimping (trawling) takes place from the Pamlico District south. Areas of high activity are the tributaries of Pamlico Sound, most notably the Neuse River, Pamlico River and their tributaries. Recreational fishermen in North Carolina do not require a license to use seines and cast nets.

In South Carolina, a license to cast net for shrimp over bait during a regulated recreational season has been required since 1988. The season is restricted to 60 days during the white shrimp season generally between mid-September to mid-November. In Georgia, a Recreational Fishing License is required to engage in the not-for-sale harvest of shrimp with a cast net, seine and for the not-for-sale harvest of bait shrimp with a trawl.

The major areas for recreational shrimping in North Carolina are from Carteret County south to the state line and to a lesser extent in the tributaries of Pamlico Sound. In South Carolina, recreational shrimping takes place along the entire coast, with most activity from Winyah Bay southward to the South Carolina-Georgia state line. Georgia's sport bait trawling zones occur throughout the coastal area. Recreational beach seining is concentrated on Tybee, Sapelo, St. Simons, Jekyll and Cumberland Islands. In Florida, major sport shrimping areas are the St. Johns River area, the area around Ponce De Leon Inlet and in the southern part of the state in Biscayne Bay (SAFMC 1993).

In South Carolina, shrimp seines may be used year-round. Also, if the catch is kept for personal (non-commercial) use, a shrimp cast net not thrown over bait (without shrimp bait) can be used from May 1 through December 15 with a 48 quart limit, and 12 dozen limit from December 16 to April 30. A study conducted in South Carolina showed that shrimping over bait produces relatively little finfish bycatch compared to traditional cast netting for shrimp (Whitaker 1992).

In Georgia, cast netting for shrimp is the most popular recreational shrimping activity. Currently, the recreational catch limit in Georgia is 48 quarts of heads-on shrimp (30 quarts of shrimp tails) per day per boat. Also, certain estuarine zones are open for recreational live bait shrimping with single 10 foot trawl nets. Persons engaged in recreational, or sport, bait shrimping are limited to two quarts of bait per person, with no more than ½ pint dead, or four quarts per boat, with no more than one pint dead. Recreationally caught bait shrimp cannot be sold or consumed. Harvesting is restricted to the period ½ hour before official sunrise until ½ hour after official sunset.

Gear used by the recreational shrimp fishery in Florida consists of dip, drop and bridge nets, seines and cast nets. Cast nets and seines can be used by recreational fishermen in specified inside waters with no size restrictions.

Allowable Gear

The Shrimp Fishery Management Plan allows North and South Carolina, Georgia and east Florida to request a closure in federal waters adjacent to closed state waters for brown, pink or white shrimp following severe cold weather that results in an 80% or greater reduction in the population of white shrimp (whiting, royal red and rock shrimp fisheries are exempt from a federal closure for white shrimp).

During a federal closure, a buffer zone is established extending seaward from shore to 25 nautical miles, inside of which no trawling is allowed with a net having less than 4" stretch mesh. Vessels trawling inside this buffer zone cannot have a shrimp net aboard (i.e., a net with less than 4" stretch mesh) in the closed portion of the federal zone. Transit of the closed federal zone with less than 4" stretch mesh aboard while in possession of penaeid (white, brown and pink) species will be allowed provided that the nets are in an unfishable condition, which is defined as stowed below deck.

Bycatch reduction Devices (BRDs) - On a penaeid shrimp trawler in the South Atlantic EEZ, each trawl net that is rigged for fishing and has a mesh size less than 2.5", as measured between the centers of opposite knots when pulled taut, and each try net that is rigged for fishing and has a headrope length longer than 16.0 ft. must have a certified BRD installed. The following BRDs are certified for use by penaeid shrimp trawlers in the South Atlantic EEZ: extended funnel, expanded mesh and fisheye.

Turtle Excluder Devices (TEDs) are required in the penaeid shrimp fishery.

5.2.1.1.3 Commercial deepwater shrimp fishery

Given the distance from shore, depth of water, and gear necessary to harvest rock shrimp, there is no recreational fishery. The rock shrimp commercial fishery has existed off the east coast of Florida for approximately thirty years once extending from Jacksonville to Cape Canaveral. The relatively recent beginning for this shrimp fishery, compared to other southeast shrimp fisheries can be attributed to the lack of a viable market for the crustacean once considered "trash." Rock shrimp found a niche in the local fresh market and restaurant trade during the early 1970s, and became a regional delicacy. The increase in participants and market opportunities for smaller rock shrimp brought about a subsequent change in harvesting patterns as the fishing grounds extended south as far as St. Lucie County (SAFMC 1996a). Limited sporadic harvest has also occurred off Georgia, North Carolina and South Carolina. A limited access program was established in 2003 for vessels harvesting, in possession of and landing rock shrimp in Georgia and Florida. Expanding markets created growth within the industry that in turn has changed the composition of the rock shrimp fishery including the harvesting and the intermediate sectors (SAFMC 1996a).

In the south Atlantic region commercial trawlers are essentially the only user group exploiting the rock shrimp resource. Rock shrimp (*Sicyonia brevirostris*) harvested by commercial vessels is the only one of six species of *Sicyonia* reported for the south Atlantic coast that attains a commercial size (Keiser 1976). When the rock shrimp industry began, few vessels participated on a full-time basis with some vessels making a few trips a year when the white and brown shrimping ended, or as a bycatch of the penaeid shrimp fishery (Dennis 1992). During the period 1986 to 1994 there was an increase in effort in terms of the number of vessels participating (SAFMC 1996a).

Rock shrimp have been harvested along Florida's east coast and at one time, this fishery extended into south Georgia (statements at Public hearings for Shrimp Amendment 5). The increase in participants and market opportunities for smaller rock shrimp brought about a subsequent change in harvesting patterns as vessels began fishing as far south as St. Lucie County. This shift in effort to the south reflected new participation in the fishery as the majority of those harvesting these new areas were from the Gulf region. A control date for this fishery of April 4, 1994 was set to put the industry on notice that the Council could at some future date develop a limited access program for this fishery (SAFMC 1996a).

Amendment 1 to the Shrimp Plan established a requirement for vessel permits and dealer permits, and prohibited trawling for rock shrimp in an area off of Florida. These measures were published in the Federal Register on September 9, 1996.

Season
The peak rock shrimping season generally occurs from July through October (SAFMC 2002). Historically, the fishery did not begin until August or September (SAFMC 1996a). To a degree, the amount and timing of effort in the rock shrimp fishery are dependent on the success of the white and brown shrimp fisheries.

Harvest Area Information
During development of Shrimp Amendment 1, the Rock Shrimp Producers Association submitted information to the Council indicating that the harvest area extended between just north of New Smyrna Beach to Stuart between 36.6 m (120 ft) and 47.5 m (156 feet) and between 61 m (200 ft) and 73 m (240 feet) (SAFMC, 1996a). The fishable grounds are hard sand to shell hash bottoms, which run north and south with a width as narrow as one mile. There was an effort shift to the south of Cape Canaveral which exposed the known concentrations of *Oculina* coral and the *Oculina* Bank HAPC to bottom trawls. Trawling was prohibited in the HAPC (a 4 x 23 nm strip bounded by latitude 27°30' N and 27°53' N and longitude 79°56' W and 80°00' W) in 1982 as one of the measures under the Coral Fishery Management Plan (GMFMC and SAFMC 1982). In addition, Amendment 1 to the Snapper Grouper Fishery Management Plan prohibited the retention of snapper grouper species caught by roller rig trawls and their use on live/hard bottom habitat north of 28° 35' N latitude (SAFMC 1988). Furthermore Amendment 1 to the Shrimp Plan (SAFMC, 1996a) prohibited trawling in the area east of 80° 00' W longitude

between 27° 30' N latitude and 28° 30' N latitude shoreward of the 183 m (600 ft) contour.

In recent years, fishing activity has been concentrated off the Atlantic coast of Florida and particularly near Cape Canaveral (Sea Grant Louisiana 2006; SAFMC 1999). Some sources describe the coast between Jacksonville and St. Lucie Inlet as being of particular importance (Hill 2005b in Oceana 2007).

Trawl Vessels

There are two types of vessels in the rock shrimp fishery: ice or fresh boats and freezer boats. Most new rock shrimp trawlers are 75-80 feet in length and are rigged to tow two to four nets simultaneously. The double-rigged shrimp trawler has two outrigger booms from whose ends the cable from the winch drum is run through a block to the two nets (Figure 5.2.2-1). Testimony at Amendment 1 hearings indicated that a standard freezer trawler was around 73 feet and would pull four forty-foot nets.

Essentially the only gear used in the rock shrimp fishery is the trawl which consists of: (1) a cone-shaped bag in which the shrimp are gathered into the tail or cod end; (2) wings on each side of the net for herding shrimp into the bag; (3) trawl doors at the extreme end of each wing for holding the wings apart and holding the mouth of the net open; and (4) two lines attached to the trawl doors and fastened to the vessel. A ground line extends from door to door on the bottom of the wings and mouth of the net while a float line is similarly extended at the top of the wings and mouth of the net. A flat net is more often used when fishing for rock shrimp since they burrow into the bottom to escape the trawl. This net has a wider horizontal spread than other designs and is believed more effective (SAFMC 1996a).

Some vessels use twin trawls, which are essentially two trawls on a single set of doors, joined together at the head and foot ropes to a neutral door connected to a third bridle leg. Thus, instead of towing two seventy-foot nets the vessel tows four forty-foot nets. This rig has some advantages in ease of handling and increased efficiency. At the time Amendment 1 was developed industry advisors indicated that the cod end mesh size commonly used in the industry was between 1 7/8 and 2 inches stretched mesh measured on the diagonal (SAFMC 1996a).

The tow length varies depending on many factors including the concentration of shrimp. Large boats fishing offshore waters make much longer drags lasting several hours. Testimony at public hearings for Shrimp Amendment 1 indicated that vessels may drag up to 30 to 35 miles over a number of tows in one night fishing for rock shrimp (SAFMC 1996a).

5.2.1.2 Economic description of the shrimp fishery

This section describes the economic environment of the South Atlantic rock and penaeid shrimp fisheries. The section is primarily divided into three sub-sections. First, these fisheries are described generally where information is presented at a highly aggregated level. This information provides a larger context to the more detailed and disaggregated information that follows. In the second sub-section, the federal permit requirements that affect participants in these fisheries are described. This information is critical as it determines which entities are likely to be impacted by the management actions considered in this Amendment, and thereby in turn determines what information is necessary to determine the impacts of the actions and the alternatives being considered under each. A detailed description of the entities potentially impacted by the actions in this Amendment is presented in the third sub-section. This final sub-section is further broken down into descriptions of the harvesting (i.e., vessels), dealer/wholesaler, and processing sectors of the industry, respectively. The greatest level of attention and detail is given to the harvesting sector, and particularly the harvesting sector of the rock shrimp fishery since the actions considered in this Amendment primarily deal with this group of entities. For this group of vessels, additional descriptive information is provided based on the current status of their permits as well as their recent operational characteristics (for example, whether or not the vessel has been commercially active in general and specifically within the South Atlantic rock shrimp fishery). Such information is needed to identify the specific vessels that will be potentially impacted by the actions considered in this Amendment, as well as the nature and magnitude of those impacts.

5.2.1.2.1 General Description of and Recent Trends in the South Atlantic Rock and Penaeid Shrimp Fisheries

As Amendments 1 (SAFMC 1996a), 5 (SAFMC 2002), and 6 (SAFMC 2004) to the South Atlantic Shrimp Fisheries Management Plan (FMP) describe in detail, the South Atlantic rock shrimp fishery is quite volatile, demonstrating significant ups and downs in terms of landings, revenues, and vessel participation from one year to the next. These Amendments describe the nature of the fishery from its inception through 2002. Amendment 6 also provides considerable information on the nature and history of the South Atlantic penaeid shrimp fishery. The information from those Amendments is incorporated herein by reference. The purpose of the information provided in this section is to update this historical information and specifically focus on the years 2003 through 2006, though information specific to the rock shrimp fishery and its participants has been updated through 2007. *However, all landings-related information for 2007 should be considered preliminary.* These years were selected since data on earlier years has been provided in previous Amendments. The provisions in Amendment 5 became effective in 2003, particularly the limited access endorsement program for the rock shrimp fishery, and 2006 is the most recent year for which complete landings data are available for the penaeid shrimp fishery. However, given the nature of certain regulations governing the limited access component of the rock shrimp fishery, landings data through 2007 for this component of the fishery and its participants are needed to properly assess the impacts of the actions under consideration in this Amendment.

Landings data can be analyzed from different perspectives. For example, it is common for landings to be compiled according to the port or state of landing. This is in fact how commercial fisheries landings data are commonly reported on the NOAA Fisheries Service website. Information at this level is important when there is a need to address the importance of a particular species or group of species to a specific port, community, or state. Table 5.2.1-1 reports all shrimp (penaeid, shrimp, and other minor shrimp species) landings and revenues during the years 2003 through 2006 in the South Atlantic States (i.e., North Carolina, South Carolina, Georgia, and the east coast of Florida, not including Monroe County). These landings may come from both South Atlantic and non-South Atlantic waters (e.g., Gulf of Mexico waters). Landings data of this nature are used to assess trends in the fishery as a whole over recent years.

According to this information, total shrimp landings in the South Atlantic were fairly stable in 2003 and 2004, and in fact nearly identical to reported landings in 2001 and 2002. However, the data also indicate that the decline in shrimp prices that began and was most significant in 2001 continued during 2003 and 2004. Between 2001 and 2004, the aggregate price of shrimp in the South Atlantic declined by approximately one-third in nominal terms. In real terms (i.e., after accounting for inflation), the decline was even greater. And although prices apparently increased slightly in 2005, landings decreased precipitously, specifically by nearly 40%. In fact, landings and revenues in the South Atlantic shrimp fishery in 2005 were at their lowest level since 1978, nearly three decades ago. Although landings recovered somewhat in 2006, close to the levels seen in 2001-2004, prices fell again to approximately the same level experienced in 2003 and were thus very low by historical standards. However, preliminary landings data for 2007 suggest that, while production in 2007 may still be approximately the same as in 2006, and thus low by historical standards, prices may have increased back to a level comparable to those seen in 2001, which would represent an increase of nearly 20% over 2006 prices.

Considerable caution must be used in the use and interpretation of aggregate shrimp prices such as those reported in Table 5.2.1-1. Such prices do not take into account variations in the size composition of the landings and it is well established that larger shrimp command higher market prices, even though the magnitude of the price premium attached to larger shrimp has shrunk considerably in the past several years. So, for example, the aggregate price of shrimp could increase from one year to the next, not necessarily because the price of shrimp has increased, but simply because larger size shrimp have made up a larger proportion of the total landings. A complete analysis of trends in South Atlantic shrimp prices by standardized size counts/categories has not yet been conducted in part because such data have not been consistently collected in all States over the past several years.[1]

---

[1] Florida's trip ticket data is the primary source of the problem, where it has not been uncommon for dealers to report their shrimp size data in terms such as "small," "medium," "large," and "jumbo." There is no known method to convert such categories into standard size count categories, in part because it is highly unlikely that a common interpretation of these terms is being applied across all reporting dealers. However, it should be duly noted that the shrimp size count information in Florida's trip ticket data has improved and become more consistent in 2006 and 2007, and thus an attempt to re-analyze all of the South Atlantic shrimp price data will be attempted in the near future.

Table 5.2.1-1. Shrimp Landings and Revenue in South Atlantic states, 2003-2006 (Personal communication from the National Marine Fisheries Service, Fisheries Statistics Division, Silver Spring, MD).

Year	Landings (Heads-on pounds)	Revenue (Nominal)	Average Price per Pound
2003	24,011,340	$41,175,716	$1.71
2004	25,990,290	$42,757,771	$1.65
2005	15,747,918	$29,391,036	$1.87
2006	21,724,377	$37,740,648	$1.74

However, such an analysis can and has been conducted for shrimp prices in the Gulf. For the most part, the price trends in the South Atlantic data are comparable to those found in the Gulf. For example, as in the South Atlantic, the decline in shrimp prices began in 2001 and generally continued through most of 2004. However, the largest price decline took place in 2002 as opposed to 2001. Further, Gulf shrimp prices began to increase in the latter part of 2004 and this increase continued through much of 2005. However, Gulf shrimp prices began to decline in the last quarter of 2005 after Hurricanes Katrina and Rita and this decline continued through 2006. In fact, Gulf shrimp prices in 2006 reached their lowest levels in decades, somewhat contrary to what is suggested by the aggregate South Atlantic shrimp data, which suggests the low point was experienced in 2004. Furthermore, Gulf shrimp prices appear to have declined much more between 2001 and 2006, by approximately 50%, compared to prices in the South Atlantic. Similar to the preliminary South Atlantic data, preliminary data from the Gulf suggests that prices rose in 2007, particularly for the 30-count size and larger shrimp. However, the increase in the Gulf was only about 5%, and thus considerably less than what is suggested by the preliminary South Atlantic data.

Table 5.2.1-2 provides a breakdown of the South Atlantic shrimp landings data according to state of landing between 2003 and 2006. These data provide additional insight into how the fishery has changed in recent years, such as the fact that trends in production and prices have not been the same across all states. In 2003, production between the four states was relatively equal. However, since that time, east Florida has consistently been the dominant state of production in the fishery, and in fact almost equaled the production of the other three states combined in 2004. Production has consistently declined in each year in both Georgia and South Carolina. In North Carolina, production also decreased between 2003 and 2005, but then rebounded considerably in 2006, nearly back to the level experienced in 2003. Conversely, landings on the east coast of Florida have fluctuated considerably from year to year, increasing significantly in 2004, but falling even more precipitously in 2005, and then rebounding again in 2006. Thus, although the declines in South Carolina and Georgia have been steady during these years, the decline in North Carolina and particularly east Florida led to the nearly record low level of total production in 2005. Preliminary data for 2007 suggests that landings in South Carolina and particularly Georgia have continued to decline and landings in east Florida have continued their up and down pattern in recent years by falling below their 2006 level.

Conversely, the ability of the fishery as a whole to maintain its overall level of production from 2006 to 2007 appears to be due to a significant increase in landings in North Carolina, possibly back to levels experienced in 2000 and 2002. Thus, contrary to the past three years, North Carolina will be the primary leader in shrimp production for 2007. However, unlike in 2000 and 2002, the relatively high level of production in North Carolina during 2007 appears to be due to a significant increase in white shrimp landings, as opposed to the more historically predominant brown shrimp. Reasons for this somewhat surprising result are currently under investigation, as is its potential relationship to the historically low levels of pink shrimp production in that state.

Table 5.2.1-2. Shrimp Landings and Revenue in South Atlantic states, by state 2003-2006.
(Personal communication from the National Marine Fisheries Service, Fisheries Statistics Division, Silver Spring, MD).

Year	State	Landings (Heads-on pounds)	Revenue (Nominal)	Average Price per Pound
2003	Florida East	6,231,956	$11,832,752	$1.90
2004	Florida East	11,357,169	$15,955,615	$1.40
2005	Florida East	4,940,298	$10,038,438	$2.03
2006	Florida East	8,527,276	$15,115,434	$1.77
2003	Georgia	5,478,740	$9,676,197	$1.77
2004	Georgia	4,978,825	$9,954,480	$2.00
2005	Georgia	4,493,325	$8,371,931	$1.86
2006	Georgia	3,810,588	$7,002,796	$1.84
2003	North Carolina	6,167,393	$10,930,644	$1.77
2004	North Carolina	4,880,849	$9,462,867	$1.94
2005	North Carolina	2,357,536	$4,409,143	$1.87
2006	North Carolina	5,736,664	$9,141,456	$1.59
2003	South Carolina	6,133,251	$8,736,123	$1.42
2004	South Carolina	4,773,447	$7,384,809	$1.55
2005	South Carolina	3,956,759	$6,571,524	$1.66
2006	South Carolina	3,649,849	$6,480,962	$1.78

Somewhat surprisingly, the trends in prices are also slightly different across the four States. For example, the aggregate price of shrimp has steadily increased in South Carolina, which is inconsistent with other noted price trends. As noted earlier, this trend could be due to larger shrimp composing a larger proportion of the total shrimp landed in that state, though other factors could also be at play. And while prices increased in 2004 in not only South Carolina, but North Carolina and Georgia as well, prices decreased significantly in east Florida. This price decline is clearly driving the price decrease in that year for the fishery as a whole. As discussed later, the price decline in east Florida was driven by a decline in the price of pink shrimp specifically. And while shrimp prices in east Florida rebounded significantly in 2005, they decreased slightly in Georgia and North Carolina. With the exception of South Carolina, shrimp prices decreased in all other states in 2006. Preliminary data suggest that prices increased in 2007 across all states.

Table 5.2.1-3 provides a breakdown of the South Atlantic shrimp landings according to species, excluding rock shrimp which are examined separately, between 2003 and 2006. So-called "marine" shrimp is a conglomerate of landings where the species of shrimp landed is not identified by the reporting dealer or it is a mix of species (i.e., in effect, the species is unknown). Therefore, interpretations of that set of data would not be particularly useful. And though consistently present, royal red shrimp are a minor species within the overall fishery. As has generally been the case in recent history, white shrimp has been the primary species of harvest between 2003 and 2006. Preliminary data suggest that its predominance in the total landings will be even greater in 2007, though from the state of North Carolina rather than South Carolina and Georgia, as has usually been the case in the past. Primarily due to production in east Florida, pink shrimp landings have been relatively stable during this time period, though increased somewhat significantly in 2006. However, preliminary data suggest a steep decline in pink shrimp production in 2007. Though brown shrimp landings were relatively close to white shrimp landings in 2003, they have fallen dramatically over the past four years, with much of that decline occurring in 2004. In fact, brown shrimp production in 2006 was less than one-third of its level in 2003. Preliminary data suggest that landings may have rebounded somewhat in 2007.

Table 5.2.1-3. Shrimp landings and revenue in South Atlantic states by species, 2003-2006.
(Personal communication from the National Marine Fisheries Service, Fisheries Statistics Division, Silver Spring, MD).

Year	Species	Landings (Heads-on pounds)	Revenue (Nominal)	Average Price per Pound
2003	SHRIMP, BROWN	9,478,261	$14,339,865	$1.51
2004	SHRIMP, BROWN	5,415,156	$9,227,991	$1.70
2005	SHRIMP, BROWN	4,436,744	$7,244,469	$1.63
2006	SHRIMP, BROWN	3,046,798	$5,010,256	$1.64
2003	SHRIMP, MARINE	30,998	$79,650	$2.57
2004	SHRIMP, MARINE	86,925	$219,768	$2.53
2005	SHRIMP, MARINE	348,506	$634,513	$1.82
2006	SHRIMP, MARINE	266,067	$408,815	$1.54
2003	SHRIMP, PINK	443,019	$940,413	$2.12
2004	SHRIMP, PINK	648,730	$1,028,943	$1.59
2005	SHRIMP, PINK	484,567	$560,176	$1.16
2006	SHRIMP, PINK	927,521	$907,585	$0.98
2003	SHRIMP, ROYAL RED	270,605	$410,747	$1.52
2004	SHRIMP, ROYAL RED	69,466	$139,168	$2.00
2005	SHRIMP, ROYAL RED	126,982	$211,752	$1.67
2006	SHRIMP, ROYAL RED	148,979	$282,271	$1.89
2003	SHRIMP, WHITE	11,032,356	$21,259,090	$1.93
2004	SHRIMP, WHITE	13,814,718	$27,725,627	$2.01
2005	SHRIMP, WHITE	10,223,292	$20,616,288	$2.02
2006	SHRIMP, WHITE	14,383,934	$26,960,659	$1.87

The prices of the primary species (white and brown) tended to move in the same direction between 2003 and 2006. For example, the prices of both white and brown shrimp increased slightly between 2003 and 2004, were relatively stable in 2005, while both fell in 2006. Conversely, the price of pink shrimp fell dramatically, by over 50%, between 2003 and 2006. This decline is more precipitous than trends in other shrimp price data during this time, and thus some of the decline may be due to changes in the size composition of pink shrimp landings (i.e., smaller shrimp may be making up a larger proportion of the landings in more recent years). Further research and improvements in size data are needed to test this hypothesis.

Since rock shrimp are the primary species of interest with respect to actions under consideration within this Amendment, landings and revenue information for this species is presented separately. In Table 5.2.1-4, similar to information in Table 5.2.1-4, data regarding rock shrimp landings and revenues in the South Atlantic states are presented, though preliminary data for 2007 is also included. However, from a management perspective, the landings of greatest interest are those coming from a particular body of water (e.g., South Atlantic waters under the Council's jurisdiction) or a particular group of vessels (e.g., vessels that possess a particular type of permit or endorsement issued under one of the Council's FMPs). Thus, in the current case, it is more appropriate to examine rock shrimp landings harvested from South Atlantic waters and rock shrimp landings by vessels with South Atlantic limited access rock shrimp endorsements. The former is presented in Table 5.2.1-5 for the years 2003 through 2007. These data and subsequently discussed landings and revenue information represent a compilation of Florida trip ticket data, Gulf shrimp landings data, other South Atlantic states' trip ticket data and Standard Atlantic Fisheries Information Systems (SAFIS) data, the latter two of which are maintained by the Atlantic Coastal Cooperative Statistics Program (ACCSP)[2].

Table 5.2.1-4. Rock shrimp landings and revenue in South Atlantic states, 2003-2007. (Personal communication from the National Marine Fisheries Service, Fisheries Statistics Division, Silver Spring, MD and Southeast Fisheries Science Center, Fisheries Statistics Division Miami, FL).

Year	Landings (Heads-on pounds)	Revenue (Nominal)[3]
2003	2,756,101	$4,145,951
2004	5,955,295	$4,416,274
2005	127,827	$123,838
2006	2,951,078	$4,171,062
2007*	233,712	$434,938

*2007 data are preliminary

[2] 2007 trip ticket data for South Carolina and North Carolina was provided by the North Carolina Department of Environment and Natural Resources and the South Carolina Department of Natural Resources respectively.
[3] Nominal values are those that have not been adjusted for inflation.

Table 5.2.1-5. South Atlantic rock shrimp landings, revenue, and participation, 2003-2007.[4]

Year	Number of Harvesting Vessels	Landings (Heads-on pounds)	Revenue (Nominal)	Average Price per Pound	Average Landings per Vessel	Average Revenue per Vessel	Number of Trips	Average Landings per Trip	Average Revenue per Trip
2003	97	2,980,623	$4,489,905	$1.51	30,728	$46,288	360	8,280	$12,472
2004	85	6,591,583	$5,012,147	$0.76	77,548	$58,966	300	21,972	$16,707
2005	21	109,281	$99,611	$0.91	5,204	$4,743	29	3,768	$3,435
2006	44	3,018,322	$4,264,576	$1.41	68,598	$96,922	142	21,256	$30,032
2007*	26	240,550	$441,277	$1.83	9,252	$16,972	78	3,084	$5,657

*2007 data are preliminary

The information in Tables 5.2.1-4 and 5.2.1-5 illustrate that the South Atlantic rock shrimp fishery has continued its historically cyclical nature in recent years. Recall that landings in 2002 were at their lowest level in over two decades (i.e., since 1980). In 2003, landings increased significantly, comparable to landings seen between 1997 and 1999. And in 2004, landings increased further, back to levels similar to those experienced in 2000 and 2001 even though the number of participating vessels decreased from 97 to 85 vessels. However, in 2005, landings plunged to their lowest level since South Atlantic rock shrimp landings were first tracked back in 1978 and the number of participating vessels similarly plunged to only 21 vessels. And although landings, revenues, and even prices rebounded in 2006, vessel participation in 2006 (44 vessels) was considerably less than in 2003 or during the previous decade. The fact that landings and revenues per trip and per vessel were relatively high in 2006, even compared to previous "good years," suggests that factors outside the fishery played a role in limiting participation. In 2007, production and the number of harvesting vessels fell back to levels just slightly above their historic lows in 2005. Using the MSY/OY figure of approximately 4.912 million pounds for this fishery as a reference point, landings were above this reference point in 2004, below it in 2003 and 2006, and significantly below this value in 2005 and 2007.

Thus, it would appear that the fishery's cyclical nature has intensified in the past four years. It is highly likely that the instability of various economic factors has exacerbated the fishery's biological volatility. Although a definitive explanation cannot be provided at this time, it is likely that the extremely low level of landings in 2005 were not only a function of biological factors (e.g., relatively low abundance), but also economic factors (e.g., historically low rock shrimp prices, particularly relative to other potential target species, and high fuel prices, given that rock shrimp are harvested in more distant waters relative to penaeid species) and possibly natural disasters (e.g., the impact of Hurricane Katrina on vessels from ports in the Gulf of Mexico, particularly in Alabama). For example, rock shrimp prices fell dramatically in 2004, by 50%, relative to 2003. Rock shrimp prices basically remained at this historically low level in 2005, likely

[4] With the exception of 150lbs in 2003 and 22lbs in 2004, all reported landings of rock shrimp from South Atlantic waters could be ascribed to a specific vessel, which reflects a marked improvement in the quality of the data in this respect since the analysis for Amendment 5 was conducted.

discouraging potential participants from engaging in the fishery. And although the number of trips is only a very rough estimate of effort, and thus landings per trip is similarly only a rough estimate of abundance, landings per trip was also very low in 2005 and similarly provided a significant disincentive for other vessels to prosecute the fishery that year. And though rock shrimp prices were considerably higher in 2007 than in 2005, so too were fuel prices. In a distant water fishery such as rock shrimp, the higher fuel expenses likely offset any incentive to participate in the fishery generated by the higher price for rock shrimp. And, as in 2005, the landings per trip were very low, and in fact slightly lower than in 2005. The combination of these two factors likely explains the low level of production in 2007.

Except in 2005, the landings and revenue figures in Table 5.2.1-5 are slightly larger than those in Table 5.2.1-4, which would indicate that some of the rock shrimp harvested from South Atlantic waters are being landed in Gulf of Mexico ports. Information in Amendment 5 (SAFMC 2002) suggests that participation in the fishery by vessels with homeports in the Gulf of Mexico increased during the 1990s through at least 2000. In combination with data from the NOAA Fisheries Service website, information in Amendment 5 also suggests that the "leakage" of rock shrimp landings from South Atlantic waters to Gulf ports was considerably larger in previous years, particularly in 1999 and 2000, relative to the 2003-2007 time period. And though the subject requires more research, it appears likely that market forces, particularly fuel prices, have caused it to be far less economically viable in recent years for vessels to harvest rock shrimp from South Atlantic waters, particularly off the east coast of Florida, and then transport and land them in Gulf ports, with the exception of Key West, which basically serves as a "dividing point" between South Atlantic and Gulf waters and, to a lesser extent, the Ft. Myers/Ft. Myers Beach area.

5.2.1.2.2 Federal Permit Requirements in the South Atlantic Rock and Penaeid Shrimp Fisheries

Federal permit requirements in the South Atlantic rock shrimp fishery were initially implemented under Amendment 1 to the South Atlantic Shrimp FMP (SAFMC 1996a). Specifically, the regulations that implemented Amendment 1 state that "for a person aboard a vessel to fish for rock shrimp in the South Atlantic EEZ or possess rock shrimp in or from the South Atlantic EEZ, a commercial vessel permit for rock shrimp must be issued to the vessel and must be on board." Since available information suggests that the rock shrimp fishery in the South Atlantic is prosecuted exclusively within federal waters, this requirement implies that rock shrimp in the South Atlantic can only be harvested by vessels with a federal South Atlantic rock shrimp permit. At the time of its implementation, and currently, this permit is "open access" in nature. That is, the Council did not impose any restrictions on the number of permits that could be issued or the nature of the vessels to which the permits could be issued. Therefore, in effect, a permit would basically be issued to any vessel whose owner applied for one. Amendment 1 also required permits for rock shrimp dealers. Specifically, the regulations indicate that "for a dealer to receive rock shrimp harvested from the South Atlantic EEZ, a dealer permit for rock shrimp must be issued to the dealer." Both the vessel and dealer permit requirements went into effect in November 1996. The dealer permit requirement has remained unchanged and is still in effect at this time, the importance of which is discussed under the description of the dealer/wholesaler sector in the South Atlantic rock shrimp fishery.

As has often been the case in open access fisheries, the number of open access rock shrimp permits exceeded expectations within a few years following the implementation of the vessel permit requirement. Participation in the fishery increased as did potential and expected participation in the future. As noted in Amendment 5 (SAFMC 2002), although the maximum number of active vessels (i.e., vessels with landings in a particular year) reached an apex of approximately 153 vessels in 1996, the number of permits and thus potential participants commonly averaged around 400 vessels in the late 1990s and 2000. As such, considerable concern existed with respect to "latent capacity" in the fishery and its ability to expand effort to levels that would be both biologically and economically unsustainable. The Council determined that the fishery could only sustain, biologically and economically, a maximum of 150 vessels. As a result of this determination, a limited access program was implemented under Amendment 5 for that portion of the fishery in the EEZ off of east Florida and Georgia, an area which covers the fishery's primary fishing grounds (i.e., the majority of the landings come from this area).

Amendment 5 consistently discusses the implementation of a limited access "permit," which indicates that the Council intended to implement a new "stand-alone" permit for the harvest of rock shrimp in the EZZ off of east Florida and Georgia. However, the implementing regulations state that "effective July 15, 2003, for a person aboard a vessel to fish for rock shrimp in the South Atlantic EEZ off Georgia or off Florida or possess rock shrimp in or from the South Atlantic EEZ off Georgia or off Florida, a limited access endorsement for South Atlantic rock shrimp must be issued to the vessel and must be on board" (emphasis added). This distinction has apparently been the source of some confusion for certain fishery participants and in fact is the reason for one of the actions under consideration within this Amendment. The issue may sound like mere semantics; however, the distinction is important for the following reason. First, it must be kept in mind that the new requirement did not replace the existing requirement for vessels harvesting South Atlantic rock shrimp to possess an open access permit. Second, an endorsement is basically an instrument that is "attached" to a permit. That is, in order to have the endorsement, a vessel must have the permit as well since the endorsement is "attached" to the permit. In this case, that permit would be the originally required open access permit. Thus, vessels harvesting rock shrimp from federal waters off of east Florida and Georgia must have both the limited access endorsement and the open access permit. The former cannot be issued or legally used for harvesting purposes without the latter. Similarly, possession of only the open access permit does not allow for the legal harvest of rock shrimp from the EEZ off of east Florida or Georgia. However, the open access permit requirement still applies to vessels that harvest rock shrimp from federal waters off of North and South Carolina.

Another important aspect of the rock shrimp limited access endorsement is that vessel owners must regularly renew their endorsements in order for the endorsements to be considered “active.” A vessel’s endorsement must be active in order for it to be used for harvesting purposes or to be transferred to another vessel. The latter point is important since these endorsements are fully transferable. The issue of transferability is important for other reasons discussed later in this section. Specifically, the regulations state that “the Regional Administrator (RA) will not reissue a limited access endorsement for South Atlantic rock shrimp if the endorsement is revoked or if the RA does not receive a complete application for renewal of the endorsement within 1 year after the endorsement’s expiration date.” Thus, after an endorsement’s expiration date, the endorsement can still be renewed for up to one year after that date. During this time, the endorsement is considered to be “renewable,” though it cannot be transferred nor is it legal for the vessel with the endorsement to harvest rock shrimp from federal waters off of east Florida or Georgia. If an endorsement has not been renewed by the end of the one-year time period after the expiration date, the endorsement will be “terminated.” A terminated endorsement is “non-renewable” and non-transferable and thus, in effect, is permanently retired from the fishery. Thus, the terms “terminated” and “non-renewable” are synonymous and may be used interchangeably. Though the open access permits must also be active in order for vessels to legally harvest rock shrimp from federal waters off of North and South Carolina, and can expire, no limitation exists with respect to when they can be renewed or obtained and thus they are never “terminated” per se. By definition, since they are open access permits, any vessel owner can obtain a permit at any time.

In addition to the creation of the limited access program, the Council also wanted to ensure that, after the program’s implementation, the fishery remained economically viable, benefits of the program accrued to “serious” participants in the fishery, and the issue of latent permits/capacity did not resurface. At the time the Council deliberated over the actions in Amendment 5, the rock shrimp fishery was still relatively healthy from an economic perspective and that many owners of non-qualifying vessels wanted to participate in the fishery. As such, the Amendment also included a “use it or lose it” requirement. Specifically, vessels with endorsements would have to harvest at least 15,000 pounds of South Atlantic rock shrimp in at least one out of every four calendar year time period. The Council concluded this provision was necessary to ensure a more stable supply of rock shrimp for consumers, but also believed that the poundage level was sufficiently low and the period of time sufficiently long to allow vessels to participate in other fisheries that may be economically preferable in the short-term without forcing them to forego such opportunities simply to maintain their endorsement and for vessel owners to replace lost or retired vessels.

Specifically, the implementing regulations state that “a limited access endorsement for South Atlantic rock shrimp that is inactive for a period of four consecutive calendar years will not be renewed. For the purpose of this paragraph, ‘inactive’ means that the vessel with the endorsement has not landed at least 15,000 lbs. (6,804 kg) of rock shrimp from the South Atlantic EEZ in a calendar year.” Although the regulations refer to an “inactive” endorsement and the Amendment refers to an “inactive” permit, that terminology is not carried forward throughout the remainder of this section or in the impacts analysis as it would likely only create additional confusion in conjunction with the terminology used by the Southeast Region's Permits Office as discussed above. Rather, the analysis will simply discuss whether a vessel has met this requirement or any other landings requirement that the Council may be considering and the likely impacts of such.

The combination of the landings requirement, the effective date of the limited access endorsement, and the fully transferable nature of the endorsements has created some additional issues. At the time Amendment 5 was implemented, analyses indicated that approximately 168 vessels were expected to qualify for South Atlantic limited access rock shrimp endorsements. However, after all appeals were heard and determinations were made by NOAA Fisheries Service, South Atlantic limited access rock shrimp endorsements were in fact issued to 155 vessels, thus effectively capping participation in the fishery at this level. Recalling that the Council believed that the fishery could support no more than 150 active vessels, the implementation of the Amendment led to a fishery with almost exactly the desired number of vessels. Thus, it would be logical to conclude that the Council would not consider additional, significant vessel/endorsement attrition from the fishery to be desirable. As previously noted, these endorsements are fully transferable, meaning that they can be transferred to another owner of that vessel, another vessel owned by the same owner, or an entirely different vessel and owner. As a result, the universe of vessels holding these endorsements has changed over time. In turn, when a vessel initially obtained its endorsement, and thus the period of time each vessel with a current endorsement has held that endorsement, differs across vessels. This fact is critical with respect to the current 15,000-pound landings requirement.

Specifically, for vessels that initially received their endorsements in 2003, given that the requirement to possess the endorsements in order to operate in the fishery was not effective until July 15, 2003, NOAA Fisheries Service made an internal policy decision, reflected in a Fishery Bulletin sent to all endorsement holders in September 2003, to not start the four year "clock" with respect to vessels attaining the minimum landings requirement until January 1, 2004. In general, this adjustment would be expected to work to the benefit of the initial endorsement recipients since they would not be forced to count the last 5½ months of 2003 (i.e., a partial calendar year) as one of their "calendar years." Thus, vessels initially obtaining their endorsements in 2003 would have calendar years 2004 through 2007 to meet the 15,000-pound landings requirement in a single calendar year. On the other hand, this decision would presumably not preclude a vessel owner from counting landings from 2003 towards meeting the requirement, at least with respect to whether the requirement was met during the 2003-2006 time period. However, even if the vessel did meet the requirement in 2003, but did not in any subsequent year through 2007, then it would not have met the requirement for the four-year time period running from 2004 through 2007 and thus would lose its endorsement under the current regulations. The primary point is that, although a vessel may meet this requirement in its first four-year cycle, the four-year time period is recurring from year to year and the requirement must be met in every four-year time period. In a fishery experiencing an economic downturn, the impact of this requirement on fleet size could be dramatic over several years.

However, NOAA General Counsel has determined that the regulations allow for each vessel's four year "clock" to start at the time it initially obtained the endorsement, as opposed to when the endorsement was first issued to its initial recipient. Thus, all current vessels with endorsements are not operating on the same "clock." As such, the four-year time period in which a vessel must meet the landings requirement depends on the year the vessel initially obtained its endorsement. To be consistent with the previously noted policy decision in which the four-year timeframe for vessels obtaining their endorsements in 2003 was not started until January 1, 2004, it is assumed that the same logic would be applied to vessels obtaining their endorsements in subsequent years. For example, if a vessel initially obtained its endorsement in August 2005, then its four year clock for meeting the landings requirement need not begin until January 1, 2006, and thus this vessel would have calendar years 2006 through 2009 to meet the current landings requirement. However, since the regulations do not explicitly preclude a vessel owner from doing so, it is assumed that, if it is to the vessel owner's advantage, the year in which the endorsement was initially obtained can be counted as one of the four years within which the 15,000-pound landings requirement must be met.

Finally, the Council required federal permits for trawler vessels harvesting penaeid shrimp from federal waters in the South Atlantic under Amendment 6 (SAFMC 2004). Specifically, the regulations state "for a person aboard a trawler to fish for penaeid shrimp in the South Atlantic EEZ or possess penaeid shrimp in or from the South Atlantic EEZ, a valid commercial vessel permit for South Atlantic penaeid shrimp must have been issued to the vessel and must be on board." This requirement became effective in April 2006 and therefore has only been in effect for approximately two years. These permits are "open access" in nature and thus any vessel owner can obtain one at any time and there are no restrictions with respect to how many can be issued. Thus, like the open access rock shrimp permit, these permits can expire, but they can be renewed or a new one obtained at any time and never "terminate." It is worth noting that, at this time, no federal dealer permit requirement exists for the South Atlantic penaeid shrimp fishery.

5.2.1.2.3 Number of Federal Permits

The following is an analysis of data pertaining to the previously discussed permits and endorsements from both the current Permit Information Management System (PIMS) and historical Rbase permits databases. With respect to the open access rock shrimp and penaeid shrimp permits, these data were valid and accurate as of March 31, 2008, while data pertaining to the limited access rock shrimp endorsements were valid and accurate as of April 1, 2008. The two different dates were selected to provide the most useful and accurate information possible. Specifically, permits always expire at the end of a particular month. And thus, the number of permits always decreases, particularly open access permits, on the first day of each month. Since vessel owners tend to renew their permits as the month progresses, the number of permits returns to its typical level at the end of each month. Thus, the number of open access permits at the end of the most recent month was used to ensure that they would not be systematically underestimated. Similarly, the status of the limited access rock shrimp endorsements typically changes on the first of each month and the endorsements' status is critical to the impacts analysis.

Thus, the decision was made to use the most current information possible with respect to the status of these endorsements in terms of how many are active, renewable, or terminated/nonrenewable.

Based on the available data, it was determined that there are 266 open access rock shrimp (RS) permits, 620 penaeid shrimp permits (SPA) and, as already noted, 155 limited access rock shrimp endorsements (RSE). The distribution of these permits across communities is presented in the description of fishing communities. The number of permits cannot simply be summed in order to determine the number of vessels possessing such permits/endorsements because many vessels possess two or all three of these permits/endorsements. The total number of vessels that possess one or more of these permits/endorsements is 694 and thus this is the maximum number of vessels that could be potentially impacted by the actions considered in this Amendment. For reasons explained later, it is also important to note that, of these 694 vessels, approximately 293 also possess Gulf shrimp moratorium permits and therefore only about 400 of these vessels are "unique" to the South Atlantic shrimp fisheries.

Of course, all vessels with active RSEs also possess open access RS permits. And it would be expected that the vast majority of vessels with active or renewable RSEs would also have an SPA permit since it is common for penaeid shrimp to be incidentally harvested on trips that primarily target rock shrimp. Conversely, for vessels that do not have an active or renewable RSE, a minority probably possess an RS permit only since rock shrimp are rarely harvested on penaeid shrimp trips in federal waters off of North and South Carolina. However, few vessels that possess an RS permit but not an RSE would likely not have an SPA permit since it would be nearly impossible for a vessel to only harvest rock shrimp in federal waters off of North and South Carolina without also harvesting penaeid shrimp. The data support these hypotheses. Specifically, of the 155 vessels with RSEs, 104 also possess an SPA. Of the 516 vessels that possess an SPA but not an RSE, only 121 possess an RS permit. Of the 620 vessels with an SPA permit, only 223 have an RS permit. And of the 266 vessels with RS permits, 223 also possess a SPA.

Table 5.2.1-6 presents information regarding the number of RSEs that are currently active, renewable, and terminated. This table will be referenced frequently given that it contains considerable information critical to the impacts analysis. Based on the information in columns 3 and 4, of the 155 RSEs that have been issued, 105 are active, 20 are renewable (i.e., 125 are active or renewable), and 30 have been terminated. Thus, at this time and unless the Council takes additional action to alter the status of some or all of the terminated RSEs, the maximum number of vessels allowed to operate in the limited access component of the fishery (i.e., the "cap") has already been reduced from 155 to 125 vessels. This change represents a nearly 20% reduction in the maximum fleet size, and this maximum fleet size is approximately 17% below the Council's desired fleet size. And if the vessels currently possessing renewable RSEs do not renew them in a timely manner, the maximum fleet size could further decrease.

One other piece of information is important with respect to the limited access endorsements. In the preliminary analysis that was conducted for this Amendment, it was estimated that the market value of these endorsements was approximately $10,000. However, this estimate was based only on information during the first two years of the limited access program. Since that time, data indicate that the market value of these endorsements has been steadily declining. Given the economic downturn in the rock and penaeid shrimp fisheries, such a result is to be expected since the market value of the endorsements should reflect industry participants' expectations of future profitability in the industry. As fishery participants' expectations become more pessimistic (i.e., expected profitability declines), the market value of the endorsements will decrease. Over the past five years, the average selling price of these endorsements has fallen to $5,000, and in fact this was the highest selling price of an endorsement over the past year. Thus, the market value of these endorsements is estimated to be $5,000, and that may be an overestimate.

Finally, with respect to rock shrimp dealer permits, the number of permits at any given point in time has varied between 40 and 50 over the past five years. During calendar years 2006 and 2007, 46 different dealers possessed one of these permits at one point or another. And, as will be discussed in the next section, only a fraction of these dealers are typically involved in the fishery in any given year or even across a several year time period. However, contrary to vessels with permits and/or endorsements, none of the actions being considered in this Amendment would directly impact dealers with rock shrimp permits or directly alter the number of such permits that can be issued. The only dealers expected to be indirectly impacted by the actions in this Amendment are those that have been or are expected to participate in the fishery.

Table 5.2.1-6. Distribution of South Atlantic rock shrimp endorsements (RSE).

[5] The number of active endorsements and the number of renewable endorsements are the first and second numbers in the parenthetical respectively.

5.2.1.2.4 Description of harvesting sector, dealer sector, or processing sector.

This section provides a detailed description of the harvesting sector (i.e., vessels), dealer sector, or processing sector. Entities in the harvesting sector are characterized according to their landings activities and associated revenue across various fisheries during the 2003 through 2007 time period. These vessels are also described according to their physical and certain operational characteristics. Vessels are described in the aggregate according to the types of permits or endorsements they possess. However, these descriptions are broken down further according to the status of their endorsements (for vessels that possess RSEs), whether they were active in commercial fisheries, and specifically whether they were active in the South Atlantic rock shrimp fishery. Again, these breakdowns are necessary to more accurately assess the potential impacts of particular actions considered in this Amendment on particular groups or "types" of vessels.

Description of harvesting sector (i.e., vessels), dealer sector, or processing sector
Although vessels with RS and SPA permits will be briefly characterized in this section, the focus is on vessels with RSEs since the majority of the actions considered in this Amendment are likely to directly impact all or some of these vessels. In fact, these actions will likely determine the size, structure and composition of the South Atlantic rock shrimp fishery for years to come. Because of one particular action considered in this Amendment, all 694 vessels will be briefly examined as a single fleet.

<u>Vessels with Rock Shrimp Limited Access Endorsements and Commercially Active</u>
Because of the focus on vessels with RSEs, it is necessary to refer again to certain information contained in Table 5.2.1-6. First, as already indicated, the total number of vessels initially receiving limited access endorsements was 155, and this fact is reflected in the table. These 155 vessels represent the total universe of vessels considered throughout much of the impacts analysis. Some vessels have obtained their endorsements via transfers in the years after the initial endorsements were issued. So although many endorsements were initially obtained in 2003, others were not. Column 2 of Table 5.2.1-6 presents a breakdown of the number of vessels initially obtaining their endorsements in each year. Specifically, of the 155 current vessels with endorsements, 107 were initially obtained in 2003, while the other 48 were initially obtained in subsequent years (2004 through 2008). These 155 vessels can be partially characterized based on their physical and operational characteristics as well as their commercial harvesting activities in and outside of the South Atlantic rock shrimp fishery during the 2003 through 2007 time period, both across the entire time period and from year to year. In some cases, these characteristics remained fairly constant and thus changes from year to year are not examined. In other cases, the changes from year to year are significant and thus become the focus of the analysis.

Since it is possible that some actions may directly or indirectly affect all vessels with RSEs, the physical and operational characteristics of all vessels with RSEs are presented in Tables 5.2.1-7 and 5.2.1-8. These data indicate that this fleet, though having some heterogeneity, is fairly homogeneous (i.e., the means of these characteristics are fairly large relative to the standard deviations). The average or typical vessel in this fleet is approximately 20 years old, nearly 73 feet (22 m) in length, gross tonnage of 132 tons, with a fuel capacity of approximately 16,000 gallons and a hold capacity of more than 63,000 pounds of shrimp. The average vessel typically uses four nets of an average length between 55 and 60 feet (16.7-18 m), and uses between three and four crew on each trip. More than 90% of these vessels are "large" while less than 9% are "small." The vast majority (more than 87%) has on-board freezing capacity and more than two-thirds have steel hulls. The remaining vessels are nearly equally split between fiberglass and wood hulls.

It is also possible that only commercially active vessels (i.e., those with landings from a commercial fishery) may be impacted. Statistics regarding commercially active vessels are provided in Tables 5.2.1-9 through 5.2.1-12. Of the 155 vessels currently possessing RSEs, 145 were commercially active at some point between 2003 and 2007, though not all were active in every year, and thus 10 vessels with RSEs were not commercially active during these years. All of the commercially inactive "vessels" were in fact state registered boats. Thus, as would be expected, the statistics in Tables 5.2.1-9 and 5.2.1-10 indicate that the commercially active vessels with RSEs are relatively more homogeneous, newer, larger, and more powerful on average relative to all vessels with RSEs. In other words, the vessels with endorsements that have dropped out of commercial fishing in recent years have tended to be those that are older, smaller, and less powerful.

In Tables 5.2.1-11 and 5.2.1-12, and all other tables reporting the distribution of vessels' landings and revenues, all revenues are gross revenues rather than net revenues and reported in nominal terms. Also, revenues have been broken down into the following categories: South Atlantic rock shrimp (SRS), Gulf shrimp, Gulf non-shrimp, South Atlantic penaeid shrimp, South Atlantic non-shrimp, and Northeast non-shrimp. According to information in Table 5.2.1-11, the commercially active vessels averaged nearly $284,000 in total revenue per year. Their dependence on South Atlantic rock shrimp revenues was relatively low as they only accounted for 7% of total revenues on average during this time. These vessels were most dependent on Gulf shrimp revenues during these years, as they accounted for nearly 46% of their total revenues on average. Revenues from South Atlantic penaeid shrimp landings and Northeast non-shrimp landings were also important, with each representing approximately 22% of their total revenues on average. The vast majority of the Northeast non-shrimp revenues came from Atlantic sea scallop landings.

Table 5.2.1-7. Physical characteristics and selected statistics for all vessels with limited access rock shrimp endorsements[6].

[6] The 2006 Vessel Operating Units File (VOUF) was the source of data for crew size, number of nets, and net size. The Permits database is the source of data for all other characteristics. Characteristics data was not available for every permitted vessel for a variety of reasons (e.g. tonnage data is not available for state registered boats, vessel owners do not always provide the requested data on their application form, etc.).

Table 5.2.1-9. Physical characteristics and selected statistics for all commercially active vessels (2003-2007) with limited access rock shrimp endorsements.[7]

[7] In this table, and others presenting statistics over the entire 2003-2007 time period, as opposed to each year individually, vessels active in a greater number of years during that time period are inherently given a higher weight in the calculation of the means and standard deviations since as each observation represents a combination of vessel and year and thus they will represent a greater proportion of the observations relative to vessels that were active in fewer years.

[8] SRS landings and revenues in this table will not be equivalent to those in Table 3.4-2 because of those accrued by vessels that did but no longer possess an endorsement, in addition to minor amounts that could not be ascribed to a specific vessel or to a vessel that lacked an endorsement.

Thus, although South Atlantic rock shrimp landings were not unimportant to these vessels' operations, they were considerably more dependent on other fisheries. However, the nature of that dependence has changed considerably during these five years. That is, the distribution of revenues across fisheries varied considerably from one year to the next and certain patterns emerged over time. For example, in 2003, these vessels were highly dependent on the Gulf shrimp fishery with nearly two-thirds of their total revenues coming from this fishery. The vast majority of their other revenues came from the South Atlantic penaeid and rock shrimp fisheries. In 2004, dependence on the Gulf shrimp fishery lessened considerably, with less than 50% of their total revenues coming from that fishery and more than 30% coming from the South Atlantic penaeid shrimp fishery. Dependence on revenues from the South Atlantic rock shrimp fishery remained about the same between these two years at around 11-12%. However, these vessels' operations changed dramatically in 2005. As previously noted, South Atlantic rock shrimp landings were very low in 2005 and, as a result, accounted for only 0.2% of these vessels' total revenues. Landings from the South Atlantic penaeid shrimp fishery were still relatively important, though far less so than in 2004, accounting for nearly 16% of their total revenues. And although revenues from the Gulf shrimp fishery were still relatively important, accounting for approximately 44% of their total revenues in 2004, landings from Northeast non-shrimp fisheries were almost as important accounting for nearly 40% of total revenues on average. The vast majority of these revenues were the result of landings from the sea scallop fishery. The Northeast sea scallop fishery has seen a significant recovery both biologically and economically in recent years. Sea scallop landings and prices were particularly high in 2005.

In 2006, revenues from the Gulf shrimp, South Atlantic penaeid shrimp, and South Atlantic rock shrimp fisheries increased in absolute terms relative to their 2005 levels, while those from the Northeast non-shrimp fisheries fell slightly. But, in 2007, with the significant decline in the rock shrimp fishery, as occurred in 2005, they apparently shifted more effort into the South Atlantic penaeid shrimp fishery, while revenues from Gulf shrimp and Northeast non-shrimp fisheries declined slightly. Thus, by 2007, these vessels' operational changes resulted in them being most dependent on revenues from the Gulf shrimp fishery, followed by Northeast non-shrimp fisheries, the South Atlantic penaeid shrimp fishery, with each accounting for no less than 26% of these vessels' total revenues. In effect, these vessels changed their operations in such a way that, as a fleet, their landings and revenue "portfolio" has become more diversified over time. In an economic environment that has become increasingly uncertain in recent years, particularly in the Southeast's shrimp fisheries, this is exactly the approach these vessels' owners should have engaged in to spread risk and thereby protect their investments. Furthermore, at least in the short-term, their strategy appears to have worked remarkably well at least in terms of gross revenues, which increased on a per-vessel basis by from 2003 to 2006, average total revenues increased each year from approximately $203,000 in 2003 to $350,000 in 2006, or by approximately 70% on average. Although these vessels' total revenues decreased slightly in 2007 to approximately $321,000 on average, they were still quite high relative to 2003 through 2005. However, without accompanying cost information, it is not possible to determine how these vessels' costs and therefore profitability have changed during this time.

Another distinction among vessels with endorsements can be made between those with and without South Atlantic rock shrimp landings. Of greatest interest with respect to potential impacts from management actions are those with such landings. Statistics regarding these particular vessels are presented in Tables 5.2.1-13 through 5.2.1-17. With respect to most physical and operational characteristics, this group of vessels differs little from those who have been active in any commercial fishery. During 2003 through 2007, the only noticeable difference is that a higher proportion of vessels that were specifically active in the rock shrimp fishery tended to have steel hulls with on-board freezing capacity, and a lower proportion had wood hulls and used ice for storage purposes. However, based on information in Table 5.2.1-15, a somewhat surprising trend can be seen over this time period with respect to the physical characteristics of the vessels participating in the rock shrimp fishery. Specifically, from 2003 through 2005, the fishery was trending towards newer, larger, and more powerful vessels using larger nets. But this trend reversed in 2006 and 2007, and vessels participating in the fishery are becoming slightly older, smaller, less powerful, and using smaller nets. Though a definitive conclusion cannot be offered without additional data, particularly cost data, it is hypothesized that this change is related to the ever increasing price of diesel fuel and the fact that newer, larger, more powerful vessels that use larger nets also tend to be less fuel efficient. As such, it may be particularly unprofitable for these types of vessels to operate in or travel to a more distant, offshore fishery such as rock shrimp, particularly when other, possibly more lucrative fisheries requiring less fuel use may be available to them.

Somewhat coincidentally, according to information in Table 5.2.1-16, the average total revenue of RSE vessels with rock shrimp landings is almost identical to the average for all commercially active vessels. However, the distribution of those revenues, and thus their dependence on particular fisheries, is quite different. Specifically, these vessels are most dependent on revenues from the South Atlantic penaeid fishery, accounting for 38% of total revenues on average, followed by Gulf shrimp at 35% of total revenues, and South Atlantic rock shrimp at nearly 22%. Revenues from Northeast non-shrimp fisheries such as the sea scallop fishery are not at all important to this group of vessels.

But, as with all commercially active vessels with endorsements, this group of vessels has seen its average total revenues generally increase after 2003. The changes have been somewhat less dramatic, with total revenues only increasing from nearly $246,000 to nearly $323,000 per vessel on average between 2003 and 2005, or slightly more than 31%, and then decreasing slightly in 2006 and 2007, but still remaining above $300,000 on average. These vessels' dependence on revenues from South Atlantic rock shrimp have basically followed the same pattern during these years compared to all commercially active vessels with endorsements. And also similarly, these vessels were most dependent on revenues from the Gulf shrimp fishery in 2003 and 2004. However, in 2005, rather than shifting their effort into Northeast non-shrimp fisheries, these vessels shifted their effort into the South Atlantic penaeid fishery. And in 2006, revenues from the South Atlantic penaeid and rock shrimp fisheries comprised nearly 74% of these vessels' total revenues. And in 2007, when rock shrimp landings declined significantly, these vessels' became almost completely dependent on revenues from the South Atlantic penaeid fishery, which accounted for nearly 82% of their total revenues on average. Along with the information on physical characteristics, this information suggests that the only vessels that have continued to operate in the rock shrimp fishery over the past two years are "local" vessels, i.e., those that also operate in the South Atlantic penaeid fishery. Most or all of the newer, larger, more powerful vessels that, at least at one time, came from the Gulf have opted to operate in the Gulf shrimp fishery, which had a particularly abundant year in 2006 and would allow them to economize their fuel expenses, or have shifted into the Northeast sea scallop fishery, which has seen high prices and relatively high abundance in recent years.

As previously discussed, some of these vessels' endorsements are currently active (i.e., they have not expired), some have expired but are still renewable (i.e., they are still within the allowed one-year time frame to renew their endorsement after expiration), while others have expired but are currently terminated/nonrenewable (i.e., they did not renew their endorsements within one year after expiration). Thus, it is potentially important to examine how vessels may differ according to the current status of their endorsements.

Table 5.2.1-13. Physical characteristics and selected statistics for vessels with limited access rock shrimp endorsements and SRS landings between 2003 and 2007.

	Crew Size	Number of Nets	Net Size (ft)	Vessel Age	Length	Horsepower	Fuel Capacity (gallons)	Gross Tons	Hold Capacity (pounds)
Minimum	1	2	30	5	17	125	3,200	67	800
Maximum	5	4	80	42	93	1,720	48,000	205	160,000
Mean	3.6	3.9	56.1	19.7	76.9	601.5	16,598	132.7	68,842
St. Dev.	0.6	0.3	10.7	9.9	8.0	183.7	8,123	23.0	28,828

Table 5.2.1-14. Distribution of additional physical characteristics for vessels (2003-2007) with limited access rock shrimp endorsements and SRS landings between 2003 and 2007.[9]

Hull Type	Percent	Refrigeration	Percent	Vessel Size Category	Percent
Steel	79.6	Freezer	96.6	Large	99.5
Fiberglass	13.0	Ice	3.4	Small	.5
Wood	7.4				

[9] Though these characteristics were mostly consistent between 2003 and 2007, some noticeable changes took place in 2007. Specifically, representation of steel hulled vessels with on-board freezing capacity in the fishery declined by approximately 10%, while vessels with fiberglass or wood hulls and no such capacity increased concomitantly. These changes are consistent with those noted in Table 5.2.1-15, though information in that table suggests changes began in 2006. The reasons for this change are not apparent at this time, though higher fuel costs associated with operating larger, more powerful vessels may have played a role.

Table 5.2.1-15. Average physical characteristics by year for vessels with limited access rock shrimp endorsements and SRS landings between 2003 and 2007.

Year	Crew Size	Number of Nets	Net Size (ft)	Vessel Age	Length	Horsepower	Fuel Capacity (gallons)	Gross Tons	Hold Capacity (pounds)

Vessels with Active or Renewable Rock Shrimp Endorsements

With respect to the 125 vessels with currently active or renewable endorsements, statistics regarding their physical, operational, landings, and revenue characteristics are in Tables 5.2.1-18 through 5.2.1-23. The data indicate that 117 of these 125 vessels participated in some type of commercial fishing activity during these five years, while the other eight vessels were not engaged in commercial fishing. Again, all eight vessels that were not active in commercial fishing are state-registered boats. In general, the physical and operating characteristics are "between" those noted for all vessels with rock shrimp endorsements and those that were commercially active, though not significantly different from either. Also, total landings and revenues, the distribution of landings and revenues, and the trends in this distribution between 2003 and 2007 for vessels with active or renewable rock shrimp endorsements are very similar to those noted for all commercially active vessels with endorsements, both across all years and from year to year. The only difference is that the vessels with active or renewable rock shrimp endorsements are slightly more dependent on revenues from the various shrimp fisheries in the Southeast region and slightly less dependent on revenues from Northeast non-shrimp fisheries (i.e., sea scallops) relative to all commercially active vessels with rock shrimp endorsements. This finding suggests that it may be the vessels with terminated endorsements that have become the most highly involved in the Northeast's sea scallop fishery.

Table 5.2.1-18. Physical characteristics and selected statistics for vessels with active or renewable limited access rock shrimp endorsements.

Vessels with Terminated Rock Shrimp Endorsements

Regarding the 30 vessels with terminated endorsements, statistics regarding their physical, operational, landings, and revenue characteristics are in Tables 5.2.1-24 through 5.2.1-29. This group of vessels is quite different from the other groups of vessels previously discussed. First, with respect to physical and operational characteristics, vessels with terminated endorsements are, on average, older, smaller, and less powerful relative to those with active or renewable endorsements. They also tend to use fewer crew and smaller nets on average. Further, although nearly the same proportion have on-board freezing capacity, a much smaller proportion of these vessels are steel-hulled, and thus a much higher proportion have either fiberglass or wood hulls. These differences hold regardless of whether the comparison is between all vessels with terminated as opposed to active or renewable endorsements or only those that are commercially active. However, it is still the case that, on average, commercially active vessels with terminated endorsements tend to be somewhat newer, larger, and more powerful on average compared to all vessels with terminated endorsements.

According to the data, 28 of the 30 vessels with terminated endorsements have been involved in commercial fishing at some point during the past five years. Therefore, the proportion of vessels with terminated endorsements active in commercial fishing is almost identical to that for those with active or renewable endorsements. However, based on the information in Tables 5.2.1-28 and 5.2.1-29, the nature of that activity has been quite different. Specifically, relative to the vessels with active or renewable endorsements, these vessels' total revenues were significantly less in 2003, about the same in 2004 through 2006, but higher in 2007. To provide some perspective on the magnitude of this change, on average, these vessels' total revenue per year increased by 129% between 2003 and 2007, which is even more striking than the increase in total revenues for the vessels with active or renewable endorsements. Furthermore, during this time period, these vessels were considerably more dependent on revenues from Northeast non-shrimp fisheries (approximately 42% of total revenues compared to 19% for active and renewable endorsement holders), considerably less dependent on revenues from the Gulf shrimp (approximately 32% compared to 50% for active and renewable endorsement holders), and equally dependent on the South Atlantic penaeid fishery (approximately 22% of total revenues for both groups), and much less dependent on revenues from the South Atlantic rock shrimp fishery (approximately 4% of total revenues as compared to 8% for those with active or renewable endorsements). However, these differences between the two groups of vessels did not always exist.

In 2003, the distribution of revenues from the various fisheries between these two groups of vessels was very similar in that they were most dependent on Gulf shrimp landings, followed by South Atlantic penaeid shrimp, and South Atlantic rock shrimp landings respectively. However, changes in the distribution of landings and revenues thereafter for vessels with terminated endorsements do not mirror those seen for vessels with active or renewable endorsements. For example, in 2004, although dependence on revenues from the South Atlantic penaeid shrimp fishery increased, as with vessels with active or renewable endorsements, the vessels with terminated endorsements remained relatively dependent on revenues from Gulf shrimp landings while dependence on revenues from

South Atlantic rock shrimp landings declined, contrary to the vessels with active or renewable endorsements. In 2005, these vessels' operations changed dramatically such that nearly 53% of their revenues came from Northeast non-shrimp fisheries, only 26% came from Gulf shrimp landings, and approximately 21% came from South Atlantic penaeid shrimp landings. In 2006 and 2007, their dependence on Northeast non-shrimp landings became even more pronounced, representing approximately 70% of their total revenues, with Gulf shrimp and South Atlantic penaeid shrimp landings accounting for only 22% and 5-6% of their total revenues, respectively. After 2004, these vessels had little or no landings of South Atlantic rock shrimp. In effect, relative to vessels with active or renewable endorsements, vessels with terminated endorsements changed from being primarily dependent on revenues from the Gulf shrimp fishery in 2003 and 2004 to being primarily dependent on revenues from the Northeast sea scallop fishery in 2005 and particularly 2006 and 2007. That is, rather than diversifying their landings and revenue portfolio during this time period, they simply changed the fishery in which they specialize. Moreover, these vessels basically divested themselves of the South Atlantic rock shrimp fishery after 2004.

Vessels with Open Access Rock Shrimp Permits and South Atlantic Penaeid Permits
Though not the primary focus of the actions considered in this Amendment, information pertaining to vessels with open access South Atlantic rock shrimp permits is presented in Tables 5.2.1-30 through 5.2.1-35 and information pertaining to vessels with South Atlantic penaeid shrimp permits is presented in Tables 5.2.1-36 through 5.2.1-41. Table 5.2.1-42 presents an overall picture of landings and revenue for all vessels with South Atlantic shrimp permits/endorsements across the 2003 through 2007 time period.

Compared to vessels with limited access rock shrimp endorsements, vessels with open access rock shrimp permits tend to be somewhat smaller and less powerful on average. Proportionally fewer have steel hulls and a much lower percentage have on-board freezing capacity. Given that vessels with endorsements are a significant subset of vessels with open access permits, this result implies that vessels with open access permits that do not have endorsements are probably quite a bit smaller, less powerful, and less technologically advanced than those that do have endorsements. As with the other vessel groups that have been discussed, those vessels with open access rock shrimp permits that have been commercially active are somewhat larger and more powerful compared to all vessels that possess such permits. Of the 266 vessels with these permits, 245 (92%) have been commercially active in fishing at one point in time or another between 2003 and 2007, though not all of these vessels were active in each year, varying between 198 and 255 in 2004 and 2007, respectively.

With respect to their landings and revenues, vessels with open access rock shrimp permits are actually quite similar to vessels with terminated rock shrimp endorsements. For example, their average total revenues between 2003 and 2007 are nearly identical, at approximately $272,000. Further, from 2003 through 2007, they were most dependent on revenues from Northeast non-shrimp fisheries, followed by Gulf shrimp, and South Atlantic penaeid shrimp. Their involvement in the South Atlantic rock shrimp fishery during this time has been very limited, particularly during the past three years. Furthermore, as with the vessels with terminated endorsements, their dependence on revenues from the Northeast non-shrimp fisheries has grown over time, though not quite to the same extent given that only between 48 and 55% of their revenues came from these fisheries between 2005 and 2007. That is, revenues from the Gulf shrimp and South Atlantic penaeid shrimp fisheries are still important to these vessels.

Compared to the other vessel groups previously discussed, vessels with South Atlantic penaeid shrimp permits are the most dissimilar. Specifically, compared to vessels with rock shrimp endorsements or permits, vessels with penaeid shrimp permits are considerably older, smaller, less powerful, and less technologically advanced, though their gear and number of crew are comparable. A much higher proportion of these vessels rely on ice for storage purposes and a much higher proportion have fiberglass and particularly wood hulls. Also, the differences among all vessels with such permits and those that are commercially active are minimal at best, again contrary to vessels with rock shrimp permits or endorsements. Of the 620 vessels with penaeid shrimp permits, 585 (94%) have been involved in commercial fishing at some point during the past five years. Though again, not all of these vessels were commercially fishing in each year, ranging from 491 in 2003 to 512 in both 2004 and 2006.

In terms of landings and revenues, on average, these vessels' total revenues between 2003 and 2007 were considerably lower (approximately $179,000) than for vessels with rock shrimp permits or endorsements. Somewhat surprisingly, like the commercially active vessels with endorsements, these vessels were most dependent on revenues from the Gulf shrimp fishery (36%), followed by revenues from Northeast non-shrimp fisheries (29%), and the South Atlantic penaeid shrimp fishery (26%). An additional 7% of their revenues came from South Atlantic non-shrimp fisheries. Another similarity is that their average total revenues steadily increased from $124,000 in 2003 to $221,000 in 2006, or by approximately 78%. Their average total revenues decreased somewhat in 2007 due to a decline in revenues from the Gulf shrimp fishery and South Atlantic non-shrimp fisheries. Also similar to what was seen for the vessels with rock shrimp permits or endorsements, these vessels became much more dependent on revenues from the Northeast non-shrimp fisheries, though not to the same extent as vessels with rock shrimp permits or endorsements. Still, revenues from Northeast non-shrimp fisheries accounted for between 36% and 39% of these vessels' total revenues on average in 2006 and 2007, while revenues from the Gulf shrimp and South Atlantic penaeid shrimp each accounted for around 30% of total revenues. Thus, even within this group of vessels, diversification across the fleet as a whole has taken place, with some vessels specializing in Northeast non-shrimp fisheries, others in the Gulf shrimp fishery, and others in the South Atlantic penaeid shrimp fishery.

<u>All Vessels with South Atlantic Penaeid or Rock Shrimp Permits/Endorsements</u>
Finally, as previously noted, many vessels possess two or all three of these permits/endorsements. The total number of vessels that possess one or more South Atlantic penaeid or rock shrimp permits/endorsements is 694. Information regarding these vessels' physical and operational characteristics is presented in Tables 5.2.1-42 and 3.4-43. Since the vast majority of these vessels possess penaeid shrimp permits, these vessels' physical and operational characteristics are nearly identical to those with penaeid shrimp permits on average. That is, this fleet of vessels is very heterogeneous with respect to its physical characteristics. For example, approximately 65% of the vessels are large while 35% are small. Less than 40% have on-board freezing capacity while nearly 60% rely on ice for storage purposes. With respect to their hulls, the fleet is approximately evenly split between steel, wood, and fiberglass. On average, this group of vessels is somewhat smaller, older, less technologically advanced and uses less crew and gear relative to vessels that only possess limited access rock shrimp endorsements.

The same logic applies to these vessels' participation in and distribution of landings and revenues across commercial fisheries. Specifically, 648 of these 694 vessels, or more than 93%, were active in commercial fishing at some point between 2003 and 2007. Further, information in Table 3.4-44 indicates that revenues from the Gulf shrimp, Northeast non-shrimp, and South Atlantic penaeid shrimp fisheries have accounted for 36%, 31% and 24% of these vessels' total revenues on average between 2003 and 2007, respectively, which again is very similar to the distribution for vessels with penaeid shrimp permits. The average total revenue per vessel during this time was approximately $185,000, which is comparable to vessels with penaeid shrimp permits though 35% less than vessels that possess a limited access rock shrimp endorsement.

Recent Economic Condition of the South Atlantic Shrimp Fisheries

To the extent possible, landings, revenues, and prices have been described in the aggregate and according to particular groups of vessels with various types of South Atlantic shrimp permits or endorsements. Limited historical information on vessel costs and profitability was discussed in Amendment 6 (SAFMC 2004) and is incorporated herein by reference. However, the only relatively recent information on costs and profitability was limited to shrimp trawlers in South Carolina. Given the reduced importance of the South Carolina fleet within the overall fishery and the fact that very few South Carolina vessels participate in the limited access rock shrimp fishery, those data are not only outdated but undoubtedly not representative of the vessels potentially impacted by the actions in this Amendment. An attempt was made to voluntarily collect information on South Atlantic shrimp vessels' costs and net revenues in 2005. This project was only partially successful in its attempts to collect the desired data (i.e., the achieved sample size was considerably smaller than the desired sample size). It was determined that the collected information was likely not representative of the fishery as a whole or specifically of vessels participating in the federal component of the fishery. However, some information on how vessels' costs have likely been changing during the past several years is presented below, as are insights into why domestic shrimp prices declined, almost continually, from 2001 through 2006.

According to available information, the shrimp fisheries in the Southeast region had a banner year in 2000. However, economic conditions took an abrupt turn in the latter half of 2001. Current evidence indicates that as shrimp imports surged in that year, macroeconomic conditions deteriorated, and when the post-September 11-era began, the industry was hit by sharply declining prices and higher insurance premiums. The deteriorating trend apparently continued through 2002 and 2003, exacerbated by increases in fuel prices that began in the latter part of 2002 and continued through 2003. According to average price data reported by the Bureau of Labor Statistics (BLS), from 2002 to 2003, fuel prices increased between 21% and 29%, depending on the selected fuel price index. Regardless of which index is used, fuel prices increased significantly which, in turn, significantly increased shrimp vessels' operating costs.

However, rapidly declining prices appear to have been the primary source of the recent deterioration in the industry's economic condition. Revenues decreased even more as a result of relatively lower landings in 2001 and 2002 relative to 2000. According to Haby *et al.* (2003), increases in shrimp imports have been the primary cause of the recent decline in U.S. shrimp prices. A complete discussion of the factors contributing to the increase in imports can be found in Haby *et al.* (2003). In general, recent surges in imports have been caused by increases in the production of foreign, farm-raised shrimp. More specifically, increased competition from shrimp imports has been due to three primary factors: 1) changes in product form due to relatively lower wages in the exporting countries, 2) shifts in production to larger count sizes, and 3) tariff and exchange rate conditions which have been favorable to shrimp imports into the U.S. With respect to the first factor, lower wage rates have allowed major shrimp exporters (e.g., Thailand) to increase production of more convenient and higher value product forms, such as hand-peeled raw and cooked shrimp. With respect to the second factor, changes in farming technology and species have allowed production of foreign product to shift towards larger, more valuable sizes. As a result of these factors, imports are more directly competing with the product traditionally harvested by the domestic industry, thereby reducing the latter's historical comparative advantage with respect to these product forms and sizes. Finally, with respect to the third factor, the lack of duties on shrimp imports into the U.S., the presence of relatively significant duties on shrimp imports into the European Union, and the recent strength of the U.S. dollar relative to foreign currencies have created favorable conditions for countries exporting products to the U.S.

As Haby *et. al.* (2003) note, the increase in imports caused the domestic industry's share of the U.S. shrimp market to decrease from 44.6% to 14.8% between 1980 and 2001. While the growth in imports was relatively steady throughout most of this time period (for example, 4-5% in the late 1990s), shrimp imports surged by 16% in 2001. Since 2001, which is the last year accounted for in their analysis, shrimp imports have continued to rise. Although the increase in 2002 was a modest 7.2%, relative to the increase in 2001, a significant increase of 19.1% occurred in 2003 according to the most recently available data. These increases led to further erosion in the domestic industry's market share and additional price declines.

Available information at the time indicated that domestic shrimp prices had continued to decline in 2003, which would lead to the expectation that vessels may not have been able to cover their variable costs. If vessels cannot cover their variable costs, they will be forced to cease operations (i.e., exit the fishery) until conditions change. Many changes have continued to occur that would likely affect the economic status of the Gulf shrimp harvesting sector. Most of these changes would be expected to adversely affect the industry's economic status. For example, fuel prices have risen significantly since 2002. Probably the best proxy to use for fuel prices paid by commercial shrimpers (or commercial fishermen in general) is the diesel fuel price paid by farmers, statistics for which are generated by the USDA. This price is more appropriate than the diesel fuel price "paid on the street," which is typically generated by the BLS, because it removes fuel excise taxes, which neither commercial fishermen nor farmers pay. The diesel fuel price per gallon paid by farmers changed as follows in each year from 2002 and 2006: $.96, $1.24, $1.31, $1.97 and $2.28, respectively. This represents a price increase of nearly 138% between 2002 and 2006, with the largest increases occurring in 2003, 2005, and 2006. Preliminary data for 2007 indicates that fuel prices increased further to as much as $2.43 per gallon on average. Early data in 2008 indicates that diesel fuel prices may be more than a $1 higher at present, which could cause the fuel costs associated with operating in the commercial shrimp fishery to be nearly prohibitive unless shrimp prices were to increase proportionally, which recent history suggests is unlikely.

To provide some context, it is helpful to think of how these fuel price increases translate into increases in a typical vessel's fuel expenses. With respect to the cost of filling up a shrimp vessel, the average fuel capacity of a commercial active vessel with a limited access rock shrimp endorsement is approximately 17,000 gallons (see Table 5.2.1-9). Thus, between 2002 and 2007, the cost of filling up an "average" active rock shrimp vessel rose from approximately $16,300 to more than $41,300. Thus, the cost of filling up a typical rock shrimp vessel with fuel has increased nearly 153% between 2002 and 2007.

As previously noted, shrimp prices increased somewhat in late 2004 and through much of 2005. These price gains were likely due to the impact of duties imposed on imported shrimp and the relative stabilization in the volume of imports coming into the U.S. In 2004, shrimp imports increased by only 1% over their 2003 level. And in 2005, shrimp imports increased by only 2.5% over their level in 2004. However, shrimp imports once more surged into the U.S. market beginning in late 2005 and through 2006, and this is more than likely the primary cause of the general price decreases for domestic shrimp during that year. Specifically, shrimp imports were approximately 11.6% higher in 2006 than they were in 2005. Preliminary data do seem to suggest that prices have increased in 2007, particularly for the 30-count and larger size categories, based on data from the Gulf shrimp fishery. In general, though depending on the size category, prices appear to have returned to their levels in 2005 and possibly 2004. Not coincidentally, preliminary 2007 data also appear to indicate that imports have not only stabilized, but may have actually decreased by as much as 5% in 2007.

Rock Shrimp Dealers

As previously noted, between 40 and 50 dealers have typically held rock shrimp dealer permits at any given point in time during recent years and 46 dealers held one at one time or another during 2006 and 2007. Thus, it is not unexpected that 36 dealers purchased South Atlantic rock shrimp between 2003 and 2007. Some dealers apparently have obtained these permits on the off-chance that one or more of the vessels they typically buy shrimp from harvest South Atlantic rock shrimp. Further, not all of these dealers were active in each year and most were in fact active in only one or two years during this time. However, a careful review of the landings and permit data has revealed some disturbing information. Specifically, of the 36 dealers that have purchased South Atlantic rock shrimp in the past five years, only 21 of them had the legally required federal South Atlantic rock shrimp dealer permit (i.e., 15 dealers did not have the required permit). For some of these dealers, the alleged amount of South Atlantic rock shrimp illegally purchased was relatively minor. In other cases, the amount was more substantial. As can be seen in Table 5.2.1-45, in the aggregate, these non-permitted dealers are not the most significant dealers in the fishery with respect to landings and revenue. And during 2004, 2005, and 2007, the amount of rock shrimp alleged to have been illegally purchased was relatively trivial or non-existent. However, the problem was more widespread in 2003 and 2006 when more than 7% and approximately 6% of the landings were apparently purchased by dealers that lacked the required permit. These amounts cannot be considered trivial and the problem should be addressed in some manner.

Table 5.2.1-45. South Atlantic rock shrimp landings and revenue, federally permitted and non-federally permitted rock shrimp dealers, 2003-2007.

Year	Landings (Permitted)	Revenue (Permitted)	Landings (Non-Permitted)	Revenue (Non-Permitted)	Landings (All)	Revenue (All)
2003	2,755,465	$4,169,465	225,159	$320,443	2,980,623	$4,489,905
2004	6,588,574	$5,009,071	3,009	$3,080	6,591,583	$5,012,147
2005	109,281	$99,612	0	$0	109,281	$99,611
2006	2,840,711	$3,964,522	177,610	$300,058	3,018,322	$4,264,576
2007*	236,468	$428,169	4,081	$13,108	240,550	$441,277

*2007 data are preliminary

Although these allegedly illegal purchases may have repercussions for the non-permitted dealers, and possibly even for their permitted competitors, these sales may also have impacts on the vessels from which the rock shrimp were purchased. Specifically, if the rock shrimp were in fact illegally purchased, in general, they cannot count towards those vessels' catch histories and, moreover, they cannot be counted towards meeting the current 15,000-pound landing requirement. As such, it is quite possible that some vessels may not meet the landings requirement, not because they had insufficient landings, but because some or all of those landings were sold through dealers without the federal permit. Although the allegedly illegal purchases of rock shrimp in 2003 may not be critical in this regard, those made in 2006 certainly could be.

Notwithstanding this important issue, it is still necessary to characterize the detailed landings and sales activities of all dealers participating in the fishery regardless of whether they were or currently are permitted to purchase South Atlantic rock shrimp. For current purposes, it is most important to examine changes in the number of dealers in the fishery and their purchasing activities in recent years. In turn, this information will yield insights into the relative importance of the fishery to these dealers and how they have adapted to changes in the harvesting sector.

According to information presented in Table 5.2.1-46, the number of dealers active in the South Atlantic rock shrimp fishery was fairly stable from 2003 to 2004 (23 and 22 dealers, respectively), fell dramatically in 2005 to a level not seen in recent history (7 dealers), increased somewhat in 2006 (14 dealers), and then decreased again in 2007 to a level slightly above the historic low in 2005 (10 dealers). As would be expected, this trend in the number of participating dealers closely mirrors that of the number of participating vessels.

Also as expected, these dealers' dependence on South Atlantic rock shrimp purchases also closely mirrors the dependence of vessels, or more specifically vessels with RSEs that had South Atlantic rock shrimp landings in particular, on South Atlantic rock shrimp revenues. Landings and revenues are broken down into the following categories: South Atlantic rock shrimp, Gulf shrimp, Gulf non-shrimp, South Atlantic non-shrimp, and other South Atlantic shrimp (primarily penaeids). For example, in 2003, South Atlantic rock shrimp purchases accounted for nearly one-quarter of these dealers' total purchases, and thus they were fairly dependent on these purchases at the time. In 2004, the average South Atlantic rock shrimp landings per dealer increased fairly significantly. However, because of the significant decrease in rock shrimp prices, and because purchases of penaeid shrimp and other types of seafood increased even more, causing their total revenues to increase on average, their dependence on rock shrimp purchases decreased slightly in that year. And in 2005, given the steep decline in rock shrimp landings, their total revenues decreased, but not significantly as their purchases of Gulf shrimp and South Atlantic penaeid shrimp increased fairly significantly and thus mostly compensated for the lack of rock shrimp. And in 2006, their dependence on rock shrimp increased again, basically back to the same level seen in 2003. However, though fewer in number, the dealers participating in the rock shrimp fishery were actually better off on average in 2006 than those in 2003. In addition to the recovery in rock shrimp landings and sales, with the exception of South Atlantic penaeid shrimp landings and sales, landings and sales in all other species categories increased, thereby leading to a significant increase in total revenues. Again, somewhat similar to the trend in the rock shrimp harvesting sector, participating dealers' dependence on rock shrimp declined precipitously in 2007, as did their dependence on Gulf shrimp sales. However, once more, their total revenues increased on average, due to significant increases in South Atlantic penaeid shrimp sales and particularly revenues from non-shrimp landings from the South Atlantic.

So, as in the harvesting sector, even for the dealers that remain involved in the South Atlantic rock shrimp fishery, they have adjusted their "portfolio" of seafood purchases in order to stay in business. However, one major difference is the source of this diversification. Unlike vessels, which are mobile and can travel in order to diversify their landings (e.g., vessels that have shifted into the Northeast scallop fishery), dealers are based on land and must diversify into other local fisheries. Of course, their ability to adjust does not mean that other dealers no longer involved in the rock shrimp fishery have been able to adjust as well. In fact, it is quite likely that some dealers that used to be involved in the fishery are no longer in business, though a definitive conclusion on this subject will require additional research. Further, the ability of these dealers to adjust their purchases of seafood may not satisfy the desires of certain companies (e.g., processors, institutional buyers, restaurants, etc.) that want to purchase rock shrimp and would prefer a steady supply of the product from year to year.

Rock Shrimp Processors

At present, data on shrimp processors in the Southeast region (i.e., South Atlantic and Gulf) are only available through 2006 since these data are typically not available until the September following each calendar year. Based on a review of these data from 2003 through 2006, no rock shrimp were processed by any processors in the South Atlantic. The processing of rock shrimp appears to be specialized and only handled by a select number of processors primarily located in the Panhandle area of Florida. Processing of rock shrimp by firms in this particular area has likely been driven by the presence of a seasonal fishery for rock shrimp in the Gulf in the areas off of the Panhandle and Big Bend area on the west coast of Florida. Since no shrimp processors in the South Atlantic are involved in the processing of rock shrimp, it is assumed that the processing of South Atlantic rock shrimp takes place in the Gulf.[11] Given existing data constraints, it is not possible to directly determine how much of the rock shrimp processed by these firms comes from the South Atlantic as opposed to the Gulf. However, the data suggest that not all rock shrimp harvested from either region is processed. Thus, the following information focuses on firms that process rock shrimp and, in order to provide some context, also provides some information on the current and historical status of the Gulf shrimp processing sector in general.

Statistics describing rock shrimp processors are provided in Table 5.2.1-47. The number of firms involved in rock shrimp processing has remained fairly constant in most recent years, with 7 firms participating in the industry in 2003 and 6 firms participating thereafter. Of the 7 processors in 2003, 6 were small processors (i.e., those with less than $5 million in processed value) and 1 was large (i.e., more than $20 million in processed value). One small processor stopped processing rock shrimp in 2004 and had exited the shrimp processing industry completely by 2006. Also by 2006, one of the small processors had become a medium sized processor (i.e., between $5 million and $20 million in processed value).

Though processed rock shrimp poundage and value has been somewhat up and down during these years, the general trend appears to be downward. This fact is more clearly illustrated by the decreased dependence of these processors on rock shrimp as opposed to penaeid shrimp. On average, rock shrimp accounted for 24% of these processors' total processed value, but only accounted for 11%, or less than half, by 2006. Contrariwise, these firms' total processed poundage and value has trended upwards during this time. As explained below, this trend is reflective of consolidation in the Gulf shrimp processing sector, as well as relatively high shrimp abundance in the Gulf in 2006.

As would be expected, the trends in poundage and prices fairly closely mirror those in the harvesting sector. For example, as with landings, processed poundage increased slightly from 2003 to 2004, fell significantly in 2005, and then recovered somewhat in 2006. Similarly, as with the ex-vessel price to harvesters, the processed value per pound decreased significantly from 2003 to 2004 ($4.99/lb to $3.94/lb), though the proportional decrease in the processed price was less than the decrease in the ex-vessel price, but then subsequently recovered to $4.93/lb in 2005. However, the processed price fell in 2006 to $4.17/lb contrary to the ex-vessel price. Although it is typical for the processed price to

[11] Uncertainty exists with respect to the accuracy of this assumption, not only because existing data collection systems do not track the movement of shrimp from dealers to processors, but also because the collection of processing data in the South Atlantic and Gulf is voluntary in nature. Therefore, it is possible that the processing data used in this analysis is incomplete.

exceed the ex-vessel price, the differential in the case of rock shrimp is clearly larger than the differential typically seen between processed and ex-vessel prices for penaeid shrimp. Again, this illustrates the fact that the processing of rock shrimp is a highly specialized activity that apparently adds a considerable amount of value added to the final product.

Table 5.2.1-47. Production, value, and employment in the rock shrimp processing sector, 2003-2006.

Statistic	Year	Rock Shrimp Processed Pounds	Rock Shrimp Processed Value	Total Processed Pounds	Total Processed Value	Rock Shrimp as % of Processed Value	Employment

Total	2006	633,110	$2,640,466	14,259,655	$46,960,169	N/A	91
Average	2006	105,518	$440,078	2,376,609	$7,826,695	11	15
St. Dev.	2006	140,601	$644,020	3,531,637	$11,871,521	20	18

With respect to the Gulf shrimp processing sector in general, currently available information indicates that the number of Gulf shrimp processors decreased from 74 to 55 between 2002 and 2006, which reflects additional consolidation in the Gulf shrimp processing sector from what had taken place in previous years. The data also indicate that the surviving firms have expanded their production (i.e., average production per firm has increased, thereby causing an increase in the number of large processors), which has helped to maintain the value of their production in the face of generally declining prices (i.e., processed value per firm has remained relatively stable).[12] Also, in general, the firms that have exited the industry in the last few years are the smaller processors. In 2006, eight processors left the industry (five small and three medium/large). Rather interestingly though, three new processors entered the industry and, in effect, “picked up the slack.” The entry of these new processing firms was timely given the significant

[12] Even though ex-vessel prices decreased significantly in 2006, prices at the processor level were surprisingly unchanged from 2005, a finding that deserves further investigation.

increase in the volume of processed shrimp in 2006, which was driven by the significant increase in domestic landings and led to an increase in the processed value per firm.

The data also indicate that a majority of these firms are highly dependent on the processing of food shrimp. Unfortunately, it has not been historically possible to determine with certainty how much of the shrimp being processed is domestic as opposed to imported by using the NOAA Fisheries Service's processor data. However, by cross-referencing multiple data sources, Keithly *et al.* (2005) attempted to approximate this figure.[13] According to their findings, use of imports by domestic processors increased steadily through the 1980s and for example, in 1986, accounted for about one-third of production. Between 1992 and 1994, which was apparently the peak period, domestic and imported product accounted for nearly equal proportions of total processed shrimp products in the Southeast region. Even though, as noted previously, imports have continued to increase since then, Southeast shrimp processing activities have not increased proportionately as a result.

Keithly *et al.* (2005) hypothesized that this outcome is a direct result of a significant and steady decrease in the deflated price of processed shrimp from over $7.00/pound in the early 1980s to less than $4.00/pound in recent years. This decline has also precipitated a decline in processors' marketing margins (i.e., per unit profitability). As a result of the declining margins, some processors have adjusted by increasing output in order to compensate; but many have been unable to make such an adjustment, and thus have been forced to exit the industry. This is illustrated by the fact that the number of Gulf shrimp processors fell from 124 to 72 between 1980 and 2001. Thus, the situation illustrates the classic case of an industry in economic decline, wherein the number of firms falls, and those who remain become larger in size (as measured by output). That is, the industry has become more concentrated. Moreover, Keithly *et al.* (2005) concluded that, if production of farm-raised shrimp continues to increase and a substantial portion of that production enters the U.S. market, the price of processed shrimp will continue to decline; margins will continue to narrow; and consolidation will continue to occur as additional firms exit and remaining firms attempt to compensate by increasing their output.

A more recent study by Keithly *et al.* (2006) supports many of the conclusions and hypotheses offered in Keithly *et al.* (2005), and also helps to explain the changes that have occurred in this sector between 2002 and 2004, as noted above. In the recent study, Keithly *et al.* (2006) conducted a survey of shrimp processors in order to better estimate their marketing margins and their dependency on domestic as opposed to imported product. The survey information was combined with data from the NOAA Fisheries Service's processor database for analysis. A critical finding of this study is that shrimp processors' marketing margins have continued to decrease in recent years because the price of processed shrimp has been declining at a faster rate than the price of raw product. The decrease in the price of processed shrimp has been caused by increased imports of

[13] The one weakness with their approach is the assumption that all domestic production is utilized by the processing sector. While this assumption would be plausible under stable economic conditions, it is less reasonable in dire economic times when harvesters shift from traditional sales channels and instead sell directly to the public.

value-added product that directly compete with the domestic processors' product. The price decline has caused marketing margins to decrease, which in turn has forced firms to either exit the industry or increase their production. In general, smaller processors have exited while medium to larger sized processors have expanded, probably due to differences in their respective access to financial capital (i.e., smaller firms likely have less access to financial capital than their larger counterparts).

In addition, the study found that, in recent years, domestic processors have used a very limited amount of imported, raw product and instead are heavily dependent on domestically harvested product, contrary to popular belief. As such, the health of the processing sector is heavily dependent on domestic harvesting production. Keithly *et al.* (2006) note that the remaining firms' ability to maintain operations is dependent on their ability to expand, assuming processed shrimp prices continue to decline, which would be the case if imports of value-added product continue to increase. Therefore, if domestic harvesting production decreases, processors will be constrained in their ability to expand production, and additional consolidation of the industry will be likely. The decrease in Gulf shrimp landings in 2005 may have exacerbated the decline in the economic health of the Gulf shrimp processing sector. On the other hand, as previously noted, domestic landings rebounded significantly in 2006, which in turn likely helped to stabilize the processing sector and in fact encouraged three new firms to join the industry. Various reports also indicate that the processing sector was significantly impacted by Hurricane Katrina, either directly as a result of wind/storm surge damage or indirectly as a result of population shifts/displacement which in turn created labor shortages. Processors located in Biloxi, D'iberville, and Ocean Springs, Mississippi as well as in New Orleans and Violet, Louisiana were particularly hard hit (IAI 2007). However, the data suggest that most of these processors were back in operation, at least to some level, in 2006.

Global shrimp supply trends

Shrimp is produced throughout the world with more than 100 countries reporting production in 2003. United States shrimp imports expanded from about 260 million pounds (headless, shell-on basis) in 1980, to 563 million pounds in 1989 and 579 million pounds in 1990 (Vondruska 1991). Imports continued to steadily increase and reached 721 million pounds in 1996. Subsequently, this growth continued at a more rapid rate and in 2000 imported shrimp products, converted to shell-on headless weight, was estimated at 1.024 billion pounds (Haby et al. 2003).

During 2000 to 2003 the quantity of imports of all product forms increased (Table 5.2.1-48). It must be noted that these imports are not converted to equivalent shell-on weight and are not directly comparable to the statistics referenced in the previous paragraph. The cost of shrimp imports was $3.7 billion in 2003 (http://www.st.nmfs.gov/st1.html). The increase in the breaded/frozen shrimp category more than quadrupled during 2000 to 2003, and is noted because of its possible negative impact on the segment of the domestic processing sector which relies on adding value through breading. While the breaded fraction of total shrimp imports has increased from 4.2 million pounds in 2000 to 19.3 million pounds in 2003, breaded shrimp represented only 1.7 percent of total shrimp imports in 2003 (Table 5.2.1-48).

Table 5.2.1-48. Shrimp imported into the United States by product category (pounds): 2000-2003. Source: NOAA Fisheries web site (http://www.st.nmfs.gov/st1.html).

Total	759,169,037	880,741,653	944,466,006	1,109,888,072

When the fraction of total U.S. shrimp supplies attributable to domestic landings as opposed to imports is calculated using shell-on, headless values for domestic landings but product weights for imported shrimp, imports represent only about 70% of the total U.S. shrimp supply (i.e., the domestic market share is approximately 30%). Total domestic shrimp landings in 2001 and 2002 averaged 366.3 million pounds (http://www.st.nmfs.gov/st1.html). This quantity represents both warm water and cold water domestic shrimp harvests. However, as would be expected, the domestic market share estimate drops by approximately 15% when imports are converted from product weights to a shell-on, headless equivalent (Haby et al. 2003). Thus, imports comprise at least 85% of the U.S. shrimp supply. Determining the most appropriate market form (e.g., live weight, shell-on, headless, etc.) depends on the purpose for which the information is to be used. For example, Fisheries of the United States expresses commercial shrimp landings in two different market forms: round or live weight and shell-on, headless weight. Live or round weight is typically used when comparing the biomass of different species. However, since shell-on headless weight is the customary market form packed by primary processors, it is the more appropriate market form to use when determining the contribution of domestic landings to U.S. shrimp supplies. Further, although shrimp imports are expressed in actual product weights in the foreign trade segment of Fisheries of the United States, these weights are converted into shell-on, headless equivalents when determining the contribution of imports to U.S. shrimp supplies.

Much of the increase in shrimp imports to the United States since the 1980s came from farm-raised production. During the early 1980s, the growth in imports was attributed to farm raised production in Ecuador. Currently, most of the production and supply to the U.S. market originates from Asian countries led by Thailand and China. In fact, imports of shrimp products from Thailand are at about the same level as domestic landings from the Gulf of Mexico and South Atlantic states (Table 5.2.1-49a).

Table 5.2.1-49a. Top countries exporting shrimp to the United States (pounds): 2000-2003.

Country	2000	2001	2002	2003

The continual trend for increased imports has also resulted in decreased prices for imported shrimp products and is observed for all product forms. The price of imports will also be affected by the demand for shrimp in the other major markets of Japan and Europe. Import restrictions or an economic recession in either of these countries would have a downward influence on U.S. import prices for shrimp products.

Table 5.2.1-49b. Average price (per pound) of shrimp imported into the United States by product category: 2000-2003.

Product	2000	2001	2002	2003

A more detailed examination of domestic prices in South Carolina indicates that since 2002 price per pound has decreased for all domestic shrimp count sizes by at least 28% (Table 5.2.1-50).

A study conducted in 1988 examined the economic consequences of shrimp imports to shrimp harvesters in the South Atlantic and Gulf of Mexico (Keithly et al. 1989). Results of this econometric model demonstrated that farm raised shrimp elevated U.S. import levels by about 175 million pounds. At that time (1989) 563 million pounds of shrimp were imported. This model also indicated that import prices and domestic dockside prices would have been about 70% higher in the short run in the absence of imports of farm-raised shrimp. The authors suggested, however, that any rise in domestic warm water ex-vessel prices brought about by a reduction in U.S. shrimp imports would encourage additional effort in the domestic shrimp fleet and this would dissipate initial gains in profits as well as increase total harvest costs for the industry. Ward (1992) found that there was an asymmetrical response between change in vessel profits and entry/exit behavior in the Gulf of Mexico shrimp fishery. There is a higher probability that vessels will enter the fishery if profits increase while for the same magnitude in decreased profits fewer vessels will exit the industry.

Another econometric study directly evaluated the impact of shrimp imports on prices to South Atlantic shrimpers (Houston and Nieto 1988). Results suggest that shrimp imports have a different effect on regional markets. There was a significantly greater impact on South Atlantic shrimp prices, than on Gulf of Mexico, West Coast or New England markets. Although the authors concluded that restricting imports of shrimp would increase dockside prices in the short run, the merits of that action are debatable because new entrants would be expected to dissipate any economic rents derived from the fishery in the long run.

From the point of view of shrimp fishermen, imports decrease benefits by depressing dockside prices as demonstrated by Keithly et al. (1989). However, imports increase the aggregate U.S. supply of shrimp leading to lower retail prices for consumers (Anderson 1986). Thus, consumers in this country clearly benefit from imports although there are also balance of trade considerations with imports, which affect the buying power of U.S. consumers in the long run. Import restrictions would probably raise both dockside and retail prices and increased retail prices would decrease benefits to consumers. In addition, import restrictions would also impact U.S. wholesalers and retailers who currently depend on imports for a substantial portion of their sales volume.

Profile of the shrimp fishery in the South Atlantic states

Information from previous amendment documents and more recent databases showed that the contribution of each species to total landings varies in a relatively consistent pattern among the four southeastern states. In North Carolina, brown shrimp dominates total harvest, and generates more than 60% of overall revenue. In contrast to other South Atlantic states, white shrimp makes up a smaller component of the overall catch. In some years, pink shrimp catches in North Carolina can exceed 500,000 pounds (Table 5.2.1-51).

In South Carolina and Georgia, there are virtually no pink shrimp in the landings which are dominated by white shrimp. In 2002, white shrimp accounted for nearly 80% of the revenue from all shrimp species in Georgia and nearly 75% of the revenue from all species in South Carolina (Table 5.2.1-52, Table 5.2.1-53). The relative contribution of brown shrimp to the catch varies yearly, but rarely exceeds the catch of white shrimp. Nevertheless, this species is somewhat important to the shrimp industry in these two states. Most of the pink shrimp harvest on the east coast of Florida comes from the offshore areas around the Dry Tortugas and the Florida Keys. In northeast Florida, some pink shrimp enter the catch primarily as a bycatch of the rock shrimp fishery. Overall shrimp revenue in Florida's South Atlantic fishery is not dominated by the harvest and sale of any one species (Table 5.2.1-54). White shrimp is probably the most important species in terms of overall revenue in the northeast Florida shrimp fishery (SAFMC 1993). In some years, rock shrimp accounted for the dominant share of ex-vessel value (Table 5.2.1-54).

Table 5.2.1-51. Ex-vessel value of shrimp landings in North Carolina by species (Source: NCDMF, 2008).

Species	1999	2000	2001	2002

Total	$36,672,390	$38,227,850	$31,486,961	$23,688,605

Data presented in previous amendments indicated that in North Carolina almost all of the shrimp catch comes from internal waters. In South Carolina, it was estimated that about 5 to 10% of the shrimp catch is taken in the EEZ. In Georgia, because of extensive nearshore shoaling, significant effort is expended beyond three miles, and a higher percentage of the catch was reportedly taken from the EEZ (SAFMC 1996b). In Florida, it was estimated that 12 to 15% of the non-rock shrimp catch came from the EEZ. The more recent data used in Amendment 6 to the Shrimp FMP confirms that a substantial quantity of the shrimp harvest is taken in state waters. An average of 20% of the shrimp catch in the South Atlantic was recorded as harvested within Federal waters. This may not represent the total harvest taken from Federal waters. Tows on a single shrimp trip could traverse several locations or statistical reporting areas yet only one location is reported for each trip on the data reporting form. Thus, harvest from several locations could be attributed to one area especially in the case of multi-day trips.

In terms of the ex-vessel revenue generated, the states of North Carolina and Florida are more important to the South Atlantic shrimp industry (Table 5.2.1-51, Table 5.2.1-54). The revenue generated by the shrimp industry in Georgia and South Carolina is fairly comparable. It must be noted that the sum of landings and value in these four states will be less than the same statistics presented in Table 5.2.1-5 for the entire South Atlantic. This is due to the fact that the shrimp profile for the entire South Atlantic also includes statistics on shrimp caught in the South Atlantic and landed at Gulf of Mexico ports and shrimp landings in the Atlantic where the area caught or state landed was unknown.

The industry in all four states faced lower prices in 2001 and 2002 compared to previous years. For the three states where vessel level landings are available it appears that vessel identification information is not always reported or it is not possible to link landings to a particular vessel. Compliance with this reporting requirement in the states of Georgia and North Carolina appears to have improved over time. Of concern are the data from Florida. For 2002, it was not possible to identify the vessels that landed 1.31 million pounds of shrimp in Florida (Table 5.2.1-55).

There are two ways to represent shrimp catches on the east coast of Florida. The first table contains the data on shrimp harvested on the east coast of Florida some of which was landed at ports on the west coast of Florida (Table 5.2.1-55). The second table contains data on shrimp catches landed at east coast Florida ports (Table 5.2.1-56).

Table 5.2.1-55. Shrimp harvested from the east coast of Florida (South Atlantic): annual landings, ex-vessel revenue and effort.

Year	1997	1998	1999	2000	2001	2002

The value of all seafood landed on the east coast of Florida amounted to $48.14 million in 2001 and $38.9 million in 2002 (NOAA Fisheries 2003b). The average dockside value of shrimp landings in those years amounted to $16.69 million (using data presented in Table 5.2.1-15). Therefore, east coast shrimp landings comprised an average of 38% of the value of seafood sold at the dock in the past two years. In comparison, for South Carolina the total ex-vessel value of commercial landings was $23.9 million and $20.8 million dollars in 2001 and 2002 respectively (NOAA Fisheries 2003b). Shrimp comprised an average of 40% of the total value for those two years. Shrimp harvests comprised an average of 75% of the total ex-vessel revenue of landings in Georgia during the years 2001 and 2002. Reported commercial landings for the state of Georgia were $14.8 million and $15.1 million in 2001 and 2002 respectively (NOAA Fisheries 2003b).

In contrast, North Carolina's shrimp harvesting sector is relatively less important to the entire commercial industry in this state.

The ex-vessel value of shrimp comprised 16% of the average overall value of commercial landings in 2001 and 2002 ($94.6 million) (NOAA Fisheries 2003b).

In North Carolina, brown shrimp and white shrimp landings were lower than normal in 2001 (Table 5.2.1-57). This 5.1 million pound decline coupled with lower prices decreased overall shrimp revenue by $13.5 million compared to 2000. Revenue and landings increased in 2002. However, average prices decreased in 2002 even though the supply increased by 4.7 million pounds over the harvest in 2001 (Table 5.2.1-57).

Vessels fishing in inshore areas					

North Carolina and Florida have the largest fleets in the South Atlantic shrimp harvesting sector. Vessels in these states' shrimp fishery tend to be more diverse. Many vessels participate in other non-shrimp fisheries, and shrimp species comprise a smaller proportion of their overall revenue base compared to vessel firms in other states. Also, many of the restrictions that apply to shrimp trawling in inshore areas of other states do not exist in North Carolina. This provides more opportunities for smaller vessels to participate in the North Carolina shrimp fishery. As a result of these differences in operations, catch per vessel may not be directly comparable across all states.

The decrease in shrimp landings in South Carolina and Georgia during 2002 and 2001 is reflective of a reduction in white shrimp harvest in both states (Table 5.2.1-58., Table 5.2.1-59). In North Carolina, average ex-vessel prices were lower in 2002 and 2001 even though supply declined. In the Georgia fishery, there has been a steady decline in number of trips from 1997 through 2001. In contrast, the number of trips harvesting shrimp fluctuated during this time period with no distinct trend for North Carolina (Table 5.2.1-16).

It was not possible to determine the actual number of vessels that operated in the South Carolina shrimp fishery since this state recently implemented a trip ticket program in 2003. The number of trawler licenses sold may not equate to the number of vessels participating in this fishery as some vessel owners may purchase a license in a given year but not go shrimping. However, the marked decrease in license sales indicates a reduced demand for shrimp fishing in 2001 and 2002 (Table 5.2.1-58).

It would be misleading to interpret the observed trend of increased vessel participation with actual changes in fleet size in the Georgia fishery because there is a large portion of shrimp landings not associated with any vessel in years prior to 2002. Compliance with the vessel identification reporting requirement improved substantially in 2002 compared to previous years. Other data from commercial shrimp license sales may provide a better indicator of participation trends in the Georgia shrimp fishery. License sales data for fiscal year 1998/99 through 2003/04 are 496, 467, 469, 484, 407 and 362 respectively. There is a noticeable decrease in license sales during the last two years compared to previous years. There may also have been a shift in the composition of the fleet during this period as the number of Coast Guard registered vessels has consistently declined throughout the entire time period while the number of state registered boats actually increased in fiscal years 2000/01 and 2001/02, before dropping sharply in 2002/03 (Travis, NOAA Fisheries, pers. comm. 2004).

In 2001 the State of Georgia began requiring all commercial castnet shrimpers to report as dealers. Castnet shrimpers often sell directly to the consumer and/or split their catch between several small markets. By requiring all castnetters to report as dealers, Georgia is able to collect more reliable trip level data. The marked increase in shrimp dealers in 2002 can be attributed to two factors: more castnetters selling their catch rather than keeping it for personal consumption; and more shrimp trawl owners marketing their own catch rather than selling to a shrimp packing house. For reporting purposes, those vessel owners are considered dealers. In the past, it was very unusual for vessel owners to market their entire catch directly to final consumers and retail outlets. With shrimp prices at an all-time low, vessel owners are employing non-traditional marketing methods in an attempt to command higher prices than the packing house can offer. Thus, there has not been an actual increase in the number of shrimp docks in Georgia but there was an increased number of individuals acting as dealers. For the other states there is a definite increase in the number of dealers in 2002 compared to 2000.

Seafood dealer operations are usually diverse in that they depend on more than one type of seafood product. For example, dealers in the shrimp industry may also handle clams, oysters and finfish. The relative health of these separate seafood markets would determine the financial viability of dealer operations or fish houses. Some dealers and vessel owners may also operate processing facilities where there is considerable value added to the final shrimp product.

The declining trend in prices and ex-vessel revenue in the shrimp harvesting sector, observed across all states, could play a major role in the financial solvency of dealers and fish houses that depend on shrimp. These businesses would be especially vulnerable if they are not able to transition to alternative sources of revenue from other fisheries.

Reduced revenues in the shrimp harvesting sector would also result in reduced economic activity to the sectors of the economy that are directly and indirectly associated with the shrimp industry in the South Atlantic. If vessels respond to lower revenues by reducing input costs, there would be negative effects on the sectors that supply inputs such as fuel and gear. If there is a reduction in the number of vessels, there would be further direct economic losses to impacted industries since annual and fixed expenditures would not be incurred. Apart from the direct effects there will also be indirect and induced effects on other sectors of the economy (the multiplier effect) which could have far reaching implications in the short-term. Assuming the economy is operating at full employment, economists theorize that these economic losses are distributional, and unlike net revenue to commercial fishermen there is no resulting changes in national GDP (gross domestic product). It is assumed that these monetary resources would be redirected to purchases that increase economic activity in other industries/sectors. The economy will adjust to these changes in the long run but there could be sectoral and regional shifts in the number of jobs, wages and business revenue.

Recreational fishery

Data on the number of recreational shrimp fishermen and recreational shrimp catches are not routinely collected throughout the South Atlantic region. Recreational licenses are only required for certain gear types and licensing requirements are not consistent across all states making it somewhat difficult to estimate total participation. However, there have been a number of ad hoc studies conducted to provide estimates of catch, participation and effort information on these recreational fisheries. Some of these studies are dated and estimates of catch and participation may not reflect current activity levels or recreational harvest of penaeid shrimp.

In South Carolina, sales for shrimp baiting permits increased from 5,509 in 1988 to a record high of 17,497 in 1998. After 1998, there was a decline in permit sales (Table 5.2.1-60). South Carolina conducts a post-season annual survey of these license holders to collect information on participation, effort and catches. Recreational shrimp harvests have fluctuated over time but ranged from a low of 0.91 million pounds in 2000 (an unusually poor year) to a high of 3.63 million pounds in 1997. In certain years, the recreational harvest by shrimp baiters comprised a large proportion of the total fall shrimp harvest (Table 5.2.1-60). The estimates from this survey does not represent the total recreational shrimp catch in South Carolina since landings of all shrimp species caught by recreational shrimpers using other gear are not recorded.

Table 5.2.1-60. Summary of results from the annual shrimp baiting surveys in South Carolina (Low 2002, SCDNR 2008).

Year	Permits issued	Participants	Trips	Pounds (heads on) million	Pounds/ participants
1987		21,735	40,101	1.80	83

It has been speculated that shrimp baiting could reduce the catches of commercial shrimp trawlers in South Carolina in the fall season (Henry et al. 2001). In fact, the findings from this cost and earnings study indicated that commercial shrimp vessels in the larger size categories could exit the industry if the harvest declined. This would reduce economic benefits in the commercial harvesting sector. However, recreational shrimp baiting also generates economic activity within the State of South Carolina from expenditures on travel, fuel, poles, bait and other items to participate in this sport.

From a survey conducted in North Carolina it was estimated that recreational shrimpers caught 91,000 pounds of shrimp, or less than 3% of the reported commercial catch in 1979 (Maiolo and Faison 1980). A more recent survey of recreational/commercial gear license holders conducted by the North Carolina Division of Marine Fisheries during 2002 estimated that this group made 5,035 trips. Shrimp accounted for 101,154 pounds of the 118,468 pounds captured by the use of shrimp trawls. Blue crab and flounders were the only other species contributing greater than 1,000 pounds to the overall shrimp trawl harvest (NCDNR 2003). A combined telephone/intercept access survey was carried out in coastal Georgia during 1989 to estimate recreational shrimp catch and effort. Total cast netting participation was estimated at 47,723 and 23,298 individuals during the summer and fall waves respectively. These cast netters were estimated to have taken 184,887 total trips and to have caught 576,000 pounds of shrimp, most of which were white shrimp (Williams 1990). There are no estimates of recreational shrimp catches for Florida, but it is believed that the recreational catch is substantial.

5.2.1.3 Social and cultural environment

Introduction

This Section identifies "shrimp" communities throughout the U.S. Southeast and focuses on recent data regarding shrimp fishing, shrimp fishermen, and ultimately the potentially impacted communities themselves. These "shrimp" communities were identified based on factors such as commercial licenses held by local residents, the number of shrimp "dealers" in such communities as the value of the shrimp landed. Information for many of the South Atlantic community descriptions were referenced from the report, *Potential Fishing Communities in the Carolinas, Georgia and Florida: An effort in baseline profiling and mapping* by Jepson *et al.* (2006). Demographic data came from the U.S. Census Bureau Decennial census. Other fishery dependent data were derived from the Accumulated Landings System (ALS) database and licensing information from the NMFS Regional Office. Each state is addressed and communities are selected based on data from the Southeast Regional Office which highlight the number of licensed shrimp fishermen most likely impacted by potential policy changes. Communities from the Gulf were also included as many Gulf shrimpers and dealers from the region are also impacted by participation in the South Atlantic shrimp fisheries (the community descriptions are based on reports created by Impact Assessment Inc.). The potentially impacted communities are discussed on a state by state basis with individual communities listed in alphabetical order, no way reflecting on the relative importance of shrimp to the region, state or local economy.

5.2.1.3.1 *North Carolina Shrimp Communities*

Beaufort Community Description

Beaufort was built on a former Native American village, called Warelock which translates to "fish town" or "fishing village." It is located near Cape Lookout and borders the southern portion of the Outer Banks. Because of its physical characteristics, especially the deep water harbor, it is an ideal home to vessels of all sizes and types and maintains a maritime infrastructure making it a favorite stop-over for transient boaters. Originally a fishing village and port of safety, it was known as "Fishtowne" until incorporated in 1722.[1] In addition to the fishing activities in Beaufort, a whaling community called Diamond City existed on Shackleford Banks, a barrier island six miles to the southeast by boat. This community was present during the eighteenth and nineteenth centuries. The export economy of the areas centered round lumber, barrel staves, rum, and molasses. However, when the port declined as a trade center, commercial fishing gained greater importance and became the primary economic activity. Up until recently, Beaufort served as home port for a large menhaden fishing fleet and had numerous processing facilities for menhaden products.[2]

Currently, tourism, service industries, retail businesses and construction are the important mainstays of the area, with many shops and restaurants catering to visitors from outside the area. Beaufort's population has slightly increased from 3,808 in 1990 to 4,216 in 2007

(Table 5.2.1-61). The community has some exclusive homes along the waterfront but overall most housing is modest. Even with modest housing Beaufort has seen its housing values more than double from $65,400 in 1990 to $128,500 in 2007 (Table 5.2.1-61). It is home to both the NOAA Center for Coastal Fisheries and Habitat Research and Duke Marine Sciences Center. Directly across the bridge from Morehead city is Radio Island, which is the commercial fishing hub for Beaufort. There are a few private boats along the waterfront in downtown Beaufort, but the commercial enterprises are predominantly located on Radio Island. The waterfront does have two tour/party boats, in addition to private boats, some of which may be smaller charter vessels. There are several marinas in the community and several businesses that provide support services for both the recreational and commercial fishing industries. According to one individual, Beaufort is a commercial fishing community, although less so now, than in the past. This seems to be largely due to fewer young people getting into the fishing business as it does not seem to pay well. This same individual has seven trawlers and four small snapper/grouper boats as part of his business. There are accounts that during summer months three longline vessels travel from New York and dock at his facility. The majority of fish purchased is marketed in Virginia and farther north. Shrimp is a large part of the local seafood industry, but, like everywhere else throughout the southeast region imports are having an impact on the domestic market lowering prices.

Fish houses and facilities are commonly full service in that they serve as a fish house, with processing, ice, fuel, as well as gear and net repair. Like many facilities related to the commercial fishing industry, the glory days of fishing have past them by and many owners have sold-out or relocated leaving in their wake developers who have come to take advantage of the prime coastal real estate. During research in 2002 it was noted that there existed an ice plant across the bridge from Beaufort which has now become a condominium development. The pressure to redevelop has even affected the last shad factory in the state, located on Front St. in Beaufort. Popular fisheries such as the shad fishery have been eliminated and as one remaining owner suggests shad built the fishing industry in Beaufort. While there are efforts or forces to put it out of out of business due to the property valuable, he will hold on until it is time to retire. Asked if he would like his family to continue on the business when he retires, he said no, and that there was little future anymore in this type of fishing.

In 2002 fishermen estimated that on Radio Island there were 20 trawlers that docked there permanently. Another local fisherman said that his fish house used to process year round, but now only operates seven months of the year due to various seasonal closures. This has forced employment levels to change, as for one fish house owner who used to employ four people year round, he now only needs to employ two. It was in1987 that Beaufort had its best year for shrimp. This benefit was said to have a positive impact on the local communities as most the fishermen involved in the fishery live in Beaufort or Morehead City. There are three fish houses in Beaufort, one of which deals primarily in bait. In 1987 there were about 25 larger commercial vessels (70-90') in addition to a lot of smaller boats; now there are approximately 11 large commercial vessels in Beaufort.[3]

Shrimp has always been an important and valuable species in Beaufort, currently second to summer flounder (Figure 5.2.1-1). In 2006 Beaufort landed 630,885 pounds of shrimp valued at $914,602 (Table 5.2.1-62). There were only 10 federally permitted vessels in Beaufort in 2001and those vessels held primarily coastal pelagic permits (Jepson *et al.* 2006). Most of the employment that is fishing related according to census business pattern data is related to boat building with 184 persons employed in that business. Others are employed in fish processing and fish and seafood. There are over 400 commercial vessels registered with the state from Beaufort with almost 300 standard commercial fishing licenses. There are 172 shellfish licenses and 32 dealer license (Jepson *et al.* 2006).

Engelhard Community Description

Engelhard is located on the shore of Far Creek (Pamlico Sound) and is said to date as far back as 1650. It features a dredged channel that tailors to the many types of commercial fishing boats. The community is small (population), and described as having a laid back atmosphere. Its existence seems to depend equally on commercial fishing and agriculture.[4] Between 1990 and 2000 the community experienced a slight decrease in population and a decrease in unemployment (Table 5.2.1-63). Engelhard holds an annual Seafood Festival every May with this year, 2008, being the 21st year in existence.[5] The event is described as family oriented with a blessing of the fleet, live music, a pageant, and of course local food. One of the most popular local species is shrimp. In fact, shrimp is the second most valuable commercial species in Engelhard, just after summer flounder (Figure 5.2.1-2). In 2006 Engelhard brought in 862,740 pounds of shrimp, taken during 427 trips (Table 5.2.1-64).

<u>Swan Quarter Community Description</u>
Swan Quarter is located in Hyde County and is one of the oldest counties in North Carolina. Swan Quarter was settled by Samuel Swann in the 1700's near the head of Swan Bay, along the Pamlico Sound.[7]
Fishing, oystering, and crabbing have long been the principal occupations of Swan Quarter citizens. This salty duty is supplemented by farming the rich land surrounding the town. Today, the village sees many more visitors than in times past. Tourists pass through on their way to and from the Ocracoke-Swan Quarter ferry, located nearby. The increased traffic doesn't seem to have changed the town much, however.[8] Swan's Quarter has seen a steady population with a large increase in unemployment from 2.30% in 1990 to 5.30% in 2000 (Table 5.2.1-65).

Shrimp in Swan Quarter is second in value and pounds landed to blue crabs (Figure 5.2.1-3). Swan Quarter fishermen landed 346,887 pounds of shrimp valued at $613,910 (Table 5.2.1-66).

5.2.1.3.2 *South Carolina Community Descriptions*

McClellanville Community Description

The population of McClellanville dropped in the 1990 census but has since increased again in the 2000 census to 459 and is currently at 741 (Table 5.2.1-67). The median household income has almost doubled from 1990 to 2006 while the median housing value has increased from $78,600 in 1990 to $225,700 in 2006 (Table 5.2.1-67).

There are 4 vessels with federal permits homeported in McClellanville and all four have rock shrimp permits (Jepson *et al.* 2006). All employment in fishing related business is in fish and seafood and the percent employed through fishing has increased from 12.6% in 1990 to 18%in 2000 (Table 5.2.1-67). There are 133 state permits in McClellanville, with 52 of those being saltwater licenses. There are 27 trawler licenses, 16 handheld equipment licenses and 5 wholesale dealer licenses.

Mt. Pleasant Community Description

The first inhabitants of the Mount Pleasant area were the Sewee Indians. The first English settlers arrived around 1680 under the leadership of Captain Florentia O' Sullivan. He had been granted 2,340 acres and each time a new family arrived, they were allotted several hundred acres. The first small settlement of the area was the village of Greenwich, which was adjacent to Jacob Motte's "Mount Pleasant" estate. Motte's estate was purchased in 1803 and divided into 35 large lots. In 1837, the village of Greenwich was merged with Mount Pleasant. Many of the families in this area had timber concerns and some maintained the ferries. Mount Pleasant also played a leading role in the first major military engagement of the Revolutionary War in 1775. After the war, the area was known as a resort town with many stores and rentals available. The area is still widely known as a vacation area and "model town" in South Carolina.[10] Mount Pleasant has seen its population double every ten years from 1970 to 1990 and reached 59,113 in 2006. The number of persons in the labor force has dropped slightly to 69.9 percent while percent unemployed has increased from 1.5% in 2000 to 3.3% in 2006. Average wage and salary has risen substantially but so has the number of persons living below the poverty level.

While there are only 6 vessels with federal permits homeported in Mount Pleasant, there are 12 persons listed as fishing and 28 persons employed in fish and seafood and markets (Jepson *et al.*2006). There are 170 state permits in Mt. Pleasant with 57 saltwater licenses. There were 23 trawler licenses and 11 wholesale dealer licenses.

<u>Murrells Inlet Community Description</u>

Murrells Inlet is known as the Seafood Capital of South Carolina. The origin of its name remains a mystery, however Murrells Inlet was officially named by the post office in 1913. The first settlers of the area were Native American Tribes. It is stated that beginning in the 16th and 17th Centuries, Spanish and English colonists arrived in the area. The frequency of ships led to pirate activity and pirates were said to have utilized the Inlet's winding creeks for refuge and a hiding place. Historically, large tracts of land were cultivated into successful rice plantations. By 1850, almost 47 million pounds of rice were produced in this area. Murrells Inlet was used a port during the Civil War to sneak cotton and other products to England in exchange for war supplies, such as food and medicine. The Civil War led to the decline of the rice culture and in 1916, the last remaining commercial rice grower was out of business. By this time, commercial and recreational fishing became a popular industry. By 1914, captain-led fishing excursions cost $5 per person for a day trip out of the Inlet on a 20-foot skiff. Today, charter, recreational and commercial fishing are still popular in Murrells Inlet. Murrells Inlet has seen its population increase to a high of 5,519 in 2000. The percent of the population in the labor force has remained practically the same while unemployment has risen from 3 percent in 1990 to 5.2 percent in 2000 (Table5.2.1-69). The number of persons working in farm, fish and forestry occupations has seen a decline like most communities.

There are a total of 33 vessels with federal permits. The majority have king mackerel and snapper grouper class 1 permits. Almost half of those permitted vessels have charter permits for either coastal pelagics or snapper grouper (Jepson *et al.*2006). There are four federal dealers in the community. Most of the fishing employment is in fish and seafood markets with 10 persons employed in that sector out of the 16 total. There are 111 state permits issued to residents of Murrells Inlet. Forty-four of those permits are for saltwater licenses. Another 14 are for handheld equipment and 12 are for crab pots. There are 10 wholesale dealer licenses held by Murrells Inlet residents (Jepson *et al.*2006).

Wadmalaw Island Community Description

Wadmalaw Island was landed upon by Captain Robert Sandford and the crew of the Berkeley Bay in mid-June of 1666 after an excursion up the Bohicket Creek.[12] Wadmalaw Island is located southwest of Johns Island and more than halfway encircled by it. To the north it is bordered by Church Creek; to the northeast and east by Bohicket Creek; to the south by the North Edisto River; and to the west by the Bohicket Creek. The island's only connection to the mainland is via a bridge over the Wadmalaw River. The island is about 10 miles long by 6 miles wide. It has a land area of 108.502 km² (41.893 sq mi).[11]

[11] Zepke, Terrance. 2006. Coastal South Carolina. Pineapple Press Inc. Publishing. p.157.
[12] http://en.wikipedia.org/wiki/Wadmalaw_Island_South_Carolina

Wadmalaw Island has seen a decrease in unemployment from 5.90% in 1990 to 3% in 2000 (Table 5.2.1-70).

5.2.1.3.3 Georgia Community Descriptions

Midway Community Description

Midway, located in Liberty County, was named after the Midway River in England and settled in 1754.

Currently Midway has a major industrial park with nine manufacturing facilities.[13] Midway has seen a slow population increase and a steady unemployment rate (Table 5.2.1-71). Blue, hard crabs were the number one caught species in 2006 (Table 5.2.1-72 and Figure 5.2.1-4)

Table 5.2.1-71. Midway, GA demographic data from 1990-2006 (Source: U.S. Census Bureau Decennial census).

<u>Richmond Hill Community Description</u>

Richmond Hill, found in Byron County, is located 20 miles from Savannah on Georgia's coast with a total area of 10 square miles. Richmond Hill has a history that is similar to that of our nation: Exploration, Indian and Colonial settlements, the American Revolution, the War Between the States, Henry Ford Era, and recent military conflicts.[15] For centuries, the Guale people inhabited the shores of the Ogeechee River, taking advantage of the seafood and temperate climate. Spanish exploration in the late 1500s led to English settlement by 1792.[15] Then in 1862 Fort McAllister was built for the civil war and was the site of the end of Sherman's March to the Sea in 1864.[15] During this time the town was known as Ways Station. It was renamed in 1939 to its current name, Richmond Hill, after Henry Ford moved into the town and built an estate. The Ford era transformed this town through their philanthropic efforts, turning the backwater town of Ways Station into a vibrant community with new schools and employment opportunities.[15]

The next major development in Richmond Hill was Fort Stewart Military Reservation that was built prior to World War II and is still in operation.[14] More recently the J.F. Gregory City Park opened in 1999 in Richmond Hill where the first annual "Great Ogeechee Seafood Festival" was celebrated.[14]

Richmond Hill has seen an increase a moderate increase in population from 1990 to 2006 and a slight decrease in unemployment from 2.60% in 1990 to 1.80% in 2000 (Table 5.2.1-73). Blue, hard crabs were the number one species caught by pounds in 2006 (Table 5.2.1-74 and Figure 5.2.1-5).

<u>St. Mary's Community Description</u>
St. Mary's has seen steady population growth since 1970. The percent of the population in the labor force has remained fairly constant while unemployment has risen to 3.9 percent (Table 5.2.1-75). Average wage and salary has risen consistently over the years along with a rising median housing value. Those employed in farm, fish and forestry sector have seen a steady decline in their numbers since 1970 also.

There were only 2 vessels registered with federal permits from the community (Jepson *et al.*2006) but there were 42 persons listed in the fishing. The state has 19 vessels registered with 9 of those having shrimp gear and 13 of those owners considered full time fishermen (Jepson *et al.*2006). Blue, hard crabs were the top species caught in 2006 in St. Mary's (Table 5.2.1-76 and Figure 5.2.1-6).

<u>Townsend Community Description</u>

Townsend has seen a slight increase in population and steady unemployment rates (Table 5.2.1-77). Median household income has only slightly risen from $23,324 in 1990 to $32,300 in 2006 while median housing value has greatly increased from $33,000 in 1990 to $102,600 in 2006 (Table 5.2.1-77). Blue, hard, crabs were the number one species caught in 2006 with 538,127 lbs. (Table 5.2.1-78 and Figure 5.2.1-7).

5.2.1.3.4 Florida Community Descriptions

Atlantic Beach Community Description

The community of Atlantic Beach has remained fairly small throughout its history. The arrival of Henry Flagler's Florida East Coast Railroad in 1900 helped spur development and prominence within this coastal community. However, it was not until the construction of the Mayport Naval Station in the 1940s and the completion of the Matthews Bridge in the 1950s that the area truly became ready for development. Beginning in the 1990s, the Atlantic Beach community embarked on environmental endeavors regarding their aquatic resources. They created the Tideviews Preserve and the Dutton Island Preserve.

Preserve, fishing off the pier is a popular activity for park visitors. Atlantic Beach has seen steady growth in its population. There has been a decline in the percent of the population in the labor force and unemployment has dropped to 2.1 percent in 2000 (Table 5.2.1-79). Average wage and salary rose significantly between 1980 and 1990, but only slightly in 2000. Jobs in the sector of farm, fish and forestry have fluctuated over the past three decades, but dropped to low levels in 2000. Although there is only one vessel with federal permits in Atlantic Beach (Jepson *et al.* 2006) there are 56 persons employed in the fish and seafood sector. In 2006 blue, hard crabs were the top species by pound (Table 5.2.1-80 and Figure 5.2.1-8).

Cocoa Beach Community Description

Cocoa Beach is six miles long and not more than a mile wide located on a barrier island between the Atlantic Ocean and the Banana River Lagoon on Florida's Central East Coast. Cocoa Beach is a residential community and a tourist destination with 12,800 permanent residents increasing to 30,000 persons during peak tourist season.[20]

Cocoa Beach has seen a fairly steady population while the median housing value has almost tripled from $127,000 in 1990 to $308,000 in 2006 (Table 5.2.1-81). In 2006 King Mackerel were the top species caught by pound (Table 5.2.1-82 and Figure 5.2.1-9).

<u>Fort Pierce Community Description</u>
The Spanish built Fort Santa Lucia on the Jupiter Inlet in 1565 from which the county now draws its name-St. Lucie County.[21] Permanent U.S. inhabitance of Fort. Pierce dates back to the Seminole Indian War. US Army Lt. Col. Benjamin Kendrick Pierce, for whom the town is named, built a fort in 1837 to use as the army's headquarters. The war ended in the early 1840s, making way for settlement and development: "Water transportation, fishing and canning fish were key to the area's early economy."[22] The arrival of Henry Flagler's railroad in the early 1900s opened Fort. Pierce's economy to the rest of the east coast. Fort. Pierce beach was used as a naval base during World War II.[23]

The culture of fishing has been in the area since its inception. Anecdotes passed down from one generation to the next of Fort. Pierce residents describe the abundance of fish in the area in the late 1800s and early 1900s. One such story, told by Newman (1953) in her book, *Early Life Along the Beautiful Indian River*, tells of a man who bound his shirt at the sleeves and waist and cut a plunging neckline. He would then stand in the water until the shirt was full of fish and then empty it out into a bucket on the shore. In the late 1800s, a man from the nearby town of Titusville helped to create the commercial fishing sector in Fort. Pierce. He would bring the fish to Titusville for shipping to the rest of the east coast. The first icehouse for packaging fish was built in 1900 (Newman, 1953).

Recreational fishing has also become a popular pastime in Fort. Pierce and the rest of St. Lucie County. This is due in large part to the fleet of Spanish galleons that sunk off the St.

Lucie and Martin Counties coastline. These artificial reefs have created excellent fishing and diving spots for locals and tourists. The reefs attract spiny lobsters, marlin, snook, flounder, and grouper.[24] Some of the more popular fish in the St. Lucie River include channel bass, snook, ladyfish, jack crevalle, and trout. Black sea bass is another famous catch in the area.[25] Most charter fishing boats in the area offer half, three-quarter, and full-day trips for dolphin, sailfish, wahoo, amberjack, tuna, kingfish, snapper, and grouper. Fort Pierce has seen moderate population growth over the past three decades while unemployment has increased from 4.90% percent in 2000 to 11.5% percent in 2006 (Table 5.2.1-83). Average wage and salary has grown slowly over the past ten years while the number of persons living under the poverty level has risen significantly. The number of people working in farm, fish and forestry has remained relatively high for both occupation and industry over the years with both categories having over 1000 persons in each. There are over 100 vessels with federal permits homeported in Fort. Pierce and most of those have coastal pelagic permits (Jepson *et al.* 2006). There are over 260 persons employed in the boat building sector of fishing related employment. In 2006 Spanish mackerel were the top species caught by pound (Table 5.2.1-84 and Figure 5.2.1-10).

Melbourne Community Description

The city of Melbourne is located on east central Florida's Space Coast in Brevard County. The contemporary city of Melbourne is the result of the 1969 merger of the separate communities of Melbourne and Eau Gallie.[27] Today Melbourne is also a part of the Palm Bay-Melbourne-Titusville metropolitan area.[28] The city is close to 40 square miles in size, with about 75% of that land in use with a population of approximately 77,000 that is continuing to grow at a modest rate.[26] While most of Melbourne is located on the Florida mainland, a small portion is located on a barrier island. The Indian River Lagoon separates the mainland from the island.[26] Melbourne's industry is centered on defense and technology companies with a high concentration of high-tech workers.[28] Melbourne has seen its population rise greatly from 59,649 in 1990 to 76,963 to 2006 (Table 5.2.1-85). Unemployment has slightly risen from 3.20% in 2000 to 4.40% in 2006.

The Banana and Indian Rivers run through Brevard County and offer excellent flats fishing for a wide variety of species. The popular Mosquito Lagoon is located at the north end of Brevard County and offers good redfish fishing. Brevard has two inlets: the Sebastian Inlet which is located at the south end of the Indian River and Port Canaveral which is located at the north end of the Banana River. These inlets offer fishing for snook, redfish, tarpon, and flounder.[29] In 2006 hard, blue crab were the top species by pound (Table 5.2.1-86 and Figure 5.2.1-11).

<u>Merritt Island Community Description</u>

Merritt Island's population has grown slowly over the past three decades. The percent of the population in the labor force has dropped slightly over the past ten years, but unemployment has increased slightly (Table 5.2.1-87). Average wage and salary have increased to over $40,000 for the year 2000, but the number of persons living under the poverty level has also grown considerably. As for most coastal communities the number of people working in the farm, fish and forestry sector of the economy has dropped significantly over the past decade but has shown a steady decline prior to the 2000 census. Merritt Island has only 8 vessels with federal permits and half of them have charter permits (Jepson *et al.* 2006). There is substantial employment represented in the fishing related sector of boat building with over 1100 persons employed in that sector according to (Jepson *et al.* 2006). In 2006 blue, hard crab were the top species by pound (Table 5.2.1-88 and Figure 5.2.1-12).

Miami Community Description

In 1891 Julia Tuttle moved to Florida and purchased 640 acres of land on the north bank of the Miami River. Tuttle then talked railroad builder Henry Flagler into extending his railroad into Miami, building a luxury hotel and laying out a new town. These developments resulted in the birth of a new city. The city of Miami was incorporated on July 28, 1896.[31]

The city of Miami is located in Miami-Dade County on the Miami River, between the Florida Everglades and the Atlantic Ocean. The population of Miami has steadily increased from 358,548 in 1990 to 404,048 in 2006 (Table 5.2.1-89). In 1990 the median household income was only $16,925 and has only slightly risen to $25,211 in 2006 while the median housing value has increased from $79,200 in 1990 to $248,500 in 2006. Unemployment remains high but has decreased from 6.50% in 1990 to 4.4% in 2006. In 2006 shrimp were the top species caught by pound (Table 5.2.1-90 and Figure 5.2.1-13).

Port Orange Community Description

On April 26, 1867 the community of Port Orange was established on the banks of the Halifax River. It was not until the mid 1970s when Dunlawton Avenue was extended from the FEC railroad to Nova Road did Port Orange start to see the early growth that would happen in the mid 1980s. According to the 1970 US Census, there were only 3,871 calling Port Orange home (Cardwell & Cardwell, 2000). With the second western extension of Dunlawton all the way out to Interstate 95, did Port Orange begin to blossom into the large metropolitan community that we know today.[32] Now some 140 years later, Port Orange is a community of 54,851 people extending 28 square miles (Table 5.2.1-91). In 2006 sandbar shark were the top species caught by pound (Table 5.2.1-92 and Figure 5.2.1-14).

St. Augustine Community Description

St. Augustine has the distinction of being the oldest European city in the United States. First sited by the Spanish explorer Don Juan Ponce de Leon in 1513, it was not settled until 1565 by Don Pedro Menendez de Aviles, a Spanish admiral, in the name of King Phillip II.[33] The town's boom did not occur until the 1880s with the arrival of Henry M. Flagler. His goal was to turn St. Augustine into a winter resort for wealthy Americans. It was this thinking that transformed the town. The construction of the railroad linked the city with much of the east coast. Flagler built three large hotels to help fulfill his dream of a tourist mecca. By the mid-1900s, St. Augustine's local economy was dominated by tourism.[34] The commercial fishing industry began in the St. Augustine/Fernandina area around 1900 with the arrival of a Sicilian immigrant named Sallecito Salvador. He placed an engine on his boat that allowed him to pull a shrimp seine across the ocean floor in 1902, and in 1906, he began his company, S. Salvador & Sons. Salvador moved his business to St. Augustine in 1922, where it thrived until 1929. Shrimp catch levels soared from about 1934 to 1940.[35]

These stories illustrate the longstanding culture of fishing in the St. Augustine area and the importance it holds for many of the fishing families there. Commercial fishing still continues at the port, the oldest continuously active port in the United States. Boat building, tourism, and recreational activities are also important to St. Augustine's port.[36]

St. Augustine has seen a steady decline in its population since 1970 until recently in 2006 (Table 5.2.1-93). Both the percent of population in the labor force and unemployment have remained relatively stable over the years. Average wage and salary has grown steadily, while the number of person living below the poverty level has dropped. The number of people employed in farm, fish and forestry has also dropped significantly over the past three decades, with the most pronounced decline from 1990 to 2000. St. Augustine has 28 vessels with federal permits and the majority of them have charter permits for either snapper grouper or coastal pelagics (Jepson *et al.* 2006). There is significant employment in fishing related business as there are over 370 people employed in boat building (Jepson *et al.* 2006) and another 75 in the seafood processing sector. In 2006 blue, hard crab were the number one species caught by pound (Table 5.2.1-94 and Figure 5.2.1-15).

<u>Fort Myers Community Description</u>

Fort Myers is located on the east banks of the Caloosahatchee River in central Lee County. Access to the Gulf of Mexico can be over ten miles via the Caloosahatchee River to San Carlos Bay. Fort Myers served as a military operations base during the Seminole Indian Wars in the mid-1800s. Following the platting of the town in 1876, Fort Myers' economic focus turned from defense to agriculture (tomatoes, castor beans, and avocados), cattle, and logging.

The year 2000 census counted 48,208 persons in Fort Myers, an increase of 3,002 persons from the 1990 census (Table 5.2.1-95). Shrimp is the principal landing for the commercial fleet in Lee County, though a wide range of species are landed, including some pelagics (Table 5.2.1-96). There are numerous seafood dealers, marinas, and various other fishing-related businesses active in Fort Myers throughout the course of the year. Charter fishing is popular here.

<u>Fort Myers Beach Community Description</u>

Fort Myers Beach is located on the northern tip of Estero Island in western Lee County. It is surrounded by water: the Gulf of Mexico to the west, Estero Bay to the east, and San Carlos Bay to the north.

Anglo homesteaders arrived in the late 1800s and quickly developed the island's commercial fishing industry; mullet was the primary catch. Investors gradually bought up the majority of available subdivisions on the island during the 1920s; however, commercial development remained slow through the 1960s. In the meantime, the island's fishing industry continued to thrive. In particular, the Coquina clam– the area's most common shellfish– was a popular pre-war product. By the 1950s, Fort Myers Beach was an important shrimp port. In the 1960s, recreational fishing became popular in the area, with snook, trout, ladyfish, jacks, mackerel, kingfish, bonito, grouper, and tarpon being the primary species of interest. Fort Myers Beach incorporated in 1995 (Town of Fort Myers Beach).

The year 2000 population of Fort Myers Beach was 6,561, down from 9,284 in 1990 (Table 5.2.1-96). Fort Myers Beach is primarily a beach/tourist destination island. Numerous fishing-associated businesses are located here, and sightseeing and diving tours are popular activities. There is substantial recreational fishing infrastructure, as marinas, docking facilities, head boat operations, and charter boats are all available here. Fort Myers Beach is the site of docking facilities for about 60 or more Gulf shrimp vessels. Some trawler captains and crew are local, while many are transient and come from as far away as Texas. Offloading facilities, fuel, and maintenance (including net building and repair) are available at the docks.

<u>Tarpon Springs Community Description</u>

Tarpon Springs is located about 25 miles northwest of Tampa, adjacent to a well-protected anchorage near the mouth of the Anclote River. The town has roots in the commercial sponge-diving industry and still supports the largest natural sponge operation in the country. Tarpon Springs was incorporated in 1887 in Hillsborough County, but became part of Pinellas County in 1911. According to city historians, from 1905 to 1945, and again during the 1980's, a local fleet of 180 sponge boats worked from Apalachicola to Key West, bringing in $3 million annually to the local economy. A commercial fishing industry developed around 1920, with several fish houses and wholesale retail operations that continue today near the Sponge Docks. There were as many as eight fish houses operating in Tarpon Springs.

The year 2000 census enumerated 21,066 persons in Tarpon Springs, a 17 percent increase from 1990 (Table 5.2.1-98). Today, there are three active sponge factories and four active wholesale fish houses in Tarpon Springs.

Local fleet participants report that the number of active fishing vessels has decreased by half in the past ten years, going from approximately 100 to 50 vessels. They attribute the decrease to regulatory pressures, diminishing docking space, and the recent national and regional economic downturn. Most vessel owners feel that it is too expensive to rent docking space in the immediate area, and free space (that is, attached to fish house properties) is decreasing due to the increasing value and sale of waterfront property. Meanwhile, the number of recreational vessels moored at the local marinas has increased significantly. The town now has seven marinas that allow only recreational clientele. This number has increased over the past ten years, and marina owners now feel pressure to expand their docking space. One marina owner stated that he could not keep up with the number of recreational vessels coming into the community. Grouper are the top species landed in Pinellas County (Table 5.2.1-99 and Figure 5.2.1-17).

<u>Grand Bay Community Description</u>

Grand Bay is located in Mobile County, 25 miles south of the Gulf of Mexico. Grand Bay was founded in 1870 and in 2000 had a population of 3,918 (Table 5.2.1-100). Two wholesale seafood dealers are based here. One processes primarily oysters and the other crab. Most commercial fishermen who live in Grand Bay work from Bayou La Batre. The fleet is highly productive in shrimp, crabs, and oysters. Four Gulf shrimp permit holders were working from the area in 2003.

Fairhope Community Description

Fairhope is located along the eastern shore of Mobile Bay in west-central Baldwin County, approximately 25 miles northeast of the Gulf of Mexico. Fairhope was established as a "utopian" community by "single-tax colonists" in 1894. These political idealists embraced theories advanced by Henry George, advocating no taxes other than a single land tax. One of the first local endeavors was to build a municipal pier, completed in 1885.

The year 2000 population of Fairhope was 12,480 persons, up from 8,485 in 1990 (Table 5.2.1-101). Several locally-owned shrimp boats are docked at one marina; according to the manager, the owners are retired and fish only occasionally.

Two marina managers stated that most of their customers are interested in pleasure boating rather than fishing. Four charter operations are based here, as is a small group of commercial license holders. Shrimp were the principal commercial landings during 2002 (Table 5.2.1-102 and Figure 5.2.1-18).

5.2.1.3.6 *Mississippi Communities*

Pascagoula Community Description

Pascagoula is located in Jackson County and is bordered by three bodies of water: Pascagoula Bay to the west, Mississippi Sound to the south, and Point aux Chenes Bay to the east. The Gulf of Mexico is roughly ten miles south.

This city is home to the Naval Station Pascagoula and one of Mississippi's leading and busiest deepwater ports, the Port of Pascagoula. The shipbuilding industry is very active in Pascagoula, as are the oil and petrochemical industries. The year 2000 census enumerated 26,200 persons in Pascagoula, an increase of 301 from 1990 (Table 5.2.1-103). The Pascagoula seafood industry is an important source of local jobs and income. The shipbuilding industry is particularly important, however, and one of the larger shipbuilding operations in the area employees more than 11,000 persons. The operation is the largest employer in the state. As of the year 2000, six seafood processors employed an average of 24 persons each. Some 12.4 million pounds of seafood totaling 8.2 million dollars were processed in Pascagoula that year. A large fleet of small boat commercial operators is also based here; most pursue shrimp and various finfish in the inshore and nearshore waters of the sound and Gulf. Menhaden is the number one species landed (Table 5.2.1-104 and Figure 5.2.1-19).

5.2.1.3.7 *Texas Communities*

Port Arthur Community Description

Port Arthur is located along the Intracoastal Waterway and Sabine Lake in eastern Jefferson County. Port Arthur is about 14 miles north of the Gulf of Mexico and the Gulfgate Bridge connects it with Pleasure Island and provides access to the Sabine Lake Causeway. The town of Port Arthur was founded in the late 1800s by railroad pioneer Arthur E. Stilwell, with financial support from Dutch investors. Growth occurred in the early 1900s after the port opened for shipping. Economic prosperity was closely tied to the Spindletop oil field in nearby Beaumont. The Gulf Oil Corporation and Texaco established refineries in Port Arthur. The year 2000 census reported a population of 57,755 persons, a loss of 969 from 1990 (Table 5.2.1-105). Extensive fishing-related infrastructure is in place here, including numerous boat builders and brokers, marinas, processors, and retail and wholesale seafood dealers. A fleet of charter vessels is also based here. A relatively large fleet of trawlers is based here, with 35 persons holding Gulf shrimp permits in 2003. Shrimp are the number one species landed (Table 5.2.1-106 and Figure 5.2.1-20).

5.2.1.4 Bycatch in the Shrimp Fishery

5.2.1.4.1 Bycatch in the Penaeid Shrimp Fishery

Description of bycatch in the penaeid shrimp fishery prior to the use of BRDs

The discarded bycatch of fish and invertebrates in the penaeid shrimp trawl fishery is highly variable according to season and area. The following information reflects bycatch levels and composition in the penaeid shrimp fishery prior to the requirement for use of bycatch reduction devices (BRDs). It has been documented that federally approved BRDs reduce overall finfish bycatch by approximately 30% in the South Atlantic. These devices also reduce the numbers of weakfish and Spanish mackerel in the catch by 40%.

Results of initial studies to document bycatch in the penaeid shrimp fishery were described in Amendment 2 to the South Atlantic Shrimp Fishery Management Plan (SAFMC 1996b). Previous determinations of the ratio of finfish (lb) to shrimp (lb heads on) in North Carolina indicated that the daytime ratios were consistently higher than the nighttime ratios due to larger shrimp catches rather than lower finfish catches.

The first integrated bycatch program was part of the congressionally mandated Bycatch Research Program from February 1992 through December 1996. This program was carried out to characterize the entire southeast shrimp fishery prosecuted in both the Gulf and South Atlantic region. To ensure the integrity and validity of the results, the following research protocols were followed:

1. A voluntary observer program using trained observers was undertaken. The program included vessel insurance and compensation for cooperating vessels.
2. Using a stratified sampling approach indexed to shrimping effort, NOAA Fisheries and other cooperating institutions deployed observers throughout the fleet to document bycatch during normal fishing operations using standard data collection methods.
3. All data were entered into a common database managed by NOAA Fisheries' Southeast Fisheries Science Center's Galveston Laboratory.
4. Characterization data were analyzed, and these data and analyses were made available to other program researchers and fishery managers.

For characterization sampling, the entire catch of each trawl was sampled, and all species quantified. For BRD evaluations, a select group of finfishes and other species were quantified, with the remainder of the catch grouped into general categories. Therefore, both bycatch characterization sampling and BRD evaluation data were use to determine general categories of bycatch. Sampling was stratified based on shrimp effort, and given that the South Atlantic shrimp fishery accounts for approximately 10-15 % of the total U.S. shrimp production, the sampling effort was limited for some temporal and spatial strata. Nevertheless, the sampling that occurred provided a sufficient basis for NOAA Fisheries to characterize the fishery in the South Atlantic region. During that program, observers logged a total of 920 sea days documenting bycatch in the South Atlantic shrimp fishery. The majority of the effort was expended during 1992 through 1994.

In response to this federally mandated research program, NOAA Fisheries began cooperative work with the shrimp industry through the Gulf and South Atlantic Fisheries Foundation. The cooperative bycatch research program studied bycatch and gear options in shrimp trawl fisheries throughout the southeast region. The study estimated the catch rate for shrimp and bycatch in the South Atlantic penaeid shrimp fishery.

The South Atlantic observer program included 920 sea days of sampling effort from February 1992 through December 1996. These sea days were accomplished during 604 trips, varying in length from 1 to 54 days (Nance 1998). The results of the program are detailed in Nance (1998) and Nance et al. (1997), and presented in Tables 5.2.1-107 and 5.2.1-108. In summary, the study indicated that about 27 kg (59.5 lb) of organisms per hour are taken during trawling operations, and that the finfish to shrimp ratio for the South Atlantic shrimp fishery was 2.83 to 1 by weight and 2.35 to 1 by number. Finfish comprised the majority (51%) of the catch by weight, followed by non-commercial invertebrates (31%), and commercial shrimp species (18%), including brown shrimp, white shrimp, pink shrimp, seabobs, sugar/blood shrimp and rock shrimp. Finfish represented about 54% of the 1,450 organisms taken per hour during normal trawling operations. Non-commercial invertebrates and commercial shrimp species each comprised about 23% of the catch by number (Nance et al. 1997).

Shrimp trawl catch per hour changed seasonally, being lowest during the first trimester of the year (ca. 12 kg/hr [26.5 lb/hr]), while the summer and post-summer seasons had very similar catch rates at around 28-30 kg per hour (Table 5.2.1-107). Finfish catch rates always comprised more than 44% of the catch, while shrimp catch rates were approximately 15% to 18% in the summer and post-summer periods, respectively, but 37% in the pre-summer season. Finfish catch by weight for the entire shrimp fishery was highest between May and August. The highest catch rate of finfish by number occurred in September through December, with nearly 1,800 individual finfish caught per hour. Shrimp catches were higher then too, resulting in a finfish to shrimp ratio of only 2.59 individual finfish to 1 shrimp.

Similarly, shrimp trawl catch per hour differed by latitude as well. By weight, the northern area (>34 N) had the highest overall catch rates (37 kg/hr [81.6 lb/hr]), while areas to the south of 34 N had catch rates at around 25 kg/hr (55.1 lb/hr) (Nance et al. 1997).

Table 5.2.1-107. Average percent composition of shrimp trawl catch by season in the South Atlantic (NOAA Fisheries 1998).

Catch	**Weight**	**Weight**	**Weight**	**Number**	**Number**	**Number**
Time period	Jan-April	May-Aug	Sept-Dec	Jan-April	May-Aug	Sept-Dec
Finfish	44%	58%	44%	65%	58%	44%
Shrimp	37%	15%	18%	11%	26%	17%
Crustaceans	9%	14%	14%	21%	14%	9%
Invertebrates	9%	13%	25%	3%	3%	30%
Total catch (per hr)	12 kg 26.5 lb	30 kg 66.1 lb	28 kg 61.7 lb	850	1350	1800
Finfish:Shrimp ratio	1.19 to 1	3.87 to 1	2.44 to 1	5.91 to 1	2.23 to 1	2.59 to 1

Additional information collected during the Bycatch Program was presented in Amendment 2 to the Shrimp FMP. When looking at catch according to depth of the fishing effort across all shrimp fisheries, the highest bycatch of finfish came from vessels fishing in 60 ft (18.3 m) or greater depths, with 56% of the catch being finfish and 18% shrimp or a ratio of 3.1 finfish caught for each shrimp caught (Table 5.2.1-108).

Table 5.2.1-108. Percent average hourly shrimp trawl catch by area and depth (Data Source: NOAA Fisheries 1995).

Area	**Finfish**	**Shrimp**	**Crustaceans**	**Invertebrates**	**Total Catch (number)**	**Finfish to Shrimp**
South Atlantic < 18.3 m (60 ft)	46%	29%	11%	14%	1229	1.6 to 1
> 18.3 m (60 ft)	56%	18%	21%	5%	726	3.1 to 1
Florida < 18.3 m (60 ft)	37%	30%	27%	6%	1207	1.2 to 1
> 18.3 m (60 ft)	43%	29%	23%	4%	802	1.5 to 1

* 393 sea days, 63 trips and 679 tows

When summarizing catch of the South Atlantic shrimp fleet by species, cannonball jellyfish constituted 14% of the catch by weight and brown shrimp made up 8% of the catch by weight and 13% of the catch by number (Figure 5.2.1-21, Figure 5.2.1-22). White shrimp constituted 9% of the catch by weight and 10% of the catch by number. The highest catch of an individual finfish species was spot, which accounted for 9% of the catch by weight and 10% by number (Figure 5.2.1-21, Figure 5.2.1-22).

BRD research program

The second part of the congressionally mandated Bycatch Research Program, from 1992 through 1996, involved the development and review of bycatch reduction devices (BRDs). These trawl gear modifications were identified as the most cost-effective and least disruptive way to minimize finfish bycatch in the shrimp fishery. A four-phase development program was successfully used under this program structure to develop several BRD designs that are used in the fishery. Within this framework, the research and development of candidate devices was carried out independently by NOAA Fisheries, Sea Grant, state agencies, universities and industry, drawing on a variety of funding sources, primarily the Saltonstall-Kennedy (S-K) and MARFIN (Marine Fisheries Initiative) grants programs.

From 1992 to 1996, fishery researchers and commercial fishers developed and tested a total of 145 bycatch reduction device (BRD) designs throughout the southeast region. Research conducted by the Gulf and South Atlantic Fisheries Foundation, Inc. (Foundation), indicated that reductions in general catch and bycatch were 22% or less (Table 5.2.1-109). Spanish mackerel catch rate was reduced by 0%-83% and weakfish catch rate was reduced by 6%-58% (Table 5.2.1-110). The State of North Carolina also conducted testing on BRDs and Table 5.2.1-111 presents a summary of the observed reduction rates for BRDs that were proposed for use in federal waters when Shrimp Amendment 2 was developed (SAFMC 1996b). Detailed information on reductions associated with TEDs and BRDs are presented in Shrimp Amendment 2 (SAFMC 1996b) and included here by reference.

Table 5.2.1-109. Summary of reductions (kg/hr) attributed to BRD designs tested in the South Atlantic during 1993 and 1994 (Sources: Watson, NOAA Fisheries, pers. comm. 1995 and Branstetter, GSAFDF pers. comm. 1996).

	Fish-eye 4"Hx7"W 30 meshes from front	Fish-eye 5"Hx 12"W 30 meshes from front	Fish-eye 5"Hx 12"W 45 meshes from front	Large mesh extended funnel

Comm. shrimp (kg/hr)	-3(27)	-1(66)	-1(116)	+2(156)
Misc. fish spp. (kg/hr)	-15(26)	-6(66)	-14(122)	-22*(156)

* statistical difference from zero where Ho = CPUE of control net - CPUE of the BRD net = 0. Numbers in ( ) represent sample size.

Table 5.2.1-110. Reduction rates (kg/hr) for weakfish, shrimp and Spanish mackerel for the large mesh extended funnel BRD tested primarily off Georgia and South Carolina (1995 GSAFDF data); (Data Source: Watson, NOAA Fisheries, pers. comm. 1995).

Large mesh extended funnel	Reduction rate (kg/hr)	Number	95% Conf.
Weakfish	-37%	63	35%-39%
Spanish mackerel	-44%	26	39%-48%
Shrimp	+2%	63	

Table 5.2.1-111. Reduction rates (kg/hr) for weakfish and Spanish mackerel for Florida fisheye and large mesh extended funnel BRDs tested primarily off North Carolina (NCDMF 1992-1994 data) (Data Source: Watson, NOAA Fisheries, pers. comm. 1995).

Florida fisheye		Reduction rate (kg/hr)	Number = 213
	Weakfish	-58%	
	Spanish mackerel	-34%	
	Shrimp	-8%	
Large mesh extended funnel		Reduction rate (kg/hr)	Number = 36
	Weakfish	-56%	
	Spanish mackerel	-83%	
	Shrimp	-2%	

The fisheye tested by NCDMF off North Carolina reduced weakfish bycatch by 58% with high reductions for other species including spot and Atlantic croaker, which were reduced by more than 50%. The NCDMF tests showed that the fisheye reduced total finfish bycatch by 48% and total biomass by 28% (SAFMC 1996b).

A comparison of reduction rates attributable to various fisheye configurations tested aboard commercial trawlers in North Carolina between 1992 and 1994 indicated that the 9" by 9" fisheye reduced total biomass by over 60% and the 5.5" by 6.5" fisheye showed the greatest finfish reduction of about 60%. The 9" by 9" fisheye reduced Spanish mackerel approximately 50% and the 5.5" by 6.5" fisheye reduced weakfish by over 70% (Table 5.2.1-112). Tests of large mesh extended funnel BRDs were conducted by NCDMF and showed reduction rates of 55% in finfish numbers and 56% in the number of weakfish (SAFMC 1996b).

Table 5.2.1-112. Reduction rates (kg/hr) for weakfish, trout and Spanish mackerel for large mesh extended funnel and midsize fisheyes tested primarily off South Carolina and Georgia (1993-1994 NOAA Fisheries and GSAFDF data) (Data Source: Watson, NOAA Fisheries, pers. comm. 1995).

Large mesh extended funnel	Reduction rate (kg/hr)	Number	95% Conf.
Weakfish	-6%	39	
Spanish mackerel	-38%	67	16%-59%
Trout	-27%	148	15%-39%
Shrimp	+3%	186	

Midsize fisheye w/hard TEDs 30-mesh position	Reduction rate (kg/hr)	Number	95% Conf.
Weakfish	-40%	58	29%-52%
Spanish mackerel	-34%	47	24%-44%
Trout	-29%	174	21%-37%
Shrimp	+3%	268	3%-10%

Midsize fisheye, w/soft TEDs 30-mesh position	Reduction rate (kg/hr)	Number	95% Conf.
Weakfish	-7%	26	-
Spanish mackerel	-0%	20	-
Trout	-20%	32	-
Shrimp	-2%	112	-

Midsize fisheye, 45-mesh position	Reduction rate (kg/hr)	Number	95% Conf.
Weakfish	-16%	95	
Spanish mackerel	-0%	30	
Trout	-81%	4	
Shrimp	+3%	160	

These evaluations resulted in the approval of 3 BRD designs for use by the South Atlantic penaeid shrimp fishery. Regulations implementing the actions described in Amendment 2 to the FMP were promulgated effective April 21, 1997. The final rule established a requirement, with limited exceptions, for the use of certified BRDs in penaeid (brown, pink and white) shrimp trawls towed in the South Atlantic exclusive economic zone (EEZ).

Re-evaluations of all Gulf of Mexico and South Atlantic datasets generated by NOAA Fisheries and the Foundation were utilized in determining the effectiveness of BRDs for use in the eastern Gulf of Mexico (Amendment 10 to the Gulf of Mexico Shrimp Fishery Management Plan; Table 5.2.1-113). The BRDs currently certified in the South Atlantic (the fisheye and the expanded mesh) achieve a 30% reduction in overall finfish bycatch.

Table 5.2.1-113. Reduction rate estimates of various BRDs and one TED for the Gulf of Mexico and South Atlantic
(taken from GMFMC Shrimp FMP Amendment 10).

*Negative values represent a nominal increase. Source: NOAA Fisheries (unpublished data).

It has been demonstrated that the use of a turtle excluder device (TED) also reduces finfish bycatch in penaeid shrimp trawls. A number of experimental trials were conducted in Cape Canaveral, Florida, during 1986 to test the bycatch reduction capability of various TED designs and configurations. Based on the results of these trials, the Atlantic States Marine Fisheries Commission Weakfish Management Board granted a 23.9% TED credit for weakfish reduction (GSAFF 1999). However, many of those TEDs were soft (net webbing) TEDs that were never certified for use by NOAA Fisheries. Soft TEDs have much greater bycatch exclusion capability than hard (metal grid) TEDs.

The Foundation tested several hard TEDs during the late 1990s for their bycatch exclusion capabilities. A common TED, the Super Shooter, had 0% reduction in finfish bycatch compared to the catch of a "naked" (no TED) net (GSAFF 1997). NOAA Fisheries has similar data on the results of a variety of hard TEDs and none have demonstrated more than a minimal reduction in finfish catch.

Currently, only one soft TED is certified. Changes to the TED regulations (68 FR 8456, February 21, 2003) have greatly modified the shape, size and configuration of hard TEDs. No information is available on the bycatch exclusion capability of these TEDs. However, their configurations would suggest that little bycatch reduction would be expected, except for the mechanical exclusion of large fishes such as sharks and rays.

Bycatch Practicability Analysis for Penaeid Shrimp Fishery

The Magnuson-Stevens Act requires the Council to establish a standardized bycatch reporting methodology for federal fisheries and to identify and implement conservation and management measures that, to the extent practicable and in the following order: (A) minimize bycatch and (B) minimize the mortality of bycatch that cannot be avoided (16 U.S.C. 1853(a)(11)). The Act defines bycatch as fish that are harvested in a fishery, but that are not sold or kept for personal use. This definition includes economic discards and regulatory discards and excludes fish released alive under a recreational catch-and-release fishery management program (16 U.S.C. 1802(2)). Economic discards are fish that are discarded because they are undesirable to the harvester. This category of discards generally includes certain species, sizes and/or sexes with low or no market value. Regulatory discards are fish that are required by regulation to be discarded such as fish below a minimum size limit, but also include fish that may be retained but not sold.

NOAA Fisheries outlines at 50 CFR 600.350(d)(3)(i) ten factors that should be considered in determining whether a management measure minimizes bycatch or bycatch mortality to the extent practicable. These are:

1. Population effects for the bycatch species;
2. Ecological effects due to changes in the bycatch of that species (effects on other species in the ecosystem);
3. Changes in the bycatch of other species of fish and the resulting population and ecosystem effects;
4. Effects on marine mammals and birds;
5. Changes in fishing, processing, disposal and marketing costs;
6. Changes in fishing practices and behavior of fishermen;
7. Changes in research, administration and enforcement costs and management effectiveness;
8. Changes in the economic, social or cultural value of fishing activities and non-consumptive uses of fishery resources;
9. Changes in the distribution of benefits and costs; and
10. Social effects.

Agency guidance provided at 50 CFR 600.350(d)(3)(ii) suggests the Councils adhere to the precautionary approach outlined in the Food and Agriculture Organization of the United Nations Code of Conduct for Responsible Fisheries (Article 6.5) when faced with uncertainty concerning these ten practicability factors. According to Article 6.5 of the Code, using the absence of adequate scientific information as a reason for postponing or failing to take measures to conserve target species, associated or dependent species, and non-target species and their environment, would not be consistent with a precautionary approach.

The South Atlantic penaeid shrimp fishery occurs in an area extending from Fort Pierce, Florida to Pamlico Sound and Ocracoke Inlet, North Carolina. The federal fishery is primarily prosecuted with otter trawl gear (SAFMC 1993). Other gear (e.g., cast nets, haul seines, wing nets, etc.) also is used, but accounts for a minor portion of the annual commercial landings. Trawl gear is predominantly used in federal waters. Management actions implemented by the Council to minimize bycatch in the penaeid shrimp fishery and the effects of those actions on finfish and invertebrates and on sea turtles are described below. Section 3.1.12.1.3 contains an evaluation of the effects of management measures on bycatch and bycatch mortality of finfish using the ten practicability factors provided at 50 CFR 600.350(d)(3)(i).

In summary, technological devices mandated for use in the South Atlantic penaeid shrimp trawl fishery are estimated to reduce finfish bycatch by at least 30% and to reduce sea turtle bycatch by as much as 97%. More data are needed to improve the reliability of information on the current level of finfish bycatch, which generally continues to exceed the catch of shrimp. However, based on a review of the status of the five species of greatest concern in the South Atlantic (weakfish, king mackerel, Spanish mackerel, Atlantic croaker and spot), there is no evidence to indicate that the mortality of finfish caused by the shrimp trawl fleet (with TEDs implemented) is having a significant adverse affect on finfish stocks. This practicability analysis concluded that current management measures minimize bycatch and bycatch mortality to the extent practicable in the penaeid shrimp fishery.

Bycatch in the shrimp trawl fishery could have adverse socioeconomic effects on finfish fisheries that target the same species that are taken as bycatch in the shrimp fishery. But any adverse effects associated with reducing the number of fish available to the directed commercial and recreational finfish fisheries are likely outweighed by the socioeconomic benefits of the high value shrimp fishery in which some level of bycatch is unavoidable. The revenue generated by the South Atlantic commercial shrimp fishery is the highest in the region relative to other commercial harvesting sectors.

The technology certified by the Council for use in the penaeid shrimp fishery attempts to balance the above described biological, ecological, social and economic tradeoffs by reducing finfish bycatch while minimizing shrimp loss. As a result, current management measures are believed to have minimized finfish bycatch and finfish bycatch mortality to the extent practicable. Researchers continue working to improve the performance and efficiency of bycatch reduction devices.

<u>Managing finfish and invertebrate bycatch in the penaeid shrimp fishery</u>

The key focus of the Shrimp FMP when it was implemented in 1993 was to provide for concurrent closures of state and federal waters following severe winter weather to eliminate fishing mortality on overwintering white shrimp when necessary to ensure the sustainability of the stock (SAFMC 1993). The Council recognized at the time that mortality in the shrimp trawl fishery had an adverse impact on a number of finfish stocks that are important to commercial and/or recreational fisheries in the South Atlantic, including the weakfish, king mackerel, Spanish mackerel, Atlantic croaker and spot (Nance 1998). But an amendment to the Magnuson-Stevens Act in 1990 specifically prohibited the Council from implementing bycatch reduction measures until January 1, 1994. This prohibition was later extended for three months.

The intent of the 1990 Magnuson-Stevens Act incidental harvest provision was to ensure that bycatch reduction requirements were based on reliable information on the magnitude and composition of bycatch, and that such requirements minimized adverse effects on shrimp fishery participants to the extent practicable. The 1990 Magnuson-Stevens Act amendment authorized a 3-year study of bycatch in the Gulf of Mexico and South Atlantic shrimp trawl fishery to characterize bycatch and to develop gear options that could reduce bycatch with minimum loss of shrimp production. Results of these studies are summarized in sections above.

Upon completion of this study, the Council developed Amendment 2 to the Shrimp FMP (SAFMC 1996b). Effective April 1997, Amendment 2 required that shrimp trawl gear operating in federal waters of the South Atlantic use one of three BRDs certified by the Council based on their ability to reduce finfish bycatch while minimizing shrimp loss. These federally approved BRDs include the 12x5 fisheye, the extended funnel BRD and the expanded mesh BRD, which are estimated to achieve a 30% reduction in overall finfish bycatch.

<u>Managing sea turtle bycatch in the penaeid shrimp fishery</u>

The South Atlantic penaeid shrimp trawl fishery also is regulated to minimize interactions with sea turtles, all species of which are listed as either threatened or endangered under the 1973 ESA. The incidental take and mortality of sea turtles as a result of trawling activities has been documented along the Atlantic Ocean seaboard. Federal regulations under the ESA require most shrimp trawlers operating in the South Atlantic to have a NOAA Fisheries approved turtle excluder device (TED) installed in each net that is rigged for fishing to provide for the escape of sea turtles. To be approved by NOAA Fisheries, a TED design must be shown to be at least 97% effective in excluding sea turtles during experimental TED testing (68 FR 8456; February 21, 2003).

The use of TEDs is believed to have had a significant beneficial impact on the survival and recovery of at least some sea turtle species (68 FR 8456; February 21, 2003). However, information from Epperly and Teas (2002) demonstrated that these devices, as originally designed, were not adequately protecting all species and size classes of turtles. Leatherback sea turtles were too large to escape through the TED openings. According to a biological opinion completed in December 2002, as many as 2.5% of the loggerhead turtles in the Atlantic also were too large to exit through the TEDs (68 FR 8456; February 21, 2003). Consequently, NOAA Fisheries amended regulations in February 2003 to 1) modify the dimensions of approved TEDs so that they are effective at excluding leatherbacks and large sexually mature loggerhead and green turtles, and 2) modify trynet and bait shrimp exemptions to the TED requirements to decrease lethal take of sea turtles.

In the 2002 Biological Opinion, NOAA Fisheries determined that “shrimp trawling in the southeastern United States under the proposed revisions to the sea turtle conservation regulations and as managed by the fishery management plans for shrimp in the South Atlantic and Gulf of Mexico is not likely to jeopardize the continued existence of endangered green, leatherback, hawksbill and Kemp’s ridley sea turtles and threatened loggerhead sea turtles” (NOAA Fisheries 2002). The new rule is expected to decrease shrimp trawl related mortality by 94% for loggerheads and by 96% for leatherbacks (68 FR 8456; February 21, 2003).

Bycatch practicability analysis

Population effects for the bycatch species

The population effects of bycatch mortality are the same as fishing mortality from directed fishing efforts. If not properly managed and accounted for, either form of mortality could potentially reduce stock biomass to an unsustainable level. One important difference in the effects of the penaeid shrimp trawl fishery and directed fisheries on finfish is that fishes taken in shrimp trawls are generally small and young. Juveniles are more expendable in one respect because they occur in high numbers, and relatively few actually survive to adulthood. But the reproductive potential of a stock can be compromised if fish are not provided sufficient opportunities to reproduce before they are exposed to fishing or bycatch mortality. The risk of stock collapse increases markedly if the fish are subject to fishing or bycatch mortality before they mature (Myers and Mertz 1998).

Early weakfish management plans indicated that bycatch of juvenile weakfish in the shrimp trawl fishery reduced yield per recruit and spawning stock biomass per recruit of the weakfish stock. The amount of weakfish discarded in the shrimp trawl fishery often approached or exceeded directed landings in South Atlantic states (Nance 1998). BRDs have reduced discards of weakfish and other finfish species by at least 30% since that time. Although some soft TEDs were also documented to reduce finfish bycatch, most of the current hard TED configurations suggest that they will have little impact on bycatch reduction, except for the mechanical exclusion of large fishes such as sharks and rays.

The current level of bycatch in the penaeid shrimp trawl fishery continues to be substantial despite these advancements in bycatch reduction. However, bycatch mortality is incorporated in assessments of finfish stocks where bycatch estimates are available (e.g., weakfish and sharks) (Nance 1998). Additionally, the sustainability of finfish species taken as bycatch in shrimp trawls does not appear to be threatened by this source of mortality.

The following summarizes available information on the status of the five species of greatest concern in the South Atlantic: weakfish, king mackerel, Spanish mackerel, Atlantic croaker and spot. Two of these five species, Atlantic croaker and spot, represent major components of the total shrimp trawl finfish bycatch. The remaining species are represented in the catch in lesser numbers. All were selected for review by Nance (1998) because of their commercial and recreational importance, and because bycatch mortality has the potential to significantly impact their abundance.

The weakfish stock has been declining since the late 1990s (ASMFC 2004a). King mackerel and Spanish mackerel are neither overfished nor experiencing overfishing (NOAA Fisheries 2003a). Spanish mackerel stock biomass has more than doubled since the mid-1990s (ASFMC 2004b). The first coast-wide assessment of the Atlantic croaker stock has not yet been completed (ASMFC 2004c). However, the 2001 review of the Atlantic croaker FMP based on a more limited assessment indicates that the population is increasing in size and expanding in age/size structure (Desfosse et al. 2001). Data are inadequate to conduct a formal, coast-wide assessment of spot. But the current BRD and minimum size limit requirements are believed to have reduced mortality sufficiently to protect this stock until an assessment can be completed (ASMFC 2004d).

Observed increases in nesting levels of the Kemp's ridley sea turtles exemplify the significant beneficial impact of TEDs on the survival and recovery of several sea turtle populations. The total annual mortality of Kemp's ridley turtles has been reduced by 44%-50% since 1990, when TEDs became more widely used in U.S. waters. Once the most critically endangered sea turtle, Kemp's ridley nesting levels have increased from 700-800 nests per year in the mid-1980s to over 6,000 nests in 2000. Recent modifications to the TED rule designed to better protect larger species of sea turtles are expected to decrease shrimp trawl related mortality by 94%-96% for loggerheads and leatherbacks, respectively (68 FR 8456; February 21, 2003).

Ecological effects due to changes in the bycatch of shrimp (effects on other species in the ecosystem)

There is limited bycatch of shrimp in the shrimp trawl fishery because nearly all shrimp harvested is marketed. Interaction with BRDs and trawl gear could result in some mortality on those shrimp that subsequently escape the devices. However, the BRDs certified by the Council minimize shrimp loss to the extent possible and have not adversely affected the status of shrimp stocks. According to NOAA Fisheries' most recent report to Congress, none of the South Atlantic penaeid shrimp stocks is overfished or experiencing overfishing (NOAA Fisheries 2003a). Consequently, the ecosystem effects of such losses are expected to be minimal.

Changes in the bycatch of other species of fish and invertebrates and the resulting population and ecosystem effects

Reductions in finfish bycatch attributed to the mandated use of BRDs may result in increased predation on shrimp if affected finfish are shrimp predators. Only 14 of 161 fish species examined during NOAA Fisheries' offshore bycatch characterization surveys on commercial vessels from 1992-1996 were identified as predators on penaeid shrimp. These are the Atlantic croaker, sand seatrout, spotted seatrout, silver seatrout, ocellated flounder, inshore lizardfish, bighead searobin, smooth puffer, red snapper, lane snapper, Spanish mackerel, rock sea bass, dwarf sand perch and Atlantic sharpnose shark (Nance 1998).

Predator-prey relationships are largely dependent on the size structure of predator and prey populations. Juvenile fish that could not prey on large shrimp because of their small size may be able to do so if their exclusion from trawl gear allows them to grow larger. However, it is also possible that some fish will reduce their preference for shrimp as they grow larger and their dietary habits change (Nance 1998).

Simulations using an ecosystem-based model of the interactions among shrimp and finfish stocks in the Gulf of Mexico indicate that shrimp stock biomass could increase by 4.7% or decrease by 17% depending on bycatch exclusion rates and assumptions relative to predator selection of shrimp prey (Nance 1998). Predation is the primary cause of the simulated decrease in shrimp stock biomass. A reduction in the amount of nitrogen recycled from discards is a contributing factor. However, nitrogen returned to the ecosystem through discards is minimal in comparison to the large nitrogen input from rivers (Nance 1998).

The possible outcomes simulated by the model are uncertain, as multiple factors that are not well understood will influence the actual response of the ecosystem to changes in shrimp trawl bycatch. Generally, scientific data are inadequate to reliably predict ecosystem effects, particularly with respect to stock size, and interactions between predators and prey, and species, such as bottomfish, sharks, birds and dolphins, which compete with each other for food and other resources (Nance 1998; Cook 2003). Consequently, the ecosystem model is based on a number of assumptions about which scientists are uncertain, including a discard mortality rate of 100%. The limitations of the model are discussed more fully in Nance (1998).

Changes in the bycatch of non-shrimp invertebrates (e.g., crustacea and molluscs) also could have ecosystem effects. These species have ecological functions in addition to serving as prey for other invertebrates and fishes. For example, some species, like barnacles and hydrozoans, condition habitat for other organisms by providing a growing surface or by contributing to the bioturbation of bottom sediments.

Effects on marine mammals and birds

Under Section 118 of the Marine Mammal Protection Act (MMPA), NOAA Fisheries must publish, at least annually, a List of Fisheries (LOF) that places all U.S. commercial fisheries into one of three categories based on the level of incidental serious injury and mortality of marine mammals that occurs in each fishery. The 2003 List of Fisheries classifies the Southeastern U.S. Atlantic Shrimp Trawl fishery as a Category III fishery, meaning that the annual mortality and serious injury of a stock resulting from the fishery is less than or equal to 1% of the maximum number of animals, not including natural mortalities, that may be removed from a marine mammal stock while allowing that stock to reach or maintain its optimum sustainable population (68 FR 135; July 15, 2003). No changes in this fishery's classification were proposed in the 2004 proposed LOF (69 FR 71; April 13, 2004).

Species of large whales protected by the ESA can be found in or near the area in which the South Atlantic shrimp trawl fishery occurs. The slow speed (1 to 2 knots) at which shrimp trawlers operate while trawling is sufficient to allow both whales and fishing vessels time to avoid a collision. There have been no reported interactions between large whales and shrimp vessels in the South Atlantic. A biological opinion conducted by NOAA Fisheries in December 2002 identified the chances of the South Atlantic shrimp trawl fishery affecting these species as "discountable" and determined they were not likely to be adversely affected (NOAA Fisheries 2002). Discountable effects are defined as effects that are extremely unlikely to occur.

There have been no documented seabird-gear interactions in the South Atlantic penaeid shrimp fishery. This finding is based on more than 117,000 hours of observer coverage while trawling on 1,310 trips completed from February 1992 through December 2003 during 12,749 sea days in the U.S. Gulf of Mexico and southeastern Atlantic. A total of 668 trips (1,475 sea days) occurred off the east coast, and 5 trips (127 sea days) targeted waters off both the east coast and in the Gulf of Mexico (E. Scott-Denton, NOAA Fisheries, personal communication). Seabirds that feed on discards would be expected to be affected by any increases or decreases in the amount of discards produced by the shrimp trawl fishery (Nance 1998; Cook 2003). Discards and offal produced by fishing vessels makes food more easily available to seabirds, and have been linked to population increases in a number of species (Cook 2003).

Changes in fishing, processing, disposal and marketing costs

Penaeid shrimp fishermen have experienced direct costs as a result of the BRD and TED requirements. The cost of a BRD ranges from about $20 for a fisheye design to less than $100 for the large mesh extended funnel (SAFMC 1996b). The cost of outfitting small fishing vessels with BRDs is estimated at $200 (four BRDs at a cost of $50 per BRD). These vessels trawl with two nets. Larger shrimp vessels typically use four nets, and keep a spare set onboard. As a result, these vessels are required to purchase approximately eight BRDs, with a resulting cost of $400. The purchase of these gear modifications is a recurring expense. Currently, the cost of a TED typically used for an offshore, larger vessel runs approximately $320 to $350. For shrimpers whose TED frames were large enough to be compliant with the new rule and only needed to have the opening modified – the cost ran approximately $50. In general, shrimpers will have their TEDs re-worked every year, which if it does not require replacing the TED, will run approximately $100/TED.

The use of BRDs could result in some shrimp loss. But studies suggest that the use of BRDs or similar techniques to reduce finfish capture would not negatively affect shrimp production in the long-term if finfish exhibit even moderate selectivity against shrimp as prey (Nance 1998). The amount of shrimp loss associated with the three BRDs certified for use in the South Atlantic region is expected to be minimal.

The bycatch reduction achieved by BRDs could benefit shrimp fishermen by reducing the time required to cull unwanted species. Reducing culling time could improve the quality of the shrimp processed by decreasing the amount of time it takes to get shrimp into cold storage. The net economic effect of BRDs has not been quantified. But anecdotal information indicates that some fishermen favor using these devices because they increase net revenue per trawling operation (SAFMC 1996b).

Changes in fishing practices and behavior of fishermen

Some fishermen could perceive BRD and TED requirements as unnecessarily restrictive. However, there are few data available to adequately define how the requirements are perceived, and how these perceptions have changed fishing practices and behavior. A survey conducted by Kitner in 1987 to collect information on shrimp fishermen’s response to TEDs found that reactions were more favorable among those who had experience with the devices. The fishermen’s response to the BRD requirement in Shrimp Amendment 2 was similar. Those fishermen most familiar with BRDs appeared to be most accepting of the regulations. However, the Council received relatively few comments in opposition to the regulation overall. This could indicate that the industry was resigned to having to use the new technology. Also, it could indicate that shrimp fishermen understand the value of BRDs.

Bycatch mortality can reduce the availability of finfish to directed fisheries. Finfish taken in shrimp trawls are generally juveniles, and most of these fish would likely be subject to natural mortality before they become available to directed fisheries. However, bycatch mortality can adversely affect the status of stocks taken in directed fisheries by reducing the opportunity for bycatch species to mature and reproduce before they are subject to mortality. Because declining landings have precipitated the imposition of state and federal catch restrictions in some directed fisheries, participants in those fisheries likely perceive the BRD requirement as a regulation that promotes equity in the fisheries (Nance 1998).

Changes in research, administration and enforcement costs and management effectiveness

Research needed to understand the effectiveness of BRDs and TEDs is costly, as are administrative and enforcement efforts needed to implement and enforce these regulations. However, the implementation of these gear modification requirements has improved management effectiveness by decreasing turtle and finfish bycatch in the fishery.

Changes in the economic, social, or cultural value of fishing activities and non-consumptive uses of fishery resources

The combined landings from U.S. shrimp fisheries in 2002 ranked highest in value of all domestic fisheries that year (NOAA Fisheries 2003b). The South Atlantic shrimp fishery generates the most revenue for the commercial harvesting sector in this region. During the last two years for which data are available (2001 and 2002), commercial shrimp landings in the South Atlantic generated an average of $63.56 million annually (Section 5.4.1.1 above).

The U.S. Congress recognized the need to balance the costs of bycatch reduction with the social and economic benefits provided by the shrimp fishery when it mandated the study of shrimp trawl bycatch (and potential gear modifications) through the 1990 reauthorization of the Magnuson-Stevens Act. The resulting cooperative bycatch research program was effective in identifying gear options that could reduce shrimp trawl bycatch with minimum loss of shrimp production.

While BRD and TED requirements certainly present direct costs to participants in the shrimp fishery, they could reduce overall costs by making operations more efficient. Additionally, studies of BRDs suggest that the use of these devices or similar techniques to reduce finfish capture would not negatively affect shrimp production in the long-term if finfish exhibit even moderate selectivity against shrimp as prey (Nance 1998).

Decreases in bycatch mortality attributed to these technologies are believed to have contributed to the survival and recovery of at least some sea turtle populations and finfish stocks. The societal benefits associated with recovering these species are not easily quantified, but are believed to outweigh any short-term costs to penaeid shrimp fishermen related to the required use of bycatch reduction technology.

Changes in the distribution of benefits and costs

Prior to the mandated use of bycatch reduction technology in the penaeid shrimp fishery, there was a general perception that benefits and costs were not equitably distributed between the shrimp trawl fisheries and directed finfish fisheries and between the shrimp trawl fisheries and the broader public. Commercial and recreational fishermen who target finfish taken incidental to the trawl fishery believe that shrimp fishermen should share the burden of regulations needed to sustain declining fish stocks (Nance 1998). And at least some members of the public view bycatch as unnecessary waste. Discarded finfish provide an ecological service in that they are consumed by other marine species. However, the ecological role of discarded finfish would have been different had they been allowed to mature. The mandated use of BRDs and TEDs was intended to address these perceived inequities while maintaining a productive, high value shrimp fishery.

Social effects

There are few data available to adequately define the social effects of BRD and TED requirements. Penaeid shrimp fishermen could be experiencing negative effects related to the costs of installing and using the devices and to feeling overregulated. They also could be experiencing positive effects related to improved efficiency. The concerned public is likely experiencing social benefits related to knowing that the organisms they value for aesthetic and existence reasons are better protected. However, some members of the public could be of the opinion that the reductions in bycatch achieved through BRD and TED requirements are insufficient.

Conclusion

This section evaluates the practicability of taking additional action to minimize bycatch and bycatch mortality in the South Atlantic penaeid shrimp fisheries based on the findings in above and using the ten factors provided at 50 CFR 600.350(d)(3)(i). In summary, technological devices mandated for use in the South Atlantic penaeid shrimp trawl fishery are estimated to reduce finfish bycatch by at least 30% and to reduce sea turtle bycatch by as much as 97%. More data are needed to improve the reliability of information on the current level of finfish bycatch, which generally continues to exceed the catch of shrimp. However, based on a review of the status of the five species of greatest concern in the South Atlantic (weakfish, king mackerel, Spanish mackerel, Atlantic croaker and spot), there is no evidence to indicate that the mortality of finfish caused by the shrimp trawl fleet (with TEDs implemented) is having a significant adverse affect on finfish stocks. Therefore, the Council concluded that current management measures minimize bycatch and bycatch mortality to the extent practicable in the penaeid shrimp fishery.

5.2.1.4.2 Bycatch in the Deepwater Shrimp Fishery

The discarded bycatch of fish and crustaceans in the rock shrimp trawl fishery is highly variable by season and area. Comments received from industry representatives at scoping meetings and public hearings for Amendment 1 to the Shrimp Plan indicated that the catches have very little bycatch north of Cape Canaveral and in deeper water. As vessels began fishing earlier in the year, in June and July versus August or September, discards of unmarketable juvenile rock shrimp increased dramatically. Industry representatives also indicated that beyond 36 meters (120 ft) 90% of the catch is rock shrimp; therefore, it can be assumed that the remaining is bycatch (SAFMC, 1996a). The data on bycatch from trips that target rock shrimp are still limited, however. There was an early attempt to characterize the catch composition of rock shrimp trips in the South Atlantic. However, only one rock shrimp bycatch characterization observer trip was completed between January 26 and February 4, 1995 (SAFMC 1996a).

In order to document species associated with rock shrimp benthic habitats, NMFS SEFSC Pascagoula Laboratory compiled lists of species associated with rock shrimp catches in research trawling efforts for finfish and shrimp conducted between 1956 and 1991 (See Appendix A in Shrimp Amendment 5). At a minimum, these lists will provide potential bycatch associated with rock shrimp trawling. In order to identify possible key species caught in association with harvestable levels of rock shrimp, only trawl records when rock shrimp catches met or exceeded 40 pounds per hour per 40 foot of head rope were used based on input from public hearings and discussions with people in the industry.

From industry accounts, as the rock shrimp fishery developed and vessels began fishing earlier in the year, in June and July versus August or September, discards of unmarketable juvenile rock shrimp increased. Members of the South Atlantic Rock Shrimp Advisory Panel recommended gear modifications that were implemented in Amendment 5 to the South Atlantic Shrimp Plan to address this problem (SAFMC 2002).

The most recent information on bycatch in this fishery comes from a preliminary report of a NOAA Fisheries observer study conducted during the period September 2001 through December 2002 (See Appendix C in Shrimp Amendment 6). Nine rock shrimp trips were observed from September 2001 through December 2002. Six trips occurred off the east coast of Florida, two trips operated in the Gulf of Mexico and off the east coast of Florida and one trip targeted Gulf of Mexico waters exclusively.

A total of 177 tows was sampled from eight trips off the east coast of Florida. A total of 233 unique species was collected. There were 37 species of crustacea, 166 fish species, 29 other invertebrate species and 1 category of miscellaneous debris. All of these vessels were using BRDs voluntarily. Therefore, the results of the sampling reflect the catch that was not excluded by BRDs.

The following summarizes the main findings in this report:

1. Rock shrimp comprised 10% of the catch by weight and 13% by number.
2. Extrapolated catch per unit effort (CPUE) for rock shrimp was 3.6 kilograms per hour (approximately 7.9 pounds per hour).
3. Penaeid shrimp comprised 6% of the catch by weight and 4% by number.
4. Finfish comprised 54% of the catch by weight and 32% of the catch by number.
    - i. During the summer 2002 (June, July and August) 53% of the catch (by weight) was finfish (65 tows observed).
    - ii. During the fall 2002 (September, October and November) 54% of the catch (by weight) was finfish (41 tows observed).
    - iii. During the winter 2002 (December, January and February) 64% of the catch (by weight) was finfish (8 tows observed).
    - iv. CPUE of finfish was highest in winter 2002 (27.1 kg./hr) followed by fall 2002 (19.8 kgs/hr) and summer 2002 (19.0 kgs/hr).

Weight extrapolations from the species composition samples for both years, all areas, seasons and depths indicate that:

1. Dusky flounder (*Syacium papillosum*) comprised 13% of the total catch.
2. Iridescent swimming crab (*Portunus gibbesii*) comprised 10% of the total catch.
3. Rock shrimp comprised 10% of the total catch.
4. Inshore lizardfish (*Synodus foetens*) comprised 9% of the total catch.
5. Longspine swimming crab (*Portunus spinicarpus*) at 8%.
6. Spot (*Leiostomus xanthurus*) at 6%.
7. Blotched swimming crab (*Portunus spinimanus*) at 5%.
8. Brown shrimp (*Farfantepenaeus aztecus*) at 4%.
9. Red goatfish (*Mullus auratus*) at 2%.
10. All other species combined comprised 33% of the total weight.

Data from one additional trip in 2002 were not included in these results because the data were not computerized at the time the report was prepared. These observed trips were sampled during an atypical rock shrimp season where harvest was especially low compared to previous years. Thus, these findings should be considered preliminary and a more realistic evaluation of this fishery is expected from analyses of results at the completion of this observer program.

A different catch composition could be observed during a year when rock shrimp harvest is at a “normal” level. From preliminary data on rock shrimp landings and industry reports it appears that rock shrimp harvests rebounded during 2003. Observer coverage in the rock shrimp fishery extended through 2003. Information from these trips will be analyzed and presented to the Council for future evaluation of the rock shrimp fishery. From preliminary data for the 2003 portion of the observer coverage program, it appears that rock shrimp catch rates were higher and they comprised a larger proportion of the catch compared to the 2002 observer data. For all 125 tows in the 2001/2002 observer program, rock shrimp made up 9.6% of the overall catch. A preliminary examination of the data from the 95 tows observed in 2003 indicated that 21.3% of the total catch was comprised of rock shrimp (Scott-Denton, NOAA Fisheries, Southeast Fisheries Science Center, pers. comm. 2003).

See Section 5.4.1.4 for more detailed information on bycatch in the South Atlantic shrimp fisheries.

Bycatch Practicability Analysis for the Deepwater Shrimp Fishery

Bycatch is defined as fish harvested in a fishery, but not sold or retained for personal use. This definition includes both economic and regulatory discards, and excludes fish released alive under a recreational catch-and-release fishery management program. Economic discards are generally undesirable from a market perspective because of their species, size, sex, and/or other characteristics. Regulatory discards are fish required by regulation to be discarded, but also include fish that may be retained but not sold.

Agency guidance provided at 50 CFR 600.350(d)(3) identifies ten factors to consider in determining whether a management measure minimizes bycatch or bycatch mortality to the extent practicable. These are:

1. Population effects for the bycatch species;
2. Ecological effects due to changes in the bycatch of that species (effects on other species in the ecosystem);
3. Changes in the bycatch of other species of fish and the resulting population and ecosystem effects;
4. Effects on marine mammals and birds;
5. Changes in fishing, processing, disposal, and marketing costs;
6. Changes in fishing practices and behavior of fishermen;
7. Changes in research, administration, and enforcement costs and management effectiveness;
8. Changes in the economic, social, or cultural value of fishing activities and non-consumptive uses of fishery resources;
9. Changes in the distribution of benefits and costs; and
10. Social effects.

The Councils are encouraged to adhere to the precautionary approach outlined in Article 6.5 of the Food and Agriculture Organization of the United Nations Code of Conduct for Responsible Fisheries when uncertain about these factors.

The South Atlantic rock shrimp fishery is concentrated in an area off northeast Florida south to Jupiter Inlet. The fishery is prosecuted primarily by commercial otter trawl gear. Management measures regulating harvest in the fishery include requirement of bycatch reduction devices (BRDs), a minimum mesh-size restriction, a limited access program, and area closures (east of 80°W longitude, between 27°30'N and 28°30'N latitude, in depths less than 100 fathoms). The primary purpose of the area closures is to minimize the impacts of the rock shrimp fishery on essential bottom habitat, including the fragile coral species located in the *Oculina* Bank Habitat Area of Particular Concern (HAPC). These closures are enforced using vessel monitoring systems (VMS) (SAFMC 2002).

The magnitude and composition of bycatch in the rock shrimp fishery based on a preliminary report of observer coverage of the southeastern Atlantic rock shrimp fishery from September 2001 through September 2006. Samples from 221 successful tows (eight vessels with 838.3 hours of trawling) were analyzed for species composition by weight and numbers. By weight, 49% of the total catch throughout the study period was composed of finfish. Weight extrapolations from the species composition samples indicated dusky flounder was the finfish caught in the greatest number (13% of the total catch), followed by the inshore lizardfish (11%), spot (5%), and horned sea robin (2%). Rock shrimp represented the second largest component of the catch by weight (19%). Non-shrimp crustaceans comprised 18%: the iridescent swimming crab was the non-shrimp crustacean caught in the greatest number (7%) followed by the longspine swimming crab (6%) and the blotched swimming crab (3%). Non-crustacean invertebrates (8%), penaeid shrimp (4%), and debris (2%) comprised the smallest portion of the total catch. Highest catch per unit effort (CPUE) for rock shrimp was in 26-45 fathoms, while CPUEs for finfish, invertebrates and other crustaceans were highest in 0-25 fathoms.

Population Effects for the Bycatch Species

The population effects of bycatch mortality are the same as fishing mortality from directed fishing efforts. If not properly managed and accounted for, either form of mortality could potentially reduce stock biomass to an unsustainable level. One important difference in the effects of the shrimp trawl fishery and directed fisheries on finfish is fishes taken in shrimp trawls are generally small and young. Juveniles are more expendable in one respect because they occur in high numbers, and relatively few actually survive to adulthood. But the reproductive potential of a stock can be compromised if fish are not provided sufficient opportunities to reproduce before they are exposed to fishing or bycatch mortality. The risk of stock collapse increases markedly if the fish are subject to fishing or bycatch mortality before they mature (Myers and Mertz 1998).

The current level of bycatch in the penaeid shrimp trawl fishery continues to be substantial despite these advancements in bycatch reduction. However, bycatch mortality is incorporated in assessments of finfish stocks if estimates are available (e.g., weakfish and sharks). Additionally, the sustainability of finfish species taken as bycatch in shrimp trawls does not appear to be threatened by this source of mortality (Nance 1998).

Little is known about the status of those finfish (e.g., dusky flounder, inshore lizardfish, spot, and red goatfish) and invertebrate (e.g., iridescent swimming crab, longspine swimming crab, and blotched swimming crab) species present in rock shrimp trawl bycatch in the greatest numbers. None of these species have undergone (or are likely to undergo) formal stock assessments because most, with the exception of spot, are not targeted in commercial or recreational fisheries. Data are inadequate to conduct a formal, coast-wide assessment of spot. But fishery managers believe a combination of BRD and minimum size limit requirements is sufficient to protect this stock until such an assessment can be completed (ASMFC 2004).

Observed increases in nesting levels of the Kemp's ridley sea turtles exemplify the significant beneficial impact of TEDs on the survival and recovery of several sea turtle populations. The total annual mortality of Kemp's ridley turtles has been reduced by 44-50% since 1990, when TEDs became more widely used in U.S. waters. Once the most critically endangered sea turtle, Kemp's ridley increased nesting levels from 700-800 nests per year in the mid-1980s to over 6,000 nests in 2000. Recent modifications to the TED rule, which were designed to better protect larger species of sea turtles, are expected to decrease shrimp trawl related mortality by 94 and 96% for loggerheads and leatherbacks, respectively (68 FR 8456; February 21, 2003).

During five years of observer coverage in the Southeast Atlantic rock shrimp fishery (Appendix C), 11 sea turtles (six loggerhead, two Kemps ridley, three unidentified) were captured in trawls. Three escaped through TEDs, nine were released alive and conscious, and two were released in unknown condition.

NOAA Fisheries Service determined in a 2002 Biological Opinion that shrimp trawling in the southeastern United States under the proposed revisions to the sea turtle conservation regulations and as managed by the South Atlantic and Gulf of Mexico Shrimp FMPs is not likely to jeopardize the continued existence of endangered green, leatherback, hawksbill or Kemp's ridley sea turtles, or threatened loggerhead sea turtles.

Anecdotal information suggests bycatch of the coral, *Oculina varicosa*, in the rock shrimp trawl fishery was negatively affecting that species. *Oculina* coral fragments may continue to survive after an impact (Brooke and Young 2003, 2005). However, the likelihood impacted corals could be smothered by sediments, or sufficiently removed from the current's influence as to deprive them of nutrients, is greatly increased. Researchers estimate past fishery-related impacts, primarily from trawl gear, have greatly reduced the amount of intact *Oculina* coral habitat remaining within the *Oculina* Experimental Closed Area (Reed *et al.* 2007). The Vessel Monitoring System (VMS) requirement implemented through Amendment 5 to the Shrimp FMP (SAFMC 2002) is expected to improve compliance with the prohibition on rock shrimp trawling within the *Oculina* HAPC.

Ecological Effects Due to Changes in Bycatch

Rock shrimp discards in the fishery have not been quantified. Anecdotal reports indicate economic discards of unmarketable juvenile rock shrimp have increased as the temporal and spatial distribution of the fishery has changed over time. Vessels fish earlier in the year and have moved south relative to historical fishing. However, the mesh-size restrictions implemented through Amendment 5 (SAFMC 2002) were intended to address this problem. Consequently, the ecosystem effects of rock shrimp discards (if any) are likely to be minimal.

Changes in Bycatch of Other Fish Species and Resulting Population and Ecosystem Effects

If affected finfish are shrimp predators, reductions in bycatch due to BRDs may result in increased predation on shrimp. During NOAA Fisheries Service's offshore bycatch surveys on commercial vessels from 1992-1996, only 14 of 161 fish species were identified as predators on penaeid shrimp. These are the Atlantic croaker, sand seatrout, spotted seatrout, silver seatrout, ocellated flounder, inshore lizardfish, bighead searobin, smooth puffer, red snapper, lane snapper, Spanish mackerel, rock sea bass, dwarf sand perch, and Atlantic sharpnose shark (Nance 1998).

Predator-prey relationships largely depend on the size structure of predator and prey populations. Juvenile fish that are too small to prey on large shrimp may be able to do so later if their exclusion from trawl gear allows them to grow larger. However, it is also possible some fish will reduce predation on shrimp as they grow and their dietary habits change (Nance 1998).

Changes in the bycatch of non-shrimp invertebrates (e.g., crustaceans and mollusks) also could have ecosystem effects. These species have ecological functions in addition to serving as prey for other invertebrates and fishes. For example, some species, like barnacles and hydrozoans, condition habitat for other organisms by providing a growing surface or by contributing to the bioturbation of bottom sediments.

Effects on Marine Mammals and Birds

Bycatch of marine mammals and seabirds is not considered to be a problem in the South Atlantic rock shrimp fishery. The southeastern U.S. Atlantic shrimp trawl fishery is classified as a Category III fishery, meaning the annual mortality and serious injury of a stock resulting from the fishery is less than or equal to 1% of the maximum number of animals, not including natural mortalities, that may be removed from a marine mammal stock while allowing that stock to reach or maintain its optimum sustainable population (68 FR 135; July 15, 2003).

No documented seabird-gear interactions were recorded on 1,310 trips in the Gulf of Mexico and southeastern Atlantic penaeid and rock shrimp fisheries between February 1992 and December 2003 (E. Scott-Denton, NOAA Fisheries, personal communication). However, the potentially high level of bycatch in the rock shrimp fishery could be affecting some seabird species. Cook (2003) notes the availability of discards and offal has been linked to population increases in a number of species.

Changes in fishing, processing, disposal and marketing costs

The potentially high bycatch in the rock shrimp fishery could adversely affect production by unnecessarily increasing drag time, culling time, and crew fatigue. Regulatory measures implemented to reduce bycatch have direct costs related to purchasing and installing new technology, or limiting where and/or when a vessel could operate. But such measures could result in long-term benefits if they increase the efficiency of shrimp trawl operations. BRD technology reduces shrimp trawl bycatch with minimal cost to shrimp fishermen.

Changes in Fishing Practices and Behavior of Fishermen

At least some participants in the rock shrimp fishery deny a bycatch problem exists. Consequently, regulatory requirements to reduce bycatch could provide a disincentive to responsible participation in the fishery. For example, fishermen could potentially ignore a BRD or closed season requirement, or violate the prohibition on trawling within the *Oculina* Bank HAPC. The VMS requirement is expected to improve compliance with seasonal closure regulations and ease the enforcement burden.

Changes in Research, Administration, and Enforcement Costs and Management Effectiveness

Bycatch in southeastern shrimp trawl fisheries has been a priority issue for scientists and administrators for a number of years. This focus is likely to continue as the Council addresses future management needs in the fishery.

Changes in the Economic, Social, or Cultural Value of Fishing Activities and Non-Consumptive Uses of Fishery Resources

The U.S. Congress recognized the need to balance the costs of bycatch reduction with the social and economic benefits provided by the shrimp fishery when it mandated the study of shrimp trawl bycatch (and potential gear modifications) through the 1990 Magnuson-Stevens Act reauthorization. The resulting cooperative bycatch research program identified gear options that could reduce shrimp trawl bycatch with minimum loss of shrimp production.

While BRD and TED requirements certainly present direct costs to participants in the shrimp fishery, they could reduce overall costs by increasing efficiency. Additionally, studies suggest the use of BRDs or similar techniques to reduce finfish capture would not negatively affect shrimp production in the long-term if finfish exhibit even moderate selectivity against shrimp as prey (Nance 1998).

Decreases in bycatch mortality attributed to these technologies are believed to have contributed to the survival and recovery of at least some sea turtle populations and finfish stocks. The societal benefits associated with recovering these species are not easily quantified, but are believed to outweigh any short-term costs to penaeid shrimp fishermen related to the required bycatch reduction technology.

Changes in the Distribution of Benefits and Costs

Prior to the mandated use of bycatch reduction technology in the rock shrimp fishery, people perceived benefits and costs were not equitably distributed between the shrimp trawl fisheries and directed finfish fisheries, and between the shrimp trawl fisheries and the broader public. Commercial and recreational fishermen who target finfish taken incidental to the trawl fishery believe shrimp fishermen should share the regulatory burden needed to sustain declining fish stocks (Nance 1998). Some members of the public view bycatch as unnecessary waste. The mandated use of BRDs and TEDs was intended to address these perceived inequities while maintaining a productive, high value shrimp fishery.

Social Effects

Few data are available to adequately define the social effects of BRD and TED requirements. Shrimp fishermen could experience negative effects related to the costs of installing and using the devices and to feeling overregulated. They also could experience positive effects related to improved efficiency. The concerned public is likely to experience social benefits related to knowing that the organisms they value for aesthetic and existence reasons are better protected. However, some members of the public may believe bycatch is not sufficiently reduced through BRD and TED requirements.

Conclusion

This section evaluates the practicability of taking additional action to minimize bycatch and bycatch mortality in the South Atlantic rock shrimp fishery by using the ten factors provided at 50 CFR 600.350(d)(3)(i). In summary, technological devices mandated for use in the South Atlantic shrimp trawl fishery are estimated to reduce finfish bycatch by at least 30% and to reduce sea turtle bycatch by as much as 97%. More data are needed to improve the reliability of information on the current level of bycatch, which generally continues to exceed the catch of shrimp. However, no evidence exists to indicate the mortality of finfish caused by the rock shrimp trawl fleet (with BRDs and TEDs implemented) is having a significant adverse affect on finfish stocks. Therefore, the Council concluded that current management measures minimize bycatch and bycatch mortality to the extent practicable in the rock shrimp fishery.

5.2.2 Snapper Grouper

5.2.2.1 Description of fishing practices, vessels and gear

Additional detailed description of the snapper-grouper fishery is contained in Snapper Grouper Amendment 13C (SAFMC 2006), Snapper Grouper Amendment 15A (SAFMC 2007), and Snapper Grouper Amendment 15B (SAFMC 2008)] and is incorporated herein by reference. The following section updates and summarizes the operations of the commercial and recreational sectors of the snapper grouper fishery as part of the overall human impact on the South Atlantic ecosystem.

Commercial fishery

Commercial fishermen utilize vertical lines, longlines, black sea bass pots/traps, spears, and powerheads to harvest snapper grouper species. An economic survey of commercial snapper grouper vessels along the South Atlantic coast done in the mid-1990s found that the average length of a boat was 32.7 feet, with nearly all sampled boats being less than 50 feet in length. Boats with bottom longlines tended to be the longest, had the most powerful engines, the greatest fuel capacities, and the largest holding boxes for fish and ice. On the other hand, boats with vertical lines, especially in the southern area, tended to be the shortest, had the least powerful engines, the smallest fuel capacities, and the smallest holding boxes for fish and ice.

Vertical Lines

The vertical line sector of the commercial snapper grouper fishery operates throughout the Council's area of jurisdiction from the North Carolina/Virginia border to the Atlantic side of Key West, Florida. According to NMFS Logbook data, there were 15,302 trips reported in 2001 in which vertical line (hook and line) gear was identified as the main gear for that trip. Fishermen use this gear in about 13 to 110 fathoms (78 to 660 feet) of water, both day and night.

The majority of hook and line fishermen use either electric or hydraulic reels known as "bandit" gear due to its resemblance to slot machines ("one-armed bandits") that are used in casinos. Boats generally have 2 to 4 bandit reels attached. A typical bandit reel is attached to the gunwale of the boat and consists of a fiberglass reel that holds about 1,000 feet of cable; an L-bar or spreader, which keeps the leader from tangling with the main line; a pulley to feed the cable from the reel through the L-bar; a fiberglass arm; and an electronic or hydraulic reel motor.

Captains of boats with bandit gear maneuver the boat back and forth across an area of high relief that runs northeast and southwest looking for fish using a color machine and relying on fishing spots that have been previously marked on their plotter. The captain uses the color machine to differentiate bottom type and fish presence, and can tell what kind of fish may be in the area based on where they appear in the water column, the size of the air bladder that shows up on screen, and how the fish are congregated.

Fishing begins with a baited line that is thrown out over the gunwale of the boat as the fisherman releases the drag on the spool of the bandit reel and sends the line down in search of the bottom or desired depth. If dropping on a spot for the first time, the fisherman may have to adjust the depth at which s/he fishes, first finding the bottom and then reeling up the line enough to be fishing above the bottom.

Fishermen tend to either "sit and soak" or "get up and down" when using bandit gear in the mid-shelf fishery (mostly targeting vermilion snapper and some groupers). When they sit and soak, they are fishing live or dead baits with circle or "jap" hooks and letting their rigs (generally a 20- to 40-foot leader with 2 hooks) soak near the bottom for anywhere from 15 minutes to an hour. Fishermen will use the sit-and-soak method to catch grouper and some snapper, such as red snapper in about 13 to 50 fathoms (78 to 300 feet) of water. When fishermen get up and down, they are actively fishing 2 to 3 straight hooks per reel with cut bait. When fishing this way, the line is tended constantly and brought up to the surface as soon as a bite is felt. Fishermen using the get-up-and-down method catch most of the vermilion snapper, triggerfish, and porgies. Fishermen also fish for grouper using this method, but with larger hooks.

When fishing for deepwater snapper grouper species (primarily snowy grouper but also large red porgy, blueline tilefish, Warsaw grouper, and speckled hind) in 50 to 100 fathoms (300 to 600 feet) of water, fishermen bait multi-hook rigs with anywhere from 2 to 10 circle hooks with squid, Boston mackerel, or other cut bait.

In South Florida, fishermen use handlines to harvest yellowtail snapper, which is mostly a day boat fishery. Fishermen chum for yellowtail by grinding or cutting up bait fish and distributing the chum on top of the water with the intention of drawing the yellowtail snapper closer to the surface in a school to make them easier to catch. The fish are caught on handlines with "j" hooks and then chill-killed for high quality. Sometimes these fishermen use a splatter or spider pole to catch the fish when chumming, which is a 10- to 12-foot bamboo pole with a single line and a barb-less hook attached.

There is no consistent day/night pattern of fishing within the vertical line sector of the South Atlantic snapper grouper fishery. The time of day and/or night varies from captain to captain as a matter of personal preference. The majority of the bandit fleet fishes year round for snapper grouper. The only seasonal differences in catch are associated with the spawning season closures in March and April for gag grouper. Most fluctuations in fishing effort in the vertical line fishery are a result of the weather, such as hurricanes and tropical and winter storms, which limit effort. When king mackerel are running, some fishermen stop bandit fishing for snapper grouper species to target king mackerel.

Longlines
The Council allows the use of bottom longlines only in waters deeper than 50 fathoms (300 feet) and north of St. Lucie Inlet, Florida. Fishermen with longline gear onboard may only retain deepwater species. Fishermen use this gear to target snowy grouper and golden tilefish, while incidentally catching blackbelly rosefish.

Longline boats are typically bigger, have longer trips, and cost more to operate than bandit boats because they operate farther offshore. From a port such as Charleston, South Carolina, a South Carolina longline boat will travel 90 miles offshore to reach the fishing grounds, stay out for as many as 9 to 10 days, and incur expenses equivalent to $2,500.

The longline is located on a spool about midway back on the stern of the boat, and a spool generally holds about 15 miles of cable. When fishing begins, the cable is paid out through a fair lead on top of the spool and then another at the stern of the boat. A poly- ball and a high flyer are paid out first to mark the longline at one end. At the stern are usually two crewmembers that stand near baskets full of made up rigs (previously baited hooks and leaders). As the line pays out, they snap the leaders onto the mainline as fast as possible, but generally every two feet.

While the line is paying out, the Captain may steer the boat in a zigzag fashion or make exaggerated turns to set the gear in the desired location. Some crews use weights as the Captains make big turns to prevent the mainline from rolling over and drifting on top of itself. When the desired amount of longline is paid out, the crew breaks it loose from the drum and snaps on another poly-ball and high flyer to indicate the end of the longline.

The amount of mainline that is paid out and the length of soak time of the line varies by boat and circumstance. Sometimes boats will set out 5 miles of cable at a time making as many as 4 or more sets a day, while others will set out 15 miles at a time and make only 2 sets a day. Soak time will vary depending upon how well fishing is going; however, the longest amount of time that longline gear is in the water is about 2 hours. The gear is hauled back from a haul back station with a boom that swings over the side of the boat that helps feed the cable through a block and pulley system. As the line is hauled back on board, catch is removed from the leaders, leaders are removed, and the main line is fed back into the level wind and back to the spool.

Longlines are fished only from daylight to dark because sea lice come out at night and eat the flesh of fish that would hook up on the line. Snapper grouper fishermen use longlines all year long with little or no seasonal fluctuation barring a busy hurricane season.

Black Sea Bass Pots
Black sea bass pots are used exclusively to target black sea bass, though bycatch of other snapper grouper species is allowed. The pots have mesh size, material, and construction restrictions to facilitate bycatch reduction and to prevent ghost fishing if pots are lost. All sea bass pots must have a valid identification tag attached.

Fishing practices within the black sea bass pot fishery vary by buoy practices, setting/pulling strategies, number of pots set, and length of set, with seasonal variations. Many fishermen set individual pots with one buoy line per pot. Others set doubles, which are two pots attached to one buoy line. Individual pots may also be connected to a ground line. This configuration is commonly referred to as a "trawl" and has a buoy line on each end. Indications are that only one person in North Carolina may be fishing with trawls. Both sinking and floating buoy lines are used. Many fishermen off North Carolina use floating lines because they are less likely to get hung up on the bottom, while several South Carolina fishermen reported using sinking lines. In South Carolina, fishermen report using ¼-inch poly line attached to a buoy or high flyer. Buoy lines are typically 200 feet (61 meters) in length. In the South Atlantic EEZ, the use of buoys is not required but, if used, each buoy must display the boat's assigned official number and color code.

Fishermen use different strategies for targeting black sea bass, but the most common technique is "precision setting" in which fishermen target areas located with on-board electronics, set pots on suspected aggregations of fish, and locate, pull, and move pots depending upon how well an area is producing. Pots may be clustered with only a few set in one area and numerous set in a different area depending upon the availability of hard bottom and how successful the catch rate. There may be anywhere from a 3 to 5 mile (4.8 to 8 kilometers) distance between pots or just 10 to 14 feet (3 to 4.5 meters). Another strategy scatters pots over a wide area or in rows, regardless of bottom habitat, and leaves the set of pots with the intention of having the fish come to the pot. This technique targets more migratory individuals and the pots tend to stay in the water for a longer period of time.

How pots are fished varies depending on the fisherman, season, or area. Typically, fewer pots (on average 60 or less) are fished during the winter than during the summer with the majority of fishermen taking their pots in every night. In the summer when more fish are scattered, the fishermen may fish a few hundred pots and leave them out for extended periods of time, pulling them no more than twice a day. During the winter, soak times are shorter with pots being pulled 2 to 3 times a day or more. Pots set as doubles or in trawls usually have longer soak times than those individually set. In general, how long pots are soaked or whether they are removed daily depends upon the number of pots set, gear configuration, season, and the preference of the fisherman. Preferences may also vary by region.

The South Carolina black sea bass pot fishery is mainly a winter fishery. The season begins in November and, depending upon the water temperature (the colder the better for bass trapping), generally goes through April. Pots are fished individually with short soak times (in some cases about an hour), and the number of pots fished range from 6 to 30 depending upon the fisherman. Most fishermen haul their pots from the water when they return home. In the fall, most pots are set in 70 to 90 feet (21.3 to 27.4 meters) of water, and as the season progresses, fishermen tend to move their pots out to about 100 to 200 feet (30.5 to 36.6 meters). Most trips are day trips.

The North Carolina pot fishery is mainly a winter fishery as well; however, some fishermen continue to pot fish through the summer. The number of pots fished typically ranges from

25 to 60, but more pots are fished in the summer. Fishermen usually set their pots in water depths ranging from 30 to 90 feet (9 to 27.4 meters), though in areas further south, pots are generally set at depths ranging from 70 to 100 feet (21.3 to 30.5 meters). The duration of most trips is one day, however, some extend over multiple days. Roughly half of the fishermen in North Carolina pull their pots when heading home, while the other half leaves them and lets them soak for several days.

Overall, it appears that for the South Atlantic black sea bass pot fishery, the number of trips tends to be greater during the winter months than the summer. Data from the Reef Fish Logbook Program show that there were 1,054 trips in 2001 in which sea bass pots were reported as the main gear. Of these trips, 53 percent were conducted from November through March. Logbook data going back to 1998 show a range of 63 to 72 percent of reported trips occur during the November through March time period with the number of trips falling off in March.

Assessing the actual fishing effort at any given time within the black sea bass pot fishery is difficult. Many participants are active in other fisheries, including the recreational charter fishery during the summer months. The effort placed in the black sea bass pot fishery is often dependent on how well the income generated by black sea bass fishing compares to the income generated by the fisherman's other endeavors. Many snapper grouper permit holders maintain pot endorsements, but are not active in the pot fishery.

The number of fishermen permitted to fish with pots is higher than the actual number fishing. In South Carolina, logbook data suggests that as many as 50 to 60 fishermen are permitted to use pots as either their primary or secondary gear, but only a quarter of them are actively involved in pot fishing during the season.

Since most fishermen tend to fish only a portion of their pots while keeping the remaining pots available to replace any losses during the season, the number of tags purchased is often not an accurate count of how many pots are actively being fished.

Powerheads and Spears

In federal waters, fishing commercially by diving and killing the fish by spear or powerheads is most commonly practiced off the coast of Florida. The use of powerheads to kill snapper grouper is illegal in the EEZ off the coast of South Carolina (50 CFR 622.31(g)) and in Special Management Zones. Powerheads, or bangsticks, are underwater firearms that usually use 12-gauge or .357 Magnum rounds. Sharp contact from a thrust against a solid object activates a heavy, spring loaded, stainless steel firing pin, which detonates the round from a short barrel. Much of the damage inflicted on the target comes from the rapidly expanding gases forced into the body by the barrel end pressed at that moment against it.

There are 3 common methods to kill fish. First, in clear water, some fishermen shoot just a spear, because it has the capability of being more accurate at longer distances (40 to 50 feet) than a powerhead. Second, there is a traditional powerhead (also known as a bangstick), which is a powerhead attached to a metal shaft or wooden pole. The initial injury to the fish comes from a spear tip and then the powerhead is used to kill the fish. The third way is when a powerhead is on the shaft of the spear and once the trigger is pulled, the powerhead hits the fish and the round is detonated in the fish.

Bottom time is a function of depth. It is also important to separate total dive time from spearing/working time on the dive. The following two estimates of spearing/working times on the bottom are based on input from divers:

Estimate 1: about ¾ of bottom time is spearing/working time. At 100 to 120 feet a diver has about 15 minutes of spearing/working time on the bottom, and an 80 cubic foot tank lasts about 20 minutes at 100 feet. A diver can use 4 tanks per day so total spearing/working time ranges between 1 to 1.5 hours per diver per day.

Estimate 2: the maximum allowable bottom time is about 16 minutes per tank in the summer and 12 minutes in the winter. At 4 tanks per diver per day, the maximum bottom time would be 64 minutes in the summer and 48 minutes in the winter.

Private recreational fishery

Recreational fishermen for the large part use hook and line gear although in some areas spearfishing for reef fish can be popular. Methods that recreational fishermen use to fish for snapper grouper are very diverse. The distance people can go offshore in search of reef fish depends in part on the size of their boat, engine power, comfort level, and fuel prices. Experience levels vary among recreational fishermen and therefore fishing methods and efficacy differ. Bottom fishing for snapper and shallow water grouper can be accessible to many recreational fishermen as they do not have to travel as far offshore and there is somewhat less skill involved than deep drop fishing that targets mostly big grouper. As with the commercial fleet, many recreational anglers rely on technology such as fish finders and color machines to find fish. There is little or no technology gap between the professional (for-hire and commercial) fishermen and those who fish for fun on the weekends.

Recreational anglers will use both electric and manual reels for bottom fishing. Twelve volt Electric reels such (commonly called elec-tra-mates) attach to fishing rods and reels to assist fishermen in reeling in catches from deep water. People who use electric reels tend to be more serious about fishing or who fish deeper water.

Fishermen will choose to use lighter or heavier tackle based on which species they are targeting, the level of skill of the fishermen and a multitude of other factors including limiting gear loss. Generally when fishing for grouper they will use heavier line (80 to 120 pound test) and larger hooks (6/0 and larger) which mostly calls for larger weights. Fishing for snappers, porgies and grunts generally means lighter tackle (1/0 to 4/0 hooks and 20 and 40 pound test).

Like tackle, the use of bait also varies very widely among the region and among fishermen and according to target species. Cut bait, live baits and even artificial plugs are all used to fish for various snapper and grouper species. Popular cut baits include menhaden, herring, bluefish, sardines and cigar minnows.

For-hire recreational fishery

Headboats (also called party boats) are popular in the southeast. These vessels are larger than the commercial hook and line fleet and private and charter boats. Many are longer than 100 feet in length. They provide easy and economical access to successful fishing for the beginning angler and tourist. These boats take as many as 100 people offshore to fish for snapper grouper and a host of other fish.

Fishing trips on headboats can either be all day or half day. Generally when fishing off the Carolinas on half day trips they are fishing the black fish banks targeting sea bass, porgies, sharks, flounder, and other bottom species. On all day headboat trips, they will fish 40 to 50 miles offshore to target snapper, grouper, large sea bass, and trigger fish. Occasionally larger fish such as king mackerel, cobia, amberjack, and dolphin may be landed. In general, headboats are fishing the same grounds as the commercial fleets and they can often be seen fishing side by side.

Generally, customers are provided with gear and bait. The fishing methods on headboats for snapper grouper species are similar to those of the commercial fishery and the private charter fishery. Customers will be set up with a 4/0 or 6/0 reel rigged with 80 pound test monofilament, a rig with a 16 ounce weights and the same variety of hook sizes as commercial fleet uses. Most reels will be set up with two hook rigs. Cut squid is generally the preferred bait among headboat crews because it is easy to prepare and stays on the hook longer than other baits.

Headboats will make special trips to fish during the night. Generally, headboat trips will either last half a day (4 hours) or an entire day (11 hours).

Allowable gear

Commercial

The following gear represents the only gear allowable for this fishery:

- Vertical hook-and-line including hand-held hook-and-line and bandit gear
- Spearfishing gear without rebreathers
- Powerheads, except where expressly prohibited in Special Management Zones and in the EEZ off South Carolina.
- *Bottom longline, only in depths 50 fathoms or more, and only north of St. Lucie Inlet (27°10' N. lat.), Florida. (Bottom longline cannot be used for wreckfish).
- Black sea bass pots except in SMZs and only north of Cape Canaveral, Florida (Vehicle Assembly Building), (28°35.1' N. lat.)
- Sink net fishermen (NC only) can make multi-gear trips and all legal species harvested with black sea bass pots and/or vertical hook and line gear may be retained.

*Vessels with longline gear aboard may only possess snowy grouper, Warsaw grouper, yellowedge grouper, misty grouper, golden, blueline and sand tilefish.

Black Sea Bass Pot Requirements: A black sea bass pot or trap that is used or possessed in the South Atlantic must meet the following requirements:

- For sides other than the back panel: hexagonal mesh (chicken wire) — at least 1.5 inches between wrapped sides; square mesh — at least 1.5 inches between sides; OR rectangular mesh — at least 1 inch between the longer sides and two inches between the shorter sides.
- For the entire panel, i.e., the side of the pot opposite the side that contains the pot entrance, mesh that is at least 2 inches between sides.
- It must have an escape panel or door with an opening equal to or larger than the interior end of the trap's throat (funnel) placed on at least one side, excluding the top and bottom. Its hinges or fasteners must be made of one of the following degradable materials: ungalvanized or uncoated iron wire no larger than 19 gauge or 0.041 inches diameter OR galvanic, timed release mechanisms with a letter grade no higher than J.
- It must have an unobstructed escape vent opening on at least two opposite vertical sides (excluding top and bottom) meeting the following requirements: The escape vent opening must measure at least 1 1/8 x 5 3/4" for rectangular vents, 1.75 x 1.75" for square vents (inside measure), or 2 diameter for circular vents.
- Sea bass pots must be removed from the water in the South Atlantic EEZ when the quota is reached.

Recreational

- Vertical hook-and-line including hand-held hook-and-line, and bandit gear
- Spearfishing gear without rebreathers
- Powerheads, except where expressly prohibited in Special Management Zones (SMZs). In addition, the use of explosive charges, including powerheads is prohibited in the EEZ off South Carolina.

5.2.2.1.1 Commercial Fishery

Gear and Fishing Behavior

The commercial snapper-grouper fishery utilizes vertical lines, longlines, black sea bass pots/traps, spears, and powerheads (i.e., spears with spring-loaded firearms). Vertical lines are used from the North Carolina/Virginia border to the Atlantic side of Key West, Florida. The majority of hook and line fishermen use either electric or hydraulic reels (bandit gear) and generally have 2-4 bandit reels per boat. The majority of the bandit fleet fishes year round for snapper-grouper with the only seasonal differences in catch associated with the regulatory spawning season closures in March and April for gag. Most fluctuations in fishing effort in this fishery are a result of the weather. Trips can be limited during hurricane season and also during the winter months from December through March. Some fishermen stop bandit fishing to target king mackerel when they are running.

The Council allows the use of bottom longlines north of St. Lucie Inlet, Florida, in depths greater than 50 fathoms. Bottom longline gear is used to target snowy grouper and golden tilefish. Longline boats are typically bigger than bandit boats, their trips are longer, and they cost more to operate because they operate farther offshore. A longline spool generally holds about 15 miles of cable. Longlines are fished from daylight to dark because sea lice eat the flesh of hooked fish at night. The fishery is operated year long with little or no seasonal fluctuation barring hurricane disruption.

Spears or powerheads are most commonly used off Florida and are illegal for killing snapper-grouper species in South Carolina and Special Management Zones.

Black sea bass pots are used exclusively to target black sea bass, though bycatch of other snapper-grouper species is allowed. The pots have mesh size, material, and construction restrictions to facilitate bycatch reduction. All sea bass pots must have a valid identification tag attached and more than 87% of tags in April, 2003 were for vessels with homeports in North Carolina. Fishing practices vary by buoy practices, setting/pulling strategies, number of pots set, and length of set, with seasonal variations. The South Carolina pot fishery is mainly a winter fishery with short soak times (in some cases about an hour) and relatively few pots per boat. Most trips are day trips with pots being retrieved before heading to port. The North Carolina pot fishery also is primarily a winter fishery with some fishermen continuing to pot through the summer. North Carolina fishermen tend to use more pots than those in South Carolina. Although most North Carolina trips with sea bass pots last one day, more pots are left to soak for several days than in South Carolina. Many participants in the black sea bass fishery are active in other fisheries, including the recreational charter fishery during the summer months. Many snapper-grouper permit holders maintain pot endorsements but are not active in the pot fishery.

Landings, Ex-vessel Value, Price, and Effort

Landings of all species in the snapper-grouper management unit averaged 6.77 million pounds from 2001 through 2006, with an average annual dockside value of $12.99 million in current year dollars and $13.55 million in constant 2005 dollars (Table 3-5). The shallow water groupers and mid-shelf snappers are the largest species groups by volume and value within the snapper-grouper fishery. Vermilion snapper in the mid-shelf snapper group is the largest volume species in the fishery, and accounts for 13% of total landings and 17% of dockside revenues on trips with at least one pound of snapper-grouper species. Gag is the largest volume shallow water grouper, and accounts for 6% of total landings and 10% of dockside revenues on trips that landed at least one pound of snapper-grouper species. Fishermen also landed an average of 1.84 million pounds of non-snapper-grouper species worth $1.95 million in current year dollars on trips that landed at least one pound of species in the snapper-grouper management unit. These trips included trips that targeted species in the snapper-grouper management unit and trips that landed snapper-grouper species while targeting non-snapper-grouper species.

Landings and dockside revenues declined between 2001 and 2006 for species in the snapper-grouper management unit (Table 5.2.2-1). Part of the declines appear to be attributable to variation in landings of vermilion snapper, which experienced a significant decline in 2003 due to unusually cold water temperatures in the summer and fall of 2003. Landings of vermilion snapper recovered in 2004 and 2005, but not to the levels experienced in 2001 and 2002, and declined again in 2006.

Table 5.2.2-1. Annual landings and dockside (ex-vessel) revenues for trips with at least one pound of species in the snapper-grouper fishery management unit in the south Atlantic.

Item	2001	2002	2003	2004	2005	2006	Average
	Trips with at least one pound of snapper-grouper species						
Snapper-grouper landings (million pounds, whole wgt)	7.60	7.36	6.50	6.70	6.39	6.07	6.77
Dockside revenue from snapper-grouper species (million dollars)	$13.95	$13.55	$12.12	$12.70	$12.98	$12.63	$12.99

Source: NOAA Fisheries Service, Southeast Fisheries Science Center logbook database as of October 10, 2007. *The Consumer Price Index for all Urban Consumers was used to adjust dockside revenues and average annual prices for inflation.

In addition, participation in the snapper-grouper fishery has declined over time. The number of boats with snapper-grouper permits declined from 1,264 in 2001 to 1,007 in 2005 (Table 5.2.2-2). Two types of permits were created with the limited access program for the snapper-grouper fishery that was implemented in 1998. The number of transferable permits that allow an unlimited harvest per trip declined from 959 in 2001 to 801 in 2005, while the number of vessels with non-transferable permits with a 225-pound trip limit declined from 305 in 2001 to 206 in 2005. Preliminary information suggests additional declines in 2006. The number of transferable permits declined, in part, because new entrants into the fishery must buy two permits and retire one as the condition for entry into the fishery. Furthermore, it is likely that the number of vessels in the snapper-grouper fishery declined for economic reasons. Average annual prices, as indexed by the ratio of annual commercial revenues to landings, for species in the snapper-grouper management unit remained relatively constant when adjusted for inflation, whereas fuel prices more than doubled since 2001 (Table 3-5). The net result has been a decline since 2001 in the number of vessels, trips and days fished for species in the snapper-grouper management unit (Table 5.2.2-2). The decline in the number of vessels is evident in all harvest categories except for the highest producing category of 50,000 pounds or more per year. The number of fish dealers with permits to operate in the snapper-grouper fishery reached a maximum in 2003 and has declined since then (Table 5.2.2-2).

From 2001 through 2006, an average of 922 boats averaged 15,500 trips per year on which at least one pound of snapper-grouper species was landed (Table 5.2.2-2). On average, 528 boats landed at least 1000 pounds of snapper-grouper species annually; 260 boats landed at least 5000 pounds; 173 boats landed at least 10,000 pounds; and 27 boats landed at least 50,000 pounds of snapper-grouper species.

5.2.2.1.1.1 Snapper Grouper Fishery by State

The following discussion provides annual averages from 2001 to 2006. To maintain the confidentiality of individual reporting units, summaries are provided for regions defined as North Carolina, South Carolina, Georgia and northeast Florida combined, and central and south Florida combined. The northeast Florida region consists of trips landed in Nassau, Duval and St. Johns Counties, and the central and south Florida region consists of trips landed from Flagler through Miami-Dade Counties and trips from Atlantic waters off the Florida Keys and landed in Monroe County.

The average annual quantities of snapper-grouper species harvested from 2001-2006 included 1.86 million pounds worth $3.46 million per year in North Carolina, 1.64 million pounds worth $3.44 million in South Carolina, 0.81 million pounds worth $1.65 million in Georgia and northeast Florida, and 2.46 million pounds worth $4.44 million in central and south Florida (Table 5.2.2-3). Snapper-grouper landings by state were not proportional to total days fished in each state. Boats in central and south Florida made 72% of the trips that landed species in the snapper-grouper management unit and accounted for 36% of the total snapper-grouper harvest. Conversely, boats in other states accounted for relatively larger portions of the total snapper-grouper harvest. Boats in North Carolina made 18% of the trips and landed 27% of the snapper-grouper harvest. Boats in South Carolina made 6% of the trips and landed 24% of the harvest. In addition, boats in Georgia and northeast Florida made 4% of the trips and landed 12% of the snapper-grouper harvest. Boats in South Carolina and Georgia and northeast Florida took fewer but longer trips than their counterparts in North Carolina or central and south Florida.

Gag and other shallow water groupers and vermilion snapper and other mid-shelf snappers tend to be landed in North Carolina, South Carolina, and Georgia and northeast Florida, while jacks and shallow water snappers tend to be landed in central and south Florida (Tables 5.2.2-4 and 5.2.2-5). The species groups that accounted for more than 10% of total landings and revenues in North Carolina include shallow water groupers with nearly 22% of total pounds landed and nearly 30% of total revenues on trips with at least one pound of snapper-grouper species; black sea bass with 20% of total landings and 19% of total revenues; and mid-shelf snappers with 18% of total landings and 25% of total revenues. In South Carolina, the shallow water groupers accounted for 27% of total pounds and 38% of total revenues, and the mid-shelf snappers accounted for 26% of total pounds and 30% of total revenues. In Georgia and northeast Florida, mid-shelf snappers accounted for 45% of total pounds and 52% of total revenues, shallow water groupers accounted for 18% of total pounds and nearly 25% of total revenues, and jacks accounted for 16% of total pounds and 6% of total revenues. In central and south Florida, the shallow water snappers accounted for 29% of total pounds and nearly 41% of total revenues, and jacks accounted for 17% of total pounds and 10% of total revenues on trips with at least one pound of snapper-grouper species. Fishermen in central and south Florida, especially in the Keys, tend to catch larger quantities of non-snapper-grouper species such as mackerels.

Table 5.2.2-3. Average annual landings and dockside revenues for trips with at least one pound of species in the snapper-grouper fishery, averages for 2001-2006 by state.

Item	North Carolina	South Carolina	Georgia and Northeast Florida	Central and South Florida	Total

5.2.2.1.1.2 The Snapper Grouper Fishery by Gear

The following discussion provides annual averages from 2001 to 2006. To maintain the confidentiality of individual reporting units, summaries are provided for vertical lines, longlines, black sea bass pots, and all other gears combined. The all-other-gear category includes trolling lines, diving gear, nets and other gears.

Most of the snapper-grouper harvest, including vermilion snapper and gag, is taken by some type of vertical hook-and-line gear. The exceptions include black sea bass, which is harvested primarily with black sea bass pots, and golden tilefish and yellowedge grouper, which are harvested primarily with bottom longlines. Some species, such as snowy grouper, are harvested by both vertical lines and longlines. Longlines also are used in the shark fishery and may catch species in the snapper-grouper management unit as secondary species.

The average quantities of snapper-grouper species harvested from 2001-2006 included 5.36 million pounds worth $10.48 million per year with vertical lines, 0.54 million pounds worth $1.02 million with longlines, 0.53 million pounds worth $0.83 million with black sea bass pots, and 0.34 million pounds worth $0.65 million with other gears (Table 5.2.2-6). Trips with vertical lines accounted for 78% of all trips that landed species in the snapper-grouper management unit and 79% of the total snapper-grouper harvest. Trips with longlines tend to be longer than trips with other gears. Longline trips accounted for 2% of the trips and 8% of the snapper-grouper harvest. Trips with black sea bass pots represented 5% of the trips and accounted for 8% of the harvest, while trips with other gears represented 15% of the trips and 5% of the harvest.

Table 5.2.2-6. Average annual landings and dockside revenues for trips with at least one pound of species in the snapper-grouper fishery: averages for 2001-2006 by primary gear.

Some boats fish with more than one primary gear.

5.2.2.1.1.3 Long-term Trends

The snapper grouper fishery has been heavily regulated since the fishery management plan was implemented in 1983 (Figure 5.2.2-1). Apart from the response to fishery management regulations, fluctuations in landings can be partly attributed to changes in stock abundance and availability, water quality, environmental conditions, market conditions (e.g., price), and fleet dynamics. Ex-vessel prices for the various species in the fishery depend on the quantity of landings, product quality, market conditions such as the availability of imports and the relative prices of substitutes, and consumer income levels.

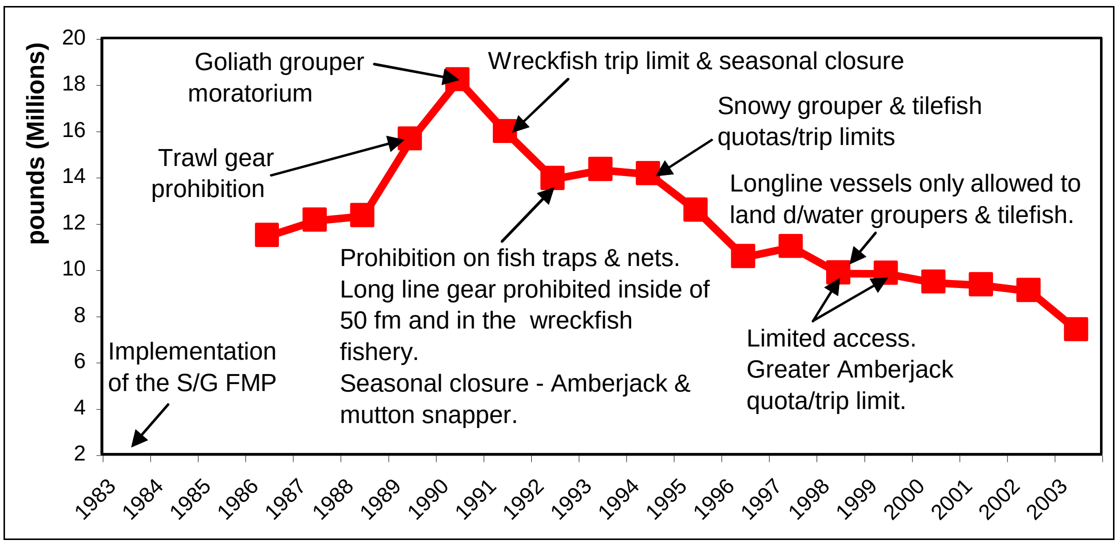

Figure 5.2.2-1. Major events in the regulatory history of the snapper grouper fishery superimposed on total snapper grouper landings during 1983-2003. Source: Accumulated landings system, Southeast Fisheries Science Center, Beaufort Lab.

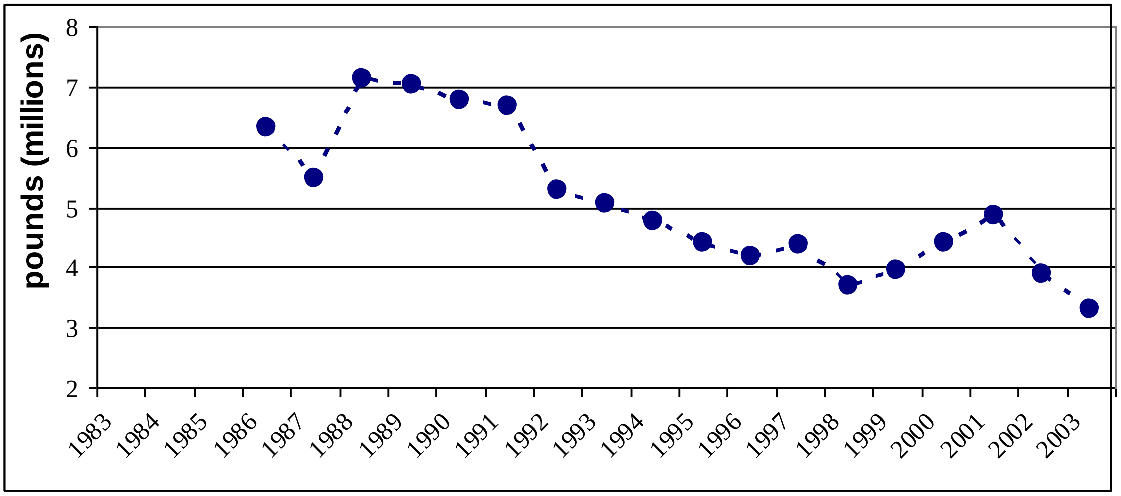

Figure 5.2.2-2. Trends in total harvest of species in Amendment 13C (SAFMC 2006) during 1983-2003. Source: Accumulated landings system, Southeast Fisheries Science Center, Beaufort Lab.

Snapper grouper ex-vessel landings and value increased from 1986 to 1990. During this period, real ex-vessel revenue increased from approximately $26 million to $35 million (Figure 5.2.2-2). Even though the overall average unit price of the fish, adjusted for inflation, was on a decreasing trend during this period (Figure 5.2.2-3), the 59% increase in landings resulted in the growth in overall ex-vessel revenue from 1986 through 1990. Data from the Accumulated Landings System (ALS) were used to examine long-term trends in prices, landings and revenue (see Appendix E in Snapper Grouper Amendment 13C, SAFMC 2006). These data will not correspond exactly to the statistics in Table 5.2.3-1 since this table contains statistics derived from the Southeast logbook database.

Since the peak in snapper grouper landings and revenue in 1990, there has been a steady decline in landings, ex-vessel revenue, and real ex-vessel revenue (Figure 5.2.2-3, Figure 5.2.2-4). The cause of this decline can be partly attributed to restrictive regulations taken to improve/maintain the health of species in the snapper grouper complex and protect essential fish habitat. This fishery was first regulated in 1983 with a number of size limit measures and gear restrictions. In 1992, Amendment 4 prohibited fish traps, entanglements nets, longlines for wreckfish, and the use of longline gear inside of 50 fathoms for snapper grouper species in the South Atlantic EEZ. Also, additional minimum size regulations and bag limits went into effect during 1992 (Figure 5.2.2-1).

The implementation of a limited access program in 1998/1999 partly contributed to the decline in the number of commercial vessels in the snapper grouper fishery (SAFMC 1997). Since 1999, the annual number of permitted vessels has declined by 375; the number of vessels with unlimited permits has declined by 244 (Table 5.2.2-1). Commercial and recreational fishermen in the snapper grouper fishery have faced additional restrictive measures implemented in Amendment 9 (SAFMC 1998c) and Amendment 12 (SAFMC 2000). A detailed account of these regulations is contained in the history of management section of this document. If current permit requirements remain in effect, it is likely fishing effort will continue to decline since each new entrant will have to purchase two existing snapper grouper permits. Also, the number of non-transferable permits will decline over time as their owners retire.

The trend in aggregate harvest of all species in this amendment follows a similar pattern to landings in the snapper grouper fishery (Figure 4.2.2-1). There was a continual decline in harvest from 1991 until 1998. However, unlike the trend in total snapper grouper landings, the total harvest of these five species increased between 1998 and 2001, before declining again during the following three years (Figure 5.2.2-1).

The average unit price for all snapper grouper species was fairly stable from 1986 to 1992 (Figure 5.2.2-4). Under normal conditions one would expect nominal prices to increase over time to account for inflation. However, landings increased during this period, which could partly account for the decreasing trend in inflation-adjusted prices up until 1991. Real prices remained relatively stable between 1992 and 2001 and declined afterwards. Other factors that influence snapper grouper prices include landings and market conditions in the Gulf of Mexico and the quantity of imports. The overall average price for snapper grouper species is calculated from data for a large number of individual species with different price trends. Also, prices for individual species will vary by size and for some species like black sea bass there is a large difference in price per lb among the various size categories.

In 2004, the volume of snappers and groupers imported into the U.S. was 43 million lbs valued at $75.6 million dollars. In comparison, domestic harvest of snappers and groupers landed at ports in the Gulf of Mexico and South Atlantic states amounted to 23.4 million lbs in 2003 (NOAA Fisheries 2004). Imports of snappers and groupers are classified into two product forms: fresh and frozen. Fresh fish comprised over 70% of total snapper grouper imports in 2004 (Table 5.2.2-7), which increased almost threefold from 16 million lbs in 1991 to 44.4 million lbs in 2003. Imports of other product forms cannot be identified by species group.

It is reasonable to expect that imports influence domestic prices. From the point of view of fishermen, imports contribute to depressing dockside prices. However, imports increase the aggregate U.S. supply of snappers and groupers, which leads to lower retail prices for consumers. Thus, consumers in this country benefit from imports, although there are also balance of trade considerations with imports, which affect the buying power of U.S. consumers in the long run. Imports also benefit some wholesalers and retailers in the fishing industry, especially at times when the domestic fishery is unable to supply market needs.

5.2.2.1.1.4 The Snowy Grouper Fishery

Landings of snowy grouper averaged 0.288 million pounds between 2001 and 2005, with average annual dockside revenues of $0.644 million in current-year dollars and $0.683 million in constant 2005 dollars (Table 5.2.2-8). Fishermen also landed an average of 1.416 million pounds of other species worth $2.434 million in current-year dollars on trips that landed at least one pound of snowy grouper.

According to NOAA Fisheries Service logbook trip reports, an average of 190 boats per year landed at least one pound of snowy grouper (Table 5.2.2-8). On average, 56 boats landed at least 1,000 pounds of snowy grouper per year, 15 boats landed at least 5,000 pounds per year, and 6 boats landed at least 10,000 pounds of snowy grouper per year. Landings and fishing effort for snowy grouper declined from 2001 through 2005.

Logbook data for 2001-2005 provided information about the extent to which snowy grouper was a primary or secondary source of trip revenue. Fishing trips were classified as targeting a particular species if revenues from that species were greater than revenues from any other individual species. (This is an imperfect measure of targeting behavior.) Snowy grouper were landed on an average of 1,332 trips per year, with less than 39% of them classified as targeted snowy grouper trips (Table 5.2.2-8). Targeted snowy grouper trips accounted for approximately 70% of total snowy grouper landings. Snowy grouper were caught frequently as a lesser source of revenue on trips for vermilion snapper, tilefishes, and other groupers, with the volume of secondary catch accounting for 30% of the average annual harvest of snowy grouper.

Snowy grouper are landed primarily with vertical lines and longlines. Trips with vertical lines accounted for 70% of landings of snowy grouper, while longlines accounted for 29% (Table 3-8). Approximately 48% of all trips with longlines that caught species in the snapper grouper management unit also caught snowy grouper, whereas approximately 9% of all trips with vertical lines in the snapper grouper fishery landed snowy grouper. Snowy grouper were landed as the primary revenue and secondary revenue species on trips with both gears. As a secondary-revenue species on trips with vertical lines, snowy grouper were landed frequently on trips that targeted vermilion snapper or other groupers. As a secondary-revenue species on trips with longlines, snowy grouper were landed on trips with golden tilefish.

On average from 2001-2005, snowy grouper were landed in approximately equal quantities in North Carolina, South Carolina and central-south Florida (Table 3-9). The greatest amount of fishing effort for snowy grouper occurred in central-south Florida, where snowy grouper contributed about 3.8% to total snapper grouper landings. Snowy grouper represented 5% of total snapper grouper landings in North Carolina and 6% in South Carolina.

***** Some boats land in more than one state.

5.2.2.1.1.5 The Red Porgy Fishery

Landings of red porgy averaged 0.048 million pounds between 2001 and 2005, with average annual dockside revenues of $0.065 million in current-year dollars and $0.069 million in constant 2005 dollars (Table 5.2.2-11). Fishermen also landed an average of 2.025 million pounds of other species worth $4.091 million in current-year dollars on trips that landed at least one pound of red porgy.

According to NOAA Fisheries Service logbook trip reports, an average of 179 boats per year landed at least one pound of red porgy (Table 5.2.2-11). Red porgy have been landed almost exclusively as an incidental species and secondary source of trip revenue since restrictive regulations were implemented in 1999. From 2001 through 2005, red porgy were landed on an average of 1,534 trips per year, with only 1% of them classified as trips for which red porgy was the single species with the largest source of revenue. Targeted trips accounted for 7% of total landings of red porgy. Approximately 84% of the total catch of red porgy between 2001 and 2005 occurred on trips for vermilion snapper or groupers, with the remaining 9% of red porgy caught on trips for a variety of other species.

Red porgy are landed primarily with vertical line gear (Table 5.2.2-12). Despite the restrictive regulatory environment on red porgy between 2001 and 2005, red porgy were landed on nearly 12% of all snapper grouper trips with vertical lines. Red porgy are landed primarily in North Carolina, South Carolina, and Georgia-northeast Florida (Table 5.2.2-13).

*Some boats land in more than one state.

5.5.2.1.1.6 The Tilefish Fishery

Landings of golden tilefish averaged 0.372 million pounds between 2001 and 2005, with average annual dockside revenues of $0.695 million in current-year dollars and $0.737 million in constant 2005 dollars (Table 5.2.2.14). Fishermen also landed an average of 0.307 million pounds of other species worth $0.450 million in current-year dollars on trips that landed at least one pound of golden tilefish.

According to NOAA Fisheries Service logbook trip reports, an average of 73 boats per year landed at least one pound of golden tilefish (Table 5.2.2-15). On average, 25 boats landed at least 1,000 pounds of golden tilefish per year, 14 boats landed at least 5,000 pounds per year, and 10 boats landed at least 10,000 pounds of golden tilefish per year. Landings and fishing effort for golden tilefish declined from 2001 through 2005.

Logbook data for 2001-2005 provided information about the extent to which golden tilefish was a primary or secondary source of trip revenue. Fishing trips were classified as targeting a particular species if revenues from that species were greater than revenues from any other individual species. Golden tilefish were landed on an average of 426 trips per year, with 65% of them classified as targeted golden tilefish trips that accounted for approximately 90% of total golden tilefish landings (Table 5.2.2-15). Golden tilefish also were caught as a secondary source of revenue on trips for snowy grouper and yellowedge grouper, with the volume of secondary catch accounting for 10% of the average annual harvest of golden tilefish.

Boats with bottom longlines account for 91% of the total harvest of golden tilefish (Table 5.2.2-16). On average, 62% of golden tilefish were landed in central-south Florida, 33% in South Carolina, and 4% in North Carolina (Table 3-15).

Table 5.2.2-14. Annual landings, dockside (ex-vessel) revenues, and fishing effort for golden tilefish, 2001-2005.

5.2.2.1.1.7 The Gag Fishery

Logbook data provide information about commercial landings for gag from 1993 through 2006. Between 1993 and 2006, commercial landings of gag ranged from a high of 0.85 million pounds (whole weight) worth approximately $2.03 million in 1996 to a low of 0.50 million pounds worth $1.32 million in 2000 (Figure 5.2.2-5). Preliminary data for 2006 indicate that landings of gag were approximately 0.50 million pounds worth $1.46 million. Dockside revenues and pounds landed fluctuate in the same direction, which suggests that ex-vessel demand is price elastic. The policy implication is that regulations that reduce industry landings in the short-term are expected to reduce dockside revenues in the short-term. Conversely, dockside revenues are expected to increase over time if regulation successfully increases biomass and landings.

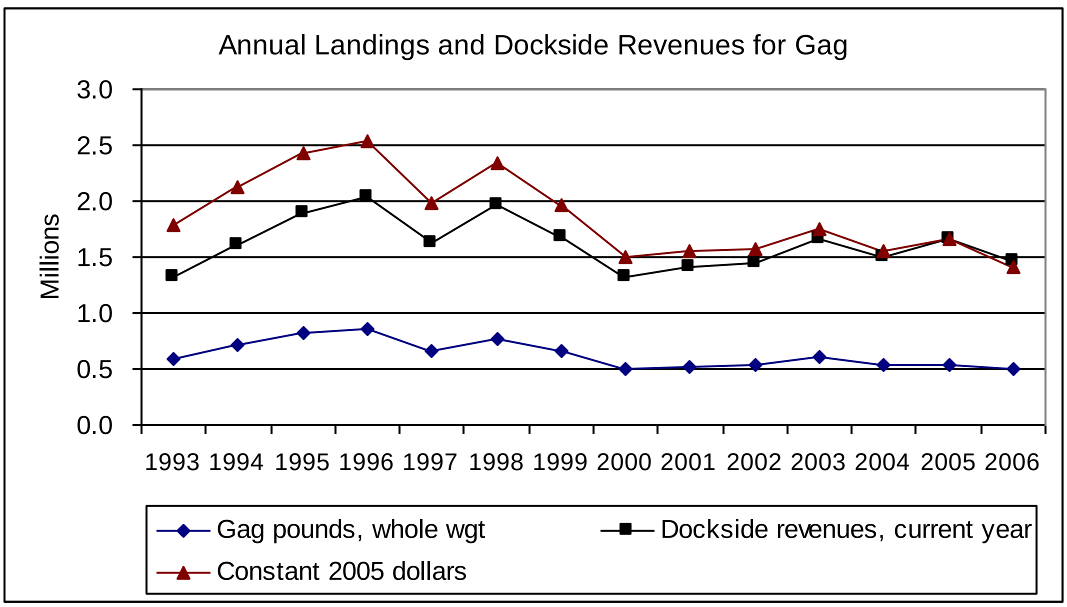

Figure 5.2.2-5. Annual landings and dockside revenues for gag, 1993-2006.

Source: NOAA Fisheries Service, Southeast Fisheries Science Center logbook database as of October 10, 2007, and NOAA Fisheries Service, Southeast Fisheries Science Center Accumulated Landings System as of October 5, 2007.

The time series for gag is defined by regulatory periods, with landings between 1993 and 1999 usually exceeding landings between 2000 and 2006. Between 1992 and 1998, the fishery for gag was regulated with a 20-inch minimum size limit. Beginning in 1999, the size limit was increased to 24 inches and the fishery was closed in March and April to protect the spawning stock. Prior to 1998, average monthly landings were highest in May and lowest in August (Figure 5.2.2-6). After the closure and larger size limit were implemented, average monthly landings increased in May, but otherwise declined in the remaining open months when compared to the 1993-1998 period, especially in September.

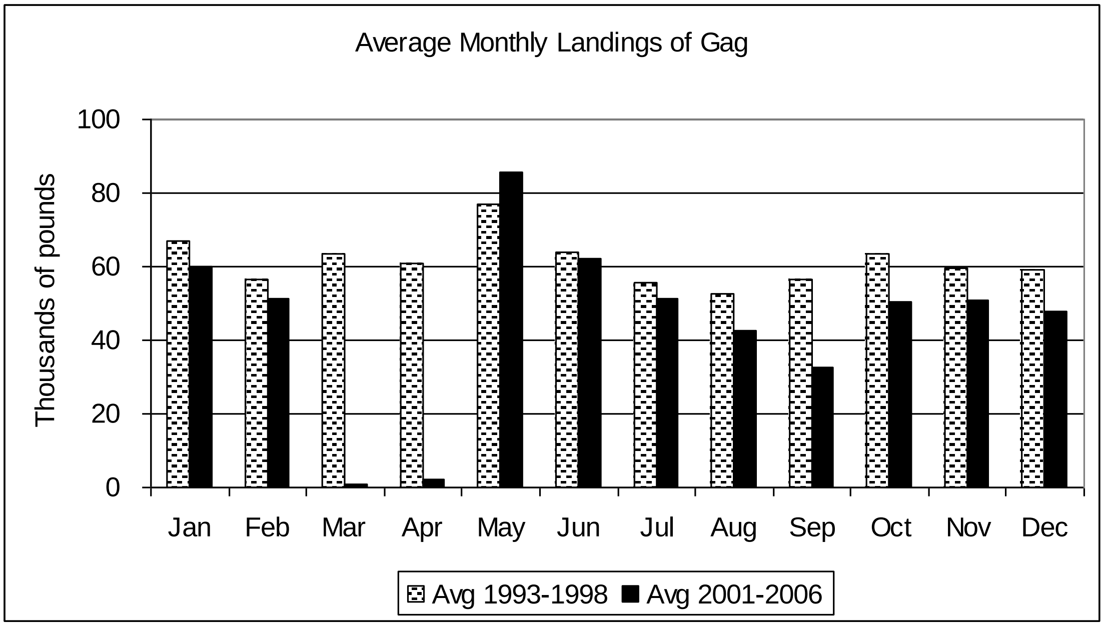

Figure 5.2.2-6. Average monthly landings of gag for the 1993-1998 and 2001-2006 periods.

Source: NOAA Fisheries Service, Southeast Fisheries Science Center logbook database as of October 10, 2007.

On average from 2001-2006, there were 2,417 trips that landed at least one pound of gag, and totaled an annual average of 0.54 million pounds of gag worth $1.52 million in current year dollars and $1.58 million in constant 2005 dollars (Table 5.2.2-17). In addition, these trips annually produced an average of 2.13 million pounds of other species worth $3.98 million in current year dollars. Gag was the primary revenue species on some trips and a lesser source of revenue on other trips.

Gag was the primary source of trip revenue on an average of 1,062 trips per year and a lesser source of revenue on 1,355 trips per year (Table 5.2.2-18). Therefore, gag was the primary source of trip revenue on less than 45% of the total number of trips on which they were landed. However, these trips accounted for approximately 67% of the total commercial harvest of gag. Trips on which gag was the primary source of revenue accounted for an annual average of 0.36 million pounds of gag worth $1.03 million in current dollars and 0.43 million pounds of other species, including other groupers, snappers, jacks, grunts, porgies and non-snapper-grouper species, worth $0.78 million. Trips on which gag was a lesser source of revenue accounted for an annual average of 0.17 million pounds of gag worth $0.49 million in current dollars and 1.70 million pounds of other species worth $3.20 million. Gag were caught as a lesser source of revenue on trips for vermilion snapper, scamp, red grouper, jacks and other species.

Table 5.2.2-18. Annual landings, dockside revenues and fishing effort on trips with gag as the primary source of trip revenue, 2001-2006.

Item	2001	2002	2003	2004	2005	2006	Average

Source: NOAA Fisheries Service, Southeast Fisheries Science Center logbook database as of October 10, 2007.

The number of boats that reported landing at least one pound of gag declined from 337 in 2001 to 257 in 2006, and averaged 299 boats per year (Table 5.2.2-17). The fleet was not uniformly productive in the fishery for gag, which is consistent with the observation that gag was the primary source of trip revenue on some trips and a lesser source of revenues on other trips. On average for 2001-2006, the top 20 boats for gag production made 20% of the trips that landed gag and recorded 44% of the total commercial harvest of gag (Figure 5.2.2-7). The top 50 producing boats made 46% of the trips and recorded 72% of the total harvest, while the top 100 producing boats made 72% of the trips and landed 91% of the total harvest. On average, 104 boats landed at least 1,000 pounds of gag per year, 34 boats landed at least 5,000 pounds per year, and 12 boats landed at least 10,000 pounds of gag per year (Table 5.2.2-18). Approximately 80% of gag is landed with vertical lines, and most of the remainder is landed with dive gear (Table 5.2.2-17).

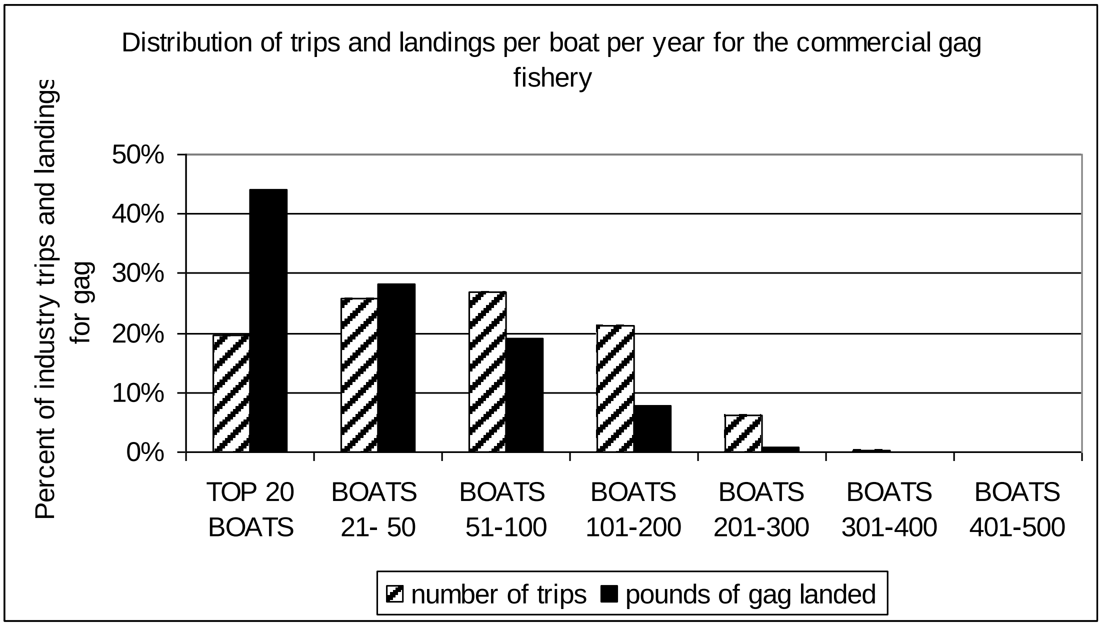

Figure 5.2.2-7. Distribution of trips and landings per boat per year, based on trips that reported at least one pound of gag.
Source: NOAA Fisheries Service, Southeast Fisheries Science Center logbook database as of October 10, 2007.

5.2.2.1.1.8 The Vermilion Snapper Fishery

Based on logbook data from 1993 through 2006, commercial landings of vermilion snapper ranged from a low of 0.68 million pounds (whole weight) worth $1.33 million in 1993 to a high of 1.65 million pounds worth approximately $3.54 million in 2001 (Figure 5.2.2-8). Landings of vermilion snapper began to increase in 1999 coincident with the implementation of more restrictive regulations for gag, peaked in 2001, and then declined through 2003 when unusually cold water temperatures reduced the availability of fish in the summer and fall of 2003. Landings of vermilion snapper recovered in 2004 and 2005, but not to the levels experienced in 2001 and 2002. Preliminary data for 2006 indicate that landings of vermilion snapper were approximately 0.86 million pounds worth $2.23 million. Dockside revenues generally displayed the same trend over time as commercial landings, which suggests that ex-vessel demand for vermilion snapper is price elastic. Hence, regulations that reduce industry landings in the short-term are expected to reduce dockside revenues in the short-term. Conversely, dockside revenues are expected to increase over time if regulation successfully increases biomass and landings.

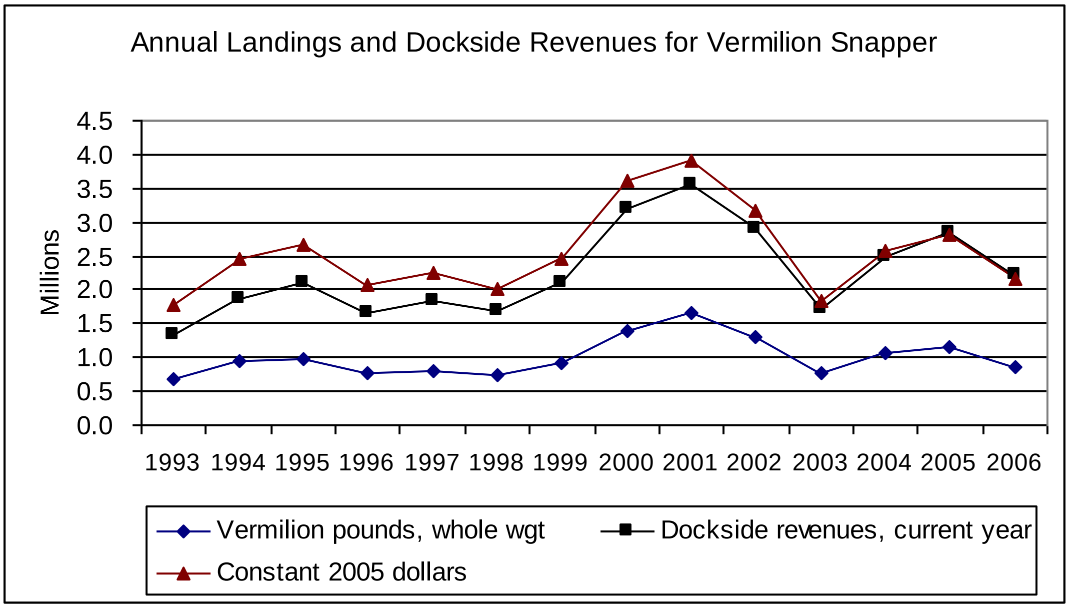

Figure 5.2.2-8. Annual landings and dockside revenues for vermilion snapper, 1993-2006.
Source: NOAA Fisheries Service, Southeast Fisheries Science Center logbook database as of October 10, 2007, and NOAA Fisheries Service, Southeast Fisheries Science Center Accumulated Landings System as of October 5, 2007.

Vermilion snapper are landed throughout the year, with peak months from August through December (Figure 5.2.2-9). Average monthly landings were higher for all months except December during the 2001-2006 period compared to the 1993-1998 period. The greatest relative monthly increases in average landings between the two periods occurred during March and April, apparently as fishermen shifted their fishing effort from gag to vermilion in response to the closed season that was implemented in 1999.

On average from 2001-2006, there were 2,423 trips that landed at least one pound of vermilion snapper, and totaled an average of nearly 1.14 million pounds of vermilion snapper worth $2.62 million in current-year dollars and $2.74 million in constant 2005 dollars (Table 5.2.2-19). In addition, these trips annually produced an average of 2.14 million pounds of other species combined worth $4.07 million in current year dollars. Vermilion snapper was the primary revenue species on some trips and a lesser source of revenue on other trips.

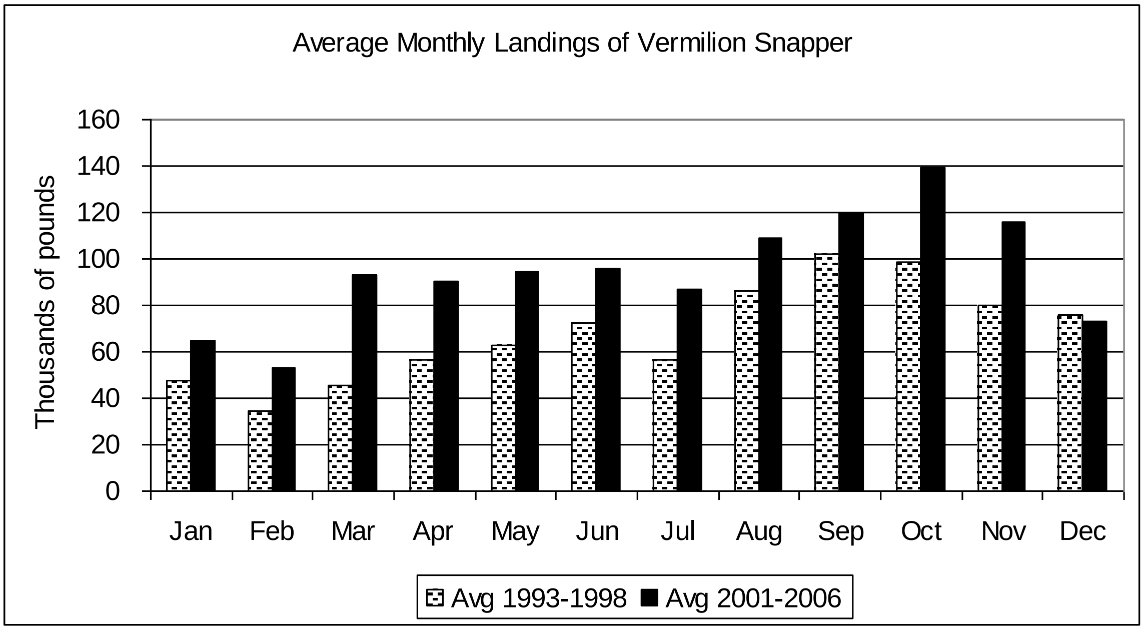

Figure 5.2.2-9. Average monthly landings of vermilion snapper for the 1993-1998 and 2001-2006 periods.
Source: NOAA Fisheries Service, Southeast Fisheries Science Center logbook database as of October 10, 2007.

Vermilion snapper was the primary source of trip revenue on an average of 1,186 trips per year and a lesser source of revenue on 1,237 trips per year (Table 5.2.2-19). Therefore, vermilion snapper was the primary source of trip revenue on slightly less than 50% of the total number of trips on which they were landed. However, these trips accounted for approximately 86% of total vermilion snapper landings. Trips on which vermilion snapper was the primary source of revenue accounted for an annual average of 0.98 million pounds of vermilion snapper worth $2.27 million in current dollars and 0.92 million pounds of other species, including groupers, jacks, grunts, porgies and non-snapper-grouper species, worth $1.53 million. Trips on which vermilion snapper was a lesser source of revenue accounted for an annual average of 0.16 million pounds of vermilion snapper worth $0.35 million in current dollars and 1.22 million pounds of other species worth $2.54 million. Vermilion snapper were caught as a lesser source of revenue on trips for gag, scamp and red grouper in the shallow water grouper fishery, and snowy grouper in the deep water grouper fishery.

Table 5.2.2-19. Annual landings, dockside revenues and fishing effort on trips for vermilion snapper, 2001-2006.

The number of boats that reported landing at least one pound of vermilion snapper declined from 295 in 2001 to 232 in 2006, and averaged 259 boats per year (Table 5.2.2-20). The fleet was not uniformly productive in the fishery for vermilion snapper, which is consistent with the observation that vermilion snapper was the primary source of trip revenue on some trips and a lesser source of revenues on other trips. On average for 2001-2006, the top 20 boats for the production of vermilion snapper made 20% of the trips that landed vermilion and recorded 50% of the total commercial harvest of vermilion snapper (Figure 5.2.2-10). The top 50 producing boats made 48% of the trips and recorded 82% of the total harvest, while the top 100 producing boats made 77% of the trips and landed 98% of the total harvest. On average, 95 boats landed at least 1,000 pounds of vermilion snapper per year, 49 boats landed at least 5,000 pounds per year, and 43 boats landed at least 10,000 pounds of vermilion snapper per year (Table 5.2.2-20). Virtually all vermilion snapper are landed with vertical lines (Table 5.2.2-20).

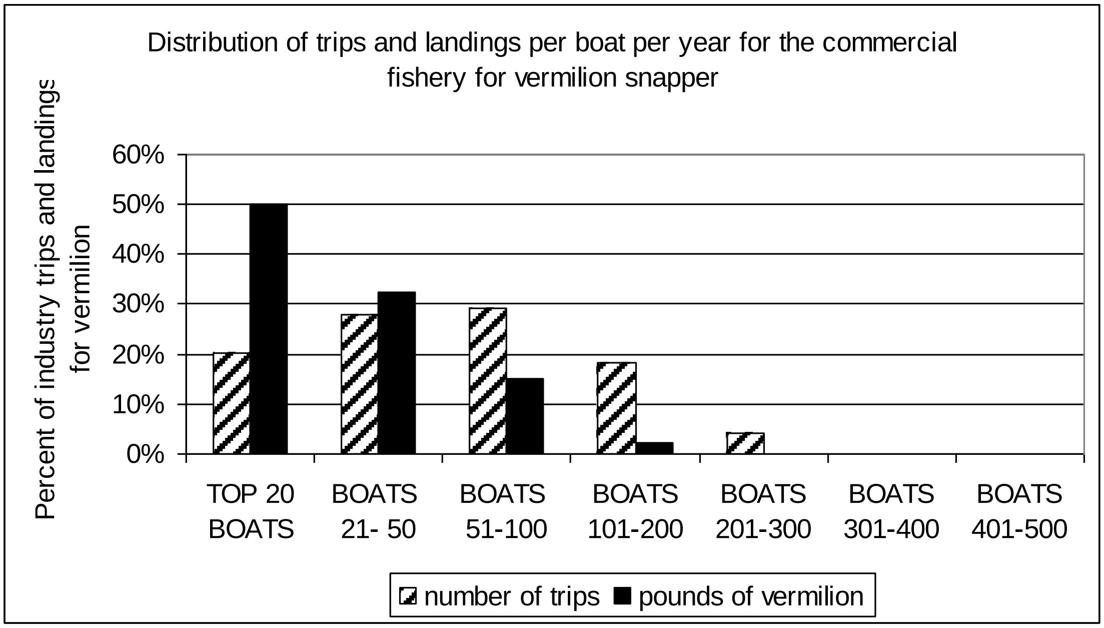

Figure 5.2.2-10. Distribution of trips and landings per boat per year, based on trips that reported at least one pound of vermilion snapper.

5.2.2.1.1.9 Imports

Imports have been a major source of seafood supply in the U.S., and the domestic snapper-grouper market is not an exception. For the period 2001-2006, imports of fresh and frozen snappers and groupers have stayed at relatively high levels, averaging at about 44.7 million pounds (Table 5.2.2-21). Compare this with the average overall landings of snapper-grouper in the South Atlantic for the same period of 6.77 million pounds (Table 5.2.2-21), and one can immediately see the dominance of imports in the snapper-grouper market. At an annual average of $79.2 million for the years 2001-2006, imports clearly dwarf the $12.99 million ex-vessel value of South Atlantic snapper-grouper landings. The dominance of imports in the snapper-grouper market may be expected to exert limits on the movement of domestic ex-vessel prices resulting from changes in domestic landings of snappers and groupers.

Table 5.2.2-21. U.S. imports of snappers and groupers, 2001-2006.

YEAR	Pounds of imports by product form Millions of pounds*			Value of imports by product form Millions of dollars		
	FRESH	FROZEN	TOTAL	FRESH	FROZEN	TOTAL
2001	31.1	8.4	39.4	$51.7	$10.6	$62.3

5.2.2.1.2 Recreational Fishery

The South Atlantic recreational fishery is comprised of the private sector and for-hire sector. The private sector includes anglers fishing from shore (all land-based structures) and private/rental boats. The for-hire sector is composed of the charterboat and headboat (also called partyboat) sectors. Charterboats generally carry fewer passengers and charge a fee on an entire vessel basis, whereas headboats carry more passengers and payment is per person. The type of service, from a vessel- or passenger-size perspective, affects the flexibility to search different fishing locations during the course of a trip and target different species since larger concentrations of fish are required to satisfy larger groups of anglers.

5.2.2.1.2.1 Harvest

Recreational snapper grouper harvest has been variable during the period 2001-2006, averaging at a little over 10 million pounds (Table 5.2.2-22). The private/shore mode of fishing accounted for around 67 percent of all harvests, followed by the charter mode (17%), then by headboats (16%). Harvests in each state also fluctuated during the same time period (Table 5.2.2-23). On average, Florida accounted for around 66 percent of total harvests, followed by North Carolina (16%), South Carolina (12%), and Georgia (6%).

Gag and vermilion snapper are the main species addressed in this amendment, but there are also other species that may be affected especially by the closure alternatives in this amendment. These other species include black grouper, red grouper, scamp, red hind, rock hind, yellowmouth grouper, tiger grouper, yellowfin grouper, graysby, and coney. For the period 2001-2006, gag averaged at 627,266 pounds, vermilion snapper at 581,567 pounds, and other species at 517,789 pounds (Table 5.2.2-24). The private/shore mode dominated the harvest of gag (71%) while the headboat sector dominated the harvest of vermilion snapper (60%). The private/shore mode also dominated the harvest of other species (56%). Summing across species, total harvest is dominated by the private/mode sector, followed by the headboat sector, and lastly by the charterboat sector.

Table 5.2.2-22. Harvest of snapper grouper species by mode in the South Atlantic.

Year	Charterboat[1]	Headboat[2]	Shore and Private/Rental Boat[1]	Total

Florida accounted for the largest amount of harvests, followed by North Carolina, then by South Carolina, and lastly by Georgia (Table 5.2.2-25). Florida accounted for the largest share in the harvest of gag (67%) and other species (46%). South Carolina, on the other hand accounted for the largest share of vermilion snapper harvests (36%).

Table 5.2.2-24. Average harvest (lbs) of gag, vermilion snapper, and other species in this amendment by sector, 2001-2006.

Sector	Gag	Vermilion snapper	Other species*	Total

Sector	Gag	Vermilion snapper	Other species*	Total
Florida	422,571	147,223	227,140	796,934
Georgia	24,377	108,430	12,936	145,743
South Carolina	33,921	219,321	86,033	339,275
North Carolina	150,726	140,772	171,878	463,376
Total	631,595	615,746	497,987	1,745,328

Source: The Headboat Survey, NOAA Fisheries, SEFSC, Beaufort Lab and MRFSS database, NOAA Fisheries, NMFS, SERO.
*Other species includes black grouper, red grouper, scamp, red hind, rock hind, yellowmouth grouper, tiger grouper, yellowfin grouper, graysby, and coney.

The species addressed by this amendment accounted for 17 percent of total recreational harvests of snappers and groupers for the period 2001-2006 (Figure 5.2.2-11). Gag and vermilion snapper accounted for 6 percent each of total harvests while other species accounted for 5 percent of total harvests. The subject species in this amendment vary in importance by sector. In the charterboat sector, the species in this amendment comprised 20 percent of this sector's total harvest (Figure 5.2.2-12). Of this sector's total harvest, vermilion comprised 8 percent, gag 7 percent, and other species 5 percent. For headboats, the species in this amendment accounted for 35 percent of total harvest (Figure 5.2.2-13). This can be broken down into 22 percent vermilion, 9 percent other species, and 4 percent gag. Among the various sectors, the private/shore mode has the lowest percentage of harvest affected by this amendment. The species in this amendment accounted for 12 percent of this sector's total harvest, with the following breakdown: 7 percent gag, 4 percent other species, and 1 percent gag (Figure 5.2.2-14).

5.2.2.1.2.2 Effort

Recreational effort derived from the MRFSS can be characterized in terms of the number of trips as follows:

1. Target effort - The number of individual angler trips, regardless of duration, where the intercepted angler indicated that the species or a species in the species group was targeted as either the first or second primary target for the trip. The species did not have to be caught.
2. Catch effort - The number of individual angler trips, regardless of duration and target intent, where the individual species or a species in the species group was caught. The fish did not have to be kept.
3. Total recreational trips - The total estimated number of recreational trips in the South Atlantic, regardless of target intent or catch success.

Estimates of average effort for the entire snapper grouper fishery are provided in Table 5.2.2-26 for trips by mode and Table 5.2.2-27 for trips by state. The total column refers to the total number of trips taken by anglers in the South Atlantic snapper-grouper fishery and not to the sum catch and target trips. On average, catch trips were highest on those taken through the private mode and lowest on those through the charter mode. The same is true with target trips: they were highest for private mode and lowest for charter mode. For the charter mode, both catch and target trips increased over time although there was some downward blip in the last year. Shore mode catch and target trips remained about flat around their means. Catch trips for the private fluctuate around their mean, but high levels were experienced in the last two years. On the other hand, private mode target trips declined over time, with a slight uptick in the last year.

For the period 2001-2006, an annual average of 295,593 trips taken by anglers caught snapper grouper species (Table 5.2.2-28). This is about 9 percent of all catch trips taken by anglers in the South Atlantic snapper-grouper fishery. An average of 96,800 trips caught gag, 81,815 caught vermilion snapper, and 116,978 caught other species. The private mode accounted for the largest number of catch trips for all species groups in this amendment. The charter and shore modes registered substantially lower catch trips than the private mode. There were more trips catching other species than either gag or vermilion, and more vermilion catch trips than gag.

The number of trips that targeted gag and vermilion snapper species (55,485) was substantially lower than catch trips. This is about 7 percent of all target trips in the South Atlantic snapper-grouper fishery. Again, the private mode dominated all other modes in terms of number of target trips. In fact, target trips by the charter and shore modes registered at very low levels (Table 5.2.2-28). There were substantially more target trips for gag (47,330) than for vermilion snapper (1,381) or other species (6,774).

Table 5.2.2-28. Average recreational effort for species, by mode, 2001-2006.

	Gag	Vermilion	Other Species	Total

The regional distribution of catch and target trips for species is presented in Table 5.2.2-29. Florida, with 233,188 total catch trips, dominated all other states, but catch trips in South Carolina (36,382) and North Carolina (17,753) were also relatively high. Florida also had the largest catch trips for each of the three species groups, followed by North Carolina, South Carolina, and Georgia.

In terms of target trips, only Florida registered large numbers while all other states showed relatively minimal target trips. In fact, Florida, with a total of 54,550 target trips, accounted for about 98 percent of all target trips for species. It may be pointed out, though, that most of the Florida target trips (85%) were for gag, and there were more target trips for other species than for vermilion snapper.

Table 5.2.2-29. Average recreational effort for snapper grouper species, by state, 2001-2006.

	Gag	Vermilion	Other Species	Total

The fact that target trips were substantially lower than catch trips has implications on the determination of the economic effects of regulations. It may be contended that target trips contain more meaningful economic valuation of the fishing experience than catch trips from the standpoint of predicting the economic outcome of regulations. One reason for this is that a target trip carries with it an indication of an angler's assignment of some positive values to the species targeted. On the other hand, some catch trips may simply be accidental and as such may not provide any indication of an angler's assignment of value on certain species. It is possible, of course, that past catch trips may shape future target trips, but this would necessitate further research to determine the nature and extent of the effects of past catch trips on future target trips. At any rate, the substantial difference between catch and target trips may imply that if regulations in this amendment were effective in reducing harvest by reducing catch trips more than target trips, then the resulting economic effects would likely be less than harvest reductions.

Similar analysis is not possible for the headboat sector since data are not collected at the angler level. Estimates of effort in the headboat sector are provided in terms of angler days, or the number of standardized 12-hour fishing days that account for the different half-, three-quarter-, and full-day fishing trips by headboats. Despite the inability to associate headboat effort with specific species, the stationary bottom nature of headboat fishing, as opposed to trolling, suggests that all headboat trips and, hence, angler days, are snapper grouper trips by intent, though not necessarily success.

Headboat angler days are presented in Table 5.2.2-30. Due to very low headboat angler days for Georgia, entries for Georgia were combined with those of Florida. For the period 2001-2006, total headboat angler days fluctuated around the mean of 238,012 days. On average, Florida accounted for the largest number of angler days (163,375), or about 69 percent of all headboat angler days. Nevertheless, the numbers for South Carolina (44,810 days) and North Carolina (27,824 days) are far from being negligible.

Table 5.2.2-30. Estimate of headboat angler days for the U.S. South Atlantic.

	Florida	South Carolina	North Carolina	Total
2001	163,389	49,265	31,779	246,434

5.2.2.1.2.3 Permits

For-hire vessels in the South Atlantic are required to have a snapper grouper for-hire permit to fish for or possess snapper grouper species in the EEZ. The number of permitted vessels for the period 2001-2006 is provided in Table 5.2.2-31. This sector operates as an open access fishery and not all permitted vessels are necessarily active in the fishery. Some vessel owners have been known to purchase open access permits as insurance for uncertainties in the fisheries in which they currently operate.

The number of for-hire permits issued in the South Atlantic snapper-grouper fishery increased over the period 2001-2006, with 1,095 permits in 2001 to 1,681 permits in 2006. Most of the increases would likely be for strictly for-hire business, since permits issued for vessels operating as for-hire and commercial entities remained about flat during the same period. The majority of snapper grouper for-hire permitted vessels were home-ported in Florida; a good number of vessels were also home-ported in North Carolina and South Carolina. Interestingly, there were several vessels with home ports in states other than those within the South Atlantic Council's area of jurisdiction. Most of the vessels with both for-hire and commercial permits were home-ported in the South Atlantic Council's area of jurisdiction.

Table 5.2.2-31. Snapper grouper for-hire permit holders by home port state.

Source: Southeast Permits Database, NOAA Fisheries, SERO.

The for-hire permit does not distinguish between whether the vessel operates as a charterboat or headboat. Based on a 1997 survey, Holland *et al.* (1999) estimated that a total of 1,080 charter vessels and 96 headboats supplied for-hire services in all South Atlantic fisheries during 1997.

5.2.2.1.2.4 Economic Value and Expenditures

Participation, effort, and harvest are indicators of the value of saltwater recreational fishing. However, a more specific indicator of value is the satisfaction that anglers experience over and above their costs of fishing. The monetary value of this satisfaction is referred to as consumer surplus. The value or benefit derived from the recreational experience is dependent on several quality determinants, which include fish size, catch success rate, and the number of fish kept. These variables help determine the value of a fishing trip and influence total demand for recreational fishing trips.

Estimates of the economic value of a day of saltwater recreational fishing in the South Atlantic indicate that the mean value of access per marine recreational fishing trip is $109.31 for the South Atlantic (Haab *et al.* 2001). While this estimate is not specific to snapper-grouper fishing trips, it may shed light on the magnitude of an angler's willingness to pay for this type of recreational experience.

Willingness to pay for an incremental increase in catch and keep rates per trip was also estimated to be $3.01 for bottom fish species by Haab *et al.* (2001). Whitehead *et al.* (2001) estimated the marginal willingness to pay to avoid a one fish red snapper bag limit decrease to be $1.06 to $2.20. Finally, Haab *et al.* (2001) provided a compensating variation (the amount of money a person would have to receive to be no worse off after a reduction of the bag limit) estimate of $2.49 per fish when calculated across all private boat anglers that targeted snapper grouper species in the South Atlantic.

These valuation estimates should not be confused with angler expenditures or economic activity. While expenditures for a specific good or service may represent a proxy or lower bound of value (a person would not logically pay more for something than it was worth to them), they do not represent the net value (benefits minus cost), nor the change in value associated with a change in the fishing experience. However, angler expenditures benefit a number of sectors that provide goods and services for salt-water sport fishing. Gentner *et al.* (2001) provides estimates of saltwater recreational fishing trip expenditures (Table 5.2.2-32). These estimates do not include expenditures in Monroe County, Florida, or expenditures in the headboat sector.

Table 5.2.2-32. Summary of expenditures on saltwater trips.

	North Carolina		**South Carolina**		**Georgia**		**Florida**	
Item	**Resident**	**Non Resident**	**Resident**	**Non Resident**	**Resident**	**Non Resident**	**Resident**	**Non Resident**
Shore mode trip expenses	$63.61	$75.53	$54.12	$104.27	$31.78	$115.13	$36.90	$141.30
Private/rental boat trip expenses	$71.28	$92.15	$35.91	$67.07	$161.34	$77.51	$66.59	$94.15

Source: 1999 MRFSS add-on survey (Gentner *et al.* 2001).

5.2.2.1.2.5 Financial Operations of the Charter and Headboat Sectors

Holland *et al.* (1999) estimated that the charterboat fee in the South Atlantic ranged from $292 to $2,000. The actual cost depended on state, trip length, and the variety of services offered by the charter operation. Depending on the state, the average fee for a half-day trip ranged from $296 to $360, for a full day trip the range was $575 to $710, and for an overnight trip the range was $1,000 to $2,000. Most (>90 percent) Florida charter operators offered half-day and full-day trips and about 15 percent of the fleet offered overnight trips. In comparison, only about 3 percent of operations in the other South Atlantic states offered overnight trips.

For headboats, the average fee in Florida was $29 for a half-day trip and $45 for a full day trip. For North and South Carolina, the average base fee was $34 per person for a half-day trip and $61 per person for a full day trip. Most of these headboat trips operated in Federal waters in the South Atlantic (Holland *et al.* 1999).

Capital investment in charter vessels averaged $109,301 in Florida, $79,868 for North Carolina, $38,150 for South Carolina and $51,554 for Georgia (Holland *et al.* 1999). Charterboat owners incur expenses for inputs such as fuel, ice, and tackle in order to offer the services required by their passengers. Most expenses incurred in 1997 by charter vessel owners were on crew wages and salaries and fuel. The average annual charterboat business expenditures incurred was $68,816 for Florida vessels, $46,888 for North Carolina vessels, $23,235 for South Carolina vessels, and $41,688 for vessels in Georgia in 1997. The average capital investment for headboats in the South Atlantic was approximately $220,000 in 1997. Total annual business expenditures averaged $135,737 for headboats in Florida and $105,045 for headboats in other states in the South Atlantic.

The 1999 study on the for-hire sector in the Southeastern U.S. presented two sets of average gross revenue estimates for the charter and headboat sectors in the South Atlantic (Holland *et al*., 1999). The first set of estimates were those reported by survey respondents and were as follows: $51,000 for charterboats on the Atlantic coast of Florida; $60,135 for charterboats in North Carolina; $26,304 for charterboats in South Carolina; $56,551 for charterboats in Georgia; $140,714 for headboats in Florida; and $123,000 for headboats in the other South Atlantic states (Holland *et al*., 1999). The authors generated a second set of estimates using the reported average trip fee, average number of trips per year, and average number of passengers per trip (for the headboat sector) for each vessel category for Florida vessels. Using this method, the resultant average gross revenue figures were $69,268 for charterboats and $299,551 for headboats. Since the calculated estimates were considerably higher than the reported estimates (22 percent higher for charterboats and 113 percent higher for headboats), the authors surmised that this was due to sensitivity associated with reporting gross receipts, and subsequent under reporting. Alternatively, the respondents could have overestimated individual components of the calculated estimates. Although the authors only applied this methodology to Florida vessels, assuming the same degree of under reporting in the other states results in the following estimates in average gross revenues: $73,365 for charterboats in North Carolina, $32,091 for charterboats in South Carolina; $68,992 for charterboats in Georgia; and $261,990 for headboats in the other South Atlantic states.

It should be noted that the study's authors were concerned that while the reported gross revenue figures may be underestimates of true vessel income, the calculated values could overestimate gross income per vessel from for-hire activity (Holland *et al.*, 1999). Some of these vessels are also used in commercial fishing activities and that income is not reflected in these estimates.

5.2.2.1.3 Social and cultural environment

Additional detailed description of the social and cultural nature of the South Atlantic snapper-grouper fishery is contained in Snapper Grouper Amendment 13C (SAFMC 2006), Snapper Grouper Amendment 15A (SAFMC 2007), and Snapper Grouper Amendment 15B (SAFMC 2008)] and is incorporated herein by reference. The following section updates and summarizes social and cultural information for commercial and recreational sectors of the snapper grouper fishery as part of the human component of the South Atlantic ecosystem. Key communities were identified primarily based on permit and employment activity. These data were obtained from the U.S. Bureau of the Census and from state and federal permitting agencies.

Permit trends are hard to determine, since several factors may affect how many vessels are homeported in certain communities, including vessel mobility, shifting stock locations, and resettlement of fishermen due to coastal development. Nevertheless, although vessel location shifts occur, static geographical representations help determine where impacts may be felt.

Data from the US Census Bureau must be used with some caution. Census data may not reflect shifting community demographics. Businesses routinely start up and fail or move and the census data collection cycle may fail to capture key changes. Further, census estimates do not include seasonal visitors and tourists, or those that live less than half the year in a surveyed area. Many of the latter group may work as seasonal employees and not be counted. Census data also misses some types of labor, such as day laborers, undocumented crew members, or family members that help with bookkeeping responsibilities.

Permit requirements for the commercial snapper grouper fishery were established in 1998 by Amendment 8 (SAFMC 1997). This amendment created a limited entry system for the fishery and established two types of permits based on the historic landings associated with a particular permit. Those who could demonstrate a certain amount of landings over a certain time period received permits that did not limit the number of pounds of snapper grouper that could be landed from federal waters (hereafter referred to as “unlimited commercial permits”). These permits were transferable. Vessels with verified landings, but did not meet the threshold were issued permits that allowed them to land 225 pounds of snapper grouper species from federal waters each trip (hereafter referred to as “limited commercial permits”). These permits were not transferable. New entry into the fishery required the purchase of two unlimited permits from existing permit holders for exchange for a new permit. This “two for one” system was intended to gradually decrease the number of permits in the fishery. These restrictions only applied to the commercial snapper grouper permit.

Impacts on fishing communities from coastal development, rising property taxes, decreasing access to waterfront due to increasing privatization of public resources, rising cost of dockage and fuel, lack of maintenance of waterways and ocean passages, competition with imported fish, and other less tangible (often political) factors have combined to put all these communities and their associated fishing sectors under great stress.

While studies on the general identification of fishing communities have been undertaken in the past few years, little social or cultural investigation into the nature of the snapper grouper fishery itself has occurred. A socioeconomic study by Waters *et al.* (1997) covered the general characteristics of the fishery in the South Atlantic, but those data are now almost 10 years old and do not capture important changes in the fishery. Cheuvront and Neal (2004) conducted survey work of the North Carolina commercial snapper grouper fishery south of Cape Hatteras, but did not include ethnographic examination of communities dependent upon fishing.

To help fill information gaps, members of the South Atlantic Council's Snapper Grouper Advisory Panel, Council members, Advisory Panel members, and representatives from the angling public identified communities they believed would be most impacted by the management measures proposed in Amendment 13C on the species addressed by this amendment. Details of their designation of particular communities, and the factors considered in this designation, can be found in Amendment 13C (SAFMC 2006).

Because so many communities in the South Atlantic benefit from snapper grouper fishing, the following discussion focuses on "indicator communities," defined as communities thought to be most heavily impacted by snapper grouper regulations.

5.2.2.1.3 .1 North Carolina

Figure 5.2.2-15. North Carolina communities with substantial fishing activity, as identified by South Atlantic Advisory Panels.

Statewide

Overview

Of the four states in the South Atlantic region, North Carolina (Figure 5.2.2-15) is often recognized as possessing the most "intact" commercial fishing industry; that is, it is more robust in terms of viable fishing communities and fishing industry activity than the other three states. The state offers a wide variety of fishing opportunities, including sound fishing, trolling for tuna, bottom fishing, and shrimping. Perhaps because of the wide variety of fishing opportunities, fishermen have been better able to weather regulations and coastal development pressures, adjusting their annual fishing patterns as times have changed.

Commercial Fishing

There has been a steady decline in the number of federal commercial snapper grouper permits North Carolina since 1999, with 194 unlimited commercial permits in 1999, but only 139 in 2004. Limited permits similarly declined from 36 to16.

State license sale and use statistics for all types of licenses also indicate an overall decrease since 1994. While the overall number of state licenses to sell any species of fish or shellfish increased from 6,781 in 1994 to 9,712 in 2001/2002, the number of license holders actually reporting sales decreased from 6,710 in 1994/1995 to 5,509 in 2001/2002 (SAFMC 2006).

North Carolina fishermen demographics are detailed in Cheuvront and Neal (2004). Ninety eight percent of surveyed fishermen were white and 58 percent had completed some college or had graduated from college. Of those who chose to answer the question, 27 percent of respondents reported a household income of less than $30,000 per year, and 21 percent made at least $75,000 per year. On average, respondents had been fishing for 18 years, and had lived in their communities for 27 years.

Cheuvront and Neal (2004) also provided an overview of how North Carolina commercial snapper grouper fishermen carry out their fishery. Approximately 65 percent of surveyed fishermen indicated year-round fishing. Gag is the fish most frequently targeted by these fishermen, with 61 percent of fishermen targeting gag at some point in the year, despite the prohibition of commercial sales and limit to the recreational bag limit in March and April. Vermilion snapper (36.3 percent) and black sea bass (46 percent) are the next most frequently targeted species. A significant number of fishermen land king mackerel during each month, with over 20 percent of fishermen targeting king mackerel between October and May. During the gag closed season, king mackerel are targeted by about 35 percent of the fishermen. Other snapper/grouper complex species landed by at least 5 percent of the fishermen in any given month were red grouper (39.5 percent), scamp (27.4 percent), snowy grouper (9.7 percent), grunts (14.5 percent), triggerfish (13.7 percent), and golden tilefish (5.6 percent). Non-snapper/grouper complex species landed by at least 5 percent of the fishermen in any given month included Atlantic croaker, yellowfin tuna, bluefin tuna, dolphin, and shrimp.

Recreational Fishing

Recreational fishing is well developed in North Carolina and, due to natural geography, is not limited to areas along the coast. Data show that North Carolina is almost on par with east Florida for total recreational fishing participation effort (data not shown; see SAFMC (2006)). A brief discussion of public boat ramps and local recreational fishing clubs, as well as sources of information used by these anglers, can be found in SAFMC (2006).

The North Carolina state legislature approved the creation of a state recreational saltwater fishing license in 2004. The license created controversy for both the recreational and commercial sectors, each believing that it will hurt or help their access to marine resources. Possession of the license, subject to exemptions, was required beginning on January 1, 2007 (http://www.ncdmf.net/recreational/NCCRFLfaq.htm).

Hatteras Village

A detailed history of this community, from its discovery by Italian explorers in the 16th century to establishment of a National Seashore in 1953, can be found in SAFMC (2006).

Overview

Census data indicate there was not a significant increase in population size in Hatteras Village from 1990 to 2000 (SAFMC 2006). The demographics of the island have shifted, as is evidenced in the decreasing percentage of the population that is actively in the workforce, perhaps reflecting a larger number of retirees in the community, and the increasing proportion of residents with higher education, also reflecting a retired, professional segment of the population. Hatteras Village has also experienced a significant increase in the percent of the population in the farming, fishing, and forestry occupations, from 5.6 percent to 10.8 percent. This may be reflective of the increasing number of persons employed in businesses related to recreational fishing, such as charter boat captains and crew, boat repair and sales, marinas, etc. See SAFMC (2006) for the raw data describing community demographics. Figure 5.2.2-16 includes two maps detailing the area.

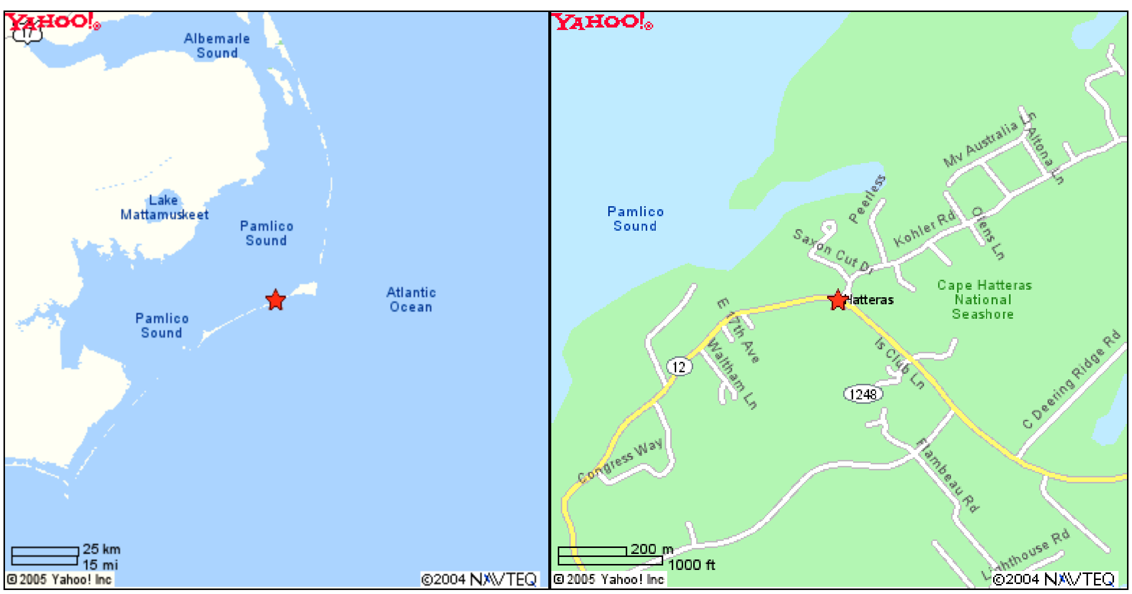

Figure 5.2.2-16. Hatteras Island and Village, Outer Banks, North Carolina. Source: Yahoo Maps, http://www.yahoo.com.

Commercial Fishing

Anecdotal information from Hatteras residents indicates the number of fish houses has decreased as tourism has increased (SAFMC 2006). Residents, however, still promote the fisherman's way of life through festivals and special community designations (SAFMC 2006).

Mirroring the statewide trend, the number of unlimited commercial permits held by residents of Hatteras decreased from 1999 (9 permits) to 2004 (5 permits). The number of limited commercial permits has remained at 3 (SAFMC 2006). Twenty people stated they were employed in fishing related industry in the 1998 census, with 18 of these employed by marinas. A listing of the six marinas and eight bait and tackle stores in Hatteras Village can be found in SAFMC (2006).

Recreational Fishing

Hatteras is host to several prestigious fishing tournaments and is homeport for the island's famous charter fishing fleet. The number of charter/headboat permits held by Hatteras residents has dramatically increased, from one permit in 1999 to 28 in 2004.

Wanchese

A history of this community, and neighboring Manteo, describing its persistence as a small, close-knit community focused on making its living from the sea, can be found in SAFMC (2006).

Source: Kitner 2005.

Figure 5.2.2-17. Map of Roanoke Island, North Carolina, showing Wanchese and Manteo.

Overview

Figure 5.2.2-17 provides a map of Roanoke Island, including Wanchese and Manteo. While Wanchese has maintained its identity as a commercial fishing community, it faces continuing pressure from developers in nearby Manteo and other Outer Banks communities. However, the town has recently approved a zoning document that would prevent unplanned growth and would help preserve working waterfronts and residential areas (Kozak 2005). A partial community profile detailing local traffic patterns, businesses, and prominent families can be found in SAFMC (2006).

The largest industrial area in Wanchese is centered on the Wanchese Seafood Industrial Park, built to enhance business opportunities in the seafood and marine trades. Tenants of the park are able to ship products overnight to major domestic and international markets through the airport in Norfolk, Virginia. The park is utilized by fishermen and seafood dealers, as well as boatbuilding and boat maintenance businesses. The park is full of activity and it is common to find large numbers of people, especially Hispanics, working in the marine trade industries.

Census statistics from 2000 show the population of Wanchese is aging and very homogenous, with little ethnic diversity. There has been a slight increase in the Hispanic population since 1990, mirroring most other communities in North Carolina. Education levels have also increased, and the poverty rate has decreased. A higher percentage of people are employed in fishing-related professions in Wanchese than in almost any other community – 10 percent – although even that number has decreased nearly 50 percent since 1990.

Commercial Fishing

Commercial landings and value for Wanchese/Stumpy Point declined from 31.9 million pounds valued at $26.1 million in 2001 to 28.7 million pounds valued at $23.2 million in 2002. In 2001, Wanchese/Stumpy Point was listed as the 28th most prominent United States port based on the value of the product landed, declining to 30th in 2002. While landings increased in 2003, to 33 million pounds, value further declined to $21 million (31st place), with further declines in both poundage (31 million pounds) and value ($20.5 million) in 2004.

Amendment 8, which limited entry into the commercial snapper grouper fishery, does not appear to have caused a decrease in the number of commercial permits held by residents of Wanchese (SAFMC 2006). In 1999, seven unlimited commercial permits were held, with eight in 2004. Three limited commercial licenses were held in both 1999 and in 2004.

One hundred twenty residents of Wanchese stated they were employed in fishing related industries in the 1998 census (SAFMC 2006). Sixteen of these were listed as employed in fishing, 56 in fish and seafood, and 40 in boatbuilding.

There were 228 commercial vessels registered and 201 state standard commercial fishing licenses issued in the community in 2002 (SAFMC 2006). Wanchese residents also held 12 dealer licenses. The town is an important unloading port for many vessels transiting to and from the Mid-Atlantic and South Atlantic.

Recreational Fishing

As of 2005, nine boatbuilding businesses were located in Wanchese, building either pleasure yachts, recreational fishing vessels or, less often, commercial fishing vessels. There were two bait and tackle businesses and two marinas in town. All these businesses rely on the fishing industry. Manteo also maintains an active private and for-hire recreational fishing community. From 1999 to 2004, there was an increase in the number of charter/headboat licenses held, from two permits to nine permits. As most of the recreational sector for the region operates out of Manteo and Nags Head, these communities would be more affected by recreational fishing restrictions than would Wanchese.

Figure 5.2.2-18. Area of Carteret County, North Carolina, showing Morehead City, Atlantic Beach (at the red star), and Beaufort.
Source: Yahoo Maps, http://www.yahoo.com.

Morehead City

In Carteret County, Morehead City, Beaufort, and Atlantic Beach form a triad of different but complementary communities in close geographic proximity (Figure 5.2.2-18). A detailed history of Morehead City, from its founding in the 1840s-1850s to its development as a center for sport and tournament fishing in recent years, can be found in SAFMC (2006).

Overview

Morehead City’s economy is currently based on tourism, fishing (commercial and recreational), light industry, government, and other service and professional industries. The town has regained its commercial viability as a modern port terminal, and benefits from its location on the “sound-side” of the Atlantic Beach resort trade. Diving has become an important tourist activity; Rodale’s Scuba Diving magazine recently named North Carolina as the best wreck diving destination in North America, and Morehead City as the best overall dive destination. Recreational fishing effort is growing quickly, as new marinas, boat storage areas, boat builders, and marine supply stores open in the city.

Detailed statistics detailing community demographics of Morehead City in 1990 and 2000 can be found in SAFMC (2006). The population of Morehead City increased from 1990 to 2000, with sizable increases in the number of people declaring non-white ethnicities. Median income increased from approximately $20,000 to nearly $29,000 from 1990 to 2000. Median home value nearly doubled, and median rent increased 35 percent. The percentage of those completing high school increased by 10 percent, and there was a seven percent increase in those receiving a bachelor's degree or higher. The poverty level decreased. However, the unemployment rate increased. The occupations of farming, fishing, and forestry employ more than one percent of the population of Morehead City.

Commercial Fishing

In 1998, 100 people were employed in fishing related businesses according to census figures, with 40 employed in marinas and 36 employed in fish and seafood businesses (SAFMC 2006). Over 200 state commercial vessel licenses, 150 state standard commercial fishing licenses, and 14 dealer licenses were issued by the state to residents of Morehead City in 2002. The number of unlimited commercial permits held by Morehead City residents was 15 in 1999 and 14 in 2004, while the three limited commercial permits held in 1999 were no longer held by 2004 (SAFMC 2006). As of 2002, the state had issued 211 commercial vessel registrations, 150 standard commercial licenses, and 14 dealer licenses to Morehead City residents. Residents of Morehead City were primarily employed by marinas (40 percent) and fish and seafood (36 percent), with 16 percent employed in boatbuilding businesses.

A narrative detailing the fishing methods, habits, and observations of a bandit-rig fisherman in Morehead City can be found in SAFMC (2006).

Recreational Fishing

The number of charter/headboat permits held by Morehead City residents nearly doubled, from seven in 1999 to 13 in 2004.

Beaufort

Beaufort is located on the coast near Cape Lookout, and borders the southern portion of the Outer Banks. Its deep harbor is home to vessels of all sizes, and its marinas are a favorite stop-over for transient boaters. A detailed history of Beaufort, from its establishment to its importance as a trade center during the 18th and 19th centuries, to its later involvement in the menhaden fishing industry, can be found in SAFMC (2006).

Overview

Tourism, service industries, retail businesses, and construction are important mainstays of the Beaufort area, with many shops and restaurants catering to people from outside the area. Census data show a slight decrease in population size from 1990 to 2000, from 3,808 inhabitants to 3,771, perhaps due to the aging population. Educational attainment rose over the last decade, and the percentage of individuals below the poverty line fell slightly. The percentage of those in the labor force decreased, another possible indication of an aging population. However, the percentage unemployed also decreased. The number of people working in farming, fishing, and forestry remained about the same from 1990 to 2000. According to census business pattern data from 1998, most of the fishing-related employment in Beaufort (total 300 persons) occurs in the boat building industry, which employs 184 residents (SAFMC 2006). Forty-eight people reported working in marinas, while others are employed in fish processing, fish harvesting, and seafood marketing.

Commercial Fishing

There has been a slight decrease in the number of unlimited commercial permits held by residents of Beaufort, from 5 permits in1999 to 4 permits in 2004. In the last two years, the one limited commercial permit held by a Beaufort resident was no longer reported. As of 2002, the state had issued 430 commercial vessel registrations, 294 standard commercial licenses, and 32 dealer licenses to Beaufort residents.

Recreational Fishing

There has been virtually no change in the number of charter/headboat permits, 1 permit in 2003 and 2004, held by residents.

Atlantic Beach

Atlantic Beach has been a popular resort town since the 1870s. The first bathing pavilion was built on Bogue Banks in 1887. Tourists flocked to the resorts, and ferry service to Atlantic Beach increased. Other resorts and tourism related development occurred over the next century, and the area remains a popular vacation destination (www.atlanticbeach-nc.com/history_part-1.html).

Overview

Atlantic Beach demographic data from 1990 and 2000 show a slight population decline since 1990, as well as decreases in the percent of the population involved in farming, fishing, and forestry (SAFMC 2006). The median age of the population has increased, perhaps a reflection of the growing number of retirees moving to this area of the coast.

Commercial Fishing

As observed in other areas of North Carolina, since limited access was put into place, the number of commercial permits has decreased from eight unlimited commercial permits in 1999 to four in 2004, and four limited commercial permits to zero (SAFMC 2006). In 1998, 60 residents of Atlantic Beach were employed in fishing related industry, with 93 percent of those employed by the marine sector. In 2002, 56 vessels were registered with the state as commercial fishing vessels, 42 standard commercial fishing licenses were held by Atlantic Beach residents, and there were ten valid dealer licenses issued to community members (SAFMC 2006).

Recreational Fishery

Since 1999, the number of federal charter/headboat permits held by Atlantic City residents has increased from six to 19, though only one permit was recorded in 2002. Of the 60 individuals reporting working in a fishing related industry in 1998, 46 worked in marinas. Two state permits were issued to recreational fishing tournaments to sell licenses in 2002 (SAFMC 2006).

Figure 5.2.2-19. General area of Sneads Ferry, North Carolina.
Source: Yahoo Maps, http://www.yahoo.com.

Sneads Ferry

Sneads Ferry is a historical fishing village located on the New River near the northern tip of Topsail Island (Figure 5.2.2-19). The river joins the Intracoastal Waterway at Sneads Ferry, with easy access to the Atlantic Ocean. A very active commercial fishing community, Sneads Ferry takes in more fish than any other Onslow County port (http://www.cbcoastline.com/areainfo.htm). It also includes Camp Lejeune, a U.S. Marine base. The Sneads Ferry Shrimp Festival has been held annually since 1971. Now grown to a two-day event, the annual shrimp festival is the town's major fund-raiser. From its proceeds, the town established a 14-acre community park and built a 7200-sq. ft. Shrimp Festival Community Building (www.sneadsferry.com/areahistory/his_sf.htm).

Overview

Census data indicate the population of Sneads Ferry increased by about 10 percent from 1990 to 2000, from 2,031 inhabitants to 2,248. Most new residents were white, and the number of black or African American residents decreased from 159 to 115. Median income increased from about $20,000 to nearly $35,000. Median home value increased from $65,000 to $110,000, but median rent remained about the same. The percentage of those completing high school increased by 10 percent and the percent of residents with at least a Bachelor's degree doubled, from six percent to 12.8 percent. The poverty level decreased from 20.9 percent to 13.5 percent, and the percentage of the population unemployed decreased from 8.3 percent to 2.2 percent. The percentage of residents employed in farming, fishing, and forestry decreased by half from 18.2 percent to 9 percent, while employment in sales and office occupations increased by over 17 percent. It is unclear who may be buying home sites on newly developed land in the town, but the town's current demographics may point to an increase in retirees in Sneads Ferry, as they are better educated, have higher incomes, and are older. The dramatic decline by approximately 50 percent of persons employed in extractive natural resource occupations may be due to increasing job opportunities outside of the community, the changing impacts of regulations, or status of the resources

Commercial Fishing

Sneads Ferry is a small town with little of the large-scale development seen elsewhere on the North Carolina coast. Many houses in the community have fishing vessels docked in front of the house or on the lawn. The white rubber boots worn by commercial fishermen in this community and many other parts of North Carolina are commonly referred to as "Sneads Ferry Sneakers", suggesting the importance of commercial fishing to the area. Most of the fishermen in town are shrimpers and net fishermen who go out daily. There is also a strong contingent of black sea bass pot fishermen resident in the town. The species with the highest consistent landings in the town are black sea bass, button clams, blue crab, flounders, mullet, shrimp, spot, and whiting.

The number of federal charter/headboat permits held by residents increased from six in 1999 to 13 in 2004, while the number of unlimited commercial permits decreased from 22 to 17, and the number of limited commercial permits remained at one (SAFMC 2006).

Over 347 commercial fishing vessels were registered with the state in 2002, and 228 residents held state-issued standard commercial fishing licenses. There were also 18 dealer licenses in the community and 169 shellfish licenses. In 1998, 16 persons were employed in fishing related industry, with 75 percent working in fish and seafood.

Recreational Fishing

Recreational fishing in Sneads Ferry is not as prominent an activity as in Morehead City. However, there are a large number of vessels with charter permits for snapper grouper homeported there. Little is currently known about recreational fishing out of Sneads Ferry, aside for its advertisement as an important tourist attraction in many websites that discuss the community. At least five marinas cater to recreational fishermen. There are two other marinas at Camp LeJeune Marine Base, just across the Neuse River. Some smaller river and sound fishing charters operating out of the area and one headboat runs from Sneads Ferry. Other than black sea bass, it does not appear that many snapper grouper species are frequently caught recreationally from Sneads Ferry.

5.2.2.1.3.2 South Carolina

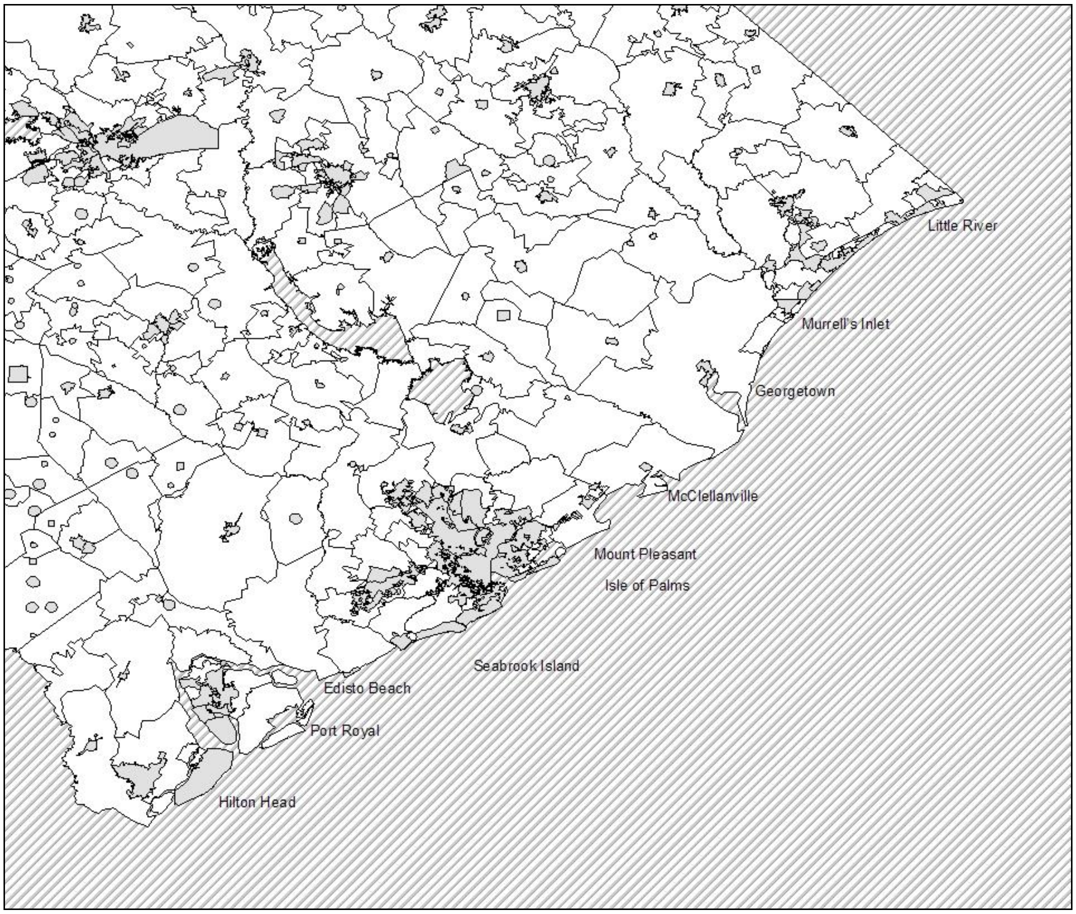

Figure 5.2.2-20. South Carolina communities with substantial fishing activity, as identified by South Atlantic Advisory Panels.

Statewide

Overview

South Carolina communities with substantial fishing activity are less developed than those in North Carolina and, over the past 20 to 30 years, the state has seen much more tourist-oriented development along its coasts than Georgia or North Carolina. In Horry County, the urban area of Myrtle Beach has expanded greatly in the past few decades, and much of the coastal area has been developed as vacation homes, condominiums, and golf courses. The communities most impacted by this development are Little River, Murrells Inlet, Pawleys Island, and Georgetown, although the latter three are located in Georgetown County (Figure 5.2.2-20). The same is true of rapid developing Charleston County, and the cities and communities of McClellanville, Mt. Pleasant, Sullivans Island, Wadmalaw and Edisto Islands feel the impact of urban sprawl from the city of Charleston. Further south along the coast, the Hilton Head Island resort development has been the impetus for changing coastal landscapes in the small towns of Port Royal, Beaufort, St. Helena Island, and Bluffton.

For the purpose of this document, only Little River will be singled out as a community with a high concentration of both commercial and recreational fishing, along with other types of coastal oriented leisure pursuits. Other analyses will consider South Carolina as a whole.

Commercial Fishing

While pockets of commercial fishing activities remain in the state, most are being displaced by the development forces and associated changes in demographics. The number of unlimited commercial permits, however, increased from 74 in 1999 to 87 in 2004, while the number of limited commercial permits decreased by 75 percent from 12 to 4 (SAFMC 2006).

Recreational Fishing

Many areas that used to be dedicated to commercial fishing endeavors are now geared towards the private recreational angler and for hire sector. The number of federal charter/headboat permits held by South Carolina residents increased from 41 in 1999 to 111 in 2004. The majority of saltwater anglers fish for coastal pelagic species such as king mackerel, Spanish mackerel, tunas, dolphins, and billfish. A lesser number focus primarily on bottom fish such as snapper and groupers and often these species are the specialty of the headboats that run out of Little River, Murrells Inlet, and Charleston. There are 35 coastal marinas in the state and 34 sportfishing tournaments (SAFMC 2006).

Little River

A history of Little River detailing its settlement in the late 1600s, its popularity as a vacation destination in the 1920s, and the concurrent rise in charter fishing, can be found in SAFMC (2006).

Figure 5.2.2-21. Little River, South Carolina, and surrounding area.
Source: Yahoo Maps, http://www.yahoo.com.

Overview

Figure 5.2.2-21 shows Little River and the surrounding area. A detailed description of changes in land-use patterns in and near Little River can be found in SAFMC (2006). Nearby Murrells Inlet is gradually transforming into a residential community for Myrtle Beach, and SAFMC (2006) argues this is also true for Little River.

Census data indicate the Little River population more than doubled from 1990 (3,470 persons) to 2000 (7,027 persons) and became more ethnically diverse with more people of American Indian or Alaskan Native, and Hispanic or Latino ethnicities. Median income increased by over 40 percent, from nearly $29,000 to over $40,000. Median home value also increased by over 40 percent, and median rent increased by nearly 35 percent. The percentage of those completing high school and those with a Bachelor's degree remained about the same. The poverty level decreased by nearly two-thirds to 4.7 percent, and the percentage of the population unemployed decreased from 6.6 percent to 3.4 percent. The percentage of residents employed in farming, fishing, and forestry decreased from 3.6 percent to 0.9 percent.

Commercial Fishing

In 1998, 38 residents of Little River were employed in fishing related industry according to the U.S. Census, with 81 percent of those employed by the marina sector. The number of snapper grouper unlimited harvest commercial permits held by community residents remained about the same between 1999 and 2004, from 15 permits to 16 permits, and one resident still held a limited harvest commercial license. Twenty-four Little River residents held state permits, with the most being saltwater licenses (8 permits) or trawler licenses (5 permits) (SAFMC 2006).

Recreational Fishing

As observed in other coastal communities described herein, the number of charter/headboat permits held by community residents increased from nine in 1999 to 16 in 2004. Three headboats operated out of Little River, and this part of the for-hire industry has a long and storied past in the community. Recreational fishing, primarily as headboat effort, came about as a way for commercial fishermen to continue fishing in the summer months. A detailed account of how recreational fishing developed in Little River can be found in Burrell (2000). Most of the private recreational fishing effort in this area occurs out of marinas in North Myrtle Beach, Myrtle Beach, and Murrells Inlet.

5.2.2.1.3.3 Georgia

Statewide

Overview

Only one community in Georgia (Townsend) lands a substantial amount of the snapper grouper species addressed in this amendment. Other parts of the state involved in the commercial harvest of seafood are focused on penaeid shrimp, blue crabs, and other finfish such as flounder, shad, croaker, and mullet.

Brunswick, the other community that has a commercial fishing presence, was once a more thriving commercial fishing community but now tourism and other related activities are competing for waterfront in the town. The most commonly harvested species in Brunswick are blue crab and different species of penaeid shrimp. According to the ACCSP website, there have been no snapper grouper species landed in Brunswick in since 2001. Other parts of the state involved in the commercial harvest of seafood are focused on penaeid shrimp, blue crabs, and other finfish such as flounder, shad, croaker, and some mullet.

Commercial Fishing

Unlike the pattern observed in many other areas, the number of unlimited commercial permits and limited commercial permits held by Georgia residents did not decrease from 1999 to 2004, with eight permits and one permit, respectively. In 2002, 947 vessels were registered with the state as commercial fishing vessels, 612 full-time state commercial fishing licenses were held by Georgia residents, and 147 residents held part-time state commercial fishing licenses. Within the commercial fishing fleet, four hundred and eighty two vessels had shrimp gear on board in that year (SAFMC 2006).

Recreational Fishing

As observed in other areas, the number of charter/headboat permits held by Georgia residents increased markedly from five permits in 1999 to 27 permits in 2004 (SAFMC 2006). Recreational vessels are located at Tybee Island close to Savannah, on the barrier islands off Brunswick, and between Savannah and Brunswick.

Townsend

A history of the area, describing its economy before the Civil War, the rise and fall of lumbering, and the building of the railroad, can be found in SAFMC (2006). Townsend is a small, rural community. In 2005, the fish house in this community was relocating inland. It is not known if this relocation was successful and whether that fish house will be handling domestically harvested fish in the future.

Overview

The population of Townsend increased by over 1,000 residents from 2,413 in 1990 to 3,538 in 2000. Although there was a large relative increase in the number of Hispanic or Latino residents, from 2 to 27, most of the new inhabitants were white (1,465 in 1990 and 2,437 in 2000). Median income increased from approximately $23,000 to $35,000. Median home value nearly tripled, from $33,000 in 1990 to $98,100 in 2000, and monthly rent nearly doubled, from $213 to $431. In 1990, 26.9 percent of residents had less than a 9th grade education, but by 2000, that number declined to 11.0 percent. The percentage of those completing high school increased by nearly 15 percent, while the percent receiving a bachelor's degree or higher remained about the same (8.4 percent to 8.9 percent). The percent of the population with an income below the poverty line deceased by four percent, but remained high at 14.6 percent. The percentage of the population unemployed increased from 3.4 percent to 6.5 percent. There has been a sizeable decline in the percentage of the population employed in manufacturing, from 29.0 percent to 16.2 percent, and the proportion of the population employed in farming, fishing, and industry remained unchanged at approximately three percent.

Commercial Fishing

A comprehensive description of the historic and current fish houses of coastal Georgia and how they operate, focusing on Phillips Seafood of Townsend, can be found in SAFMC (2006). For nearly a decade, only one fish house has consistently handled snapper grouper species. A fish house in Brunswick may have landed these species in the past, but has not reported landings since 2001.

Recreational Fishing

Offshore recreational anglers do not often target or harvest snapper grouper species in Georgia (http://www.st.nmfs.noaa.gov/st1/recreational/overview/overview.html). Of the snapper grouper species harvested, black sea bass, sheepshead, and vermilion snapper are the most commonly harvested fish at five, seven, and two percent, respectively. As of 2004, residents of the Savannah area held 11 charter/headboat permits for snapper grouper, and many of these vessels are docked on Tybee Island. Residents of the area around the city of Brunswick, including Jekyll Island and Sea Island, held four snapper grouper charter/headboat permits. Interestingly, unlike the cities profiled in the Carolinas, the number of federally permitted for-hire vessels has declined dramatically. From 2003 to 2004, the number of snapper grouper permitted for hire vessels declined from 43 to 27 (NMFS 2004). The cause of this decline is unknown.

5.2.2.1.3.4 Florida

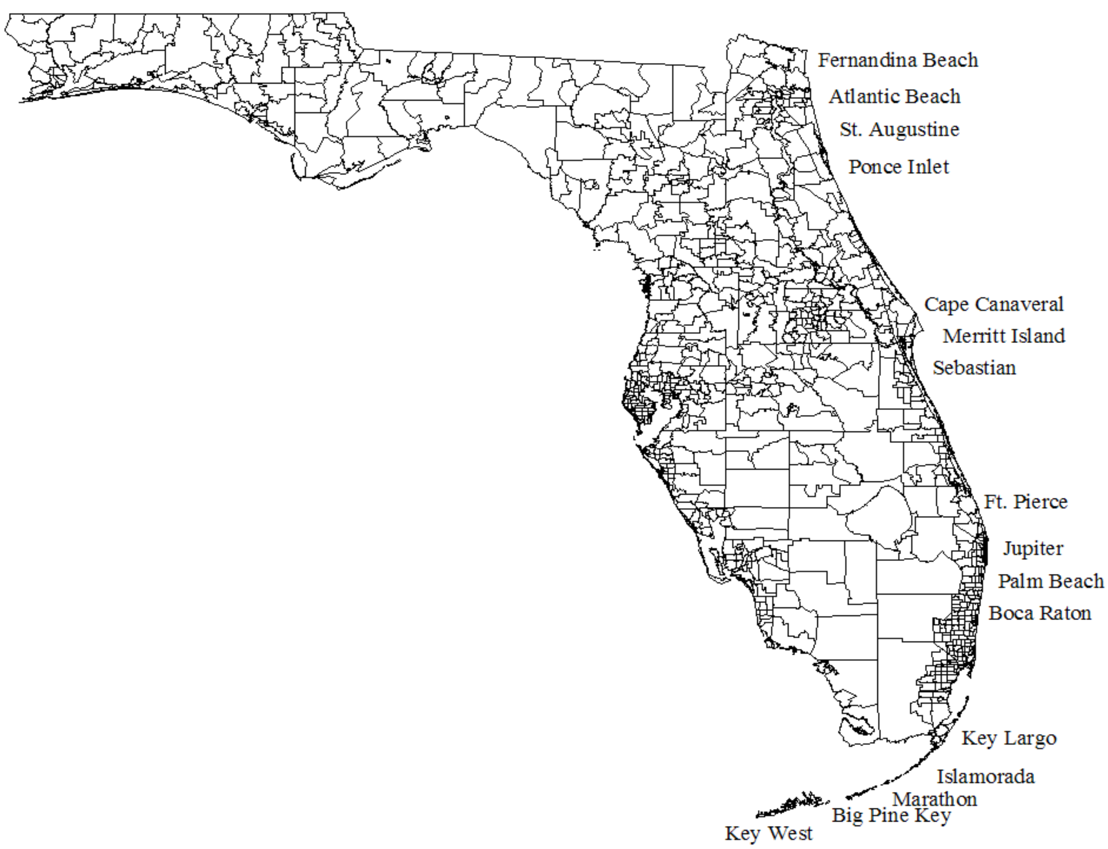

Figure 5.2.2-22. Florida communities with substantial fishing activity. Identified by South Atlantic Advisory Panels.
Source: Jepson *et al.* (2005).

Statewide

Overview

Florida stands apart from other states in the South Atlantic region in fishing behaviors, history, and demographics. Florida has one of the fastest growing populations in the United States, estimated to increase each day by 750 to 1,000 new immigrants. Twenty-five percent of all vacation homes in the United States are located in Florida's coastal counties (Coastal Ocean Resource Economics 2005).

Along with being heavily populated on land, coastal waters off Florida are also heavily used by recreational users of all kinds. This growth of a leisured class occupying coastal areas has led, in part, to conflicts over natural resource access and use-rights. One example of this type of struggle was the conflict over the use of gillnets in state waters. The conflict culminated in a state-wide ban on the use of gillnets, which dealt a resounding blow to many Florida fishermen, ending in the loss of many commercial fishing properties and the displacement of many fishermen. There have also been conflicts between the "environmental community" and commercial fishermen over the closing of the *Oculina* Bank off of Florida's central coast, and the creation of both the Florida Keys National Marine Sanctuary and the Tortugas Sanctuary, both in the Keys.

The natural geography of Florida also sets it apart from other South Atlantic states, particularly in the area from central Florida through the Keys. The weather is amenable to fishing almost year round, though hurricanes in 2004 were particularly devastating and took a toll on all fisheries in the state, both east and west coast. There was also a cold water event that started near West Palm Beach in 2003, which moved up the east coast causing a substantial decline in snapper grouper fishing that year. The continental shelf is much narrower in Florida than elsewhere in the region, allowing fishermen to access deep waters quickly and return the same day. Finally, the species of snapper grouper available to fishermen in southern Florida are different than further north, with yellowtail snapper, gag and black grouper, and other alternative species such as stone crab, spiny lobster, dolphin, kingfish, and billfish allow a greater variety of both commercial and recreational fishing opportunities. These fisheries are important to many Florida communities identified by the Snapper Grouper Advisory Panel as shown in Figure 5.2.2-22.

Commercial Sector

Considering the high population growth rates and emphasis on a tourism economy in Florida, the commercial fishing sector in Florida is still robust in some areas. Although total landings and dollar values of all species landed on the Florida East coast have decreased from 1998 to 2003 (from nearly 30 million pounds worth approximately $44 million to approximately 23 million pounds worth $33 million dollars; SAFMC 2006), there is still a considerable commercial fishing presence in east Florida.

Recreational Sector

While the commercial fishing industry, though still strong, may be in decline, the recreational sector appears to be stable. Excluding the headboat sector, although the number of participants declined in 2004 to approximately 1.9 million from 2.2 million in 2003 and from a high of 2.6 million in 2001, the number of trips taken in 2003 and 2004 remained at approximately 21 million. However, the headboat sector has exhibited a steady decline. In 2004, many homeports hosted at least one vessel holding both federal charter/headboat permits and federal unlimited commercial permits. Key West and Miami stand out, with 35 and 15 such vessels, respectively.

Cape Canaveral

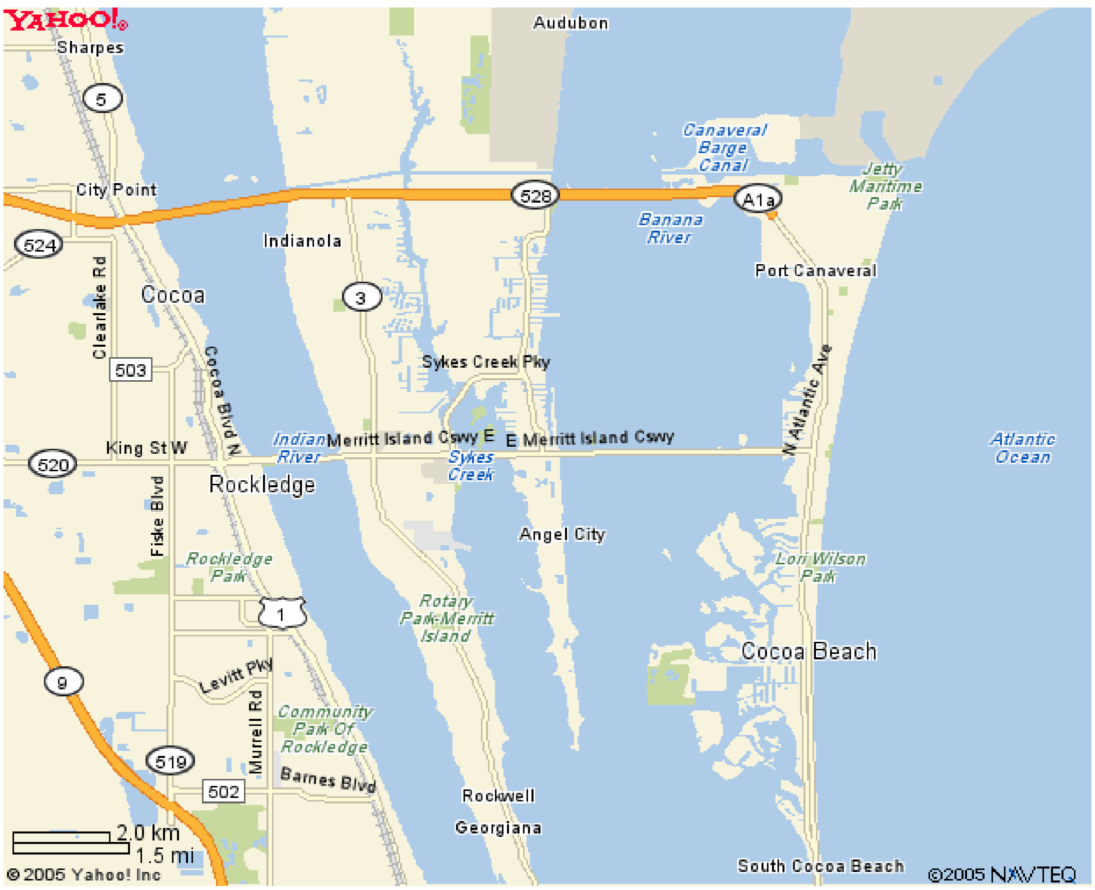

Figure 5.2.2-23. Area map of Cape Canaveral, Florida.

A detailed history of Cape Canaveral, Florida, from its first habitation 10,000 years ago, its settlement by the United States in the early 1800s, the establishment of the Banana River Naval Air Station in World War II, to NASA's arrival in 1952, can be found in SAFMC (2006). A map of the area is shown in Figure 5.2.2-23.

Overview

Cape Canaveral has a fairly homogenous, aging population, with those 65 years and older growing from 16.1 percent of the population to 23.1 percent since 1990. Overall, educational attainment has increased. The number of persons who speak a language other than English at home has increased 2.5 percent, and fewer people have incomes below the poverty line. Unemployment has decreased, but fewer people are in the labor force today than in 1990, perhaps due to an aging population. The percentage of persons in a service occupation has grown from 14.1 percent to 20.4 percent, while there has been a sizeable decline in the percent of residents employed in forestry, mining, and fishing, from 2.7 percent in 1990 to 0.4 percent in 2000.

Fisheries in central Florida generally operate in two different environments, inshore river or inlet fishing with associated lagoons, which primarily attracts recreational fishing, and offshore areas, where commercial fishing primarily occurs. Popular inshore areas include the Indian, St. Johns, and Banana Rivers and associated lagoons. Commercial exploitation of the rivers and lagoons declined after implementation of the Florida Net Ban of 1994.

Many commercial fish houses have gone out of business or have shifted to selling imported products to supplement their local supplies. At the same time, the number of businesses possessing federal dealer permits has increased from about 180 in 1999 to a little over 200 in 2001. There is some industry speculation that the increasing number of dealer permits reflects increased decentralization in the domestic fishing markets and the need to increase profits by self-marketing.

Commercial Fishing

Cape Canaveral draws fishermen from Cocoa/Cocoa Beach, Merritt Island, Melbourne, and Titusville. These fishermen target many snapper grouper species, as well as coastal migratory pelagics such as mackerel, highly migratory species such as sharks and swordfish, and shellfish such as oysters, quahogs, and shrimp. Snowy grouper and tilefish (particularly golden or sand tilefish) landings exceed 10,000 pounds per year. Total commercial landings decreased, however, from 8.9 million pounds to 6.0 million pounds from 1998 to 2004 (SAFMC 2006).

The number of unlimited commercial permits in this area increased from nine in 1999 to 16 in 2004. The number of limited commercial permits fluctuated over this period, but ultimately declined from four permits in 1999 to one in 2004 (SAFMC 2006).

The number of Florida Saltwater Products Licenses issued to residents of Brevard County (where Cape Canaveral is located) decreased from 872 in 1998/99 to 492 in 2004/05 (SAFMC 2006). This license is needed to sell marine species in the state. There have also been declines in license sales for various crustacean fisheries.

Recreational Fishing

In 2004, Brevard county supported 36 bait and tackle stores, with five in Cape Canaveral, and 70 marinas with over 3,000 wet slips, indicating the importance of recreational fishing to the area. Fourteen fishing tournaments consistently occur in the area. Additional details about these businesses and tournaments can be found in SAFMC (2006).

As in other coastal areas of Florida, there is a fairly heavy presence in Brevard County of charter boat businesses, private marinas, and other associated businesses catering to the recreational fishing sector. The number of federally permitted charter/headboat vessels in Cape Canaveral increased from zero to seven from 1999 to 2004. According to Holland *et al.* (1999), there were approximately 32 charter boats and 2 headboats in the Canaveral/Melbourne area. Current estimates from permit files show at least 38 for-hire vessels with Snapper grouper permits homeported in Cape Canaveral or Port Canaveral, which includes approximate four headboats. That is likely a low estimate for total the total number of for-hire vessels in the area since it does not include vessels in the nearby Merritt Island and in the Cocoa/Cocoa Beach areas.

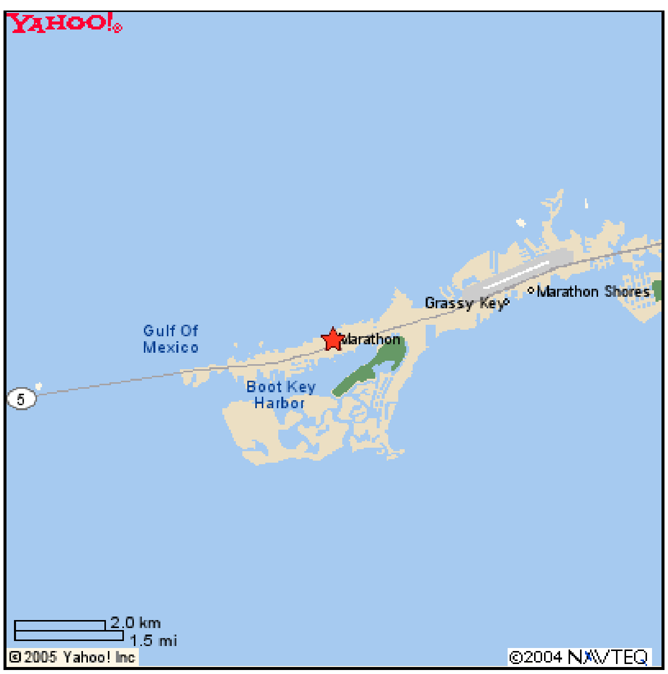

Figure 5.2.2-24. Marathon, Florida.

Source: Yahoo Maps, http://www.yahoo.com.

Marathon

A history of Marathon, detailing its settlement in the 1800s, the rise of industry, the effects of the Great Hurricane of 1935, the rise of tourism, and the importance of commercial fishing, can be found in SAFMC (2005). Figure 5.2.2-24 shows a map of Marathon, which lies in Monroe County.

Overview

Census data from 1990 and 2000 show there was an increase in overall population in Marathon from 8,857 in 1990 to 10,255 in 2000. During this period, the Hispanic population more than doubled, increasing from 1,040 to 2,095. This increase accounts for more than two thirds of the total population increase for the area. During this period of time, the median household income increased from approximately $25,000 to over $36,000.

Marathon has maintained a relatively high percentage of the total population, 4.1 percent in 2000, involved in farming, fishing, and forestry, though the percentage has declined from 8.7 percent in 1990. Since there is little commercial farming and forestry occurring in the area, the majority of percentage can be assumed to relate to fishing activities. The percentage of people that live below the poverty line decreased slightly from 15.1 percent in 1990 to 14.2 percent in 2000.

Commercial Fishing

In 1998, 184 Marathon residents were employed in fishing related industry according to the Census data, with 39 of those in the "fishing" category, 92 employed in "fish and seafood," and 47 employed by marinas (SAFMC 2006). The number of unlimited commercial permits held by community residents decreased from 65 permits to 44 permits between 1999 and 2004. Similarly, the number of limited commercial permits decreased from 43 permits to 31 permits.

Recreational Fishing

While most of the waters around Marathon are open to fishing, some areas have been set aside for eco-tourism and fish-viewing by divers and snorkelers. Sombrero Reef, said to be one of the most beautiful sections of North America's only living coral barrier reef, lies several miles offshore and is protected by the Florida Keys National Marine Sanctuary (http://www.fla-keys.com/marathon).

The importance of recreational boating and fishing to the economy of Marathon is shown by the businesses reliant upon it. As of 2004, there were at least 25 charterboat businesses, two party boat businesses, eight bait and tackle shops, and 27 marinas in the area. The number of vessels holding the federal charter/headboat permit increased from 16 in 1999 to 30 in 2004. In addition, there were seven fishing tournaments in Marathon. Most tournaments are centered on tarpon fishing. However, there are inshore and offshore fishing tournaments as well. These tournaments begin in February and run through June. Hotels and restaurants fill with participants and charters, guides and bait shops reap the economic benefits of these people coming to the area. These tournaments are positive economic pulses in the local economy, one that thrives on the existence of tourism and recreational fishing.

5.2.3.2 Bycatch

The South Atlantic Council is required by MSFCMA §303(a)(11) to establish a standardized bycatch reporting methodology for federal fisheries and to identify and implement conservation and management measures that, to the extent practicable and in the following order, (A) minimize bycatch and (B) minimize the mortality of bycatch that cannot be avoided. The MSFCMA defines bycatch as "fish which are harvested in a fishery, but which are not sold or kept for personal use, and includes economic discards and regulatory discards. Such term does not include fish released alive under a recreational catch-and-release fishery management program" (MSFCMA §3(2)). Economic discards are fish that are discarded because they are undesirable to the harvester. This category of discards generally includes certain species, sizes, and/or sexes with low or no market value. Regulatory discards are fish that are required by regulation to be discarded, but also include fish that may be retained but not sold.

NMFS outlines at 50 CFR §600.350(d)(3)(i) ten factors that should be considered in determining whether a management measure minimizes bycatch or bycatch mortality to the extent practicable. These are:

1. Population effects for the bycatch species;
2. Ecological effects due to changes in the bycatch of that species (effects on other species in the ecosystem);
3. Changes in the bycatch of other species of fish and the resulting population and ecosystem effects;
4. Effects on marine mammals and birds;
5. Changes in fishing, processing, disposal, and marketing costs;
6. Changes in fishing practices and behavior of fishermen;
7. Changes in research, administration, enforcement costs and management effectiveness;
8. Changes in the economic, social, or cultural value of fishing activities and non-consumptive uses of fishery resources;
9. Changes in the distribution of benefits and costs; and
10. Social effects.

Agency guidance provided at 50 CFR §600.350(d)(3)(ii) suggests the Councils adhere to the precautionary approach found in the Food and Agriculture Organization of the United Nations (FAO) Code of Conduct for Responsible Fisheries (Article 6.5) when faced with uncertainty concerning these ten practicability factors. According to Article 6.5 of the FAO Code of Conduct for Responsible Fisheries, using the absence of adequate scientific information as a reason for postponing or failing to take measures to conserve target species, associated or dependent species, and non-target species and their environment, would not be consistent with a precautionary approach.

Population effects for the bycatch species

The directed commercial fishery for snowy grouper is prosecuted primarily with hook and line gear (70%) followed by bottom longline gear (28%). Other gear types capture 2% of the landings. Snowy grouper is largely a commercial fishery as only 4% of the landings are from recreational sources. Golden tilefish are also primarily taken by commercial fishermen (97%) and most are caught with bottom longline gear (93%). The catch of vermilion snapper is dominated by commercial landings (68%). Almost all vermilion snapper are caught with hook and line gear. Based on data from ALS, MRFSS, and the Headboat survey during 2000 to 2003, landings from the commercial and recreational sectors were evenly split for black sea bass. The SEDAR Assessment Update #1 (2005) indicated most black sea bass were taken by the recreational sector (57%) during 2002 to 2003. Most commercial landings of black sea bass (85%) are from pots. Red porgy landings are fairly evenly split between the commercial (49%) and recreational (51%) sectors, and are almost entirely taken with hook and line gear.

Restrictions, which are currently being used to manage these species, include quotas (snowy grouper, golden tilefish), size limits (vermilion snapper, black sea bass, and red porgy), bag limits (snowy grouper, golden tilefish, vermilion snapper, black sea bass, and red porgy), closed seasons (red porgy), and minimum size limits (vermilion snapper, black sea bass, and red porgy).

Management measures in Amendment 13C would establish or reduce commercial quotas for snowy grouper, golden tilefish, vermilion snapper, black sea bass, and red porgy; modify trip limits for snowy grouper, golden tilefish, and red porgy; modify bag limits for snowy grouper, golden tilefish, black sea bass, and red porgy; establish a recreational closed season for vermilion snapper; and modify the size limits for black sea bass and vermilion snapper.

The directed commercial fishery for gag is prosecuted primarily with hook and line gear (86%) followed by diving gear (12%). Other gear types capture 2% of the landings. Landings are split fairly evenly between commercial and recreational sources. The catch of vermilion snapper is dominated by commercial landings (68%). Almost all vermilion snapper are caught with hook and line gear.

Restrictions, which are currently being used to manage these species, include quotas (vermilion snapper), size limits (vermilion snapper and gag), bag limits (vermilion snapper and gag), and closed seasons (gag).

Management measures in Amendment 16 would establish sector allocations for gag and vermilion snapper, reduce commercial quotas for gag and vermilion snapper; modify bag limits for vermilion snapper and gag; establish a recreational closed season for vermilion snapper; modify the size limits for gag and vermilion snapper; and exclude captain and crew on for-hire vessels from retaining gag or vermilion snapper.

Commercial Fishery

During 2001 to 2006, approximately 20% of snapper grouper permitted vessels from the Gulf of Mexico and South Atlantic were randomly selected to fill out supplementary logbooks. A small number of trips that reported discards but did not report numbers or species were not included in analyses. On average, the total number average number of trips per year during 2001 to 2006 was 15,500 (Table 5.2.2-33). Fishermen spent an average of 1.70 days at sea per trip.

Table 5.2.2-33. Snapper grouper fishery effort for South Atlantic.

YEAR	Trips	Days	Days per Trip
2001	17,283	29,940	1.73

For species in Amendment 13C (SAFMC 2006), the number of trips that reported discards was greatest for red porgy followed by vermilion snapper and black sea bass (Table 5.2.2-34.). Discards of snowy grouper and golden tilefish were rare. The percentage of trips that reported discards ranged from 4.03% for red porgy to 0.05% for snowy grouper (Table 5.2.2-35).

Since the discard logbook database represents a sample, data were expanded to estimate the number of discard fish in the whole fishery. The method for expansion was to (1) estimate the probability of discarding a species; (2) estimate the number of fish discarded per trip; and (3) estimate the number discarded in the whole fishery (total discarded = total trips * discard probability * discard number). During 2001-2005, an average of 124,231 black sea bass were discarded per year (Table 5.2.2-36). The number of discarded red porgy and vermilion snapper was lower (~40,000). Snowy grouper and golden tilefish were rarely discarded.

Table 5.2.2-36. Expanded number of discarded red porgy, black sea bass, vermilion snapper, snowy grouper, and golden tilefish for the South Atlantic.

YEAR	Red Porgy	Black Sea Bass	Vermilion Snapper	Snowy Grouper	Golden Tilefish

Black sea bass, vermilion snapper, and red porgy were the top three discarded species during 2001-2005 (Tables 5.2.2-37, 5.2.2-38).

For species in Amendment 15B, the number of trips reporting discards was greatest for red porgy (Table 5.2.2-37). Discards of snowy grouper and golden tilefish were rare.

The percentage of trips that reported discards ranged from 3.89% for red porgy to 0.00% for golden tilefish (Table 5.2.2-38).

Since the discard logbook database represents a sample, data were expanded to estimate the number of discard fish in the whole fishery. The method for expansion was to (1) estimate the probability of discarding a species; (2) estimate the number of fish discarded per trip; and (3) estimate the number discarded in the whole fishery (total discarded = total trips * discard probability * discard number). During 2001-2006, an average of 65,779 vermilion snapper and 5,003 gag were discarded per year (Table 5.2.2-44).

Recreational Fishery

For the recreational fishery, estimates of the number of recreational discards are available from MRFSS. There are no estimates from the headboat survey. The MRFSS system classifies recreational catch into three categories:

- Type A - Fishes that were caught, landed whole, and available for identification and enumeration by the interviewers.
- Type B - Fishes that were caught but were either not kept or not available for identification.
    - Type B1 - Fishes that were caught and filleted, released dead, given away, or disposed of in some way other than Types A or B2.
    - Type B2 - Fishes that were caught and released alive.
- During 2001-2006, 75% of gag and 39% of vermilion snapper were released by recreational fishermen (Table 67).
-
- Amendment 13C increased the size limit of vermilion snapper taken by recreational fishermen from 11 inches TL to 12 inches TL. Examination of Waves 1-5 during 2007 relative to 2006 reveal an increase in the number of discards during Waves 3, 4, and 5 when most of the vermilion snapper are caught (Table 4-67).

The percentage of fish released was highest for black sea bass (79.2%) and lowest for yellow edge grouper (0%) (Table 5.2.2-46). The number of fish released per year was greatest for black sea bass (10,323,548 individuals) and lowest for yellow edge grouper (0 individuals).

Table 5.2.2-46. Total number (A+B1+B2) of fish caught from MRFSS interviews, estimated total number of fish released (B2), percent released, and estimate total number of dead discards during 2001-2005. Source: MRFSS Web Site.

Species	Est Total	Est Released	% Released	Est Dead Discards
Snowy Grouper	44,043	5,693	12.93%	5,693
Golden Tilefish	97,690	3,124	3.20%	3,124
Speckled Hind	11,618	10,940	94.16%	10,940
Warsaw Grouper	7,444	1,668	22.41%	1,668
Yellowedge Grouper	3,756	0	0.00%	0
Misty Grouper	54	0	0.00%	0
Blueline Tilefish	23,526	4,301	18.28%	4,301
Silk Snapper	8,486	1,010	11.90%	1,010
Queen Snapper	907	319	35.17%	319
Black Sea Bass	13,039,834	10,323,548	79.17%	1,548,532
Red Porgy	308,238	183,909	59.66%	14,713
Vermilion Snapper	1,718,019	692,683	40.32%	173,171

Of species in Amendment 15B, the number of fish released was highest for red porgy and lowest for golden tilefish (Table 5.2.2-47). Total dead discards was determined by applying the SEDAR 4 (2004) suggested release mortality rates the number of fish released alive and adding the value to the number of fish released dead. Estimates of dead discards are based on accepted recreational release mortality rates: 100%, snowy grouper; 100%, golden tilefish, 15%, black sea bass; 8%, red porgy; and 25%, vermilion snapper.

Vermilion Snapper	78,487	30.71	4,658	1.82	2,556	24,280

Finfish Bycatch Mortality

Snowy grouper are primarily caught in water deeper than 300 feet and golden tilefish are taken at depths greater than 540 feet; therefore, release mortality of the species is extremely high. The Council's Scientific and Statistical Committee (SSC) indicates release mortality rates are probably near 100%.

SEDAR 2 (2003) estimates release mortality rates of 25% and 40% for vermilion snapper taken by recreational and commercial fishermen, respectively. However, release mortality rates might be higher than 40%. Release mortality rates from SEDAR 2 (2003) are based on cage studies conducted by Collins (1996) and Collins *et al*. (1999). Burns *et al*. (2002) suggest release mortality rates of vermilion snapper may be higher than estimated from cage studies because cages protect vermilion snapper from predators. A higher release mortality rate is supported by low recapture rates of vermilion snapper in tagging studies. Burns *et al*. (2002) estimate a 0.7% recapture rate for 825 tagged fish; whereas, recapture rates for red grouper, gag, and red snapper range from 3.8% to 6.0% (Burns *et al*. 2002). McGovern and Meister (1999) estimate a 1.6% recapture rate for 3,827 tagged vermilion snapper. Higher recapture rates are estimated for black sea bass (10.2%), gray triggerfish (4.9%), gag (11%), and greater amberjack (15.1%) (McGovern and Meister 1999; McGovern *et al*. 2005). Burns *et al*. (2002) suggest released vermilion snapper do not survive as well as other species due to predation. Vermilion snapper, which do not have air removed from swim bladders, are subjected to predation at the surface of the water. Individuals with a ruptured swim bladder or have air removed from the swim bladder are subject to bottom predators since fish would not be able to join schools of other vermilion snapper hovering above the bottom (Burns *et al*. 2002). Alternatively, recapture rates could be low if population size was very high or tagged fish were unavailable to fishing gear. However, Harris and Stephen (2006) indicate approximately 50% of released vermilion snapper caught by one commercial fisherman were unable to return to the bottom.

SEDAR 10 (2007) estimates release mortality rates of 25% and 40% for gag taken by recreational and commercial fishermen, respectively. A tagging study conducted by McGovern *et al.* (2005) indicated recapture rate of gag decreased with increasing depth. The decline in recapture rate was attributed to depth related mortality. Assuming there was no depth related mortality at 0 m, McGovern *et al* (2005) estimated depth related mortality ranged from 14% at 11– 20 m (36 – 65 feet) to 85% at 71 – 80 m (233 – 262 feet). Similar trends in depth related mortality were provided by a gag tagging study conducted by Burns *et al.* (1992).

A recent study conducted by Rudershausen *et al.* (2007) estimated release mortality rates of 15% for undersized vermilion snapper and 33% for undersized gag taken with J- hooks in depths of 25 – 50 m off North Carolina. Immediate mortality vermilion snapper was estimated to be 10% at depths of 25 – 50 m and delayed mortality was estimated to be 45% at the same depths. For gag caught at depths of 25 – 50 m, no immediate mortality was observed but delayed mortality was estimated to be 49%. McGovern *et al.* (2007) estimated a release mortality rate of 50% at 50 m, which is similar to the findings of Rudershausen *et al.* (2007). Rudershausen *et al.* (2007) concluded minimum size limits were moderately effective for vermilion snapper and gag over the shallower portions of their depth range.

5.2.3 Golden Crab

5.2.3.1 Description of fishing practices, vessels and gear

The Golden Crab Fishery

Description of fishing practices, vessels and gear

The description below was summarized from observations recorded by Council staff (Gregg Waugh) on a commercial golden crab fishing trip aboard the *Lady Mary*, the fishing vessel belonging to the Nielsen family. Additional information was obtained during the course of presentations by fishermen at the April 1995 Council meeting and the 2008 Golden Crab Advisory Panel meeting.

The golden crab fishery employs baited traps attached with gangions to a 5/8" polypropylene line up to 5 miles long. There are 20 to 50 traps per line, or "trawl," set 500 feet apart. Fishermen may fish 4 trawls in a two-week period pulling 100 traps one week and 100 the next (Howard Rau, Golden crab AP). In 2008, vessels in the golden crab fishery averaged 57 feet in length (Golden Crab AP, 2008)

A typical trip to fish for golden crabs begins with the vessel leaving the dock at 3:00 a.m. Bait wells to be placed in the traps are prepared on the way out. The bait consists of available fish heads and racks (cod, snapper, grouper, dolphin, mackerel or any other available fish), chicken parts, pigs' feet, etc. Four and a half hours after leaving dock, the vessel is on site and the crew ready to begin the process of picking up traps and deploying new ones. When the traps are retrieved, the empty bait container is removed and a full one is put in place. It was estimated that at least 65 tons of bait were being used in this fishery at the time this description was compiled.

The location of the traps is noted using GPS; buoys are not used to mark the location of traps due to strong currents. Trawls are set south to north with the current. Retrieval begins at the south end of the trawl. To begin retrieval of traps, the main line, which may be sitting 1,000 feet below, must be grappled. The success of this operation depends on currents and sea conditions. At different times of the year, when the current is not as swift and is moving in a favorable direction, it is easier to place the grapple on the bottom. The grapple consists of links of large chain and is used to hook the main line towards one end of the string. On the observed trip, the grapple did not appear to have disturbed the bottom. Sometimes, however, the grapple or the trap itself may have mud adhered to it when it is pulled out of the water.

Once the grapple successfully hooks the main line, the line is pulled up and looped over the pulley allowing crew members to pull over to the first trap on the line. Traps are stacked on deck as the string is worked toward the short end of the line. Upon reaching one end of the line, the vessel turns around to work the string toward the other end. It takes approximately two hours to work a string of traps. The determining factor for how long a day of fishing will last is how quickly each trap string can be grappled. Sometimes it is necessary to move traps up or down the slope, keeping the same latitude and moving in a range of 5 to 15 miles east or west in order to avoid hardbottom or to follow the crabs. After a soak period, traps may be moved as described depending on the success of the catch. Twenty to 30 lbs of crabs per trap is a desirable catch. On a good season, fishermen may catch 70 to 100 lbs per trap.

Golden crab traps have two entrances, one on the top and one on the bottom. As each trap is brought on deck, the empty bait wells are replaced with full ones. A spike coming up from the bottom of the frame holds the bait well in place. The trap string is deployed off the stern. The end of the string is weighted and its position recorded using GPS.

Towards the stern of the vessel is a spacious ice hold. As the traps are retrieved and brought on deck, golden crabs are removed by hand. The crabs are immediately placed into plastic boxes or coolers and layered with ice. As each crab is removed from the trap, a crew member checks its size (weight) and sex. All females and individuals weighing less than 1 ¼ pounds are released back into the water. Only male crabs are harvested because, since the beginning of this fishery, fishermen felt that an integral factor in the sustainable harvest of this resource was not to harvest the females. Besides, females are smaller than males and therefore less marketable.

On the observed trip, three trawls were retrieved (about 100 traps) out of which only 20-25 crabs were discarded. Such a low number of crabs are released upon trap retrieval because the majority of the culling is being accomplished through the escape panels while the traps are still submerged. Thus, escape gaps are very effective in culling out undersized individuals.

<u>Detailed trap description</u>

The modern golden crab traps are constructed of 3/8" smooth rebar. The latter makes it easier to place the stainless steel hog rings on it to hold the wire in place. The trap is 4 feet long, 30 inches wide and 18 inches high. The body of the trap consists of 1" x 2" mesh and 14 gauge galvanized wire with plastic coating. The corners of the trap are reinforced with zinc to prevent the wire from falling off. The zinc reinforcements are replaced every four or five months as they wear out. At the time this description was compiled (1995), golden crab traps cost about $100 to construct. A golden crab trap weighs approximately 30 lbs.

The trap has two funnels through which the crabs enter the trap. Initially one entrance funnel was placed in the center of the trap. However, fishermen soon realized that traps sometimes landed on the bottom upside down thus preventing the crabs' from entering the trap. The only crabs that would then have access to the bait would be the smaller ones that could enter through the escape gaps. Fishermen then designed the traps with two funnels on opposite sides of the trap that were offset to either side. That way, if the trap landed in such a way as to cover up one of the funnels, it would still be able to fish through the other.

Degradable wire is used to lock the traps. To open the trap, the wire is simply cut. Since the main trap door is shut using degradable wire, ghost fishing is not a concern if the trap becomes lost. In addition, traps are required to have two escape gaps on either side of the trap to allow females and small individuals to escape.

Allowable gear

Traps are the only allowable gear in the golden crab fishery. Rope is the only allowable material for mainlines and buoy line. Maximum trap size is 64 cubic feet in volume in the Northern zone and 48 cubic feet in volume in the Middle and Southern zones. Traps must have at least 2 escape gaps or rings and an escape panel. Traps must be identified with a permit number.

Economic Description

The golden crab Fishery Management Plan went into effect beginning on August 27, 1996 and established three golden crab fishing zones. The Northern Zone is defined as the EEZ north of 28 degrees N. latitude. The Middle Zone is contained within the EEZ between 25 degrees North and 28 degrees North latitude. The Southern Zone extends south from 25 degrees North latitude within the South Atlantic Council's EEZ. Federal permits are issued for a specific zone and fishing is allowed only in that zone for which the permit is issued.

In the South Atlantic region initially 35 vessels were granted permits to operate in this fishery: 27 permits were issued for the southern zone; 6 permits were issued for the middle zone; and 2 permits were granted to vessels for the northern zone. Other management regulations imposed by the golden crab FMP included: dealer and vessel permitting and reporting; limitations on the size of vessels; prescribing allowable gear (including escape gaps and escape panels); and prohibiting possession of female crabs (see the FMP for a complete list of measures).

Number of Participants

The number of permit holders that land golden crab has fluctuated from year to year (Table 5.2.3-1). The greatest number of vessels making landings since 1995 was 14 (Table 5.2.3-2). In recent years, only 5 to 6 vessels have landed any golden crab. The majority of vessels currently fishing for golden crab have Middle Zone permits. In 1997, 1998, and 2000, there were more vessels fishing for golden crab with Southern Zone permits than Middle Zone permits. Only in 2006 and 2007 have vessels with Northern Zone permits participated in the fishery.

2007	confidential	5	0

Information on the golden crab fishery participation was taken from logbook data (SEFSC 2008), and Accumulative Landings System (ALS) data.

Annual and Monthly Landings

Total landings and landings by zone of golden crab are shown in Table 5.2.3-3. Figure 5.2.3-1 shows these data in chart form. Golden crab landings reached a peak of over 1 million pounds in 1997. Since then, landings have averaged about 550,000 annually. However, the trend shows an average of 665,000 pounds from 1998-2002 and 355,000 pounds from 2003-2006.

The overwhelming majority of landings in recent years have come from the Middle Zone (90-100%) (Table 5.2.3-3). However, historically, a significant portion of landings came from the Southern Zone (up to 36%). Only in the past two years have any landings at all come from the Northern Zone. Landings from the Middle Zone have averaged around 470,000 pounds since 1996 with a high of about 662,000 pounds in 1997. Landings from the Southern Zone were significant 1997 through 2001. Landings peaked at about 373,000 pounds in 1997.

Table 5.2.3-3. Landings of golden crab by Zone, 1995-2007 (Source: SEFSC, 2008).

Year	Northern Zone	Middle Zone	Southern Zone	Total
1995	0	confidential	confidential	61,660
1996	0	523,160	0	523,160

2006	confidential	566,780	confidential	599,374
2007	confidential	confidential	0	502,292

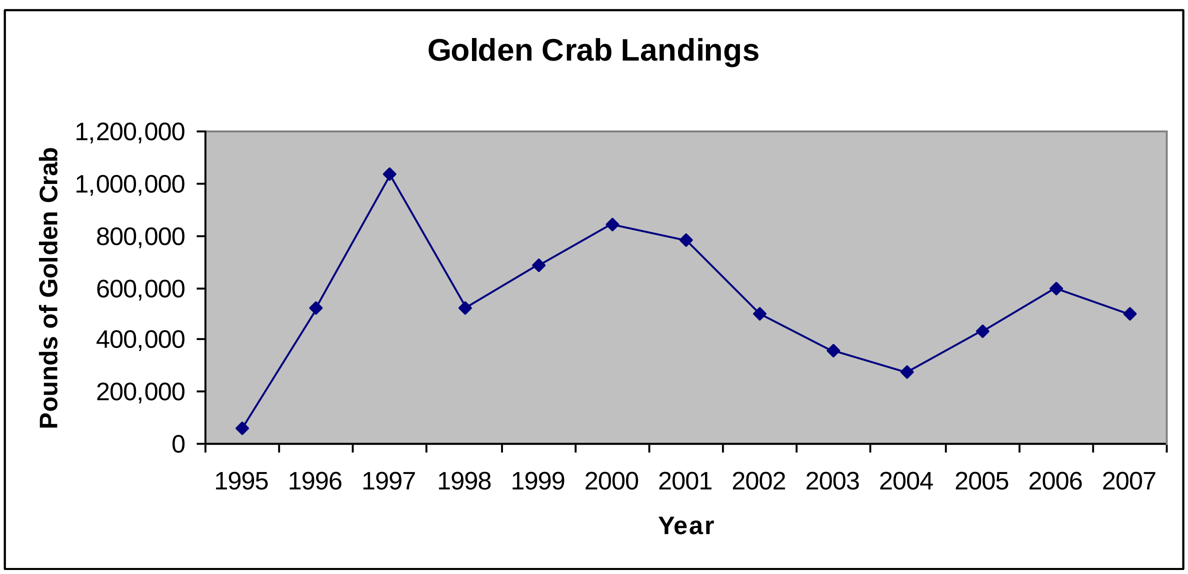

Figure 5.2.3-1. Landings of Golden Crab, 1995-2007 (Source: SEFSC 2008).

Figure 5.2.3-2 shows monthly golden crab landings from 2003 to 2007. Golden crab landings have varied widely from month to month over the past 5 years. In general, more golden crab are landed from May to December than in the first half of the year due to Keys fishermen entering the fishery in the second half of the year after the spiny lobster season winds down. On average, from 1996 to 2007, 45% of total golden crab landings were made between January and May while 55% of landings were made between May and December.

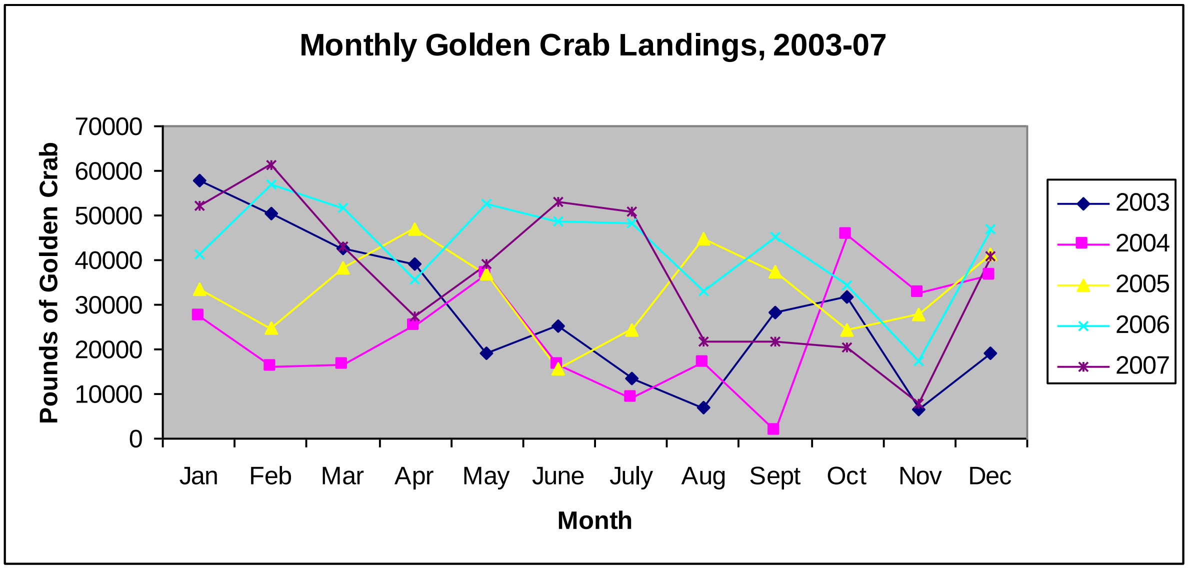

Figure 5.2.3-2. Monthly golden crab landings, 2003-2007 (Source: ALS data).

Golden crab is viewed in the marketplace as a substitute for snow crab clusters. Most of the product is processed into clusters, which is not as favored as other large crab species such as snow crabs. The golden crab market is strongly influenced by the wholesale market for snow crabs (Antozzi 1998). A large proportion of the Alaskan catch of snow crab goes to Japan and the drop in the yen reduced the export demand for this product. The excess supply entered the domestic market and lowered snow crab prices, which may be partly responsible for depressed golden crab prices. The increase in production from Russia and Canada also magnified this problem.

Antozzi (1997) concluded that the market for golden crab is inhibited from expanding due to a supply constraint. He attributes this lack of production to the difficulty and cost of operating in this fishery, which requires a sizable investment in specialized gear including on-board holding facilities that keep crabs alive. This fishery takes place in deep water and this can result in lengthy trips under adverse sea conditions. Some industry members have stated that vessels larger than 50 feet are needed to cope with rough sea conditions offshore and to provide the stability needed for trap deployment and retrieval.

The future outlook for this market will be strongly influenced by the market supply of other large crabs, and the health of export markets. The outlook on this market would improve if this product could be viewed as more than just a substitute for snow crabs.

In recent years, ex-vessel price value has ranged from $1.25 to $1.55 per pound (personal communication, Howard Rau, 2008).

5.2.3.2 Bycatch

Bycatch in the golden crab fishery is minimal and consists almost entirely of isopods (Golden Crab AP discussion, January 2008).

5.2.4 Coastal Migratory Pelagics

5.2.4.1 Description of fishing practices, vessels and gear

Commercial fishery

In the South Atlantic region, runaround gill nets are an important gear for Spanish mackerel, but other kinds of gill nets, cast nets, and handline gear now account for the majority of the landings. Though the effect of the State of Florida's 1995 prohibition on the use of various net gear had more of an impact on the Florida west coast (state waters extend to 9 nautical miles from shore), it did reduce landings on the Florida east coast (state waters extend to 3 nautical miles from shore). Reportedly, Spanish mackerel were concentrated more in state rather than federal waters off the Florida east coast in 2001-2003 than in 1995-2000, and cast nets may be used in state waters. Therefore, cast nets became an increasingly important gear and accounted for 1.88 out of 3.20 million pounds (MP) in 2003, or approximately 59% of total South Atlantic Spanish mackerel harvest. Cast nets were followed by "other" gill nets (0.44 MP), run-around gill nets (0.35 MP) and handlines (0.32 MP).

Various federal and state regulations greatly reduced the use of gill nets for king mackerel, and most are caught with handline gear. Compared with 1966-1988 when gill nets were the predominant gear for the king mackerel fishery in the South Atlantic region, king mackerel are now caught predominantly by various handline gears, which accounted for 2.78 MP out of 2.84 MP for the South Atlantic region in 2003.

Gill nets are not authorized gear for the directed commercial harvest of king mackerel, little tunny, and cobia south of Cape Lookout, North Carolina (34° 37.3'North Latitude). Off North Carolina, the majority of gill-net effort occurs within state waters. During the period between 1999 and 2003, 90% of gill-net trips targeting king mackerel were conducted south of Hatteras within 3 miles from shore using sink gill nets. In federal waters, fishermen also used sink gill nets though a small proportion (0.2%) used runaround gill nets.

The peak fishing months for king mackerel are September through November. For king mackerel, the minimum mesh size averages 5" to 6" (12.7 to15.24 cm). Typically, not more than 15 boats participate in this fishery though the number can fluctuate. Fishermen usually fish 5 or 6 nets (400 yards in length or 365.76 m) working from one net to another throughout the day. They generally fish the gear within a couple of hours, depending on the catch. As mentioned above, this fishery is not allowed below Cape Lookout, North Carolina and is rarely prosecuted above Oregon Inlet, North Carolina.

Between 1999 and 2003, over 100 gill-net trips for Spanish mackerel were conducted per month (May through October) with effort being greatest during October (over 300 trips).

Trips occurred mainly south of Hatteras (90%) of which 96% occurred within state waters. Sink gill nets are the primary gill-net gear used on Spanish mackerel trips (over 99%) with a small proportion of runaround gill nets (0.3%) and float gill nets (0.5%). The summer fishery typically involves 10 to 14 boats, and the fall fishery usually includes another 10 to 12 boats with catches generally higher after the first of September. Fishermen usually fish 3.5 inches (8.9 cm) stretched-mesh nets, the minimum mesh size allowed.

Off the east coast of Florida, cast nets have accounted for more of the landings of Spanish mackerel in recent years than gill nets, and the main season occurs in October-March, compared with May-October farther north Spanish mackerel is the primary species targeted by gill nets off the Florida east coast, and the main season for this activity is September through December. Beginning in January, many of the fishermen using gill nets switch to shark fishing or they will participate in the cast net fishery that occurs in state waters. The Spanish mackerel gill-net fishery mainly occurs between Fort Pierce to just north of Cape Canaveral. Less than 30 vessels are active in the fishery with many being outfitted to use either round-around gill nets or stab nets. Vessels fishing for Spanish mackerel in the South Atlantic EEZ off Florida north of the line directly east from the Miami-Dade/Monroe County, Florida boundary (25<20.4' N. lat.) may not have a float line longer than 800 yds. (732 m), set more than one at any one time, or soak for more than 1 hour.

Harvest in the Commercial Fishery

For the king mackerel fishery, commercial landings have been below 3 million pounds since 1989/90. Over that period of time, commercial landings peaked during the 2004/05 fishing season at 2.8 million pounds. In 2005/06, landings reached 2.4 million pounds, a decrease from 2004/05 of about 400,000 pounds (Table 8). The king mackerel fishery experiences commercial landings primarily in North Carolina and Florida. Table 5.2.4-1 provides commercial landings by area for 2001/02 to 2005/06.

For the Spanish mackerel fishery, since 1995/96 the commercial landings have been below 4 million pounds. In 2005/06, commercial landings were approximately 3.6 million pounds, a slight decrease from the 3.7 million pounds landed in 2004/05 (Table 5.2.4-2). Prosecuted predominantly in state waters from Virginia to Florida, the majority of the commercial fishery for Spanish mackerel occurs in Florida and North Carolina. Table 5.2.4-2 provides information on Atlantic migratory group Spanish mackerel commercial landings by major area.

Table 5.2.4-1 shows that North Carolina and Florida take the majority of commercial landings of Atlantic migratory group king mackerel. North Carolina landings have varied widely over the past five years with a low of 592,000 taken in 2003/04. Since then, North Carolina landings have surpassed landings in 2001/02. Central and south Florida landings peaked in 2004/05, as did North Carolina’s. However, central and south Florida landings have returned to levels similar to those occurring in 2001/02.

Table 5.2.4-2 shows that landings of Atlantic migratory group Spanish mackerel occur predominately in Florida. Atlantic landings to Florida peaked in 2003/04 and those landings have been maintained. North Carolina landings reached a five year low in 2005/06, almost 200,000 pounds less compared to 2001/02.

Table 5.2.4-1. Atlantic migratory group king mackerel commercial landings by area, thousand of pounds, 2001/02 - 2005/06.

	2001/02	2002/03	2003/04	2004/05	2005/06

Note: South Carolina and Georgia were not included in this table due to confidentiality issues.

Recreational fishery

Participation

Table 5.2.4-3 depicts the number of saltwater anglers in the South Atlantic. This includes participants engaged in all fisheries and those anglers who either fished from private/rental boats, from charter boats or by shore/beach bank mode. Overall, recreational fishing participation increased by about 450,000 (9%) from 2001 to 2005. Most saltwater anglers fish on the east coast of Florida and North Carolina. In Florida, in recent years, recreational participation hit a five year low in 2004 before rebounding in 2005 to rival participation in 2001. In Georgia, participation has increased in the past three years from a low of about 150,000 in 2002. North Carolina participation has increased to reach a five year high in 2005. South Carolina has experienced the largest percentage increase in participation by doubling since 2002.

Anglers target a variety of species including South Atlantic group king and Spanish mackerel./. A more specific estimate of recreational activity in the king and Spanish mackerel can be obtained from the harvest data reported in the latter part of this section.

Table 5.2.4-3. Participants in recreational fisheries by state, 2001-2007.

	2001	2002	2003	2004	2005	2006	2007

Recreational Fishing Effort

Shore, Charter, Private/Rental Trips

Table 5.2.4-4 shows the number of recreational fishing trips made from shore, charter vessel and private or rental vessel over the past five years by state. Trips made by headboats are included in the next sub-section. These trips are not species specific since the data set cannot be divided in that manner.

Table 5.2.4-4. Number of trips by state, 2001-2007.

	2001	2002	2003	2004	2005	2006	2007
Florida east coast	12,464,111	10,303,392	11,443,784	10,660,059	12,049,280	13,114,986	15,169,108
Georgia	806,849	619,085	971,208	935,704	851,487	790,298	926,484
North Carolina	6,649,546	5,586,122	6,733,464	7,027,118	6,785,918	7,246,517	6,979,308
South Carolina	1,675,601	1,254,295	2,097,813	2,239,474	2,126,046	2,660,933	2,577,099

Source: MRFSS, NOAA Fisheries
(http://www.st.nmfs.gov/st1/recreational/data.html).

The number of fishing trips from shore, charter vessels, and through private or rental trips in the South Atlantic reached a five year high in 2005. Florida experiences the most fishing trips with North Carolina experiencing the second largest amount (about half that of Florida). The number of recreational trips in Florida declined slightly between 2001 and 2004 and increased from 2005 through 2007. The number of trips in Georgia reached almost 1 million in 2003, 2004 and 2007. North Carolina trips reached a six year high in 2006 and ended in 2007 with about the same number of trips that occurred in 2001. South Carolina trips have increased since 2001 by about 30% with the highest number of trips occurring in 2006 and 2007.

Headboat Trips

Table 5.2.4-5 shows the total number of angler days for the headboat sector in the U.S. South Atlantic. This represents all headboat effort and not only those trips where South Atlantic group king and Spanish mackerel species were caught. These estimates are calculated from a survey where it is not possible to associate catch with a specific angler on the trip. However, it is expected that a significant portion of these trips target mackerel species.

Table 5.2.4-5. Estimated headboat angler days for the U.S. South Atlantic.

Year	Florida	Georgia	North Carolina	South Carolina	Total
2001	138,390	na	31,779	49,263	219,432
2002	125,322	na	27,601	42,467	195,390
2003	122,313	na	22,998	36,556	181,867
2004	149,542	na	27,255	50,461	227,258
2005	145,686	na	31,573	34,036	211,295

Source: The Headboat Survey, NOAA Fisheries, SEFSC, Beaufort Lab.
Note: "Na" indicates the data is not available due to confidentiality issues.
Note: With regard to data for Florida, only half of the headboat trips taken from the Florida Keys and Tortugas areas were counted in this table in order to give a better approximation of trips taken that might result in harvest of South Atlantic migratory group king or Spanish mackerel.

Table 5.2.4-5 indicates that total headboat angler days have been relatively stable over the past five years. Florida trips have increased slightly since 2001 while North Carolina trips have remained almost exactly the same, although a five year low of 23,000 occurred in 2003. The number of South Carolina angler days has decreased 31% since 2001.

Headboat operators usually offer their passengers options for choosing trip packages of different durations. It appears that the majority of headboat trips are of half a day duration in Florida (78%) and South Carolina (59%). In North Carolina and Georgia the majority of trips are full day trips (Table 5.2.4-6).

Table 5.2.4-6. Average number of headboat trips (1999-2003) by trip length and percent of total trips by trip length.

Average Number of trips 1999-2003					Percent of total trips		
State	**Full day**	**¾ day**	**½ day**		**Full day**	**¾ day**	**½ day**

Harvest in the Recreational Fishery

<u>Shore, Charter, Private/Rental</u>

King mackerel harvested by the recreational fishery has fluctuated between almost 2.7 and 6.3 million pounds since 1989/90, peaking in 1992/93 at 6.3 million pounds (Table

5.2.4-2). Table 5.2.4-7 shows harvest of king mackerel by state over the past five years. Florida and North Carolina have the highest harvest levels with Florida harvesting over twice as much as North Carolina in 2005. Florida harvest levels peaked in 2003 at over 4 million pounds before declining to 2.8 million pounds in 2005. Georgia's recreational harvest of king mackerel fluctuated a great deal over the past five years with a low of 20,146 in 2006 and a high of 130,966 in 2003. North Carolina recreational harvest of king mackerel has varied over the past five years between about 700,000 and 1.8 million pounds. South Carolina recreational harvest of king mackerel peaked in 2004 at about 240,000 before reaching a five year low in 2005 at about 120,000 pounds.

Table 5.2.4-7. Recreational harvest (lbs) of king mackerel by state, 2001-2007.

	2001	2002	2003	2004	2005	2006	2007

(Source: MRFSS, NOAA Fisheries (http://www.st.nmfs.gov/st1/recreational/data.html).
*NCDMF,2007 Annual Report , pp. III-41

The amount of Spanish mackerel harvested by the recreational fishery increased in recent years after reaching a low in 1998/99. Table 5.2.4-8 shows harvest of Spanish mackerel by state over the past five years. Florida and North Carolina recreationally harvest the majority of Spanish mackerel with the Florida harvest at about three times that of North Carolina. Florida harvest peaked in 2002 at about 1.5 million pounds and reached a five year low in 2004 at about 900,000 pounds. Georgia recreational harvest of Spanish mackerel has fluctuated between about 2,500 pounds and 35,000 pounds over the past five years. North Carolina harvest decreased from 2001 and peaked in 2004 before reaching a five year low in 2005. South Carolina harvest has achieved relatively high levels for the state over the past two years.

Table 5.2.4-8. Recreational harvest (lbs) of Spanish mackerel by state, 2001-2007.

	2001	2002	2003	2004	2005	2006	2007

Headboats

Harvest by headboats over the past five years is shown in Tables 5.2.4-9, 5.2.4-10. Harvest for the Florida Keys and Tortugas areas was halved in order to better represent potential harvest of South Atlantic migratory group king and Spanish mackerel.

Table 5.2.4-9 shows that total headboat harvest of king mackerel has increased by almost 100,000 pounds since 2001 and more than doubled since 2003 when a five year low occurred. In general, in all states, king mackerel harvests hit a five year low in 2003 when angler days also hit a five year low.

Table 5.2.4-9. Headboat harvest (lbs) of Atlantic migratory group king mackerel, 2001-2005.

	2001	**2002**	**2003**	**2004**	**2005**

Note: “Na” indicates the data is not available due to confidentiality issues.
Note: With regard to data for Florida, only half of the headboat trips taken from the Florida Keys and Tortugas areas were counted in this table in order to give a better approximation of trips taken that might result in harvest of South Atlantic migratory group king or Spanish mackerel.

Total harvest of Spanish mackerel by headboats reached a five year low in 2003 but then recovered to 2001 levels in 2005. Harvest levels varied widely over the past five years for all three states shown (Table 5.2.4-10).

Table 5.2.4-10. Headboat harvest (lbs) of Atlantic migratory group Spanish mackerel, 2001-2005.

	2001	**2002**	**2003**	**2004**	**2005**

Note: With regard to data for Florida, only half of the headboat trips taken from the Florida Keys and Tortugas areas were counted in this table in order to give a better approximation of trips taken that might result in harvest of South Atlantic migratory group king or Spanish mackerel.

<u>Characteristics of the Charter and Headboat Sectors</u>

There is no specific economic information on the for-hire sector that currently operates in the South Atlantic snapper grouper fishery. Holland et al. (1999) conducted a study of the charterboat sector in 1998 and provided information on charterboats and headboats engaged in all fisheries (Table 5.2.4-11).

Table 5.2.4-11. Charterboats and headboats operating in the South Atlantic during 1998.

State	Number of Headboats	Number of Charter Boats
North Carolina	18	207
South Carolina	18	174
Georgia	2	56
Florida-Atlantic Coast	42	413
Florida –Keys	16	230
Total	**96**	**1,080**

Source: Holland et al. (1999).

Holland et al. (1999) surmised that charterboats in Florida tend to be less specific in terms of species targeting behavior when compared to charterboats in the other South Atlantic states. In their study 47.7% of all captains in Atlantic Florida said they don't have specific targets but spend their time trolling or bottomfishing for any species. The most popular species for the Florida Atlantic vessels that had specific targets were king mackerel, dolphin, billfish, wahoo, and amberjack.

Allowable gear

Authorized commercial gears for Atlantic migratory group king mackerel north of Cape Lookout Light (34° 37.3' North Latitude), North Carolina are all gears, except drift gill nets and long gill nets. South of Cape Lookout, authorized gear includes automatic reel, bandit gear, handline, and rod and reel. A minimum size of 4.75-inch stretched mesh is required for run-around gill nets. No more than 400,000 pounds may be harvested by purse seines.

Authorized commercial gear for Spanish mackerel is automatic reel, bandit gear, handline, rod & reel, cast net, run around gill net and stab net. Minimum size of 3.5" stretch mesh required for all run around gill nets.

Other commercial coastal migratory pelagics may be harvested with longline, handline, rod and reel and bandit gear.

Coastal migratory pelagics may be caught recreationally using bandit gear, rod and reel, handline and spear.

5.2.4.2 Economic description of the fishery

Commercial fishery

Ex-vessel Prices

Annual real ex-vessel prices (2004 dollars) for Atlantic migratory group king and Spanish mackerel, during the fishing years 1981/82 through 2005/06 are shown in Table 5.2.4-12 Figure 5.2.4-1 for the Atlantic coastal states (Maine through Florida east coast). In general, prices for both species have increased since 1981/82, by 25% for Atlantic migratory group king mackerel and by about 45% for Atlantic migratory group Spanish mackerel. King mackerel prices peaked several times in the 1990s and early 2000s at about $2.03/pound and Spanish mackerel peaked at $0.82 in the late 1990s. In general, prices for Atlantic migratory group king mackerel are somewhat lower that prices received for most of the 1990s and early part of this decade while prices for Spanish mackerel have remained relatively steady over this period of time.

Table 5.2.4-12. Ex-vessel prices for Atlantic migratory group king and Spanish mackerel (2004 dollars).

Year	Atlantic king mackerel ex-vessel prices	Atlantic Spanish mackerel ex-vessel prices
1981/82	$1.42	$0.52
1982/83	$1.51	$0.48
1983/84	$1.41	$0.42
1984/85	$1.51	$0.41
1985/86	$1.66	$0.45
1986/87	$1.62	$0.50
1987/88	$1.71	$0.57
1988/89	$1.66	$0.53
1989/90	$1.75	$0.53
1990/91	$1.72	$0.51
1991/92	$1.76	$0.54
1992/93	$2.03	$0.57
1993/94	$1.92	$0.55
1994/95	$1.91	$0.59
1995/96	$1.95	$0.78
1996/97	$1.81	$0.64
1997/98	$1.76	$0.71
1998/99	$2.03	$0.69
1999/00	$1.94	$0.82
2000/01	$2.04	$0.75
2001/02	$2.03	$0.75
2002/03	$1.98	$0.73
2003/04	$1.64	$0.67
2004/05	$1.68	$0.77
2005/06	$1.78	$0.73

Note: Season is April through March for 2001/02 through 2004/05 and March through the end of February for 2005/06.

Ex-vessel prices of king mackerel, the U.S. market, and estimated imports of king mackerel and possible substitute species have been described and analyzed using econometric models (Easeley et al. 1993; Vondruska and Antozzi 1999; Vondruska 1999). The model results indicate that demand for king mackerel is relatively price elastic for the U.S. market as a whole. That is, compared with any given percentage change in market supply, the expected percentage change in ex-vessel price is much smaller, holding other factors constant.

The models also indicate statistically significant shifts in ex-vessel prices of king mackerel during the year because of variations in landings. Landings of king mackerel exhibit extreme seasonal variation in some major harvest areas, more so for the Gulf group than the Atlantic group, and this affects the annual average ex-vessel price.

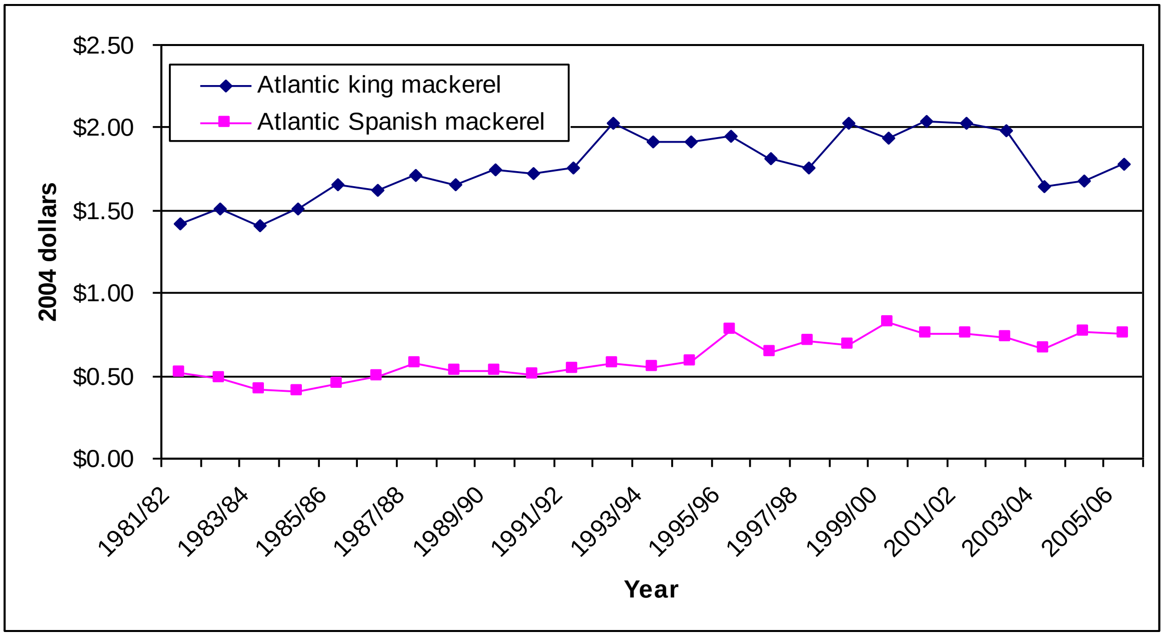

Figure 5.2.4-1. Ex-vessel prices for Atlantic migratory groups of king and Spanish mackerel, 1981-2006.

Logbook indicators of commercial fishing activity

Since 1998, fishermen have completed and submitted FMP-mandated logbooks for commercial fishing trips for king and Spanish mackerel. The data base management systems for fisherman-supplied logbooks and southeast coastal state-collected commercial landings are administered by the NOAA Fisheries Southeast Fisheries Science Center, Miami. Table 5.2.4-13 and Table 5.2.4-14 provide average values for various categories for the Atlantic migratory group king and Spanish mackerel fisheries over the past five years. The reader should note that while all federally permitted vessels are required to fill out and send in logbooks, there are vessels in state waters that fish for Atlantic migratory group Spanish mackerel that are not required to fill out logbooks.

Information from vessels fishing in state waters and not required to fill our logbooks for fishing in these areas, has not been incorporated into the data shown below. Therefore, the number of vessels is likely an underestimate of the number of vessels actually fishing for Atlantic migratory group Spanish mackerel. However, the below information is correct for the number of vessels turning in logbooks and these vessels serve as a representation of the entire fleet.

Over the past five years total commercial pounds landed pounds landed per vessel annually, and pounds landed per trip (Table 5.2.4-13) have increased while the number of vessels declined. At the same time, real ex-vessel value remained unchanged due to the decrease in ex-vessel prices from $2.03 in 2001/2002 to $1.78 in 2005/06 (Table 5.2.4-12). Ex-vessel value of Atlantic migratory group king mackerel increased in the percentage of value it contributed to all species caught in the year. The total number of trips and days away from port on fishing trips for king mackerel declined from 2001 to 2005. It appears that while the fleet has decreased in size, those remaining have increased landings but not value due to market changes. Given increasing fuel prices over the past several years, the average vessel likely experienced decreased net income since 2001.

Table 5.2.4-13. Atlantic migratory group king mackerel mean statistics, 2001/02 - 2005/06 (2004 dollars).

	2001	2002	2003	2004	2005
Vessels	750	718	715	695	661
Pounds landed (king mackerel)	2,287	2,043	2,727	3,147	2,571
Pounds landed per trip (king mackerel)	167	163	203	247	232
Real ex-vessel value (king mackerel), 2004 $	$4,288	$3,882	$4,269	$4,982	$4,249
Real ex-vessel value (% all species caught in yr), 2004 $	33.2%	31.5%	33.3%	39.3%	37.7%
Real ex-vessel value per trip (king mackerel), 2004 $	$313	$311	$317	$391	$384
Real ex-vessel value per trip (% all species), same trips, 2004 $	77%	76%	80%	81%	77%

Days away from port (king mackerel)	19.7	17.7	17.5	16.2	15.6
Days away from port (trips all species)	47.7	48.5	47.6	42	39.8

Note: Not all vessels providing logbooks provided data for every category included in the table.
Source: NMFS Southeast Coastal Fisheries Logbook, 2005/06. As of May 26, 2006. ALS data accessed August 9, 2006.

Over the past five years total commercial pounds landed pounds landed per vessel annually, and pounds landed per trip (Table 5.2.5-14) for Atlantic migratory group Spanish mackerel increased while the number of vessels declined. Annual and per trip real ex-vessel value increased while ex-vessel prices remained at the same level ($0.75) (Table 5.2.5-12). Ex-vessel value of Atlantic migratory group Spanish mackerel increased slightly in the percentage of value it contributed to all species caught in the year. The total number of trips increased slightly and days away from port on fishing trips for Spanish mackerel increased slightly from 2001 to 2005. However, total days away from port fishing for all species declined from 44 to 39 from 2001 to 2005. While the fleet decreased in size, those remaining have increased landings and real ex-vessel value has increased somewhat. Increasing fuel prices over the past several years may have negated any revenue increases.

Table 5.2.5-14. Atlantic migratory group Spanish mackerel mean statistics, 2001/02 - 2005/06 (2004 dollars).

	2001	2002	2003	2004	2005
Vessels	348	371	323	310	312

Source: NMFS Southeast Coastal Fisheries Logbook, 2005/06. As of May 26, 2006. ALS data accessed August 9, 2006.

Table 5.2.5-15 and Table 5.2.5-16 provide various statistics regarding landings, revenue, vessel specifications, trips, and crew size for the Atlantic migratory group king and Spanish mackerel fisheries. The 661 vessels that submitted logbooks with Atlantic migratory group king mackerel landings in 2005/06 were, on average, 31 feet in length, had 350 horsepower, spent 15 days away from port each year fishing for king mackerel, and used 1.5 crew members per trip for Atlantic migratory group king mackerel. Although this information does not encompass the entire population of vessels fishing for Atlantic migratory group king mackerel, this data set can provide some indication of characteristics of the fleet.

A large portion of the vessels fishing for Atlantic migratory group king mackerel obtain a significant portion of total ex-vessel revenue from the species as a percentage of all species caught in the year. The data shows that the median vessel obtains 27% of real ex-vessel value from king mackerel as a percentage of all species caught in the year. The 75th – 90th percentile range received about 70% - 100% of real ex-vessel value from king mackerel as a percentage of all species caught in that year. However, for the 75th - 90th percentile this amounts to only about $4,300 – $12,400 ex-vessel value. On a per trip basis, the 75th – 90th percentile range makes about $475 - $1000 ex-vessel per trip from landings of king mackerel. This encompasses 100% of ex-vessel value from all species for those trips.

The 312 vessels that submitted logbooks with Atlantic migratory group Spanish mackerel landings in 2005/06 were, on average, 30 feet in length, had 295 horsepower, spent 10 days away from port each year fishing for Spanish mackerel, and used 1.5 crew members per trip for Atlantic migratory group Spanish mackerel.

Table 5.2.4-15. Atlantic migratory group king mackerel statistics by vessel, 2005/06 (2004 dollars). The table features data contained in 661 logbooks.

	Mean	25th percentile	50th percentile	75th percentile	90th percentile	99^{th} percentile
Length (ft)	31	26	30	35	42	53
Horsepower	350	220	300	425	590	900
Depth fished for king mackerel (ft)	94	70	85	100	135	230
Pounds landed (king mackerel)	2571	116	643	2,521	7,136	28,465
Pounds landed per trip (king mackerel)	232	38	110	276	595	1,151
Real ex-vessel value (king mackerel)	$4,249	$193	$1,010	$4,311	$12,379	$45,254
Real ex-vessel value (% all species caught in yr)	37.7%	2%	27%	69%	100%	100%
Real ex-vessel value per trip (king mackerel)	$384	$67	$194	$474	$993	$2,392
Real ex-vessel value (% of all species caught on trip)	77	66	98	100	100	100
Real ex-vessel value per trip (% all species), same trips	77%	66%	98%	100%	100%	100%
Trips (king mackerel)	11.08	2	6	15	29	58
Crew size per king mackerel trip	1.57	1	1	2	3	4
Days away from port (king mackerel)	15.6	3	8	22	42	90
Days away from port (trips all species)	39.8	9	25	57	97	170

Note: Not all 661 vessels providing logbooks provided data for every category included in the table.
Source: NMFS Southeast Coastal Fisheries Logbook, 2005/06. As of May 26, 2006. ALS data accessed August 9, 2006.

A portion of the vessels fishing for Atlantic migratory group Spanish mackerel obtain a significant portion of total ex-vessel revenue from the species as a percentage of all species caught in the year. The data shows that while the median vessel obtains only 7% of real ex-vessel value from Spanish mackerel as a percentage of all species caught in the year, the 75th – 90th percentile range receives about 38% - 87% of real ex-vessel value from Spanish mackerel as a percentage of all species caught in that year. However, for the 75th -90th percentile this amounts to only about $4,300 – $12,400 ex-vessel value. On a per trip basis, the 75th – 90th percentile range makes about $550 - $970 ex-vessel per trip from landings of Spanish mackerel and this encompasses 100% of ex-vessel value from all species for those trips. Clearly, fishermen fishing for Atlantic migratory group king and Spanish mackerel participate in a portfolio of other fisheries and/or supplement their income by other means (second job).

Table 5.2.4-16. Atlantic migratory group Spanish mackerel statistics by vessel, 2005/06 (2004 dollars). The table features data contained in 312 logbooks.

	Mean	25th percentile	50th percentile	75th percentile	90th percentile	99th percentile
Length (ft)	30	25	28	34	40	51

Recreational fishery

The statistics presented in Section 5.2.4.1 (Recreational Fishery) document marine recreational fishing participation, recreational effort, and harvest of South Atlantic migratory group king and Spanish mackerel. Participation, effort, and harvest are indicators of the value of saltwater recreational fishing. However, a more specific indicator of value is the satisfaction that anglers experience over and above their costs of fishing. The monetary value of this satisfaction is referred to as compensating variation (same as non-market benefit). The magnitude of this non-market benefit derived from the recreational experience is dependent on several quality determinants which include fish size, catch success rate, the number of fish kept, and aesthetics. These quality variables are important not only in their determination of the value of a recreational fishing trip but also in their influence on total demand for recreational fishing trips. For example, as the population of fish increases it is expected that angler success rate would increase and the marginal value of the fishing trip to the angler would increase, provided all other conditions remain the same.

Recent estimates of the economic value of a day of saltwater recreational fishing are available for the South Atlantic from different sources. These estimates are not specific to king or Spanish mackerel but shed some light on the magnitude of an angler's willingness to pay for this recreational experience. The mean value of access per marine recreational fishing trip was estimated at $109.31 for the South Atlantic (Haab et al. 2001). Such values can be considered good estimates of the opportunity cost of time for saltwater recreational fishing.

The valuation estimates previously discussed should not be confused with angler expenditures or economic activity generated as a result of these expenditures. Angler expenditures benefit a number of sectors that provide goods and services for saltwater sport fishing. A study conducted by NOAA Fisheries (Gentner et al. 2001) provides estimates of saltwater recreational fishing trip expenditures (Table 5.2.4-17). The average expenditure per trip varies depending on the state, type of trip, duration, travel distance, and other factors. As expected, trip expenditures for non-residents are higher than for in-state residents. Compared to in-state residents, non-residents travel longer distances and incur expenses for food and lodging. Some in-state residents will incur higher trip expenses if they reside far away from the coast. These estimates do not include expenditures on recreational fishing in Monroe County or expenditures made on headboat angler trips.

Financial Operations of the Charter and Headboat Sectors

Holland et al. (1999) defined charterboats as boats for-hire carrying 6 or less passengers that charge a fee to rent the entire boat. Data from their study conducted in 1998 indicated that this trip fee reportedly ranged from $292 to $2,000. The actual cost to the passenger depended on state, trip length, and the variety of services offered by the charter operation. In the South Atlantic, depending on the state, the average fee for a half day trip ranged from $296 to $360, for a full day trip the range was $575 to $710, and for an overnight trip the range in average fee was $1,000 to $2,000. Most (>90%) Florida charter operators offered half day and full day trips and about 15% of the fleet offered overnight trips. In comparison, in the other South Atlantic states about 3% of the total charter trips were overnight trips.

Table 5.2.4-17. Summary of expenditures on saltwater trips estimated from a 1999 MRFSS add-on survey (Source: Gentner et al. 2001).

	North Carolina	South Carolina	Georgia	Florida

Item	Resident	Non Resident	Resident	Non Resident	Resident	Non Resident	Resident	Non Resident
Shore mode trip expenses	$63.61	$75.53	$54.12	$104.27	$31.78	$115.13	$36.90	$141.30
Private/rental boat trip expenses	$71.28	$92.15	$35.91	$67.07	$161.34	$77.51	$66.59	$94.15
Charter mode trip expenses	$201.66	$110.71	$139.72	$220.97	$152.45	$155.90	$96.11	$196.16
Charter fee-average-per day	$133.76	$70.59	$114.26	$109.97	$73.68	$80.99	$71.37	$100.79

Headboats tend to be larger, diesel powered and generally can carry a maximum of around 60 passengers. The average vessel length of the headboats whose owners responded to the survey was around 62 feet. In Florida, the average headboat fees was $29 for a half day trip and $45 for a full day trip. For North and South Carolina, the average base fee was $34 per person for a half day trip and $61 per person for a full day trip. Most of these headboat trips operated in Federal waters in the South Atlantic (Holland et al. 1999).

The demand for charter and headboat trips will depend on the fee charged and the quality of the fishing experience. As noted previously, variables such as catch success rates, bag (keep) limits, and aesthetics are determinants of the quality of the experience to the angler. Profits within the for-hire sector will depend on trip demand, the fee charged, and cost of the fishing operation. It is expected that the cost of fishing will bear some inverse relationship to the population size of the species as it is expected that costs of searching for fish will decrease as the population size increases.

On the east coast of Florida, the average charter vessel length and horsepower was 39 feet and 617 hp respectively. The average vessel length in North Carolina was comparable to Florida. Also, for the other states it appears that charter vessels tended to be smaller than vessels in Florida and North Carolina. Electronics such as global positioning systems (GPS) and fish finders are common on most charter vessels in the South Atlantic. Capital investment in charter vessels averaged $109,301 in Florida, $79,868 for North Carolina, $38,150 for South Carolina, and $51,554 for Georgia (Holland et al. 1999). Charterboat owners incur expenses for inputs such as fuel, ice, and tackle in order to offer the services required by their passengers. Most expenses incurred in 1997 by charter vessel owners were on crew wages and salaries and fuel (Holland et al. 1999). The average annual charterboat business expenditures incurred was $68,816 for Florida vessels, $46,888 for North Carolina vessels, $23,235 for South Carolina vessels, and $41,688 for vessels in Georgia in 1997. The average capital investment for headboats in the South Atlantic was around $220,000 in 1997. Total annual business expenditures averaged $135,737 for headboats in Florida and $105,045 for headboats in other states in the South Atlantic.

The 1999 study on the for-hire sector in the Southeastern United States presented two sets of revenue estimates for the charter and headboat sectors in the South Atlantic (Holland et al. 1999). The first set of average gross revenue per vessel estimates were those reported by survey respondents as follows: $51,000 for charterboats on the Atlantic coast of Florida; $60,135 for charterboats in North Carolina; $26,304 for charterboats in South Carolina; $56,551 for charterboats in Georgia; $140,714 for headboats in Florida; and $123,000 for headboats in the other South Atlantic states (Holland et al. 1999). These authors concluded that survey respondents were reluctant to report gross income, and it is possible that these are underestimates of the true income received by these business entities. As a result, a second set of estimates on the for-hire sector was calculated by multiplying the average trip fee by the average number of trips per year for each vessel category. Using this method the average per vessel gross revenue was estimated at $69,268 for charterboats and $299,551 for headboats operating on the Atlantic coast of Florida (Holland et al. 1999). The calculated vessel gross revenue estimate for the charter sector was 22% higher than the reported charter gross revenue per vessel on the east coast of Florida (Holland et al., 1999). The calculated vessel gross revenue figure for the headboat sector was 113% higher than the reported headboat gross revenue per vessel on the east coast of Florida (Holland et al. 1999). The second set of gross revenue estimates were only calculated for vessels in Florida. To obtain revised estimates for average gross vessel income for the other South Atlantic states, the reported per vessel gross income was multiplied by the percent increase calculated for Florida by sector. The revised estimates of average gross revenue per vessel for the other states are as follows: $73,365 ($60,135 x 1.22) for charterboats in North Carolina, $32,091 ($26,304 x 1.22) for charterboats in South Carolina; $68,992 ($56,551 x 1.22) for charterboats in Georgia; and $261,990 ($123,000 x 2.13) for headboats in the other South Atlantic states.

It must be noted that the study's authors were concerned that while the reported gross revenue figures are underestimates of true vessel income, these calculated values could overestimate gross income per vessel from for-hire activity (Holland et al. 1999). Some of these vessels are also used in commercial fishing activities and that income is not reflected in these estimates.

Permit Ownership

Amendment 15 established an indefinite limited access program for the king mackerel fishery in the exclusive economic zone under the jurisdiction of the Gulf of Mexico, South Atlantic and Mid-Atlantic Fishery Management Councils. Permits may be transferred. Tables 5.2.5-18 and 5.2.5-19 provide the number of king mackerel and Spanish mackerel permits by area, respectively. While all vessels with permits for king and Spanish mackerel are included in the table, only a portion of these fish for Atlantic migratory group king and Spanish mackerel. For our purposes, it is assumed that vessels located on the east coast of the U.S. and Florida fish for Atlantic migratory group king and Spanish mackerel. It is assumed that Florida west coast and non-coastal numbers are split evenly between fishing for Atlantic migratory group king and Spanish mackerel and Gulf migratory king and Spanish mackerel. While these assumptions are rather simplifying and perhaps not entirely realistic, they allow us to discuss the data included in the tables below in an approximate way.

In total, there are about 1,119 commercial vessels, 243 charter vessels, and 5 headboats with federal permits for king mackerel that likely fish for Atlantic migratory group king mackerel. The majority of the commercial permits are registered to vessels homeported on the east coast of Florida and Monroe County. While a large portion of the commercial and charter boats with federal king mackerel permits are registered to vessels homeported in Florida, a significant portion (21% and 40%) are homeported in North Carolina. Most of the headboat permits are registered to vessels homeported in Florida.

Table 5.2.4-18. Boats with federal permits for commercial fishing for king mackerel by region, January 2006.

In total, there are about 956 (69%) commercial vessels, 177 (70%) charter vessels, and 8 (80%) headboats with federal permits for king mackerel that likely fish for Atlantic migratory group Spanish mackerel. The majority of the commercial permits are registered to vessels homeported on the east coast of Florida and Monroe County. About 14% of commercial permits and 29% of the charter permits are homeported in North Carolina. Most of the headboat permits are registered to vessels homeported in North Carolina and points north.

5.2.4.3 Social and cultural environment

Most fishermen who participate in the mackerel fishery also participate in other fisheries. Even if mackerel fishing only accounts for a portion of the income earned by a fisherman, it is an important part and may mean the difference in someone being able to continue to fish, and the necessity to seek other types of employment. If the mackerel fishery were to experience further reductions in the catch, there could be ramifications for fishermen, fish processors, marinas, and other fishing-related businesses that draw part of their income from the mackerel fishery. If there are changes made to the current regulations for the mackerel fishery, it is assumed that the regulations would have the most impact in communities where the most mackerel are landed, the most income from mackerel earned, and the most boats are permitted for mackerel. That is, regulations will likely have the greatest impact on the communities that are most dependent on the mackerel resource. The above mentioned data can act as indicators of mackerel dependence. By comparing all of the data, it is possible to determine which counties/communities may be most impacted by changes in regulations that may affect mackerel-dependent fishermen, fishing-dependent businesses, and communities.

Measures of Fishing Dependence

Jepson et al. (2006) conducted community profiles for the South Atlantic region. These community profiles provide a snapshot of the community and its involvement in fishing using 2001 as a base year. The profiles provide historical background about the community and its involvement in fisheries or fisheries related industries. The profiles provide information on community involvement in commercial and recreational fishing as evidenced through various indicators (federal commercial permits, state commercial licenses, federal charter permits, seafood landings, fish processors and wholesale fish houses, recreational docks/marinas, and recreational fishing tournaments). Demographic information on a community basis is also provided to the extent that the data were gathered in a Federal Census.

Mackerel Fishing Communities
In general, the community profiles do not provide fishery specific information other than the number of federal and state permits associated with each community. Because not all communities profiled are likely relevant to the actions under consideration in this document, profiles that outline homeports for vessels with at least five federal commercial king mackerel, federal commercial Spanish mackerel, and federal charter/headboat permits for coastal pelagics combined, have been included. The last subsection under each state heading summarizes community engagement in that state based on several indicators that data was gathered for. These community profiles have been included in Appendix A of Draft Mackerel Amendment 18.

5.2.4.4 Bycatch

Bycatch data in the commercial CMP fisheries are primarily collected via logbooks, and recreational bycatch is collected by the Marine Recreational Fisheries Statistics Survey (MRFSS). Bycatch from commercial gill nets has recently been collected via the supplementary discard program, which was implemented in August 2001. A stratified, random sample (20% coverage) of commercial permit holders was selected each year and required to record their discards for each trip they made. For the first survey period (8/01-7/02), 15 vessels with gill-net gear were selected to fill out discard report forms. For the second survey period (8/02 to 7/03), 14 vessels with gill-net gear were selected to report. Overall, menhaden, smooth dogfish sharks, and spiny dogfish sharks were the three most frequently discarded species. There were no interactions of sea turtles or marine mammals reported (Poffenberger 2004).

5.2.5 Spiny Lobster

5.2.5.1 Description of fishing practices, vessels and gear

Commercial fishery (See Appendix A)

Private recreational fishery

Recreational landings are estimated using mail surveys. Recipients of FWC mail surveys are randomly selected from the state's saltwater fishing license database of individuals who purchased a lobster permit that was valid during the survey period. To ensure that this selection process does not over- or under- sample any geographic region, these selections were stratified based upon license sales in each of 10 residence areas defined by postal codes. The number of lobster license holders that have been attempted to survey each season has ranged from 4,000 to 5,000.

Fishing effort during the Special Two-Day Sport Season from the 1992 through the 2003fishing seasons, expressed in terms of person-days has ranged from c. 60,000 to 112,000 person-days. Fishing effort was concentrated in the Florida Keys, where effort has ranged from 39,000 to 79,000 and accounted for 64% or more of the statewide fishing effort estimate each season. Most of the remaining fishing effort occurred along the SE coast of the state, where effort ranged from 16,000 to 36,000 person-days. Fishing effort throughout the remaining areas of the state ranged from 2000 to 10,000 person-days. Annual landings during the Special Season have ranged from 249,000 to 568,000 lbs. The largest proportion of landings occur in the Florida Keys and have ranged from 163,000 to 397,000 lbs, or 60% to 70% of the annual statewide total. Landings along the SE coast during the Special Season ranged from 70,000 to 151,000 lbs, and those throughout the remainder of the state ranged from 5,000 to 58,000 lbs.

To obtain a coarse estimate of lobster fishing effort after the Labor Day holiday, mail surveys from 1993 through 1996 included questions that asked respondents about which month they intended to fish for lobsters after the survey period. Nearly 60% of respondents to the regular season survey had fished for lobsters before Labor Day, but only 37% of respondents to both surveys indicated they intended to do so during the remainder of September, and that percentage progressively decreased during the subsequent months. However, an end-of-season mail survey that was conducted after the conclusion of the 1994 lobster fishing season indicated that lobster fishing effort during those months was even lower than that indicated by respondents of the former surveys. Only 13% of those survey recipients indicated that they actually fished for lobsters after Labor Day, and no more than 10% of those respondents fished for lobster in any single month during the survey period. From that same survey, we estimated that statewide there were only 50,673 (±1SD = 9,163) person-days of lobster fishing during that period and that 148,000 (± SD = 39,000) lbs of lobsters were landed. Because of the small number of surveys from which these estimates were derived (n = 52), regional landings were not estimated. Comparing this estimate to estimates from the Special Two-Day Season and regular season during 1994 indicated that less than 7 % of lobster landings that season occurred after Labor Day.

Allowable gear

Authorized gear includes trap, pot, dip net, bully net, snare and hand harvest.
There is a 5% by catch limit by weight (of all fish lawfully aboard) for incidental harvest of spiny lobster by trawls in the EEZ. No poisons or explosives are allowed. No spear, hooks or piercing devices are allowed. A degradable panel is required on non-wooden traps. Traps may not be tended at night. Buoy and trap identification is required.

5.2.6 Live Rock Aquaculture and Allowable Octocoral

5.2.6.1 Octocoral Fishery

Description of fishing practices, vessels and gear

History of the Commercial Fishery

The commercial live octocoral fishery probably dates back to the late 1950s or early 1960s when salt water aquariums first started to become popular and the supply of marine specimens began to appear in major cities in the United States. In the early days, filtration systems tended to be crude and the average marine aquarist stocked his aquarium with fish and a few common invertebrates such as crabs, shrimp, and starfish. As the hobby grew and filtration systems improved, more and more aquarists began to stock their aquariums with difficult-to-keep invertebrates such as clams, snails, stony corals, and octocorals. By 1980 the octocoral fishery was becoming well established, and a handful of the more hardy octocoral species collected off the Florida coasts could be found in most large marine aquarium stores throughout the U.S. The demand for Florida octocorals has continued to grow, as has the list of species harvested and successfully kept in the average marine aquarium. Florida-collected octocorals dominate the U.S. market as well as some of the European and Asian markets.

The South Atlantic Council, together with the Gulf of Mexico Council, became the first fishery management councils to describe the octocoral fishery in 1982 in the original Fishery Management Plan for Coral, Coral reefs and Live/Hard Bottom Habitat (SAFMC 1982). Amendment 1 to the Coral FMP was developed in 1990. This plan set an annual harvest limit of 50,000 octocoral colonies from federal waters, allowed for a minimal bycatch of substrate around the holdfast, set allowable gears, and defined the area where harvest is permitted.

Subsequent to this, the Florida Marine Fisheries Commission ruled that octocoral harvest in Florida waters would be unlimited. If the EEZ yearly quota was reached before September 30, then harvest would be closed in Florida until the following October 1.

Over the years there has been occasional interest in collecting octocorals for use in biomedical research. Past work has mostly focused on sampling a wide variety of species and looking for chemical compounds that might be of interest to this type of research. Compounds of interest were eventually synthesized in the lab, eliminating the need to continue harvesting a specific species of octocoral for the extraction. No large-scale octocoral harvests are presently taking place in the South Atlantic EEZ.

Although octocoral harvest in the South Atlantic EEZ is legal in almost all areas from Cape Canaveral south, the overwhelming bulk of the commercial octocoral harvest is located primarily in the Florida Keys. Harvest of octocorals from state waters occurs as far north as Jupiter inlet, but it is also mostly a Florida Keys based fishery. A limited harvest also occurs in the Gulf of Mexico EEZ off Florida's southwest coast.

Licenses and Permits

Commercial harvest of octocorals in federal waters is restricted to individuals or corporations holding a federal octocoral permit or a valid Florida Saltwater Products license (SPL) with a marine life (ML) endorsement. Federal permits are available through NOAA Southeast Regional Center in St Petersburg, FL, and are not restricted in any way. Saltwater products licenses from Florida's Fish and Wildlife Commission (FWC) are unrestricted, but the ML endorsement necessary to land commercial quantities of any organism designated as a "marine life" species, which includes all octocorals, is restricted. The commercial marine life fishery in Florida waters and the adjacent federal waters is managed by a limited entry program administered by the State of Florida's

FWC, and only a limited number of the licenses currently issued are transferable and valid for harvesting octocorals.

The state of Florida also has a Special Activities License (SAL) that can be issued to researchers, public aquariums, and educational institutions that allows the harvest of octocorals in state and federal waters. The permit holder must state in the application how many and what species of octocorals they wish to harvest, and the request is reviewed by FWC staff before being issued. Requests for any substantial amounts of octocoral harvest in federal waters are referred to NOAA Fisheries for review and approval.

Recreational harvest of gorgonia is permitted with a State of Florida saltwater fishing license and is restricted to 6 specimens per day, and the harvest is considered part of the aggregate recreational bag limit of marine life, which is no more than 20 total marine specimens per license holder per day.

Reporting requirements
All octocorals harvested commercially by marine life fishermen must be reported monthly to the Florida Fish and Wildlife Research Institute (FWRI). Landings must be identified as coming from specific zones along the coast, and within each zone it must be specified as coming from state or federal waters. The FWRI has accurate state and federal landing data for octocorals going back as far as about 1990.

Octocorals harvested under a Federal Fisheries Permit must be reported to NOAA Fisheries.

Octocorals harvested by SAL holders must be reported to FWRI.

Octocorals harvested by recreational fishermen are not reported.

Harvest Methods
Almost all commercial harvest of octocorals is done by marine life fishermen for the live aquarium trade, so harvest is by hand and is done in small numbers on any given day. Because it is listed as a marine life species by the state of Florida, fishermen harvesting octocorals using a Florida SPL with ML endorsement must transport and land them in a live and healthy condition.

As many as 50 different species of octocorals are harvested off the coasts of Florida, but only about a dozen species make up the majority of the harvest. Water depth ranges from 5' to 150', but most specimens from federal waters are photosynthetic specimens from shallow waters (less than 80'). Sea fans, *Gorgonia ventalina,* and *Gorgonia flabellum* as well as all black corals of the genus Antipathes are protected in state and Federal waters and there is no allowable harvest from any state or federal waters.

The aquarium trade has specific size and shape requirements that force marine life fishermen to be very selective in their harvest. Small specimens are passed by for the most part, and few specimens larger than about 20 inches are collected because they are too big for most aquariums and are difficult to ship. The standard shipping box used by Florida shippers has an inside dimension of 15" x 15", so although a 20 inch specimen could fit diagonally in a standard box or could be bent, most wholesale shippers and purchasers prefer specimens less than 15' long. Shape and quality are other factors that fishermen must consider when selecting specimens. The ideal specimen is one that has several lateral branches and no dead spots or odd growths.

The South Atlantic Coral FMP states that harvest by non-powered hand tools is permitted, so although there are many hand tools that could be used, the majority of the harvest is done using either a dive knife, a mason's hammer, or a hammer and wood chisel. The FMP allows for the harvest of a minimal amount of substrata (1" around the base of the octocoral), and most harvesters harvest much less than this amount. Allowing the substrate around the holdfast to be harvested reduces the chance of injuring the specimen and also makes it easier for the final consumer, the aquarist, to attach it to a rock in their aquarium or place it upright in the sand.

Most marine life fishing vessels are less than 25' and are usually trailerable, open fishing boats with outboard motors, and most fishermen either work alone or with just one other person on the boat. Most divers use standard SCUBA gear, but a few use boat mounted surface supplied air systems. Marine life vessels are required to have some sort of aeration system on board to aerate the livestock both on the water and during transport to an onshore holding facility.

Harvest by SAL requires all of the above considerations, but the SAL permit may have additional requirements or exemptions that are issued by the state of Florida on a case-by-case basis.

Recreational harvest is most likely done in the same way that the commercial harvest is done and uses the same types of vessels and gear. Recreational harvesters are not required to aerate their catch, but the catch must be landed live.

The recreational Federal permit is also limited to a daily catch of 6 octocorals. This permit must adhere to the most stringent of Federal or State criteria.

Allowable gear
Hand harvest is the only allowable method. A toxic chemical may not be used or possessed in a coral area in the EEZ. A power-assisted tool may not be used to take prohibited coral, allowable octocoral or live rock. Possession in the EEZ of coral resources harvested with a power assisted tool is prohibited.

Economic description of the fishery

The FWRI collects and maintains fishery landing data for this fishery and has provided the following landing data and ex-vessel value of the catch. However, the total economic value of the catch is many times greater as the product moves from the collector to the final consumer. The traditional chain of possession of the product is collector to wholesaler to pet shop to aquarist, and traditionally the price is at least doubled at each step of the process, so a $4 octocoral reported to the FWRI will sell for at least $16 to the final aquarist, and most likely much more than that. Most of this income comes into Florida from the rest of the United States and from other parts of the world (primarily Europe).

Landing data collected by FWRI for the 2006 calendar year indicated that a total of 39,404 colonies were harvested from the South Atlantic EEZ, for an approximate ex-vessel value of $157, 616 (based on an average landed price of $4 per colony). FWRI probably has a better number than this. Harvest levels have risen and fallen over the last five years, from a low of 29,420 in 2002 to 39,404 in 2006. Harvest in 2004 and 2005 was below the level for 2003, most likely reflecting the disruptive impacts of hurricanes on the ability of the fishermen to get out and harvest. Hurricanes not only disrupt the lives of the fishermen, but they also tend to scour many areas and in many cases the scouring removes all octocorals from that habitat, further disrupting the fishermen's ability to harvest. Re-growth of a completely scoured area to a level that will sustain a harvest varies from two years to four, depending on the habitat type and the targeted species. FWRI data also indicates that there were 26 fishermen reporting landings from the South Atlantic EEZ from 2002 to 2006, and 103 fishermen reporting state landings during that same time period.

Social and cultural environment

Although the area where octocoral harvest is permitted extends from the Florida Keys north to Cape Canaveral, the entire harvest from the South Atlantic EEZ comes from the Keys with most of the harvesters either living in the Keys or in Southeast Florida. Within the Florida Keys, there is no harvest in Key Largo National Marine Sanctuary or in Biscayne National Park, and within the Florida Keys National Marine Sanctuary there are several closed areas where all consumptive harvest is prohibited.

Most fishermen that land octocorals also land other marine life specimens on the same trip, and usually multiple species of octocorals can be harvested on the same dive. Octocoral communities are always associated with hardbottom habitats, and densities vary greatly. Harvest volume is governed by demand and by the amount of holding capacity available on the fishing vessel and at the shore based holding facility.

Bycatch

Because the octocorals are almost exclusively harvested one at a time by divers, there is very little bycatch. On most of shallow water, photosynthetic species, there is no visible bycatch at all on the octocoral itself; on the substrate that surrounds the base there may be an occasional attached macro alga or sponge. Experienced harvesters usually collect octocorals in areas where the target species are abundant and they can quickly and easily remove a specimen without damaging any surrounding benthic communities.

Bycatch is slightly more common on some of the deepwater, non-photosynthetic specimens, very little of which is collected in the federal waters of the Florida Keys (most of the deepwater octocorals are collected off Broward and Palm Beach counties in state waters). Bycatch on these deepwater octocorals usually consists of small brittle stars and basket stars, and the amount and the species composition varies greatly from location to location, from species to species, and from season to season.

All octocorals most likely have communities of tiny, almost microscopic invertebrates living on them that may be specially adapted to live on each of the different species of octocorals. These invertebrates may include different shrimps, amphipods, nudibranchs, and starfish. Some of these organisms are occasionally seen on the specimens in the wild or at the bottom of containers used to transport freshly harvested specimens, but the amount per colony is generally very small. Accurate bycatch species identification and counts can only be done in a laboratory with a dissecting scope, and it is unlikely that this information is available for most of the species harvested by marine life fishermen.

The impact of harvesting octocorals is most likely not discernable. Few fish feed directly on octocorals, octocoral communities are not considered prime habitat for most fish, the selective nature of the harvest has very little impact on the overall community, and because of the rapid growth of octocorals and their short natural lifespan, there is a rapid population replacement cycle in hardbottom habitats.

5.2.6.2 Live Rock Aquaculture

Description of fishing practices, vessels, and gear

The federal live rock aquaculture fishery for the South Atlantic EEZ takes place exclusively in the Florida Keys, mostly due to the narrow continental shelf off Southeast Florida and unsuitable conditions north of there. In the Florida Keys, most of the federal aquaculture sites are in 30 to 50' of water along the outer reef edge.

Federal live rock aquaculture permits are managed by the NOAA Fisheries Southeast regional office in St Petersburg Florida. Applicants must select a suitable site in federal waters, have the site surveyed and approved by a biologist from the Florida Keys National Marine Sanctuary, provide a geologic description of the seed rock to be used, and complete all the necessary paperwork required by NOAA Fisheries. Permitting from start to finish can be accomplished in less than three months if the applicant is well prepared, but most applications take longer to be approved.

Development of an approved site requires lots of hard work both above the water and below the water. Collecting and depositing suitable rock is tedious and must be done by hand. Upland rocks, generally purchased from limestone quarries in South Florida, must be transported to the site by boat and then lowered to the bottom in baskets and placed within the designated site boundaries. The average rock size is about 5 pounds and is somewhere between the size of a soft ball and a football. High quality rocks are irregular in shape and have numerous holes in them. Low quality rocks lack the irregular shape, have few if any holes, and are a denser type of limestone.

Most aquaculturists employ off-season commercial crawfish boats to transport the rock to the site and lower it to the bottom. A medium to large sized trap boat can haul 10,000 pounds of rock, and if the rock site is close to the dock, they can take two or more trips a day to the site. Most of the big rock deposits and underwater stacking activities take place in the late spring, summer, and fall when the commercial boats are available, the weather is consistently favorable, and the water is warm and clear.

To date, all federal sites have been located in sand, so most individuals have opted to lay a foundation of larger, less desirable rocks on the sand, and then build mounds on top of these foundations. Most work is done with SCUBA gear, but some operations use surface supplied air systems which consist of low pressure, high volume air compressors, filters, pressure tanks, and long hoses that have regulators on the ends.

The time required to "grow" a high quality live rock is about two years, but there is a market for one year old "base" rock, and there are maintenance steps that can be taken to produce high quality rock in under two years. The quality of the seed rock used will also have an impact on how soon it can be harvested and what its market value will be, so hand selected seed rocks will have a higher yield than machine sorted seed rocks.

Vessel types for live rock aquaculture depend on the size of the operation and the type of business. Individuals that are selling more than a thousand pounds a week generally operate 25 to 35' vessels ranging from open, center console skiffs, with outboard motors to traditional, closed cabin vessels with inboard diesel engines. Operations of this size usually have crews of two or three people, and use mechanical lifting devices such as davits and hydraulic hoists. Individuals selling less than a thousand pounds a week tend to operate out of boats less than 25', have a crew of just two people, and pull the rock by hand. These small operators also tend to participate in the marine life fishery, and often mix marine life collecting trips with live rock harvesting stops.

After the rock is harvested, it is usually transported submerged in water to a shore based facility where it is stored prior to being shipped out. Most of the rock is shipped by airfreight out of Miami or Ft. Lauderdale FL, but some is transported by truck to wholesalers in Tampa where it is then flown out of the Tampa area airports. A limited amount of rock is also shipped by FedEx, UPS, DHL, and the United States Postal service, and some is even trucked into the southeast U.S.

Economic description of the fishery

According to data collected by the Florida Wildlife Research Institute (FWRI), 36 different license holders reported a total of 3,136,819 pounds of aquacultured live rock harvested from the South Atlantic EEZ from 2002 to 2006. These license holders were not necessarily all different fishermen and not all of them owned their own aquaculture sites.

The landings data show a clear upward trend until 2005, after which landings drop from over a million pounds in 2004 to roughly 370,000 pounds in 2005 and to just over 13,000 pounds in 2006. This precipitous drop was a direct result of two very active hurricane seasons topped off by a disastrous late season hurricane Wilma in October of 2005. Only one Upper Keys live rock site remained in production following hurricane Wilma. Landings are expected to go back up in 2007, but for many, the risks of trying to grow live rock in the exposed offshore waters of the Florida Keys far outweigh the potential benefits.

The ex vessel price for high quality live rock is around $2.00 a pound, but the price can vary from market to market and season to season. There is a considerable amount of price pressure from cheap imports coming from Haiti and Southeast Asia, which has kept the price at or below the $2.00 per pound value for the last 15 years. Aquacultured live rock is generally denser and less porous than imported wild live rock, which detracts from its value. However, aquacultured live rock also tends to have more living organisms on it, which increases its value. Other positive selling points for the aquacultured rock are that it is domestically produced, may contain live stony corals, and it is not harvested from a natural reef.

Social and cultural environment

Live rock aquaculture is primarily a Florida based fishery with state and federal aquaculture sites on both coasts of Florida. Along the East Coast of Florida in the South Atlantic EEZ, all of the aquaculture sites are in the Florida Keys from about Tavernier to Key West. Most of the permit holders are also marine life fishermen, and the live rock is one of many products that they harvest for the marine ornamental trade. Most live rock producers operate small business with less than 5 employees, and most sell their product out of the state to wholesalers and pet shops, or directly to hobbyists. Prior to the active hurricane seasons of 2004 and 2005, there were several companies based outside of the Keys that were almost exclusively dependent on live rock for their income, but after losing everything to multiple hurricanes, they have moved their operations out of the Keys or have gotten out of the business completely. The surviving live rock operations are ones that do not depend on live rock for much more than 20% of their gross income.

Bycatch

Bycatch associated with live rock harvest is varied and often sold as part of the product. Macro algae, sponges, bryozoans, octocorals, and stony corals that attach to the rock are what add value to the rock and determines what type of rock it can be sold as. Not all of these sessile organisms are desirable, so the rocks are sometimes “cleaned” on the bottom or on the boat so that these undesirable organisms are not taken back to the holding facilities.

Another type of bycatch associate with live rock harvest is the numerous crabs, shrimps, snails, worms, and tiny fish that cling to the rocks or hide in the crevices of the rocks. Often times a quick shake on the bottom loosens up a lot of these small fish and invertebrates, but many remain attached to the rock and are brought to the surface. Once on the boat, most producers sort the rock and place it into holding tanks for transport to shore, so the sorting process also releases some of the attached organisms, which are then dumped back overboard. Whatever remains on the rock at this point is taken to shore and ends up in the shore based holding facilities, and some is actually shipped to the buyer still attached to the rock.

All of the bycatch associated with live rock aquaculture is inherently created by this method of harvest. Although there is bycatch associated with this industry, it is a bycatch that is essentially produced in conjunction with the production live rock. In many ways, offshore live rock aquaculture is a type of polyculture, because many different organisms are raised at the same time on the same site. Live rock aquaculture operations are net producers of marine life because whole communities of fish and invertebrates establish themselves around the live rock site and although the harvest operations disturb these communities, they continue to thrive there from year to year.

5.2.7 Sargassum

5.2.7.1 Description of fishing practices, vessels and gear

Only one company, Aqua-10 Laboratories, harvested pelagic *Sargassum* offshore of North Carolina from 1976 to 1997; no harvest has occurred since 1997. A total of approximately 448,000 pounds wet weight of pelagic *Sargassum* has been harvested to date. Pelagic *Sargassum* was originally collected with unweighted shrimp trawls or 3' x 4' and 4' x 8' beam trawls constructed of iron pipe with 1.5 inch and 2 inch mesh bags that were 6'- 8' deep. The average capacity of the beam trawl is 200 pounds of *Sargassum*. Initially, harvest was conducted during the months of June and September by Aqua-10 contracting with a shrimp, snapper grouper, or longline vessel to harvest pelagic *Sargassum* in conjunction with their regular fishing trip. No harvest occurred from 1991 through 1994. The company reinitiated harvest activities in 1995 and had purchased a former snapper grouper vessel to conduct directed trips harvesting pelagic *Sargassum* in the South Atlantic EEZ off North Carolina. The company anticipated growth in demand and projects an increase from an average annual harvest of 1,723 pounds dry weight or 17,230 pounds wet weight, to 50,000 dry weight or 500,000 pounds wet weight annually between 1999 and 2005 to meet demand. The company is no longer in operation and , no harvest has occurred since 1997.

Pelagic *Sargassum* was sun dried, powdered, fermented, and extracted to provide a processed liquid used by Aqua-10 in plant and yield stimulants (soil and foliar), fertilizer concentrate (soil and foliar), poultry feed supplement, and livestock feed supplement.

For a summary of previous harvest activities see, "Commercial harvest of pelagic *Sargassum*: A summary of landings since June 1995 (Settle, 1997)" and a NMFS SEFSC *Sargassum* harvest report - June 13 1996. In addition, reference the thesis prepared by Lawrence Settle (Settle, 1993) titled "Spatial and Temporal Variability in the Distribution and Abundance of Larval and Juvenile Fishes Associated with Pelagic Sargassum".

William E. Campbell, owner of Aqua-10 Laboratories, provided information on the harvest and processing of pelagic *Sargassum* during the informal review and public hearing process which is contained in the Administrative record. Additional comments were provided during the September 1998 Council meeting in Charleston, S.C. and are included in a supplemental comment package compiled for the December 1998 Council meeting. Mr. Campbell gave written permission for his confidential landings data to be used. In his comments to the Council on December 3, 1998, Mr. Campbell indicated he used 4-inch stretched mesh to harvest *Sargassum*.

Allowable gear

Harvest and possession of Sargassum is prohibited south of the latitude line representing the North Carolina/South Carolina border (34º North latitude). All harvest is prohibited within 100 miles of shore between the 34º North latitude line and the line representing the North Carolina/Virginia border. Harvest is limited to the months of November through June. Official observers are required on any harvesting trip. An annual quota of 5,000 pounds landed wet weight. Nets used to harvest Sargassum be constructed of 4" stretch mesh or larger fitted to a frame no larger than 4 x 6 feet.

5.2.8 Dolphin and Wahoo

5.2.8.1 Description of fishing practices, vessels and gear

The fishery for dolphin and wahoo is prosecuted along the Atlantic coast predominately south of Virginia into the Caribbean Sea and the Gulf of Mexico. The fishery is seasonal with catches from the Atlantic occurring mainly between April and September, catches from the Caribbean primarily occurring January through June, and catches in the Gulf of Mexico mainly occurring between May and October (Table 5.2.8-1).

Historically, Atlantic recreational fishermen have landed greater than 90% of the total harvest of dolphin. In 2007, estimates of total catch indicate the commercial fishery harvested 8% of the over 9 million pounds landed. Fishermen harvested 1.96 million pounds of wahoo in 2007 of which 92% were harvested by the recreational fishery, primarily in the private/rental mode.

Commercial fishery

Dolphin

In the Atlantic, commercial fisheries for dolphin consist primarily of longline and hook and line (which includes hand line, troll, rod and reel and electric reel). The hook and line portion of the commercial fishery is conducted similarly to the recreational hook and line segment, which is described under the recreational fisheries section. The longline component of the fishery consists of longliners that primarily target highly migratory species but may also catch dolphin and longliners that target dolphin directly.

Table 5.2.8-1. Summary of locations and approximate seasonality of commercial and/or sport fisheries for dolphin (*Coryphaena hippurus*) within the western central Atlantic (Oxenford 1997). References are found in Oxenford (1997).

In development of the Dolphin Wahoo FMP, NMFS provided the Council with a characterization of the directed commercial longline fishery for dolphin in the Atlantic as consisting of approximately 3 or 4 longline vessels that direct effort on dolphin on a regular basis off the coasts of North and South Carolina and longliners who catch dolphin and wahoo but primarily target highly migratory species, mainly swordfish and shark. In the mid to late 1990s, there was an increase in longline landings of dolphin in the South

Atlantic with the participation of swordfish and shark longliners who have been adapting their gear to simultaneously target dolphin. They also focus more effort on dolphin after shark and swordfish quotas have been met. This increased participation by these other longliners may alter the makeup of this fishery as those vessels that participated in the directed fishery for dolphin withdraw for a variety of reasons. According to reports by NMFS (1995 & 1996), there may be as many as 20 longline vessels that participated in this fishery. With implementation of the FMP, federal dolphin wahoo commercial permits are required and now over 1,196, 11, 452, and 75 permits are held by applicants in Florida, Georgia, North Carolina and South Carolina respectively.

The directed fishery begins the last part of April and continues for about 3 weeks initially off the coast of South Carolina then north to Morehead City, North Carolina where dolphin become more scattered and difficult to catch near the middle of July. Most fishing occurs on either side of the Gulf Stream where eddies spin-off with early concentrations on the western side.

Vessels in the directed longline fishery make sets during the daytime using gear that is from 2 to 6 miles in length. The mainline is often 700 pound monofilament with leaders of 400 pound monofilament. There are ordinarily a total of 75 to 80 hooks per mile with a maximum of 480 hooks total. The standard No. 5 circle hooks that are used for dolphin are smaller than those normally used for conventional longline fishing. Leaders of around 18 inches are also shorter than normal with one hook per leader. No drop lines are used in this fishery and haul back is immediate. Fish are located using hook and line gear along weed lines or temperature breaks. Gear may be set in a circular pattern to facilitate haulback and as many as six sets may be made daily. Trips may average 2 days in length (NMFS, 1995 & 1996).

Longline vessels in the shark and swordfish fisheries target dolphin simultaneously by attaching small leaders to their float buoys. There is usually only one leader per buoy with approximately 100-150 such rigs employed at one time. These dolphin rigs are retrieved at the same time as the main longline which is often set overnight (NMFS, 1995 & 1996).

In addition to longlines primary commercial gear include hand lines and rod and reel (Table 5.2.8.2). The commercial dolphin fishery in New England has fluctuated with average landings for 1984-97 of 10,701 pounds. Average landings over 1994-97 were up slightly to 13,570 pounds then back down to 9,403 over 1997-2000. Commercial landings have increased between 2000-2007 reaching 23,300 with an all time high of 40,140 pounds being landed in 2007 (table 5.2.8-2). In the Mid-Atlantic, landings averaged 70,761 pounds for 1984-97, increased to 131,933 over 1994-97, and then decreased to 82,342 pounds over 1997-2000. The decrease continued through 2000-2007 reaching 45,041 as an average for the period (Table 5.2.8.3). South Atlantic landings averaged 920,870 pounds over 1984-97, increased to 1,428,484 over 1994-97, and then decreased to 1,018,863 pounds over 1997-2000. Between 2000-2007 landings in the South Atlantic averaged 492,557.

South Atlantic commercial landings are shown by state in Table 5.2.8-4. Average landings were highest in Florida followed by North Carolina, South Carolina, and Georgia; however, in 2004 and 2007 landings from North Carolina exceeded Florida. For the most recent time period (2007) landings were 290,811 pounds in Florida, 369,462 pounds in North Carolina, 56,856 pounds South Carolina, and 6,925 pounds in Georgia.

Table 5.2.8-2. Commercial landings of dolphin (pounds) in the Atlantic by primary gear type for 2002-2007 (Data Source: NMFS ALS 2008).

Wahoo

The commercial fishery for wahoo is incidental to fishing for dolphin or other pelagic species. In New England landings while being sporadic, peaked at 16,720 pounds in 1994 and dropped off to 110 and 163 pounds for 1995 and 1996 respectively. Landings for 1997 through 1999 were 75 pounds or less. Landings between 2000-2007 have averaged 222 pounds. In the Mid-Atlantic, annual commercial landings from 1984 through 1997 averaged 1,840 pounds (Table 5.2.8-6). Landings increased to an average of 3,890 pounds in 1994 through 1997 and declined slightly to 3,104 pounds for 1997-2000. In the South Atlantic annual commercial landings ranged from 25,137 pounds in 1984 to 102,277 pounds in 1995. Average landings were 85,264 pounds in 1994-97 and declined slightly to 80,486 pounds in 1997-2000 and between 2001 and 2007, further declined to an average of 45,382 (Table 5.2.8-7).

Recreational fishery

Dolphin

The recreational dolphin fishery in New England has been sporadic with the average landings from 1984-97 at 19,524 pounds to 5,588 in the period 2000-2007 (Table 5.2.8-8). The dolphin fishery in the Mid-Atlantic had average landings of 477,655 pounds for the 1984-97 period. The more recent landings average 61,903 pounds for the time period 2000-2007. Recreational landings of dolphin in the South Atlantic have increased over time but have shown wide fluctuation in catches from year to year; landings for the South Atlantic peaked at just over 12 million pounds in 1995; average landings for 2000-2007 were 8,430,861 pounds (Table 5.2.8-14).

Florida and North Carolina account for the bulk of landings. Average landings in Florida for 1994-97 were 6,398,917 pounds and declined to 4,731,124 pounds for 1997-99. Average landings 2000-2007 were 4,471,990 pounds Table 5.2.8-14). The trend was reversed in North Carolina with average landings increasing from 3,403,370 pounds to 4,243,769 pounds for the same time periods. Average landings remained fairly constant at 3,341,205 for 2000-2007. Average landings increased in South Carolina to 611,475 with a high of 2,268,963 pounds in 2007. Landings in Georgia for these same time periods was fairly constant at almost 6,000 pounds.

Recreational landings by state and mode within the Atlantic are shown in Tables 5.2.8-8 and 5.2.8-12. data through 2007. Recreational landings by state in the Mid-Atlantic are shown in Table 5.2.8-9. Landings have been variable and spread amongst the States of Maryland, New Jersey, New York, and Virginia. Over the 2000-2007 time period, Virginia and Maryland accounted for the majority of landings. Landings from the recreational sector by state and mode within the Atlantic are presented in Table 5.2.8-8 through 5.2.8-10. These tables provide more detail by State but follow the general trends described above.

The overall trend by mode within the New England, Mid-Atlantic and South Atlantic are shown in Tables 5.2.8-8, through 5.2.8-10 and 5.2.8-5; data provided through 2007. In New England (Table 5.2.8-8) private/rental now exceeds charter. Florida (Table 5.2.8-15) the private/rental catch greatly exceeds the charter catch. South Atlantic charter fleet has accounted for more of the recent landings (Table 5.2.8-10).

Wahoo

Wahoo are primarily caught using the same fishing methods as dolphin, i.e., trolling. The recreational fishery for wahoo mainly operates off North Carolina and the east coast of Florida. Annual recreational landings in the South Atlantic ranged from a low of 282,967 pounds in 1990 to a high of 2,470,098 pounds in 1986; landings in 1999 were 1,172,886 pounds and 991,559 in 2000. Average South Atlantic landings for the period 1994-1997 were 866,327 pounds and increased to 992,224 for 1997-2000. More recent information data shows (Table 5.2.8-15). In the Mid-Atlantic, for the period 1994-1997, average landings were 16,239 pounds and increased to 76,433 pounds in the 1997-2000 period (Table 5.2.8-16). In New England there were only landings in 1993 (5,738 pounds) and 1998 (5,355 pounds) (Table 5.2.8-16).

Recreational landings by state and mode (Florida) are shown in Tables 5.2.8-15 through 5.2.8-17. The charterboat sector in North Carolina landed the largest quantity of wahoo for the period 1994-1997, with an average annual landings of 363,386 pounds during this period. Total recreational landings from North Carolina averaged 502,523 pounds for the same time period. Landings from the more recent time period 2000-2007 have increased averaging 587,430 pounds with an all time high of 1,025,379 pounds recorded in 2007 (Table 5.2.8.16). The private/rental sector on Florida's East Coast accounted for the next highest average landings of 204,098 pounds during the period 1994-1997, then the private/rental fleet in North Carolina at 138,906 pounds (Table 5.2.9-16), and the charter fleet on the east coast of Florida averaging 132,349 pounds (Table 5.2.8-16) for the same period. Average annual recreational landings of wahoo for the period 2000-2007 for recreational fishermen in South Carolina were 81,512pounds (Table 5.2.8-16).

Allowable gear

Allowable gear in the Atlantic EEZ: Pelagic longline*, hook and line gear including manual, electric, or hydraulic rod and reels, bandit gear, handline and spearfishing gear (including powerheads).

*Surface and pelagic longline gear for dolphin and wahoo is prohibited within any "time area closure" in the Atlantic EEZ which is closed to the use of pelagic gear for highly migratory pelagic species (HMS).

5.2.8.2 Economic description of the fishery

Commercial fishery

Prior to the 1970s, most dolphin landings occurred in Florida; however, by the mid-70s there were significant landings in other areas within the South Atlantic region. During the late 1970s, landings increased in the northeast from Maine to Virginia (Thompson, 1999). Commercial landings of dolphin increased from 7% of total harvest in 1985 to about 19% by 1996 (Table 5.2.8-18). In 1995, commercial landings in the Atlantic exceeded 2.2 million pounds. This sector's landings exceeded one million pounds in 1989, and doubled in 1995. During the period 1997 to 1999 the proportion of commercial landings have dropped to around 11% of the total harvested in the Atlantic. The commercial harvest between 2000 and 2007 has ranged from 5% in 2001 and 10% in 2004 of the total Atlantic harvest. Recreational harvest has conversely run between 95% in 2001 to 90% in 2004.

Dolphin are caught off North and South Carolina mainly from May through July. Off Florida's east coast the main season occurs between April and June (Thompson, 1999).

Ex-vessel value of dolphin captured in the Atlantic between 2000 and 2007 are presented in Tables 5.2.8-19 through 5.2.8-23. Based on information from fishermen, the bulk of this recreational sale can be attributed to the for-hire sector.

Price Fluctuations in the Dolphin Fishery

Dolphin prices are similar to that of king mackerel. Even though landings increased significantly during the early and mid 1980s, real prices continued to increase. This trend continued until 1989 when landings doubled from the previous year and prices declined. In the 1990s price reached an all time high in 1994 despite the increase in landings during this period. Rhodes (1998) speculated that this phenomenon was the result of unmet demand for other seafood products that could be substituted with dolphin products such as mahi-mahi steaks. This increasing price trend did not continue when landings reached 2.6 million pounds in 1995. Prices declined in 1995 reaching a seven year low in 1997. Rhodes (1998) also analyzed monthly price data and surmised that in the South Atlantic region, prices are at their lowest in the first half of the year, usually May to June.

It is difficult to determine what factors are responsible for the decrease in price in the years following 1995. Part of this effect may be due to increased landings that peaked in 1995 at 2.57 million pounds. Also, imports may have played a role in this price decline, however import data on dolphin are only available from 1997. Furthermore, The Fisheries Statistics & Economics Division of the National Marine Fisheries Service (NMFS) report only imports of frozen dolphin fillets. A total of 15.75 million pounds of frozen dolphin fillets were imported at a value of $20.23 million dollars in 1997. In 1998 imports were 16.72 million pounds at a value of $23.95 million dollars. However, these figures may be underestimates of dolphin imports. Information from seafood distributors indicate that fresh, de-headed, and gutted dolphin, as well as other product forms, are also imported by U.S. buyers (Rhodes, 1998). Given the lack of historical and complete import data it is difficult to speculate on the influence of imports on domestic prices. A survey of U.S. buyers to collect data on all dolphin product forms imported into the U.S. by country of origin, time of year, and port of entry will provide some of the necessary information for market analysis.

Price Fluctuations in the Wahoo Fishery

In the United States fisheries for wahoo exist off North and South Carolina, primarily from April to September and off Florida's East Coast. The National Marine Fisheries Service first recorded landings of wahoo in the commercial catch in 1974 when they amounted to 1,000 pounds caught primarily off Florida. Landings during the period 1987 to 1993 ranged between 160,000 to 370,000 pounds (Vondruska, 1999). Recently Louisiana has landed the most. In fact in 1997 more than 50% of total wahoo commercial landings came from Louisiana (Vondruska, 1999). Price per pound was less than $1.00 until 1985. During the period from 1985 to 1994 real price fluctuated but remained below $1.23 per pound. From 1995 to 1997 the price per pound increased above $1.30 per pound.

Recreational fishery

The preceding section provides a detailed account of the historical recreational catch of dolphin in the Atlantic by mode of fishing. In summary, the total 1999 recreational harvest accounted for 91% (10,127,970 pounds total recreational harvest and 1,050,090 pounds commercial harvest) of the total U.S. harvest in 1999. Most of this recreational activity occurs in the summer months, and charter boat and private boat modes take the majority of the recreational catch of this species.

The size distribution of the catch from the recreational sector differs depending on the mode of fishing (Goodyear, 1999). Headboats harvest smaller fish compared to the other two modes. Just over 55% of the headboat catch are fish below 22 inches (550 mm) fork length. For the most part, the size distribution of fish harvested by private/rental boats and party/charter boats are fairly similar for both groups (Goodyear, 1999). Both size of fish caught and catch success rates are important determinants of the quality of the recreational experience, and thus the value of these recreational trips.

Information on the value of the dolphin recreational fishery in the Atlantic is not yet available. Apart from the economic value (consumer surplus) anglers derive from the resource, they generate significant economic impact through expenditures for recreational fishing which are important to coastal communities in the Atlantic. Data on economic impact of recreational fishing for dolphin are not available.

Like dolphin, the recreational landings of wahoo account for a larger proportion of the total harvest in the Gulf and Atlantic. In 1999 the total commercial harvest amounted to 99,159 pounds, compared to 1.41 million pounds harvested by recreational anglers. Information on the value of the wahoo recreational fishery and data on economic impact of recreational fishing for wahoo are not available.

The charterboat sector in the South Atlantic and the Gulf of Mexico depend on dolphin as one of the main attractions for their clientele. Available data indicates that this species is less important to the headboat sector (Holland et al., 1999). Of all charterboat owners surveyed as part of a study to document the characteristics and economics of the for-hire sector in the State of Florida, 26% target dolphin. This species was much more important to the charter fleet operating in the Florida Keys and Florida's Atlantic Coast. Results from this study also revealed that 53% of charterboats in North Carolina and 60% of charterboats in South Carolina target dolphin (Holland et. al., 1999).

In their study Holland et al. (1999) measured capital investment, average annual expenses, and average revenue in the for-hire sector. A summary of this data is contained in Table 5.2.8-24. On average it appears that investment in equipment is much higher in Florida compared to the rest of the South Atlantic.

In terms of fixed costs, it is unclear as to whether these expenditures were apportioned to charters and other revenue earning activities for the vessel. Some charterboats are full-time operations while others may only operate charters on a seasonal basis and could be commercial harvesters for part of the fishing year. For part-time operations the total annual fixed costs can be attributed to several activities including commercial fishing.

Table 5.2.8-24. Summary of Capital Investment, Average Annual Expenses, and Average Annual Revenue on Charterboats. Data on Florida includes information for the entire State of Florida (Source: Holland et. al., 1999).

Item	Florida	North Carolina	South Carolina	Georgia	Average for NC, SC, GA
Average Capital Investment:					
Hull and Superstructure	$90,989				$39,445
Engine	$40,518				$14,586
Electronics	$5,568				$5,900
Other Equipment and Tackle	$5,878				$4,463
Average Annual Expenditures					
Wages and Salaries	$25,810				$17,298
Fuel and Oil	$8,224				$7,575
Engine	$6,334				$2,738
Maintenance and Repair	$5,720				$4,991
Docking Fees	$4,604				
Hull and Superstructure	$3,020				
Insurance	$2,970				
Other Equipment and Tackle	$2,404				
Advertising	$2,041				
Average Total Exp.	**$68,574**	**$46,888**	**$23,235**	**$41,688**	
Average Annual Revenue	**$68,816**	**$60,135**	**$26,304**	**$56,851**	

Crew wages may be underestimates in that they do not reflect the "tips" left by customers. Out of state anglers typically give the fish they catch to the crew members on these charter vessels in lieu of a tip. Crew members, and sometimes vessel owners, sell these fish. The frequency of this practice varies by state within the South Atlantic region and may be more common in Georgia and the Florida Keys. Income derived from bag limit caught fish is not reflected in these revenue estimates or crew salaries. As a result it could be misleading to use this information to determine profitability of the charterboat fleet in each state under current operating procedures. However, these data provide a first step in describing the economic characteristics of this sector.

5.2.8.3 Social and cultural environment

There are little data available that are directly applicable to dolphin and wahoo recreational and commercial fishing communities in the U.S. Atlantic. The data that are available are only partial for some communities and then, in many cases, only some sectors in those communities (commercial, charter, and/or recreational). Until complete and comparative social research is carried out in these regions, the following overview must be considered the best available data on the social characteristics of these fishing communities.

However, the community profiles that are included in Section should be viewed as representative of fishing communities throughout the various geographic regions of the dolphin wahoo fishery. All of the communities profiled count dolphin and wahoo as a fishery that is exploited at least for a portion of the year and at least among one or more user groups. This lack of complete data should not be seen as necessarily detrimental to the analysis of possible social impacts accruing from this proposed fishery management plan. Rather, the data that are available allows for reasonable predictions of social outcomes due to management measures. What social impacts that occur in one community can then be reasonably expected to occur in other communities that are either somewhat larger or smaller, older or less historical, and with somewhat different demographic, cultural, and economic mixes. This is stated as an acceptable procedure in the CFR Sec.1502.22 when one must proceed with less than complete data.

5.2.8.4 Bycatch

Observer data and vessel logbooks indicate that pelagic longline fishing for Atlantic swordfish and tunas results in catch of non-target finfish species such as bluefin tuna, billfish, and undersized swordfish, and of protected species, including threatened and endangered sea turtles. Also, this fishing gear incidentally hooks marine mammals and sea birds during tuna and swordfish operations. The bycatch of animals that are hooked but not retained due to economic or regulatory factors contributes to overall fishing mortality. Such bycatch mortality may significantly impair rebuilding of overfished finfish stocks or the recovery of protected species. Atlantic blue marlin, white marlin, sailfish, bluefin tuna, and swordfish are overfished. The concurrent closure in this FMP was deemed necessary by NMFS to reduce bycatch and incidental catch of overfished and protected species by pelagic longline fishermen who target highly migratory pelagic species (HMS).

Appendix C of the Final Supplemental Environmental Impact Statement (FSEIS) for HMS Regulatory Amendment 1 contains data on dolphin-wahoo pelagic longline fishery analysis. The data presented on page C-66 and in Table C-4 indicate that pelagic longlines targeting dolphin do in fact result in a bycatch of HMS species.

Implementation of regulations in the SAFMC's 2003 Dolphin Wahoo FMP addressed the Magnuson-Stevens Act requirements to reduce bycatch and the mortality of bycatch. Additional detailed data on bycatch in the directed dolphin/wahoo fisheries will be provided through full implementation of ACCSP (which includes observer coverage).

5.2.9 Calico Scallop

5.2.9.1 Description of fishing practices, vessels and gear

Commercial Fishery

The commercial fishery for calico scallops has developed slowly and catches have fluctuated widely in all areas where commercial concentrations have been located. This is usually attributed to a combination of factors: yearly variations in the location and productivity of beds and problems of economically sorting, shucking, and eviscerating scallops because of their shape and small size.

Lack of knowledge by industry and resource agencies on the distribution and abundance of the calico scallop resource is one reason for the slow development of a commercial fishery until the late 1950s. Calico scallops had been taken by trawl fishermen sporadically since 1949, but no directed fishery developed from these early observations. Part of the slow development of the fishery was because trawlers were primarily equipped for shrimp fishing in different areas and depths and part was because of the absence of an established market for calico scallops.

Exploratory fishing by private organizations from 1954 to 1958 located concentrations of calico scallops in the northeastern Gulf of Mexico in the general area of Cape San Blas, Florida (Bullis and Ingle 1959; Carpenter 1967). Exploratory fishing by the Bureau of Commercial Fisheries from 1957 to 1960 revealed extensive beds of scallops in 19 to 46 m (62.3 to 150.9 ft) between Carrabelle, Florida, and Mobile, Alabama.

Beginning in March 1958, a large bed of scallops in 13 to 37 m (42.7 to 121.4 ft) northwest of Cape San Blas was fished commercially, at first using shrimp trawls and later with four-foot wide dredges (Bullis and Ingle 1959). The catch was shucked by hand and during the spring and summer of 1958, four boats produced 1,200 to 2,000 gallons of shucked meats per week. By September 1958, the yield of meat per scallop had declined to the point that fishing was no longer profitable.

Between 1959 and 1975, the commercial fishery for calico scallops in the northeastern Gulf of Mexico operated sporadically. Over this 16-year period, maximum production of approximately 16,000 pounds of shucked meats (adductor muscles) occurred in 1962 and again in 1969. In 1975, landings increased significantly and peak production in this area occurred in 1976 when 1.8 million pounds of meat valued at approximately $1.2 million was produced by the 54 vessels operating in the fishery.

In 1959, calico scallops were discovered near Cape Lookout, North Carolina, by exploratory vessels of the Bureau of Commercial Fisheries (Cummins 1971). This discovery stimulated development of a commercial fishery off Carteret County which continued sporadically to 1973. The principal scallop grounds have been located northeast and southwest of Cape Lookout in 19 to 31 m (62.3 to 101.7 ft). Commercial production of calico scallops from North Carolina waters has fluctuated widely since 1959 when three boats produced 6,500 pounds of meat valued at $2,600 (computed as ex-vessel or dockside price of meats). Peak landings occurred in 1966 when 20 vessels operating in the fishery produced 1.86 million pounds of meat valued at $369,000.

As had been the case in 1962, 1963, and 1964, scallop production from the North Carolina grounds did not exist in 1968 and 1969. While the fishery resumed again in 1970, production was below 1966 levels and from 1974 to 1978, no production came from this area. In 1979 a productive bed was again located; harvesting occurred in 1979 and 1981.

In January 1960, large quantities of calico scallops were discovered off Daytona Beach, Florida, by the Bureau of Commercial Fisheries (Taylor 1967). Further explorations conducted by the Bureau from 1960 to 1968 defined a 3,108 square kilometer (1,200 square mile) scallop bed lying in 19 to 74 m (62.3 to 242.8 ft) of water from the St. Johns River south to Ft. Pierce (Cummins 1971). Publication of these observations also stimulated development of a commercial fishery in this area which is referred to as the Cape Canaveral beds.

Since 1973 trawls have been the only gear employed in the fishery. Commercial production has generally increased since 1967 when four shrimp-type scallop vessels produced approximately 21,000 pounds of meat from the Cape Canaveral beds. In 1975, production of approximately 1.4 million pounds of meat valued at $900,000 was produced by 13 vessels trawling on the Cape Canaveral grounds. In October 1980, harvesting began on a new viable bed located about 8.1 to 9.7 km (5 to 6 mi) offshore of New Smyrna at a depth of approximately 20 m (66 ft). However, mass mortality of this bed caused fishing to cease by January 1981, and the fishery moved to other productive beds located in the Cape Canaveral area. Peak production occurred in 1984 when approximately 43 million pounds of meat valued at $23.5 million were produced by about 75-150 vessels trawling on the Cape Canaveral grounds.

South Carolina's first commercial scallop bed (Anderson and Lacey 1979) was located in June of 1977 approximately 97 km (60 mi) offshore of the South Carolina-Georgia border. In early January of 1978, seven scallop trawlers moved up from Florida and began harvesting scallops from the South Carolina beds in depths of 37 to 45 m (121 to 148 ft). By March of 1978, approximately 45 major vessels from Florida, North Carolina, Georgia, and South Carolina were actively involved in this fishery. Numerous other fishermen, particularly shrimpers, entered the fishery toward the end of the harvest, attracted by the size and quality of the beds. A total of 611,000 pounds of meat valued at $803,000 were harvested during 1978. Commercial activity continued through mid-May until production was drastically reduced due to meat size reductions during spawning. In the fall of 1981, another bed of scallops was located off South Carolina.

Three boats landed over a thousand bushels in two days during January 1982. Scallop explorations have historically been very limited offshore of Georgia, although small numbers of calico scallops have occasionally been found by shrimp trawlers and during research cruises. During 1979, large amounts of calico scallops were harvested off Key West adjacent to the Dry Tortugas shrimp grounds, shifting some activity from the Cape Canaveral beds.

Participating User Groups

The domestic fishery for calico scallops is entirely commercial. Natural fluctuations in the abundance of the resource have precluded development of a long-term, directed fishery for calico scallops in many areas where concentrations have been located. Consequently, much of the commercial production has been by shrimp fishermen who have fished for scallops, when they are available, as an alternative to shrimp fishing during poor seasons or as means of supplementing their income during the off season. (R. Cummins, Fishery Management, NMFS, S.E. Center, Charleston, S.C.; pers. comm.) has estimated that between 40-50 shrimp vessels engaged in the calico scallop fishery on a part-time basis in the early 1980s.

An exception to this is off the east coast of Florida where, due to the large size of the Cape Canaveral beds, commercial production has occurred fairly consistently since 1967. In this area, up to 10 factory-type vessels, which were specially equipped for processing calico scallops, have been engaged in the fishery intermittently since 1969. During 1980, one factory-type vessel was fishing in the area and plans were made for two more to enter the fishery in the spring of 1982. Currently there are no at-sea processing vessels in the fishery.

During 1980 and 1981, the number of vessels harvesting scallops increased to between 75 and 150. These numbers included 15 processor owned shrimp vessels which had been rigged for use in the calico scallop fishery out of Cape Canaveral. As of this writing, there were no vessels operating in the fishery.

The fishery is unusual because most boats fish for only about 12 hours per trip, and are usually away from the dock no more than 24 hours. The entire catch remains on deck unsorted. On-shore the catch is culled; shell, shell fragments, and other by-catch are removed. The clean shell stock can then be processed with very little human contact using shakers, steam, rollers (evicerators), chillers, and packaging equipment. Fresh meat can thus reach the market within 24-48 hrs of harvest (Blake and Moyer 1991). This type of fishery has been labeled a Type I processor (Anonymous 1998). In this type of processing all by-catch and waste is buried in landfills. A Type II processor culls, shucks, and packages the entire harvest at-sea, and can thus remain on the fishing ground for extended periods. Type II fishers also return all bycatch and waste to the sea.

Most of the harvest has been conducted by modified shrimp trawlers. At the peak of the fishery, about 70 vessels and 7 processing plants were active (Rockwood and Pompe 1988). North Carolina's fishing fleet peaked at around 20 vessels, and during one brief period, a fleet of about 45 vessels harvested along the South Carolina-Georgia border (Anonymous 1981). In each case, most of the vessels are shrimp boats that convert their gear for scallop harvest when the stock becomes plentiful and resources are put in place to process the catch on-shore. At present, no vessels are harvesting calico scallops, and none of the processing plants remain in operation. The most common point for landing calico scallops, Port Canaveral, Florida, has increasingly converted dock space previously used for commercial fishing to tourist related industries - marinas and cruise ship terminals.

Vessels and Gear

Three basic types of vessels have been used in the calico scallop fishery. They, in turn, have used three types of gear with some interchange of gear between vessel types. These are shrimp trawlers, scallop vessels designed for use in the sea scallop fishery, and specialized calico scallop vessels with processing equipment aboard. The first two vessel types have basically sought to land shellstock (i.e., intact scallops including shell, viscera, and edible adductor muscle meat after sorting from debris) for processing ashore. The specialized calico scallop vessels are designed to produce scallop meats with the shucking and evisceration done at sea.

Almost all of the calico scallops harvested commercially in recent years have been taken by shrimp vessels using modified otter trawls. These offshore shrimp trawlers have wood, aluminum, steel or fiberglass hulls and generally range from 15.2 to 25.9 m (50 to 85 ft) in length. Many of the newer, larger offshore vessels (22.9-27.4 m; 75-90 ft in length) are double-rigged for towing two nets simultaneously. Typically, the vessels are diesel-powered with pronounced variations between length and horsepower in single and double-rigged vessels. Generally, the vessels in the 15.2-21.3 m (50-70 ft) class are powered by 100-200 horsepower diesels. A large portion of the vessels are equipped with electronic navigational and fish finding aids. Cost of vessels depends upon size, date of purchase, and amount of equipment on board.

Calico scallop landings by vessel size category from 1994, 1995, and 1997 were provided by Martha Norris, FL FWC (Table 5.2.9-1); there were no landings in 1996. Data were provided for vessels less than 50 feet, 50-59.9 feet, 60-69.9 feet, 70-79.9 feet, and 80-89.9 feet. In order to not show confidential data, landings were combined into the two vessel size categories shown in Table 5.2.10-1. The "Unknown" category includes landings by Florida Salt Water Products Licenses (SPLs) with no associated vessel information. Vessels in the 70-89.9 foot category harvested approximately half of calico scallops landed between 1994 and 1997. In 1994 there were two vessels under 50 feet, one in 1995, and none in 1997. In fact the smallest vessels harvesting calico scallops during 1997 were in the 60-69.9 foot category.

Table 5.2.9-1. Calico Scallop Landings by Vessel Size Category. Source: Martha Norris, Department of Environmental Protection, Florida Marine Research Institute, Division of Marine Resources. July 29, 1998. Note: Pounds are in meat weight.

<u>Trawls</u>

Scallops were first caught with sea scallop dredges. During the early exploratory phase of this fishery, 1950s to early 1970s, the main gear was a 6-8 foot “tumbler” dredge - a heavy frame with a net made of 2" steel rings. This dredge could be fished with either side up (Cummins 1971). Dredges began to be replaced (in 1966) with scallop trawls. Despite higher maintenance and repair costs, trawls proved to be a more efficient means of harvest (Cummins 1971). Beginning about 1973, all harvest was conducted with modified shrimp otter trawls (Anonymous 1998). The otter trawl used in the shrimp fishery basically consists of: 1) a cone-shaped bag in which the shrimp catch is gathered in the tail or codend, and 2) trawl doors or otter boards at the extreme end of each wing for holding the wings apart and the mouth of the net open. The trawl doors are attached to the net by top and bottom leg lines on each wing of the trawl.

The following description of a scallop trawl is from Rivers (1962). The otter trawl net commonly employed in the calico scallop fishery is similar to the two-seam, semi-balloon design used in the shrimp fishery with modifications to maximize contact with the substrate while minimizing damage to the net’s webbing. Unlike the otter trawl nets used in the shrimp fishery, the scallop trawl net was designed so that it fishes with either side down, i.e., there is no overhang, and top and bottom sections are identical. This feature increases the longevity of the equipment in that when the original bottom section becomes worn, the trawl may be turned over so that the relatively unworn top becomes the new bottom. The 7.6 to 10.7 m (25 to 35 ft) scallop trawl nets are fitted with a “Texas drop chain” on the footrope and one to three “tickler chains.” The latter chains are stretched across the mouth of the trawl and attached near the trailing bottom corner of each door. The Texas chain, similar to that used on shrimp trawl nets, consists of a length of chain cut one foot shorter than the length of the leadline and fastened to it at regular intervals by 2, 4, or 6-link chain drops. The extra “tickler” chains used on the scallop trawl are designed to increase the scraping and digging action of the trawl.
The belly sections of the scallop trawl are short so that the amount of webbing exposed to wear is as small as possible. Both the nets belly and the tail-bag are reinforced with heavy chafing gear of polyethylene strands or automobile inner-tube strips in order to decrease the shearing and abrasive effects of the calico scallops on the nets. For added protection, a false belly of heavy webbing is often laced over the bottom belly of the

trawl. In addition, the leg lines between the doors and net wings are relatively short in order to facilitate the funneling effect of the doors. The complete scallop rig (boards, trawl, and accessories) is fished from a single cable that is connected to the boards by a 18.3 m (60 ft) bridle of 9.52 mm (3/8-in) wire rope.

The trawl is usually set and dragged from outrigger booms in the familiar shrimp-boat fashion. Owing to its light weight and small size, the trawl is easily handled. At the end of a drag, the splitting strap is brought to the rail of the boat and hooked to the hoisting tackle. The codend is brought aboard, and the catch dumped on deck. The trawl is then reset. Any scallops that might be in the webbing above the splitting-strap beckets are left in the net until the end of the next drag, or are allowed to spill back into the water. The time that would be consumed in making a second lift of the net to shake the scallops down into the codend and bring them aboard is used more profitably in making an additional drag. By limiting drags to 15-30 minutes or less, the catches usually fit well within the codend, and little loss is experienced.

Dredges

Dredges landed significant amounts of calico scallops from Florida beds between 1968 and 1972. While some of the vessels which have employed this gear include New England sea scallopers using 10-foot Georges Bank-type scallop dredges, most of the vessels were shrimp trawlers using scallop trawls and experimenting with tumbler dredges. A typical calico scallop dredge consists essentially of a rectangular frame measuring approximately 2.4 m wide by 0.46 m high (8 ft by 1.5 ft). The bag is made up of 50.8 mm (2 in) inside diameter rings held together with dredge links and attached to the rectangular frame. The dredge is towed on three flexible bridles (of chain or wire rope) attached at each end and center of the frame. This feature allows the dredge to “roll over” obstructions which would otherwise damage a trawl (Bullis and Cummins, 1961; Rivers, 1962). Dredges are no longer used in the fishery.

Assessment and Specifications of U.S. Harvesting Capacity

U.S. harvesting capacity is largely determined by the location and availability of scallops which vary constantly. For example, if scallops are located near a suitable port for short vessel runs to and from the grounds during cold weather periods, the shellstock would be landed and trucked to all available processing machinery presently located from North Carolina to the Florida west coast. Another example is when scallops are located many miles from the nearest suitable port during warm weather. Because shellstock is normally transported on deck, operations must be conducted at night in order to preserve quality; actual fishing time is reduced by vessel running time to port. Still another example is when scallops are located near a port such as Key West where weather is warm all year and trucks are weight limited to 36,000 pounds over the Keys bridges, thus increasing freight cost and at the same time causing a reduction in the amount of sellable finished product.

During the 1990s, some 40 to 50 vessels were involved sporadically on a part-time basis, the number depending upon conditions in the shrimp industry. About 25 vessels worked the scallop beds on a full-time basis, which includes time spent in locating new scallop beds. During late 1981 and early 1982, the number of vessels fishing the Cape Canaveral grounds varied from 75 to 150. Some processors in North Carolina and Florida offered a sizable reward to shrimpers who located a commercial size bed of scallops.

Scallop production and meat yield is so variable that the only meaningful measure is the pounds of finished product (edible meats) produced. Double-rigged shrimp-type vessels typically make four or five single-day trips per week, weather permitting. Drags are normally of short duration (10 minutes or less). Vessels are paid on a yield basis (i.e., on the amount of meats processed from landed shellstock) which reportedly ranges from two pounds to as much as six pounds per bushel. When large amounts of “trash” (old, broken, or empty shells) are encountered the yield is much lower. At the height of the fishery in the 1980s, most of the fishermen would process the entire catch dockside. No culling of the catch occurred at sea, meaning all bycatch had to be disposed of in landfills, in addition to any shell and viscera from the harvested scallops. For a time, processors were grading according to size (meat count) with larger meats commanding high prices. It was possible for a good shellstock vessel to produce several hundred 8-pound gallons per day. When scallops are found in abundance, harvesting capacity in the U.S. has been greater than processing capacity to date. The introduction of several new processing lines in 1981 (North Carolina and Florida) brought processing capacity equal to or greater than harvesting capacity. Since 2000, the loss of processing capacity has created a situation where the ability to harvest, through conversion of shrimp boats, could readily exceed the processing capacity, which is probably near zero as of 2006.

Assessment and Specifications of U. S. Processing Capacity

In 1978 there were some 16 scallop processing lines located in the southeastern U.S. and in 1979 and 1980 more were being built. However, much of the older equipment is outdated and some is not in operational condition. In 1980, two at-sea processing vessels were being outfitted with one or more processing lines. With the most effective updated shore-based processing equipment, steam is utilized in lieu of hot water for shucking. Some equipment is capable of sustained production rates well in excess of 100 gallons of meats per hour depending upon the size and condition of the meats and the amount of barnacle encrustation on the shells. Patent rights are held on most of the processing equipment and there was patent infringement litigation on a continuing basis during the 1980s. When large increases in scallop abundance occur, temporarily processing capacity is less than available shellstock. Currently, there is no active fishing, and no known processing plants for calico scallops.

The development of machine processing greatly changed the amount of effort required to process stock in relation to harvest effort. This has been referred to as the Processing/Harvesting Ratio (PHR) (Maiolo 1982). The PHR is based on Paredes et al. (1976). Prior to machine processing, hand shuckers were reluctant to process calicos because of the size which limited financial remuneration. When they did hand shuck, it is estimated that it took 13 units of effort to process stock that took one unit of effort to harvest. This ratio was reversed to 1:5, or one unit of effort to process what it took five to produce (the estimates were made in terms of hours) (Maiolo 1982). Presumably, this type of mechanized processing could be rebuilt, but significant capital would likely be needed.

Processing

Early in 1969 four factory-type processing vessels were engaged in the calico scallop fishery off Cape Canaveral, Florida. Two of these vessels, owned by a single firm, were steel hulled, and 26.2 m (86 ft) in length. They were powered by 335 horsepower diesels and had a cruising speed of ten knots. These vessels, and two similar ones, were equipped with culling, shucking, and eviscerating equipment capable of processing the catch as it was brought aboard by trawl or dredge (for a complete description of this on-board processing equipment see Cummins and Rivers 1970.) The processing time from culler to "ready for packing" required about 6 to 7 minutes. Three of the four vessels were "ice boats" which landed processed scallop meats in 10-pound containers packed in ice.

The seagoing processing machines were removed from these vessels after a few years and the reasons given are varied: the machine made the vessel unstable, the machinery was not designed for shipboard use in rough seas, and problems in maintaining constant hot water and steady temperatures (96°C; 205°F) necessary in the shucking procedure.

One processing vessel engaged in the calico scallop fishery persisted until 2003. This vessel was owned by Mr. William H. Burkhardt who served on the Council's Calico Scallop Advisory Panel. Mr. Burkhardt provided a detailed description and diagrams of the separation and evisceration process (Anonymous 1998). Mr. Burkhardt reported that "when scallops are harvested from a typical bed, shell percentages can vary from approximately 90/10 to 10/90. On the average one half of shell stock is unwanted old dead shell. The other half becomes clean new shell once the meats are removed in steam process." Mr. Burkhardt designed the adjustable separator to do the following: "(A) Select the targeted scallop size. Adjust to varying shell size/meat size with a simple mechanical adjustment. (B) Immediately return to the sea alive, small scallops under the targeted size, attached spat and other species bycatch. Research has shown that most will live if quickly returned to the sea. (C) Separate the clean scallops and immediately discharge overboard the mud, shell and bycatch." In Mr. Burkhardt's opinion, at-sea processing has the following advantages: "1. Reduces weight improving vessel safety. 2. Improves product quality by removing bacteria in the washing process. 3. Reduces or eliminates same species and other species bycatch. 4. Return shell to the original bed."

Recreational Fishery

There is no recreational fishery for the calico scallop due to the depth of water where calico scallops occur and the gear necessary to harvest calico scallops.

Allowable gear

Calico scallops may be harvested commercially in the EEZ using trawl and dredge. Hand harvest is the only allowable means to harvest calico scallops recreationally.

5.2.9.2 Economic description of the fishery

The best economic analysis of the calico scallop fishery was produced by Rockwood and Pompe (1988) and pertained only to the Brevard County harvest - most of the scallops harvested from the Cape Canaveral beds. This report was produced just after the peak fishing years of 1984-1987. The authors estimated that the industry should be able to support 500 jobs and generate 77.6 million dollars (in 1988) of total economic output for the region. The total local expenditures were around $2 for every pound of meat harvested. Total employment (fishing and related support industries) ranged from 278 to 2616 jobs over a four year period. This translates into about 1 job for every 5500 pounds of meat harvested. Expenses ranged 28 - 43% for vessel operations, 35 - 60 % for processing, and 11 - 21% for office and overhead. Total labor accounted for about 35% of expenses. At that time fuel was a very minor expense, 0.6 - 2.5% of total expenses. The increased costs of diesel fuel would certainly need to be reanalyzed. Anecdotal reports from fishers indicate that when the price of one gallon of diesel surpasses the value of one pound of scallops, the fishery is no longer profitable.

5.2.9.3 Social and cultural environment

Employment

Employment in the harvesting sector of the calico scallop fishery depends, to a large extent, on the distribution/abundance of the resource which fluctuates widely on a year-to-year basis.

Since 1970, the number of fishermen employed on vessels which have participated in the scallop fishery has ranged from 32 (in 1974) to 350-450 (in 1981) over the region as a whole, including the mid-Atlantic and New England areas. The industry peaked in the early 1980s at 2,616 jobs. For many, if not most, of these fishermen, scalloping is a part-time and/or seasonal activity which provides a means of supplementing the income they derive from other fisheries. However, with the discovery of new beds, and the opening of new processing lines, the proportion of total income derived from calico scalloping has increased significantly. For many fishermen, during 1981, income obtained from fishing for scallops represented as much as 75 percent of the total for the year. As of 2005 there were no active calico scallop fishermen.

Machine processing has generated a sizable increase in the number of laborers in the processing houses. As of December 1981, the number was estimated to be over 200 people working nearly full time at an average of $5 per hour. Previously only a portion of total income had been derived from scalloping. During 1981, however, especially in North Carolina where shrimping was poor, a greater proportion of income was derived from processing calico scallops. In regard to total wages for processing all types of shellfish and finfish, calico scallop processing shifted from playing a minor role to one which is fairly significant, and back to non-existent by 2004.

Fishing and Landing Areas

Concentrations of calico scallops and principal fishing areas are located off North Carolina, northeast and southwest of Cape Lookout; off the east coast of Florida from Ft. Pierce northward to the St. Johns River; and in the northeastern Gulf of Mexico between

Carrabelle, Florida and Mobile, Alabama (Cummins 1971). It should be noted that the location and productivity of beds within these three principal fishing grounds fluctuate annually and, to a lesser extent seasonally, and consequently, so does the distribution of fishing effort both within these areas and over the region.

In addition to the three traditional fishing areas identified above, some commercial scalloping activity has occurred offshore of Tampa and Key West, Florida, and offshore of the South Carolina/Georgia border.

Calico scallops are generally landed at ports where suitable shore-based processing facilities are located or at ports in reasonably close proximity to fishing grounds where the scallops can be quickly unloaded and transported to processing facilities. Basically, landing ports are chosen for having four criteria: 1) a sufficient depth of water on all tides, 2) a strong dock for offloading with turning space for tractor trailers, 3) adequate fuel facilities, and 4) processing plants to handle the scallops. Ports within the management area where scallops have been landed are listed below.

North Carolina:
Beaufort/Morehead City
Sneads Ferry

South Carolina:
Georgetown
McClellanville
Mt. Pleasant

Georgia:
Brunswick
Darien
Savannah

Florida:
Apalachicola
Carrabelle
Ft. Myers
Ft. Pierce
Key West
Mayport
Port Canaveral
Port St. Joe
St. Augustine
Tampa
St. Marys

Increasingly, available dock space has been converted to uses other than commercial fisheries. In Port Canaveral, FL, the primary use has become the cruise ship industry. In other areas of Florida, such as Apalachicola, seafood processing houses have been bought out and the real estate converted for use in luxury, waterfront condominiums.

Conflicts among Domestic Fishermen

The calico scallop fishery of the South Atlantic and Gulf coast has been free of competition from foreign fleets and sport fishermen. However, during late 1981, the number of boats and vessels fishing the Cape Canaveral grounds increased dramatically. Estimates of the number of boats and vessels vary from 75 to 150. In addition, these boats and vessels hailed from home ports along the Gulf of Mexico and the entire East Coast of the U.S. This large increase in number of boats and vessels, combined with the diverse makeup of the new entrants, resulted in stress and controversy. Competition became intense leading to near collisions, fishing in areas with large concentrations of small scallops, and fishing in areas with parasite infested scallops. Recriminations among fishermen and processors became common. During the 1990s, the number of vessels in the fishery was reported to be around 25 (Calico Scallop Advisory Panel and Scoping Meetings). By 2005, there were no active calico scallop vessels in either North Carolina or Florida.

5.2.9.4 Bycatch

In the 1980s, the State of Florida commissioned a study of the bycatch associated with the calico scallop fishery (Nelson 1992). The findings indicate a similar composition to the community structure found in earlier studied in the State of North Carolina (Stephan 1989). Most of the bycatch was not composed of commercial or recreationally valuable species. The most common fishes were small flounders (family Bothidae), blue spotted searobin (*Prionotus roseus*), and scorpionfishes (Family Scorpaenidae). Other common fauna were Portunid crabs and echinoderms. In current studies, common associated fauna include imperial venus (*Chione latilirata*), sea stars of the genus *Astropecten*, Venus clams, and gastropods (*Distorsio* spp.). Sand dollars (*Encope* spp.) can be common in nearby sandy bottom, which may be interspersed in the shelly habitat where scallops are more common.

One issue that developed in the 1990s was the elimination of any on-board culling. This practice meant that the entire catch was processed dockside meaning all bycatch was disposed of in landfills rather than at-sea. A concern had developed that disposal of viscera and discards was actually attracting predators and encouraging development of disease on the fishing ground. The effect of the practice was that millions of pounds of shell were removed from the habitat. The shell is believed to be the primary settlement substrate for juvenile scallops, so in effect, the practice was removing an essential fishery habitat for calico scallops. Wells and Wells (1964) had already shown that at least 112 species of fauna utilized scallop shells as settlement habitat - including juvenile scallops. Often, the weight of the epifauna can exceed that of the host shell. The effect is that the large volume of shell creates a valuable benthic community, one that is removed from the ocean when bycatch is not culled at-sea. This practice also eliminates attached juveniles and eliminates any possibility for survival of organisms present in bycatch. The potential that this large-scale removal of potential prey impacts nearby reef fish communities should be considered.

5.3 Other Managed Fisheries in the South Atlantic

5.3.1 Atlantic Menhaden

5.3.1.1 Description of fishing practices, vessels and gear

Atlantic menhaden have supported one of the United States' largest fisheries since colonial times. Landings records indicate that over 18 million mt of Atlantic menhaden have been caught by fishing fleets operating from Maine to Florida since 1940 (ASMFC 2001).

Native Americans were the first to use menhaden, primarily for fertilizer. During the 1940s, the primary use changed to high protein animal feeds and oil production.

Menhaden meal was mixed into poultry, swine, and cattle feeds as the amount used for fertilizer was decreasing. The oil was used in the manufacture of soap, linoleum, waterproof fabrics, and certain types of paint(ASMFC 2001).

Following World War II, the industry grew rapidly, reaching peak production during 1953-62. Sharp declines in landings thereafter resulted in factory closings and fleet reductions through the 1960s and into the early 1980s. Since that time, the menhaden industry has experienced major changes in processing capacity, resource accessibility, and development of new product markets.

Vessels and Domestic Harvesting Capacity (ASMFC 2001)
The early menhaden purse seine fishery utilized sailing vessels, while coal-fired steamers were introduced after the Civil War. In the 1930s, diesel-powered vessels began to replace the steamers, although a few sailing vessels were still in use. Reintjes (1969) described modern menhaden vessels and purse seines and summarized the significant technological advancements since World War II as follows:

- 1946 -- Use of spotter aircraft. Setting on a school is now directed by the spotter pilot via radio communication with the purse boats.
- 1946 -- Use of pumps to transfer fish from the nets to the carrier vessel resulted in shorter transfer time and more fishing time.
- 1954 -- Use of synthetic net material rather than cotton twine resulted in increased net life.
- 1957 -- Use of hydraulic power blocks in the purse boats to haul in the net permitted a reduction in crew size and reduced net retrieval time. Strong synthetic net material was able to withstand the increased strain from the new haul technique.
- 1958 -- Introduction of lighter, stronger, and faster aluminum purse boats to replace wooden boats.

The refrigeration of vessel holds in the 1960s and 1970s was crucial for the industry to maintain its viability. Despite restricted access to a number of traditional grounds and a reduced fleet size, refrigerated holds enabled the fleet to maximize the harvest during peak resource availability.

Refrigeration also allowed the fleet to range over a larger area and stay out longer, greatly improving the ability to catch fish when and where they are available. Currently, commercial menhaden purse seine fishing operations utilize spotter aircraft to locate schools of menhaden and direct vessels to the fish. When a school is located, two purse boats with a net stretched between them are deployed. The purse boats encircle the school and close the net to form a purse or bag. The net is then retrieved to concentrate the catch, and the mother ship comes along-side and pumps the catch into refrigerated holds.

Individual sets can vary from 10 to more than 100 mt, and large vessels can carry 400-600 mt of refrigerated fish. Over the years, vessels participating in the Atlantic menhaden purse seine fishery have varied considerably in size, fishing methods, gear type, and intensity of effort. During the early 1960s, the commercial menhaden fleet experienced significant changes as larger, faster vessels replaced outdated models. Today, the 12 vessels operating in North Carolina and Virginia range from 166 ft (51 m) to 200 ft (61 m) in length. Typical menhaden vessels generally carry two purse boats approximately 39 ft (13 m) in length. A few small vessels have only one purse boat and are called “snapper rigs.” These small boats have the ability to fish in shallow areas not available to the larger vessels. The catches of the snapper rigs (a small fraction of the total) are mostly sold for bait (sport fishery, crab pots, etc.) with minor quantities processed into meal, oil, and solubles.

The typical purse seine net has a bar mesh of 3/4 in (1.9 cm) to 7/8 in (2.2 cm). The net length ranges from about 1,000 ft (305 m) to about 1,400 ft (427 m) and the depth from about 65 ft (20 m) to about 90 ft (27 m).

Historically, the total number of vessels fishing for menhaden was generally related to the availability of the resource. Greer (1915) reported 147 vessels in 1912. During 1955 to 1959, about 115-130 vessels fished during the summer season, while 30-60 participated in the North Carolina fall fishery. As the resource declined during the 1960s, fleet size decreased more than 50%. Through the 1970s, approximately 40 vessels fished during the summer season, while nearly 20 were active in the fall fishery.

During 1980-1990, 16-33 vessels fished the summer season, and the level of effort in the fall fishery ranged from a low of 3 vessels in 1986 to a maximum of 25. During the 1990 season, the mid-Atlantic fleet, based in Virginia was composed of 20 vessels, and the south Atlantic fleet, based in North Carolina, consisted of one large vessel and two smaller vessels, each using two purse boats. One of the smaller vessels, however, fished exclusively for bait. An additional 3-4 large vessels from Virginia and/or the Gulf of Mexico fished in the south Atlantic during the fall fishery.

Due to company consolidation in 1997, there are presently 10 vessels in the mid-Atlantic fleet (at Reedville, Virginia) and two vessels in the south Atlantic (at Beaufort, North Carolina). Changes in fleet size since the 1980s are attributable to a number of factors. Reductions in effort during the mid-1980s were related largely to world commodity markets and economic considerations. The addition of vessels participating in the Gulf of Maine Internal Waters Processing (IWP) ventures reflected resource availability in Maine. Reduction of the Chesapeake fleet by several vessels was accompanied by improved operating efficiency. Vessels from the Gulf of Mexico fishery were added to the Atlantic fleet for the fall fishery in order to maximize harvest when weather and fish migratory behavior provided opportunities for large catches. In November 1997, Omega Protein purchased its competitor in Reedville, AMPRO Fisheries. For the 1998 fishing season, Omega dismantled the AMPRO factory and reduced the Virginia reduction fleet from 20 to 13 vessels. Further reductions in fleet size occurred during 1999.

All twelve vessels in the menhaden fleet currently utilize refrigerated fish holds, compared to only 60% of the fleet in 1980. Refrigeration enables vessels to deliver better quality raw material and serves to increase vessel range and extend time on the fishing grounds. This ability to maximize peak resource availability was critical in the 1970s and 1980s for the maintenance of the industry in the face of restricted access to traditional grounds and a reduced number of vessels landing at fewer plants.

Average hold capacity of menhaden vessels in the summer fishery declined from 1,101,000 standard fish (737,670 lb or 334.6 mt) in 1980, to 997,000 standard fish (667,990 lb or 303 mt) in 1990, a decrease of 9.4%. The total hold capacity of the current twelve vessel menhaden fleet is well below that of the late 1950s.

During peak landing years (1953-1962), an average of 112 vessels with a mean vessel capacity of about 678,000 standard fish (representing a total fleet capacity of approximately 76,000,000 standard fish) supplied the industry (Nicholson 1971). The fleet landed daily catches at 20 menhaden reduction plants from New York to Florida. In comparison, the 1990 fleet of 33 vessels, which operated within a more restrictive and regulated environment, landed their catch at five plants, including the foreign processing vessel. As previously noted, the current fleet of twelve vessels unloads menhaden at only two ports, Reedville, Virginia and Beaufort, North Carolina.

Fishing and Landing Areas
The Chesapeake Bay area (including the mid-Atlantic area) accounted for about 77% of the Atlantic menhaden landings in 1990 and about 73% during the 1980-1990 period. Plants in the north and south Atlantic areas, including one plant active during the fall fishery, processed about 27% of the annual landings. Three plants located in Virginia and North Carolina processed about 90% of the harvest.

In 1991, Chesapeake Bay, including the mid-Atlantic area, accounted for about 74% of the menhaden landings. The North Atlantic area contributed most of the balance of the landings, while the south Atlantic area contributed the remainder. The catch was landed at shoreside processing plants in Beaufort, North Carolina; Reedville, Virginia (2 plants); and Blacks Harbour, N.B., Canada. A Russian factory ship anchored at various locations within the territorial waters of southern Maine also processed menhaden under an IWP arrangement.

As no menhaden landings for reduction have occurred in New England since the summer of 1993,and the plant in Beaufort North Carolina closed in 2005, landings of Atlantic menhaden for reduction have been made exclusively by the Virginia vessels at Reedville, Virginia.

Between 1994 and 1997, the factories at Reedville processed an average 89% of the Atlantic menhaden catch for reduction; the remainder was unloaded at Beaufort.
Smith (1999b) summarized catch estimates of menhaden vessel captains in the Virginia and North Carolina fleets (excluding New England vessels) from Captains Daily Fishing Reports (CDFR's) during 1985-96. On average, over the twelve year study period, 52% of the catch by the Virginia and North Carolina fleets came from the Virginia portion of Chesapeake Bay, 17% was caught in North Carolina coastal waters, 16% in Virginia ocean waters, and 15% in ocean waters of Rhode Island, New York, New Jersey,

Delaware, and Maryland and Delaware Bay combined. However, the New Jersey portion of Delaware Bay has been closed to the reduction fishery since mid-1989, the Delaware portion in mid-1992, and most of Long Island Sound has now been closed to the reduction fishery.

Fishing Seasons

The directed menhaden purse seine fishery for reduction is seasonal. The presence of menhaden schools is dependent on the temperature of coastal waters. Two fairly distinct fishing seasons occur, the "summer fishery" and the "fall fishery". The summer fishery begins in April with the appearance of schools of menhaden off the North Carolina coast. The fish migrate northward, appearing off southern New England in May-June. The fishery in the Gulf of Maine may extend into early October, although menhaden may not appear in the Gulf of Maine at all in some years. Menhaden stratify by age along their migration route as smaller, younger fish remain in the southern area, while larger, older fish travel farther to the north. Peak landings occur during June-September.

The fall fishery begins about 1 November as migratory fish appear off Virginia. In early fall, this southward migration is initiated by cooling ocean temperatures. Menhaden vessels based in Reedville, Virginia harvest these fish during the fall fishery. Fishing may continue into January (and sometimes February), but is highly weather dependent. Menhaden generally leave the nearshore coastal fishing grounds in January, dispersing in ocean waters off the south Atlantic states.

Commercial Reduction Fishery

Atlantic menhaden have supported one of the United State's largest fisheries since colonial times. Menhaden have repeatedly been listed as one the nation's most important commercial fisheries species in terms of quantity. Total menhaden landings (Gulf of Mexico and Atlantic) in 1998 were 1.7 billion lb (816,467 mt) valued at $103.8 million (NMFS 1999). Preliminary Atlantic menhaden landings in 1999 totaled 416 million lb (188,662 mt) with an estimated ex-vessel value of $33.2 million (NMFS 2000).

The last reduction plant located in Beaufort, North Carolina closed in 2005 subsequently there is no longer a reduction fishery in North Carolina or the South Atlantic region.

Commercial Bait Fishery

Information on the harvest and use of menhaden for bait is difficult to obtain because of the nature of the bait fisheries and data collection systems. Harvest comes from directed fisheries, primarily small purse seines, pound nets, and gill nets, and bycatch in various food-fish fisheries, such as pound nets, haul seines, and trawls. Menhaden are taken for bait in almost all Atlantic coast states and are used for bait in crab pots, lobster pots, and hook and line fisheries (both sport and commercial). A specialized use involves live menhaden as bait for coastal pelagic species.

Reported annual landings of Atlantic menhaden for bait along the Atlantic coast averaged about 33.7 mt (about 70.0 million pounds) for the period 1985-99. Reported bait landings usually accounted for approximately 10% of the total Atlantic menhaden landings each year from 1985-97. In 1998 and 1999, reported bait landings accounted for 13.7% and 17.3%, respectively, of the total Atlantic menhaden landings. The increase in percent of coastal landings are attributed to better data collection in the Virginia snapper rig bait seine fishery and a decline in coastal reduction landings due to reductions in processing plants and fleet size.

Closure of reduction plants in New England and the mid-Atlantic may have influenced growth in the bait fishery, making more product available for the lobster and crab pot fisheries, as well as bait and chum for sport fishermen. Additionally, the passage of a net ban in Florida in November 1994 reduced the availability of bait and chum in that state, which opened up new markets for menhaden bait caught in Virginia and the mid-Atlantic states. The appearance of growth in the Atlantic coast bait fishery must be tempered by the knowledge that reporting systems for bait landings, particularly for Atlantic menhaden, have historically been incomplete at best. In most cases, recent landings estimates are more accurate, but for some states, bait landings continue to be underestimated. The nature of the fishery and its unregulated marketing are causes of the under-reporting problem. There are some well-documented, large-scale, directed bait fisheries for menhaden using gears such as purse seines, pound nets, and gill nets. There are also many smaller-scale directed bait fisheries and bycatch fisheries supplying large quantities of bait with few, if any reporting requirements. Menhaden taken as bycatch in other commercial fisheries is often reported as "bait" together with other fish species. The “over-the-side” sale of menhaden for bait among commercial fishermen is under-reported (and often unreported). Common practices, such as utilizing menhaden for bait or chum in sportfishing tournaments is difficult to estimate when quantity sales are made to individual marinas and fishing clubs.

Despite problems associated with estimating menhaden bait landings, data collection has improved in many areas. Some states license directed bait fisheries and require detailed landings records. Catch-per unit-of-effort (CPUE) data, pounds caught per hour set and pounds caught per yard of net set are also reported for directed gill net fisheries in some states.

(paragraph below form the 2005 update to the ASFMC FMP)
Landings of Atlantic menhaden by the bait fisheries (all gears combined) in 2004 amounted to 34,743 mt; this was 16% of the combined (reduction and bait) total Atlantic menhaden landings in 2004. The majority of the bait landings are from purse-seine gear operating in Virginia and New Jersey waters. Through the period 1985-1997, bait landings generally comprised about 10% or less of the total Atlantic menhaden harvest. With the decline in the reduction landings in recent years, the relative importance of the bait fishery has increased. More comprehensive reporting of bait landings has also contributed to this trend.

South Atlantic Bait Fisheries

Part of North Carolina’s landings are reported directly, while the rest are estimated from fishery-dependent sampling. The principal use for menhaden as bait in North Carolina is in the blue crab pot fishery. South Carolina and Georgia have no directed menhaden fisheries, shrimp trawl bycatch and cast netting supply menhaden to crab potters and sport fishermen in those states. Florida's east coast had substantial menhaden landings for bait from gill nets and purse seines prior to the implementation of a net ban in 1994.

Domestic Processing Activities and Products

Menhaden reduction plants, through a process of heating, separating, and drying, produce fish meal, fish oil, and fish solubles from fresh menhaden. Meal is a valuable ingredient in poultry and livestock feeds because of its high protein content (at least 60%). The broiler (chicken) industry is currently the largest user of menhaden meal, followed by the turkey, swine, pet food, and ruminant industries. The aquaculture industry has recently demonstrated an increased demand for fish meal as well.

Menhaden oil has been used for many years as an edible oil in Europe. The oil is refined and used extensively in cooking oils and margarine. In 1989, the United States Food and Drug Administration (FDA) concluded that fully and partially hydrogenated menhaden oil is a safe ingredient for human consumption. In 1990, the FDA proposed an amendment, based on an industry petition, to the standard of identity for margarine to permit the use of marine oils. It was approved in 1997 and could provide a significant new market for omega-3 rich menhaden oil.

Solubles are the aqueous liquid component remaining after oil removal. In general, most meal producers add the soluble component to the meal to create a product termed “full meal.” The use of solubles as an export product is limited because most companies in the feed industry are not equipped with the necessary storage tanks, pumps, and meters to handle a liquid product.

The world fish meal industry is in the process of adopting low temperature meal technology, a process which yields significantly higher protein content than previous technologies and produces feed components particularly valuable to aquaculturists. Investment in these new processes represents an opportunity for the U.S. industry to broaden its market base and add value to its products. Public sector support, in the form of research on markets, technology development, and new products, will be a key factor in maintaining the domestic menhaden industry’s global competitive status.

Recreational Fishery

No significant directed recreational fisheries exist for menhaden. However, menhaden are an important bait in many recreational fisheries; some recreational fishermen employ cast nets to capture menhaden or snag them with hook and line for use as bait, both dead and live.

Current status of the fishery

The 2006 coastwide harvest (bait and reduction) of Atlantic menhaden was 183,583 metric tons (ASMFC 2007). This is slightly down from 185,030 metric tons in 2005. The 2006 harvest for reduction purposes only was 157,385 metric tons. This is up 7% from the 2005 landings of 146,860 metric tons, but down 13% from the previous 5-year average of 180,833 metric tons; declines in landings during 2005 and 2006 mainly reflect the decision by Beaufort Fisheries Inc., to no longer participate in the reduction fishery. Reduction landings generally have gone down since the early 1990s (Figure 5.3.1-3). The coastwide bait harvest for 2006 was 26,198 metric tons, down 31.4% from the 2005 harvest of 38,170 metric tons, and down 28% from the average harvest of the previous five years (2001-2005)(Figure 5.3.1-1).

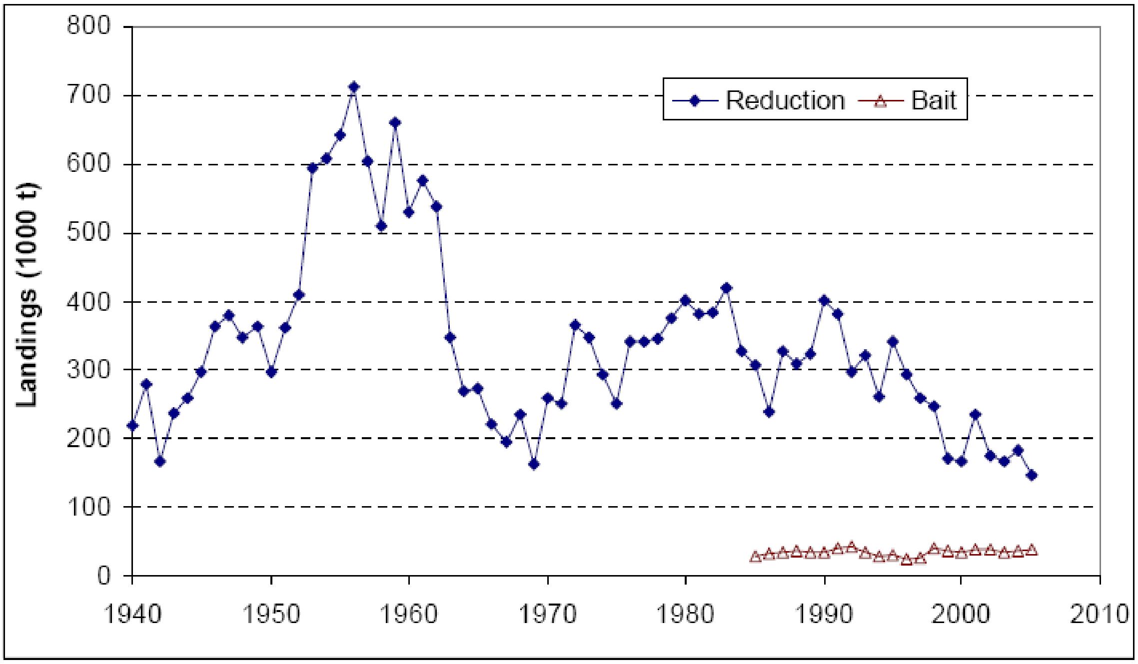

Figure 5.3.1-1. Landings from the reduction purse seine fishery (1940–2005) and bait fishery (1985–2005) for Atlantic menhaden (ASMFC 2006)

The largest percentage decrease in bait landings from 2005 to 2006 occurred in Maryland and Virginia, 59% and 51% respectively; this trend mirrors removals from Chesapeake Bay by the reduction fishery. All states from New Jersey and north reported an increase in 2006 landings over 2005. Potomac River Fisheries Commission and Florida also reported increased harvest.

The bait fishery appears to be expanding in the northern range of the species, i.e., New England, based on reported landings in recent years (Table 5.3.1-1).

Omega Protein's plant in Reedville, Virginia, is the only active menhaden reduction factory on the Atlantic coast. Eleven vessels fished out of this plant in 2006. Beaufort Fisheries Inc. has been closed since the 2004 fishing season.

Table 5.3.1-1. Menhaden Bait Landings by Region (1985 – 2006) [in 1,000s of metric tons] (ASMFC 2006, B. Muffley pers. comm. 2007)

Year	New England (ME – CT)	Mid-Atlantic (NY – MD Coast)	Chesapeake Bay (MD Bay, VA, PRFC)	South Atlantic (NC – FL)	Total (ME – FL)
1985	6.15	1.82	18.05	2.27	28.30
1986	13.75	1.31	13.64	2.44	31.15
1987	13.28	1.28	16.99	2.56	34.11
1988	19.73	1.20	12.38	2.88	36.19
1989	9.54	1.52	20.30	3.41	34.77
1990	11.19	4.38	13.98	4.07	33.61

2005	1.01	8.25	28.26	0.66	38.18
2006	1.49	9.87	14.35	0.50	26.21

Allowable gear

Atlantic menhaden may be harvested commercially in the EEZ using purse seine, trawl, gillnet and hook-and-line. Menhaden may be harvested recreationally using hook-and-line, snagging and cast nets.

5.3.1.2 Economic and social description

No recent studies have been conducted to assess the economic characteristics of the menhaden fisheries. The most recent information is included in the 1992 FMP (ASMFC 1992).

(text below excerpted from "Collection of Baseline Sociological Data to Describe The Atlantic Menhaden (Brevoortia tyrannus) Fishery by Dr. Brian Cheuvront, NCDMF)

As part of the ongoing effort to document changes in the menhaden fishery over time, Dr. Brian Cheuvront was contracted by the Atlantic States Marine Fisheries Commission (ASMFC) to conduct interviews with persons in Virginia and North Carolina who participate in the menhaden fishery. This section is directly out of Dr. Cheuvront's report to the ASMFC.

Menhaden (*Brevoortia* spp.) have repeatedly been listed as one the nation's most important commercial fisheries species in terms of quantity. Total menhaden landings (Gulf of Mexico and Atlantic) in 2002 were 1.4 billion pounds (633,985 metric tons) valued at $83.6 million. Atlantic menhaden (*Brevoortia tyrannus*) landings in 2002 totaled 385.5 million pounds (174,870 metric tons) with an estimated ex-vessel value of $22.1 million (NMFS, 2003). In North Carolina, Atlantic menhaden alone accounted for 62.4% of all finfish landed, and 13.5% of the value of all finfish landed in 2002 (NC DMF).

Historically, menhaden had many uses. It is thought Native Americans may have used menhaden for fertilizer. Colonists soon recognized the value of whole menhaden for fertilizer, and local seine fisheries gradually developed from New York to Maine. The use of whole fish as fertilizer continued into the nineteenth century. A southern fishery developed after the Civil War (Menhaden Resource Council, 2003).

The menhaden oil industry began in Rhode Island in 1811. It grew steadily, with significant mechanization, including boilers for rendering raw fish and presses for removing oil. Oil was initially used for fuel and industrial processes, while the remaining solids (scrap) were used for fertilizer. Numerous small factories were located along the coasts of the northeastern states. However, their supply was limited to fish that could be captured by the traditional shore-based seines. In 1845, the purse seine was introduced, and an adequate supply of raw material was no longer a problem. By 1870, the industry had expanded southward, with several plants in the Chesapeake Bay and North Carolina areas.

The primary use of menhaden changed from fertilizer to animal feed and other products during the period following World War I. At that time, menhaden oil was used in the manufacture of soap, linoleum, waterproof fabrics, and certain types of paints.

Following World War II the industry grew rapidly. Sharp declines in landings thereafter resulted in factory closings and fleet reductions through the 1960s and into the early 1970s. Since that time, the menhaden industry has experienced major changes in processing capacity, resource accessibility, and access to new product markets.

Nine menhaden reduction plants on the Atlantic coast closed permanently during the 1980s while two new operations began. In 1990, five reduction plants with 37 vessels processed Atlantic menhaden for fishmeal and oil. In the United States, land-based plants are currently located at Beaufort, North Carolina and Reedville, Virginia. Upper Chesapeake Bay in Maryland and the coast of New Jersey are closed to menhaden fishing operations. Most Atlantic states, however, remain open to menhaden fishing.

Currently there are only two menhaden processing plants working on the east coast of the United States. Omega Protein is located in Reedville, Virginia and Beaufort Fisheries is located in Beaufort, North Carolina. Of the two, Omega Protein processes about four to five times more menhaden than does Beaufort Fisheries. There are also a few smaller operations that fish for menhaden to be used primarily as bait for recreational fishermen and commercial crab pots.

In-person interviews were conducted involving 21 people from September to December of 2003. The in-person interviews took place in Beaufort, NC and Reedville, VA.

People interviewed included: two plant general managers, one plant bookkeeper, one oils reduction plant supervisor, one oils reduction plant machine operator, seven menhaden fishing boat crew members (captains, mates, engineer, deck hands, etc.), two commercial pound netters, two bait fishery boat captains, two recreational fishermen who target menhaden using commercial gear and three people from the Reedville community involved in community affairs, but not directly involved in the menhaden fishery (including the Fisherman's Museum director). Topics of discussion included (as appropriate) work history, fishing effort, labor, race relations, current state of the industry, fishing communities, fisheries management, conflicts between user groups, and perceptions about the future. The interviews were recorded on standard cassette tapes. Once all were completed, they were transcribed verbatim.

Work History
Nearly all of the people interviewed for this study and who were currently worked in menhaden have done so for an average of about 25 years. Several of the people interviewed in Reedville were retired from some aspect of the menhaden industry. Menhaden processing is a field where most workers come up through the ranks, including general managers, beginning as either a crewmember or as an apprentice machine operator. All found the work to be hard, but rewarding. Several respondents said they had little formal education and found working in menhaden to be as financially lucrative as any job they could expect. Most expected to remain working in the fishery until they retired or the factory ceased operations.

Only the general managers and few others in working at the reduction facilities were able to work 12 months a year. They did not work in menhaden when there were no fish to catch or process. The fishing season typically lasts longer in Reedville than in Beaufort. Many of the workers at Omega Protein are able to work 10 to 11 months of the year. Aside from some maintenance and net repair workers, most employees at Beaufort Fisheries work about 6 months of the year.

Fishing Effort
Omega Protein currently has 10 boats that fish for menhaden. Beaufort Fisheries has two. There are 4 menhaden bait fishery operations using nets that work the Chesapeake Bay. All the people interviewed said their used to be a lot more effort targeting menhaden. Pictures of the Beaufort waterfront from the 1950's show as many as 30 or so boats tied up at the docks. The last couple of decades have seen the closure of a processing plant in Southport, NC and the consolidation of American Protein in Reedville by Omega Protein.

According to one informant, Omega Protein had about 13 boats actively working about 25 years ago and American Protein had a similar number. Crews were also larger in past years.

Comparatively speaking, the boats targeting menhaden today are more successful than their predecessors. Reliance on spotter planes has increased individual trip catches. But still, as one general manager put it, “it’s not unheard of for us to travel 30 miles in one direction to get two fish.”

Labor

Much of the heavy work on menhaden boats is now mechanized. Early crews consisted of a captain, pilot, mate, one or two engineers, a cook, and as many as two dozen crewmembers to haul nets (Garrity-Blake, 1994). Nowadays, crews average approximately 14 with only 8 crew members.

Availability of labor seemed to more of an issue for Beaufort Fisheries than Omega Protein. The working season tends to be shorter and workers need additional sources of employment that they can easily leave when the fish are present. Most jobs that allow this kind of movement are low paying. So as soon as menhaden workers find better paying jobs, they leave the menhaden fishery altogether. Finding quality replacements for them is difficult.

Omega Protein employees work for most of the year and can survive financially during the periods they are not fishing. Also, a major factor is that workers in Reedville have very few options for other employment. Omega Protein is the largest employer in Northumberland County, Virginia (2001 population: 12,412). Workers in the Beaufort area (Carteret County, 2001 population: 59,901) have more alternatives for employment.

Race Relations

Garrity-Blake (1994) addressed racial issues in the menhaden industry. At that time she stated that earlier vestiges of racism were beginning to change. The general managers interviewed both said that race is not a factor in who gets hired for any position. The most important factors are experience and skill. However, in both communities, African-Americans, on average have lower level of educational achievement and occupy a large percent of the lower level positions.

The African Americans interviewed expressed that they felt no different in terms of discrimination on their jobs. One African-American man who was interviewed worked in a reduction facility for twenty years. He had an 8th grade education. He was clear that he did not have the skills for doing other work and was happy to have the job that he does because it paid well. He saw the job as an opportunity in a living environment that was short of job opportunities for most people.

Both general managers spoke highly of African-American employees and insisted that all workers in their plants were more like family than employees, regardless of race. One spoke of company sponsored and financed programs to help any employee (“black, white, or green – it doesn’t matter”) who wished to advance through the ranks, including getting any necessary boating licenses.

There were three main categories of concerns expressed regarding the current state of the industry. The first concern was largely business related. The two reduction facilities were worried about staying profitable and staying competitive. The second concern was regarding fisheries management and affected all who worked the fishery. Harvesters and general managers alike were extremely concerned regarding conflicts between user groups particularly between commercial fishery interests and the interests of recreational fishermen who are concerned that there are not enough menhaden to feed the available striped bass and other prized sport fish populations.

Business Concerns

The two plant general managers spoke about some of the larger business concerns they have. Typical business concerns such as supply and demand of product were understandably important to them. But they were also concerned about markets for their products. One of the plants will shortly be undergoing a $16-17 million expansion program designed to be able to reduce menhaden oil for human consumption as Omega-3 fatty acids. Other competitors for their products include soybeans. For these businesses, they are not just concerned with fish stocks and ability to land them, but also competition from other products.

Other business concerns include pressure from outside development, and the previously mentioned labor issues. Outside development is increasing the property values where these plants are located. There is concern that newly arrived people in the community do not understand the history, nor appreciate the positive impact the industry has had on the surrounding community.

Fisheries Management and Environmental Regulation

All harvesters and plant managers who were aware of the stock status emphasized that they were pleased that the stocks are healthy. They are resigned to having to cope and react with regulations that limit their fishing activities. One spoke of his tremendous disappointment at the fact that industry representatives were no longer on the management boards. "…they kicked us off. It must have been about three years ago because we were involved in the menhaden business and hired a couple of sports fishermen to take our place."

The reduction facilities agree with the way the fishery is currently being managed, however, they fear what they see as increasing influence from recreational interests. Menhaden pound net fishermen were not as happy with fisheries management. They were unhappy because they must remove their nets from the water because of sea turtle encounters. "They found three dead turtles out of three hundred in pound nets so they decided to have an industry wide closure. They had a mandatory closure on the pound net fishery for two weeks [in 2003] and this year coming up [2004] they're talking like six weeks of closure."

Menhaden processors must not only deal with fisheries regulatory bodies, but also with air and water quality authorities. Depending on the actions of those government agencies, they are viewed as being benign or harassment. One processor said they specifically worked with the Environmental Protection Agency on smoke stack issues and did not feel they were overly hassled. On the other hand, one general manager complained about fish kills that occurred near his processing plant had the state division of water quality visiting him “11 straight days, Saturday and Sunday included, raising hell about that [leaking] raw box. It’s been there over 100 years and never had a fish kill.”

Conflicts Between User Groups

User group conflicts represented the most salient issue for many of the people interviewed. No one interviewed stated that they ever had conflicts with other commercial fishing interests. Currently, there are 14 vessels (10 from Omega Protein, 4 independent bait vessels) whose home ports are on the Chesapeake Bay, in or near Reedville. Vessels that target menhaden tend to be larger than most other nearby fishing vessels and the commercial vessels tend to stay away from each other.

Everyone interviewed was concerned about the ongoing conflicts with groups representing recreational fishing interests. Most were seriously worried that recreational interests would win out over commercial interests. They cited the larger number of people who fish recreationally and their lobbying power. Some expressed a feeling that there is a conspiracy against commercial fishing and recreational groups are using tactics to shut down commercial fishing altogether, especially in fisheries where there is significant recreational interest. Tactics mentioned included getting persons sympathetic to their issues appointed to management boards, lobbying state and federal legislators, misrepresenting facts, and fabricating stories to implicate commercial fisheries in the demise of recreationally valued species.

Some respondents said they have heard recreational groups feel that commercial menhaden harvest, particularly from the Chesapeake Bay, is removing a vital food source for striped bass, a fish whose numbers had been greatly reduced in the past, but now is back in record numbers. The commercial fishermen point to the stock assessment that says that Chesapeake Bay harvest of menhaden largely targets age 2 and 3 fish; however, the majority of striped bass are eating age 0 and 1 fish, along with some age 2 fish. They also pointed out that even though the striped bass are now back in record numbers, the harvest of this recovered fish stock clearly favors recreational fishermen. A commercial fisherman who sometimes uses a gill net said that the only way he could keep two striped bass for his own consumption was to go out and get a recreational fishing license, because as a commercial fisherman he was not allowed to keep any striped bass.

A few people interviewed stated the reason why the recreational fishermen are targeting menhaden is because they want to end commercial fishing altogether and will use any means to do so. There were some reports of conflicts on the water with recreational fishermen, as well. Both processing plant general managers expressed that there had been occasions when a recreational vessel would see purse seine boats heading for a school of fish, a recreational vessel would speed through the school of fish trying to break them up. However, these were represented as relatively rare occurrences.

The commercial menhaden fishermen feel as if they are the underdogs in this conflict. As one commercial fisherman put it, “the [recreational] industry and big dollar businesses are behind them pushing for this. They have all their magazines. They've got a lot of people with a lot of money."

Fishing Communities

Menhaden fishing was seen as being very important to the history of both the Beaufort and Reedville communities. Elijah Reed founded the town of Reedville after the Civil War. He came to Virginia's Northern Neck with the expressed purpose of finding a place to locate a menhaden processing plant. Beaufort was settled nearly two hundred years prior to the emergence of the commercial menhaden fishery in North Carolina. One town owes its identity to menhaden; the other considers menhaden to be an important part of its history.

Omega Protein is the largest employer in all of Northumberland County, Virginia, with about 250 employees most of the year. Beaufort Fisheries employs approximately 70 individuals when there are fish to harvest and process. There are many employers in Carteret County that have more workers than Beaufort Fisheries.

The employment differences between the communities have a large effect on the current role menhaden has locally. In Reedville, Omega Protein is highly visible and the company works hard to be perceived as a good community partner. All the people interviewed in Reedville, including a few who were not directly involved in the commercial harvest of menhaden perceived Omega Protein as a good corporate citizen. For example, several years ago Omega Protein made significant changes to their infrastructure to help reduce the smell from the reduction facility in response to community concerns.

One person interviewed mentioned that sometimes when new people (known locally as "come heres") arrive in Reedville they complain about the processing facility. Over time, they realize the facility doesn't present a problem. Some people said that if Omega Protein was to close down, Reedville would cease to exist.

Beaufort Fisheries has a different relationship with its local community. Long time residents are aware of the role of menhaden in the community, but the local importance of commercial fishing to the economy was long ago supplanted by tourism and coastal gentrification. Additionally, Beaufort Fisheries is located on a property primely situated for waterfront home development.

Tourism and coastal gentrification are issues for both communities. Many of the older fishermen used to come to Beaufort years ago as part of the menhaden fleet that followed the fish. These people, especially, look at recent developments of Beaufort with disdain. One fisherman stated that the last thing he wanted for Reedville was for it to become like Beaufort with all the expensive houses and fancy restaurants.

Perceptions About the Future

Many of the people interviewed were asked whether they would recommend to a young person a career working in menhaden. Most of the respondents were too worried about the future of the commercial fishery to recommend it. Their biggest concerns were about the outcomes of brewing user group conflicts and being able to keep competitive in the markets where menhaden are used. For most, the work is hard and the outcome is uncertain. One processor general manager said, "I've got two boys and I told both of them I'm not going to allow them to come down here. I want something better for them than this." Exceptions to this feeling were among land-based workers with steady employment working at the processing plants.

Conclusions
The people who work in the menhaden industry have many things to worry about. Like all fishermen, they have to be able to find and catch the fish. But they also have to worry about competition, sometimes from non-fishery related products such as soybeans. Because menhaden are an industrial product rather than a seafood product, processors worry about additional issues such as compliance with environmental regulations of water and air quality. However, the long-term survivability of the industry may depend on the outcome of its current battles with recreational fishing interests.

Commercial menhaden harvesters and processors view the stocks as being more than adequate for the needs of both themselves and as forage food for striped bass and other fish. However, they are concerned that attacks on the menhaden industry are really attempts to eliminate commercial harvesting altogether. There is a sense that without some outside intervention their way of live may be lost in favor of recreational fishing interests. Whether or not this prophecy will be true remains to be seen.

5.3.1.3 Bycatch

(from 2001 ASMFC FMP)
Incidental bycatch of other finfish species in menhaden purse seines has been a topic of interest and concern for many years to the commercial and recreational fishing industry, as well as the scientific community (Smith 1896; Christmas et al. 1960; Oviatt 1977). Numerous past studies have shown that there is little or no bycatch in the menhaden purse seine fishery. Some states restrict bycatch to 1% or less of the total catch on a vessel by regulation.

A study of bycatch of other species in the Atlantic menhaden fishery was recently completed through funding provided by the Federal Saltonstall-Kennedy grant program (Austin et al. 1994). The Virginia Institute of Marine Science studied bycatch levels of finfish, turtles, and marine mammals in the Atlantic menhaden fishery. Results from that study indicated that bycatch in the 1992 Atlantic menhaden reduction fishery was minimal, comprising about 0.04% by number. The maximum percentage bycatch occurred in August (0.14%) and was lowest in September (0.002%). Among important recreational species, bluefish accounted for the largest bycatch, 1,206 fish (0.0075% of the total menhaden catch). No marine mammals, sea turtles, or other protected species were killed, captured, entangled or observed during sampling. A concurrent study was conducted by Louisiana State University for the Gulf of Mexico menhaden fishery (de Silva and Condrey 1997).

Additional data are available from the Gulf of Maine IWP fishery in 1991. Every catch unloaded onto the processing vessel was inspected by a state observer. A total of 93 fish were taken as bycatch along with about 60,000,000 individual menhaden (D. Stevenson, Maine DMR, pers. comm.; as cited in ASMFC 1992).

5.3.2 Striped Bass

5.3.2.1 Description of fishing practices, vessels and gear

Current status of the fishery

Total striped bass harvest (commercial and recreational) comprised 3.32 million fish in 2005, a 33.7% increase from 2002 (2.48 million fish) but only a 0.9% increase from 2004 (3.29 million fish) (ASMFC 2006). This increase in total harvest from 2004 to 2005 is attributable to the commercial harvest (1.0 million fish), which rose by 11.25% from 2004, rather than the recreational fishery (2.31 million fish), which fell by 3.0% from 2004. On the other hand, discard losses in the recreational fishery (1.52 million fish) rose by 17.5% from 2004 to 2005, meaning that the total recreational catch (harvest plus discard losses) rose by 2.0% from 2004. An estimate of commercial discard losses for 2005 is unavailable at this time. In 2004, commercial discard losses measured 0.52 million fish, or 36.38% of the total commercial catch for the year.

Recreational harvest (2.31 million fish) and discard losses (1.52 million fish) account for 60.3% and 39.7%, respectively, of the total 2005 recreational loss. Maryland recreational fisheries harvested 21.4% of total recreational landings in number, followed by Massachusetts (17.0%), Virginia (16.1%), New Jersey (13.8%), New York (10.9%), and North Carolina (6.8%). The remaining states each landed 5% or less of the total recreational landings in number.

The commercial harvest (1.0 million fish) was dominated by Maryland’s commercial fisheries, which made up 56.5% of the total commercial landings by number in 2005. Virginia accounted for 11.8% of the commercial landings by number, followed by PRFC (8.0%), New York (7.0%), North Carolina (6.6%), and Massachusetts (5.9%). The remaining states each landed 3% or less of the total commercial landings in number.
A reliable estimate for commercial discards is unavailable at the writing of this report. Thus, the 2004 data are used to portray the proportion of the total catch attributable to recreational harvest and discards and commercial harvest and discards (Figure 5.3.2-1).

Table 2. Striped Bass Landings and Discards (numbers of fish) from 2002-2005

	Recreational		Commercial	
	Harvest	Discard Losses	Harvest	Discard Losses
2002	1,828,367	1,118,538	654,062	168,201
2003	2,405,707	1,168,907	865,689	262,078
2004	2,381,823	1,373,430	907,328	518,847
2005	2,309,670	1,520,854	1,009,437	N/A

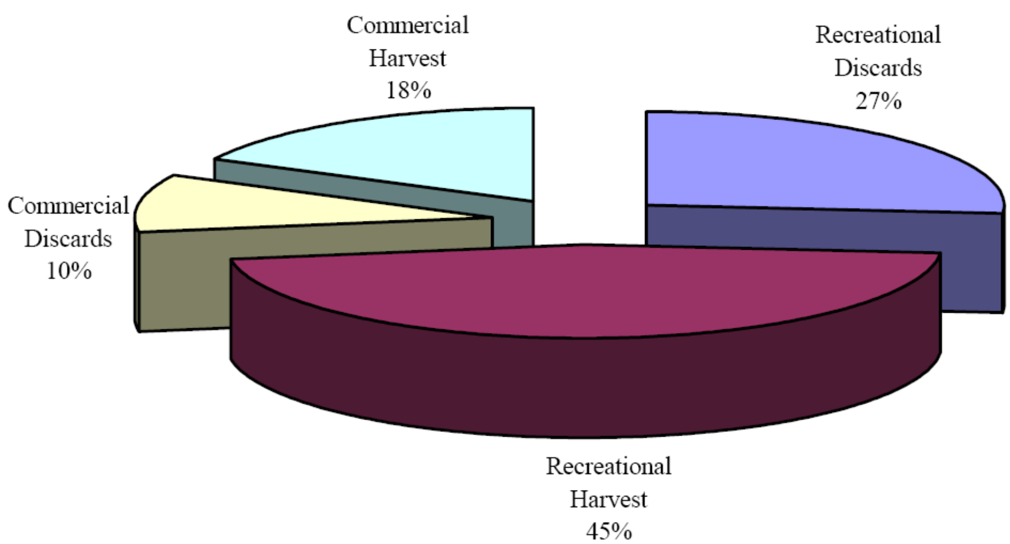

Figure 5.3.2-1. 2004 Striped Bass Total Catch (5.2 million fish)

Allowable gear

No harvest or possession in the EEZ. In state waters, the predominant gear types in the commercial fisheries are gillnets, pound nets, and hook and line. Commercial fisheries operate in 8 of the 14 jurisdictions regulated by the Atlantic States Marine Fisheries Commission FMP. Commercial fishing for striped bass is prohibited in New Jersey, Pennsylvania, Connecticut, New Hampshire, Maine and the District of Columbia. Massachusetts allows commercial fishing with hook and line gear only, while other areas allow net fisheries.

5.3.2.2 Bycatch

Studies are currently being conducted to evaluate the interactions between striped bass, bluefish, weakfish and prey species, such as Atlantic menhaden. ASMFC has contracted out for the development of a dynamic trophic model or a multispecies model to determine the effect of the abundance for a suite of species has on each other (see Section 1.4.4.2

Multispecies Management as an Element of Ecosystem Management of ASMFC's Amendment 6 to the Striped Bass FMP). As the abundance of striped bass has increased striped bass are more frequently encountered as bycatch in other fisheries, but the data on discard and frequency of interactions is limited. Amendment 6 creates a bycatch and discard mortality monitoring program to determine which fisheries are catching striped bass as bycatch and to evaluate the discard mortality associated with the gear used in these fisheries (see below). As more information becomes available, Atlantic States Marine Fisheries Commission intends to incorporate the data into the Atlantic striped bass management program.

Under Amendment 6 to the Striped Bass FMP, the Management Board will be developing a bycatch data collection and management program. However, if prior to the completion of this work the Board identifies a significant discard problem, the Board may require the state/jurisdictions to make management changes to reduce the impacts of discards.

In general, states shall undertake every effort to reduce or eliminate the loss of striped bass from the general population due to bycatch discard mortality. The Technical Committee shall examine trends in estimated by-catch annually.

Bycatch Monitoring and Research Program
The issue of striped bass discards from the commercial and recreational fisheries has increased in importance as the population has rebuilt through the 1990's. However, the data on the magnitude of discards and the mortality associated with these discards is limited. In order to increase the accuracy of the discard data, the Striped Bass Management Board will, through the adaptive management program, develop a mandatory data collection program. The program will be developed during the first two years of implementation of this amendment.

The following two paragraphs generally describe the data collection program and research projects that need to be established to address the discard data deficiencies.

The MRFSS collects information on the number of striped bass released alive from recreational fishermen, however, the mortality of these released fish has been the source of debate for a number of years. Currently, the Technical Committee applies an 8% mortality rate to all released striped bass. To further refine this mortality estimate, there are two additional pieces of information that need to be determined. First, recreational fishermen need to be surveyed to determine the proportional use of different gear type and fishing practices (e.g. fly fishing, live bait fishing, circle hooks, treble hooks, etc). The second piece of information that needs to be determined is the mortality rate associated with each of the particular gear types and fishing practices.
The latest stock assessment for striped bass (2001) noted that there is considerable uncertainty in the estimate of discard mortality from commercial fisheries. As in recreational fishing, two data elements need to be collected to increase the accuracy of the commercial discard estimates; (1) at-sea observers need to be placed on commercial vessels that are targeting striped bass as well as vessels that may encounter striped bass to

collect information on the number of fish that are being discarded from the various commercial gear types and (2) scientific studies need to be conducted to determine the discard mortality associated with all of the commercial gear types that are currently encountering striped bass.

Bycatch Management Program
Following the implementation of the discard data collection program, the Management Board will develop a bycatch management program. This program will be designed to implement penalties for "excessive" bycatch problems and/or incentives to states/jurisdictions that implement measures to minimize the impact of discards.
This program will be developed through the adaptive management process and should be ready for implementation four years after the implementation of Amendment 6 to the Striped Bass FMP.

5.3.3 Anadromous and Catadromous Species

5.3.3.1 Description of fishing practices, vessels and gear

Current status of the fisheries

American Eel (ASMFC 2006)
American eel currently support important commercial fisheries throughout their range. Fisheries are executed in rivers, estuaries, and ocean. Commercial fisheries for glass eel/elver exist in Maine, South Carolina, and Florida (though in Florida, no commercial glass eel/elver landings were recorded in 2005), whereas yellow/silver eel fisheries exist in all states/jurisdictions with the exception of Pennsylvania and the District of Columbia (though in New Hampshire, Rhode Island, South Carolina and Georgia, no commercial yellow/silver eel landings were recorded in 2005).

Commercial
Commercial landings decreased from the high of 1.8 million pounds in 1985 to a low of 641 thousand pounds in 2002. Landings of yellow/silver eels in 2005 totaled 867,861 pounds.1 New Jersey, Delaware, Maryland, and the Potomac Rivers Fisheries Commission each reported landings over 100,000 pounds of eel, and together accounted for 83% of the coastwide commercial total landings in 2005. Landings data for 2005 comes from the 2006 State Compliance Reports.

Recreational
Few recreational anglers directly target eel. For the most part, hook and line fishermen catch eel incidentally when fishing for other species. The NMFS Marine Recreational Fisheries Statistics Survey (MRFSS), which has surveyed recreational catch in ocean and coastal county waters since 1981, shows a declining trend in the catch of eel during the latter part of the 1990's. According to MRFSS2, 2005 recreational total catch was 94,119 fish, which represents a slight decrease in number of fish from 2004 (112,001 fish). Florida and Georgia combined, represent 53% of the recreational American eel catch; Florida, Georgia, Delaware, and Maryland combined, represent 78% of the recreational American eel harvest in 2005. About 87% of the eel caught were released alive by the

anglers (MRFSS 2005 total recreational harvest was 12,100 fish). Eel are often purchased by recreational fishermen for use as bait for larger gamefish such as striped bass, and some recreational fishermen may catch their own eels to utilize as bait.

Shad and River Herring

(Source: ASMFC 2006)

American shad, hickory shad, and river herring formerly supported important commercial and recreational fisheries throughout their range. Fisheries are executed in rivers (both freshwater and saltwater), estuaries, tributaries, and oceans. Although recreational harvest data are scarce, most harvest is believed to come from the commercial industry. Commercial landings for all these species have declined dramatically from historic highs. Following is a summary of fisheries by species:

American Shad

Total combined river and ocean commercial landings decreased from a high of 2,364,263 pounds in 1985 to a low of 1,390,512 pounds in 1999, but increased in 2000 to 1,816,979 pounds. Based upon landings data provided in Compliance Reports from individual states and jurisdictions, an all-time low has been reached in 2005 with landings of 680,061 pounds. This new low is likely a direct result of the closure of all ocean-intercept fisheries. Combined landings from New Jersey, Delaware, North Carolina and South Carolina accounted for 84.3% of the commercial harvest in 2005. No directed shad harvest was reported in state Compliance Reports from Maine, New Hampshire, Massachusetts, Rhode Island, Connecticut, Pennsylvania, Maryland, the District of Columbia, and Florida. The National Marine Fisheries Service reported no harvest from Massachusetts, Pennsylvania, the District of Columbia, South Carolina, Georgia, and Florida.

Shad bycatch landings from ocean waters in 2005 decreased greatly from 2004 levels, comprising 7,411 pounds, or about 1% of the coastwide total. Only five states—Maine, New Hampshire, New York, New Jersey, and North Carolina—reported landings of ocean bycatch. Substantial shad sport fisheries occur on the Connecticut (CT and MA), the Hudson (NY), the Delaware (NY, PA and NJ), the Susquehanna (MD), the Santee and Cooper (SC), the Savannah (GA), and the St. Johns (FL) Rivers. Shad sport fisheries are also pursued on several other rivers in Massachusetts, Virginia, North Carolina, South Carolina, and Georgia. In 2005, recreational creel limits ranged from zero to 10 fish per day. The exception to this is the Santee River (SC), which is permitted to have a 20 fish per day creel limit due to the approval of a conservation equivalency plan in 2000. Tens of thousands of shad are caught by hook and line from large East Coast rivers each year but detailed creel surveys are generally not available. Actual harvest (catch and removal) may amount to only about 20-40% of total catch, but hooking mortality could boost this "harvest" value substantially. Several comprehensive angler use and harvest surveys are planned or have been recently completed.

MRFSS Data for American Shad are unreliable due to the design of MRFSS that focuses on active fishing sites along coastal and estuarine areas. For 2005, MRFSS does not report the harvest or catch of any American shad.

Several creel surveys were completed in 2005 including the Hudson River (NY), the Connecticut River (CT), the Susquehanna River below the Conowingo Dam (MD), the Tar-Pamlico River (NC), the Tailrace Canal of the Cooper River (SC), the Ogeechee River (GA), and the St. John's River (FL). Of the 6,582 shad caught on the Hudson, anglers harvested only 508, a retention rate of 8%. Catch per unit effort ranged from 0.123 fish/hour in early spring to 0.585 fish/hour in late spring. Anglers in Connecticut that targeted shad were successful 32% of the time when fishing from shore and boats were successful 41.2% of the time. Total effort in Connecticut has declined 75% since the last creel survey conducted in 2000, while total catch shows a similar decline of 73.2%. In Maryland, the catch and release fishery for American shad reported a catch rate of 0.49 American shad per hour. Anglers on the Tar-Pamlico River had a total catch of 7,575 shad (combined American and hickory) with an estimated harvest of 1,212 fish (American shad = 1,192 fish), and a success rate of 1.6 fish caught per angling hour. The estimated harvest for the Cooper River recreational fishery was 14,629 fish, 65% of which were males. Fishermen surveys report that catch per hour as 1.60 shad and that 22% of fish caught were released on the Cooper River. The harvest on the Ogeechee River from January 30 through April 2, 2005, was 442 fish (379.9 pounds) with effort estimated to be 1754 hours. The creel survey on the St. John's River in Florida for the 2004-2005 season reported 1,270 shad caught with an estimated harvest rate of 21% (269 fish).

Hickory Shad

The Potomac River Fisheries Commission, North Carolina, South Carolina, and Georgia reported hickory shad commercial landings in 2005. North Carolina reported the highest landings with 173,779 pounds. In 2005, the coast-wide commercial landings for hickory shad were 179,919 pounds (from 2006 State Compliance Reports). This is a decrease from the 2004 total preliminary landings of 187,464 pounds.

MRFSS Data for hickory shad are unreliable due to the design of MRFSS that focuses on active fishing sites along coastal and estuarine areas. For 2005, MRFSS does not report the harvest or catch of any hickory shad.

River Herring (Blueback Herring and Alewife)

Commercial landings of river herring declined 90% from over 13 million pounds in 1985 to about 1.33 million pounds in 1998. In 2005, river herring landings were reported from Maine, New Hampshire, Massachusetts, New York, New Jersey, Delaware, PRFC, and North Carolina, totaling 692,827 pounds, down from 2004's total of 2,120,881 (from 2006 State Compliance Reports). MRFSS Data for river herring are unreliable due to the design of MRFSS that focuses on active fishing sites along coastal and estuarine areas. For 2005, MRFSS does not report the harvest or catch of any river herring.

5.3.4 Red Drum

5.3.4.1 Description of fishing practices, vessels and gear

Commercial

There is no directed commercial fishery for Atlantic red drum in state waters, and the EEZ was closed to harvest by the SAFMC in 1990 to prevent any directed fishery for red drum, especially for adults, from developing in these waters (ASMFC 2002) . Traditionally, landings have occurred almost exclusively in state waters as prior to the EEZ closure landings in federal waters were a bycatch of other fisheries and did not exceed 2,000 lbs in any year since 1985 (Table 5.3.4-1). Commercial landings of red drum along the Atlantic coast were high during the early 1950's and have generally fluctuated from 150,000 to 400,000 lbs since (Table 5.3.4-2).

Currently, North Carolina is the only state along the Atlantic coast with any significant annual landings of red drum and has accounted for greater than 95% of the coastwide landings since 1989. Landings of red drum in North Carolina are primarily a bycatch in other fisheries, particularly those targeting flounder, striped mullet, spotted seatrout and weakfish. Virginia consistently reports annual landings but has only exceeded 10,000 lbs in three of the last 10 years. Landings north of Virginia are less frequent. Florida has had a no sale provision on native caught red drum since January 1, 1989. In 1987, South Carolina declared red drum a gamefish and established a no sale provision except for mariculture grown fish with the appropriate documentation. Landings in Georgia are limited to hook and line captured fish and typically do not exceed 3,000 lbs. Overall Atlantic landings for the period of 1989 through 2000 were dominated by anchored and runaround gill nets followed by long hauls, pound nets and beach seines. Georgia allows the sale of red drum as long as they are within the state's regulations (size & bag limits) and the individual has their equivalent of a land and sell license – fish must be taken with hook and line

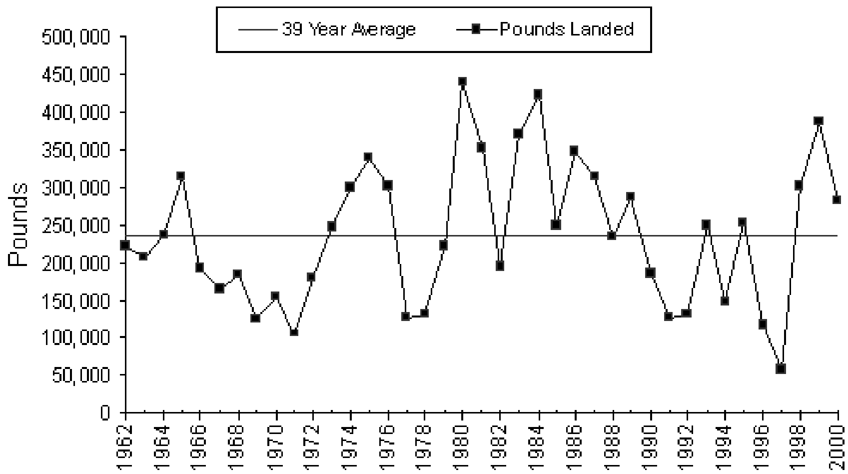
Note: East Florida – commercial harvest prohibited since late 1980s

Historic landings data along the Atlantic coast are from the period prior to when Florida and South Carolina prohibited the sale of native red drum. Commercial landings and nominal value can be subdivided into five major gear categories: gill nets, pound nets, seines, hand gear and trawls.

Figure 5.3.4-1. Red Drum Commercial and Recreational Harvest (pounds). (Source: NMFS Office of Science and Technology, 2006; state compliance reports, 2006).



North Carolina

Red drum are commercially harvested in North Carolina with a variety of gears and constitute a bycatch fishery and historically have not been a major component of commercial landings. Prior to the imposition of a possession limit on red drum greater than 32 inches TL (changed to 27 inches TL in 1992) by North Carolina, Outer Banks fishermen occasionally targeted large red drum with long haul seines in Pamlico Sound. The increase in the legal minimum size in 1991 limit for red drum from 14 to 18 inches TL reduced mortality of immature red drum. This resulted in an increase in the age of entry into the commercial fishery of about 8 months. Due to current size restrictions (18-27 inches TL), commercially harvested red drum are generally from a single year class. Therefore, catches vary annually and depend on year class strength. Age-1 and age-2 fish presently dominate the landings and the harvest of adults is prohibited.

Historically, annual landings of red drum have been highly variable from year to year. These ranged from 7,500 to 214,000 lbs during the 1970's with an average of 83,009 lbs per year whereas landings from the 1980's were greater than in the 1970's, averaging 203,813 lbs per year with a range of 52,561 to 283,020 lbs.

Landings averaged 186,932 lbs per year and ranged from 52,548 to 372,749 lbs during the 1990's. The majority of these originated from fishing operations in Pamlico and Core sounds and the Atlantic Ocean. No commercial gear dominated landings in the 1970's, although long haul and common haul seines generally were the most productive with gill and pound nets, and fish trawls occasionally contributing larger catches. During the 1980's and 1990's, anchored and run-around gill nets accounted for greater than 70% percent of annual commercial landings. Most of these net fisheries are seasonal, and target spotted seatrout, (southern and/or summer) flounder, and striped mullet along the barrier islands and mainland shorelines.

They catch red drum incidentally and make an important contribution to the overall catch.

A directed fishery used run-around gill nets to encircle schools of red drum developed in the mid-1990s. This gear accounted for 31% of the commercially catch from 1994-1998.

Prior to the implementation of trip limits in 1998, nearly half of the total annual commercial harvest of red drum was taken by a few trips which landed large amounts of red drum. Slightly more than 1% (1.1%) of the trips that landed red drum accounted for 48.5% of the total harvest. For this period, the largest landings of red drum primarily occurred behind the 'Outer Banks' from Oregon Inlet to Ocracoke during the spring and fall. Gears that typically had large landings of red drum were runaround gill and long haul nets. These were effective in circling large schools of red drum. Participation in the run-around gill net fishery increased during this period as many of these fishers actively pursued schools of red drum., A typical catch for a run-around gill net trip would range from 100 to 1000 pounds whereas a few exceptional long haul sets caught up to 10,000 pounds.

Implementation of a 100-pound trip limit on the commercial harvest of red drum in October of 1998 effectively eliminated any large-scale directed fishery for red drum. Some fishers still actively targeted this species even at these reduced harvest limits. This resulted in reduction of the daily commercial trip limit to levels ranging from 10 to 5 red drum. Also, at least 50% of the landings by weight for an individual trip consist of edible finfish other than red drum. The intent of the rule is to make this exclusively a bycatch fishery.

South Carolina

South Carolina designated red drum a gamefish in 1987. They can be sold only when transported into the State with proper documentation showing legal capture, or if the fish are produced by a bonafide mariculture operation. Red drum landings never exceeded 14,000 lbs with a nominal value of $12,000 in the last 30 years.

Georgia

Georgia had a small commercial gill net fishery prior to the 1950s, but presently there is no directed commercial fishery for red drum. Landings enter the market through recreational fishermen who sell their catch, often directly to restaurants. This is not illegal as long as they were not harvested with net gear. As a result, many red drum are not recorded in official commercial statistics.

Florida

Commercial landings on the east coast of Florida fluctuated annually between 85,000 lbs and 250,000 lbs from 1962 to 1987. Most of the catch was taken by either as bycatch of the mullet gill net fishery or by a directed fishery utilizing trammel nets. Commercial landings ceased when regulations prohibiting their sale became effective in 1988. The existence and potential red drum harvest in the EEZ off the east coast of Florida is recognized by both commercial and recreational fishermen.

Recreational

Recreational fishing for red drum along the Atlantic coast historically extended farther north than at present. Red drum was a prized sport fish as far north as Barnaget Light, New Jersey. There, surf fishermen commonly landed large adult fish (25-45 lb). This fishery no longer exists; only an occasional large red drum is caught.

The recreational fishery for trophy red drum along the South Atlantic is primarily a surf fishery along the outer beaches of barrier islands. The largest (94 lbs 2 oz) red drum ever caught by recreational angler was taken in the surf on the Outer Banks of North Carolina. Fishing in estuaries from Chesapeake Bay to Florida catch small red drum. Salt-water angling surveys indicate that 88% of red drum caught in the Mid-Atlantic region in 1965 came from sounds, rivers and bays. In 1970, only 47% were caught in estuarine waters. Along the southeastern Atlantic coast, more red drum (59%) were caught in the ocean in 1965; however, in 1970, 79% were caught in sounds, rivers and bays. Catch data for red drum on the eastern shore of Virginia from 1955 to 1965 showed small catches. Highest rates occurred during 1957 and 1962 (0.14 fish per man-hour). More fish were landed during May and September, but catch rates were highest for April, June and September. A low of 0.01 fish per man-hour occurred in 1959. A 1963 sport fishery survey in the Cape Canaveral area of Florida found that catch per unit effort was highest in October and April.

<u>Seasonality</u>

Along the barrier beaches and inlets of the North Carolina coast, surf fishing is best from March to June and mid-September to November. Large red drum are available from mid-May through early October around river mouths and high shoals in Pamlico Sound. Small fish are caught along barrier island beaches during a seven month period (June through December) with a peak period from September through December. During these months, red drum are also caught in estuarine waters, particularly around grass flats and shorelines. Red drum fishing occurs throughout the year from South Carolina to southeastern Florida with the best fishing for small fish from August to December inshore. Large fish are targeted from March to May and September to December along the beach and shoal areas. Best fishing for small red drum from St. Lucie Inlet to southern Florida is from April to August and from August to November for large ones. Adult red drum generally remain in coastal waters during spring and fall months and during late summer move offshore, presumably to spawn. Generally, adult drum move offshore during the coldest months.

<u>Fishing Gear</u>

Red drum are caught by bottom fishing, jigging and casting from shore, as well as, bottom fishing, casting, live-lining and trolling from boats. Baits include soft or shedder crabs, shrimp, clams, squid, cut or whole mullet, spot, herring or menhaden, as well as artificial lures such as spoons, jigs, weighted bucktails, feathers, plugs and streamer flies. Red drum have been harvested by gill nets and gigs for home consumption in North and South Carolina. In South Carolina, 94% of the individuals using gill nets in 1978, fished recreationally. This fishery no longer exists since the State of South Carolina declared red drum a gamefish and harvest is restricted to hook and line and, during designated months, gigs.

For-Hire Fishery (ASFMC 2002)
The for-hire fishery for red drum is charter boat fishery, concentrated on the Atlantic Coast from North Carolina to Florida, with a substantial fishery in the Gulf of Mexico as well. A head boat fishery for red drum is virtually nonexistent (ASMFC 1994b). NMFS headboat survey data from 1981 to 1997 estimated headboat landings of red drum to be far less than 1% of total recreational fishery landings (Holiman 1999).

Whitmore (1994) looked at relative directed effort in the South Atlantic charter fishery. Relative effort was based on the product of the number of boats and the number of months/12 fished. Directed red drum effort ranked 9th out of 16 species, well behind black sea bass, groupers, and king mackerel, but ahead of summer flounder, Spanish mackerel, and sharks. Nearly 50% of the relative effort occurred in Georgia, with the remaining effort distributed fairly evenly between North Carolina and South Carolina. Florida did not have a charter fishery directed at red drum in 1994 and 1995.

From 1983 to 1998, estimated red drum harvest in the South Atlantic charter fishery fluctuated between 3,348 fish (8,868 lbs.) in 1989 and 119,067 fish (283,813 lbs.) in 1995. Harvest declined annually from 1995 to 1998. The 1998 harvest of 14,769 fish (91,303 lbs.) comprised 39% of the catch and 5% (7% by weight) of the total recreational harvest. From 1983 to 1998, the percentage of party/charter boat trips targeting red drum has fluctuated between 0.20% in 1985 to 5.22% in 1995. This peak of 5.22% in 1995 coincides with peak catch and landings over the same time period. This percentage has declined annually from 1995 to 1.15% in 1998. In contrast, the percentage of anglers targeting red drum in the shore and private/rental boat fisheries in 1998 was 3.19% and 5.10%, respectively (Holiman 1999). Comparing the charter boat fisheries by state, the highest percentage of charter boat anglers targeting red drum in 1998 was South Carolina (4.4%), followed by Georgia (2.4%), Florida East Coast (0.9%), North Carolina (0.2%), and Virginia (0.0%).

Popularity of fishing for red drum by charter boat anglers has increased from 1998 to 2000 in Florida (0.9% to 3.9%) and Georgia (2.4% to 8.7%), while decreasing in South Carolina (4.4% to 2.2%) and essentially remaining very low in North Carolina (0.2% to 0.1%). In South Carolina, red drum has been the most sought-after species in the inshore charter-boat fishery from 1995 to 1999. In 1999, of 2,900 inland boat trips, 1,476 (51%) were targeted at red drum, followed by anglers targeting any species (16%), and spotted seatrout (15%). The number of permitted boats fishing in inland waters (where the majority of the effort is directed at red drum) has increased nearly annually from 39 boats in 1993 to 98 boats in 1999. Directed effort for red drum increased significantly from 1,359 angler-hours in 1993 to 12,875 angler-hours in 1999. Catch has shown an increasing trend similar directed effort from 1993 to 1999, while CPUE has fluctuated between 0.5 and 0.7 fish per angler-hour. By comparison, private boat CPUE showed the same trend though was consistently lower than charter CPUE. Of the reported 10,656 red drum caught by the charter fishery, 85% were released (Low 2001).

Seasonality

A 1994 ASMFC survey of Atlantic seaboard charter and headboat fisheries showed that the charter boats fish year-round for red drum in South Carolina and Georgia, and fish 9 months for red drum in North Carolina (data indicated no red drum charter fishery in 1994) (ASMFC 1994b). In South Carolina prior to 1998, the charter-boat effort for red drum peaked in April and during September - November. The fishery has since evolved into a year-round fishery, with substantial effort each month in 1999 (Low 2001). Charter boats near Brunswick, Georgia, will target red drum year-round, with peak the season from September through December in the saltwater marshes surrounding St. Simons Island.

Fishing Gear

Charter boats are generally not exclusive to red drum, turning to target other species when the bite is hot and at different times of the year. Fly fishing charters are gaining popularity. Fishing is for red drum is predominantly inshore and estuarine. In 1993, 15% of charter trips in South Carolina were in estuarine waters. These estuarine charters sought red drum and spotted seatrout as the principal species. The majority (70%) of South Carolina charter trips was offshore and not targeting red drum. Common fishing techniques include bottom fishing from North Carolina through Georgia, with additional live lining in North Carolina and trolling in South Carolina (ASMFC 1994). Charter boats near Cape Canaveral, Florida, will pole flat-bottom boats in estuarine waters and fish with spinning gear on light line (6-10 lbs.). In the fall near Morehead City, North Carolina, charter boats fish the estuarine waters for red drum using cut bait. Historically, Matlock (1978) indicated that charter boats were still, troll, and drift fishing in the open ocean and bays.

In South Carolina, 98% of red drum effort, and 95% of the catch is concentrated in inland waters. The remaining effort is concentrated in open ocean waters from 0-3 miles, with some effort in ocean waters >3 miles. Open ocean effort is typically bottom fishing over natural structure, but does include some manmade structure. Inland trips are typically made with smaller boats with an average of 2 anglers. Ocean trips are typically larger boats carrying an average of 4 anglers.

Current status of the fishery

Commercial Fishery

(ASMFC 2006)

Few commercial landings of red drum have been recorded in states north of Maryland since 1960 (Table 4.3.4-3). Only Rhode Island, New York, and New Jersey have reported any commercial landings since 1980. Coastwide commercial landings show no particular temporal trends, ranging from approximately 55,000 to 422,000 pounds annually between 1960 and 2005 (Figure 5.3.4-2). The greatest harvest was reached in 1980, while the lowest was reached in 2004. In 2005, coastwide commercial harvest increased to 129,980 pounds, the majority (~99%) from North Carolina (Table 4.3.4-3). Landings in Georgia (<500 lbs), Virginia (656 lbs), Maryland (37 lbs), and New Jersey (517 lbs) comprise the remaining 1% of the commercial landings for red drum.

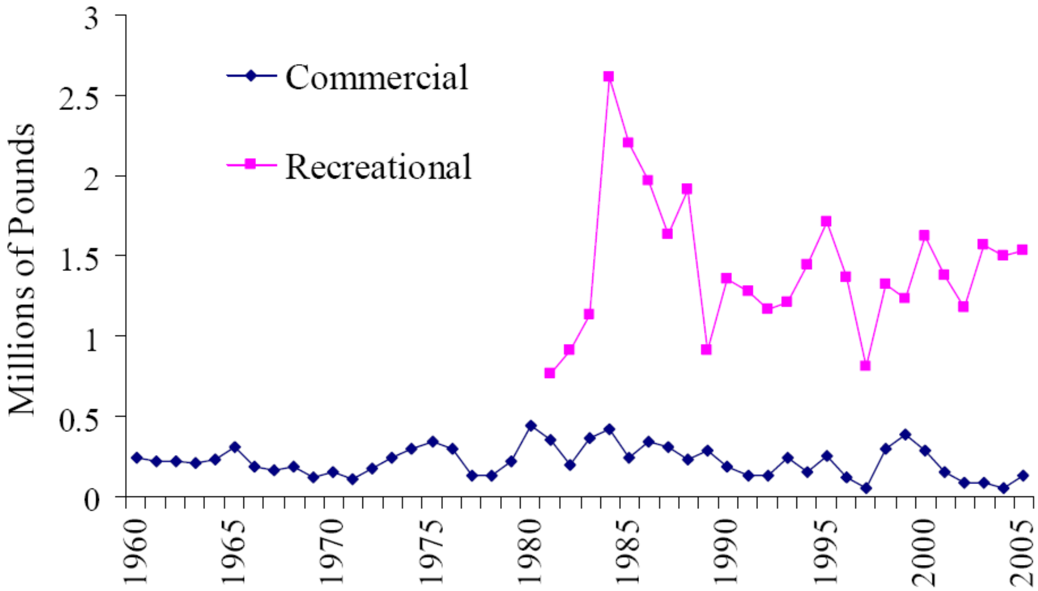


Figure 5.3.4-2. Red Drum Commercial and Recreational Harvest (pounds). (Source: NMFS Office of Science and Technology, 2006; state compliance reports, 2006).

Historically, the major commercial harvesters were North Carolina and Florida. However, commercial harvest has been prohibited in Florida under state regulations, since January 1988. South Carolina has also banned the commercial harvest or sale of native caught red drum since 1987. In North Carolina, an annual cap of 250,000 pounds limits the commercial harvest of red drum. In 1999, the North Carolina Marine Fisheries Commission implemented rules through the development of a state red drum FMP that: prohibited the possession or sale of red drum larger than 27 inches; reduced the recreational bag limit to 1 fish per day between 18-27 inches; imposed a commercial daily trip limit of seven (7) fish with a 250,000 pound annual cap; and required fishermen to attend gill nets less than five-inch stretched mesh from May 1-October 31 in order to reduce regulatory discards. In 2003, the South Atlantic State/Federal Fisheries Management Board approved a motion to allow the North Carolina Fisheries Director to raise or lower the seven fish commercial trip limit while maintaining the 250,000 pound harvest cap.

Table 4.3.4-3. Commercial landings (in pounds) of red drum along the Atlantic coast, 1960-2005 (1960-2004 Data: NMFS Fish. Stats. & Econ. Division, 2006; 2005 Data: state compliance reports, 2006).

Recreational Fishery

(ASMFC 2006)

The number of red drum harvested by recreational fishermen ranged between approximately 175,000 and 1,000,000 fish from 1981 to 1988; since then, the number has been in the 250-530,000 range (Figure 5.3.4-3). Over a million fish were taken in both 1984 and 1985, but this was exceptional. The recreational harvest for 2005 was 498,761 fish (~1.5 million pounds) (Table 5.3.4-4). By number of fish, Florida takes approximately 38% of the catch, but takes over 50% by weight. South Carolina, Georgia, and Florida are responsible for 88% of the catch by number of fish (Table 5.3.4-5). The number of red drum released by recreational fishermen was approximately 2.4 million in 2005, an increase from the previous year, and the second highest for the time series (Table 5.3.4-6).

Allowable gear
There is no harvest or possession of red drum allowed in the EEZ.

5.3.4.2 Economic and social description

Commercial fishery
Reported annual red drum commercial landings (i.e. pounds) in the Atlantic states had averaged about 322,000 pounds with an average, deflated (i.e. 1982 dollars) total value of $140,00 during the 1980's (Table 5.3.4-7), a 61% increase in the total value compared to 1970's. In contrast, the average reported landings in the Atlantic states in the 1990's were only 61% of 1980's average landings, and the total deflated ex-vessel value declined to an average of about $100,000 (Table 5.3.4-7) even though the highest nominal ($412,000) and deflated ($215,000) total ex-vessel value was recorded in 1999. In general, the overall ex-vessel prices, nominal and deflated, in the Atlantic states have generally increased since the 1970's (Table 5.3.4-7).

These trends in red drum landings and values in the Atlantic states mainly reflect the interaction of regulatory actions and market demand. Before the 1980's, commercial red drum landings in both the Atlantic and Gulf states were generally associated with commercial fishing effort in near-shore and estuarine waters and catches of juvenile red drum. In the early 1980's, the ex-vessel price of red drum began to increase significantly as Cajun-style blackened redfish was introduced to restaurant menus (Martin 1986) throughout the country. Commercial fishermen in the Gulf began targeting schooling adult red drum in the EEZ (GMFMC 1987) and concern grew in the Atlantic states that large-scale purse seine fishing would begin developing along the Atlantic coast which could lead to recruitment over fishing (ASMFC 1984). Recreational fishing lobbying efforts to assign the red drum "gamefish" status also began developing in the Atlantic states, especially Florida (e.g. Thunberg et al. 1993). In 1987, the red drum was given gamefish status in South Carolina, and Florida began taking management actions to remove red drum as a commercially targeted species. In 1988, the ISFMP (ASMFC 2001) requested that all states from Maine to Florida implement red drum regulations "...to prevent development of northern markets for southern fish." By January 1989, Florida had implemented a one-fish bag limit for recreational and commercial fishermen and a ban on sale of native red drum.

The deflated ex-vessel price of red drum has generally increased between 1994 and 2000, while the ex-vessel price index of edible fish has displayed a downward trend during the same time period (NMFS 2001a). The red drum ex-vessel price increase during this time period compared to the edible fish index would suggest that the demand for red drum has outpaced the overall demand for fish in the U.S. To make definitive statements on how changes in demand and supplies, including imported red drum products, over time have affected red drum prices would require an extensive econometric analysis and an understanding the market structure. Regardless, it appears that the increase in red drum ex-vessel prices during the 1990's probably included regulatory constraints on U.S. caught red drum commercial fishing (supplies), as well as an increase in the demand for red drum. It should also be noted that harvesting of adult red drum with a lower ex-vessel price compared to estuarine-oriented juveniles complicates the analysis of price trends during the 1970's and 1980's (SAFMC 1990b) compared to the 1990's, but other factors may moderate this complication. Specifically, the harvest of adults was obviously constrained by regulatory actions in the Atlantic states starting in the 1980's, and the higher market prices for juvenile created a strong incentive for targeting juvenile fish compared to adults.

Commercial landings of red drum in North Carolina have represented the most consistent and nearly sole source of red drum landings and related ex-vessel values in the Atlantic states. During the 1990's, North Carolina commercial harvest has annually averaged about 93% and 94%, respectively, of the total landings and deflated ex-vessel value for the Atlantic states (Table 5.3.4-7) while in the 1970's the deflated value of North Carolina landings only averaged 18% of the Atlantic total. During the 1990's, nominal total ex-vessel value for red drum landings in North Carolina averaged $163,600 fluctuating between approximately $57,000 in 1991 to $398,000 in 1999. The deflated total ex-vessel value averaged about $95,200 (Table 5.3.4-7) during the 1990's and also reached a high in 1999, about $208,000 and a low of approximately $34,400 in 1997. Both the nominal and deflated ex-vessel price of red drum in North Carolina has shown a generally increasing trend during the 1990's with the nominal price reaching a low of $0.58 in 1990 to a high of $1.08 in 1999 (Figure 5.3.4-4). The deflated ex-vessel price fluctuated between $0.65 in 1997 and $0.41 in 1990 (Figure 5.3.4-3). As previously discussed, the upward increase in North Carolina ex-vessels was probably influenced by the decline in red drum supplies due to regulatory actions in the Southeast, especially in the Gulf states.

Trends in the total annual ex-vessel value by major gear groups in the Atlantic states during the 1980's reflect the decline in Florida landings and the increase in North Carolina landings. Before 1985, red drum catches from the "Combined Gear" category, as reported for the east coast of Florida, comprised more than 50% of the total nominal ex-vessel value of Atlantic red drum landings (Table 5.3.4-8). With a decline in Florida landings after 1985, gill net catches, mostly from North Carolina, represented over 50% of the total nominal ex-vessel of Atlantic red drum landings (Table 5.3.4-8) by 1988. Seine catches also accounted for a significant portion of the total ex-vessel value during the 1986-98 period (Table 5.3.4-8).

Annual average, deflated ex-vessel prices for red drum by gear groups have been the highest from hand gears and lowest for pound nets and incidental trawl catches (Table 5.3.4-8) plus trawl prices had the lowest deflated minimum price during the 1980-2000 period. Fish size may account for the higher prices for hand gear catches compared to other gears because hand gear catches are often composed of one or two year old fish which usually fetch a higher price per pound than large adult fish which were historical caught by trawls or other gear used in the EEZ (SAFMC 1990b).

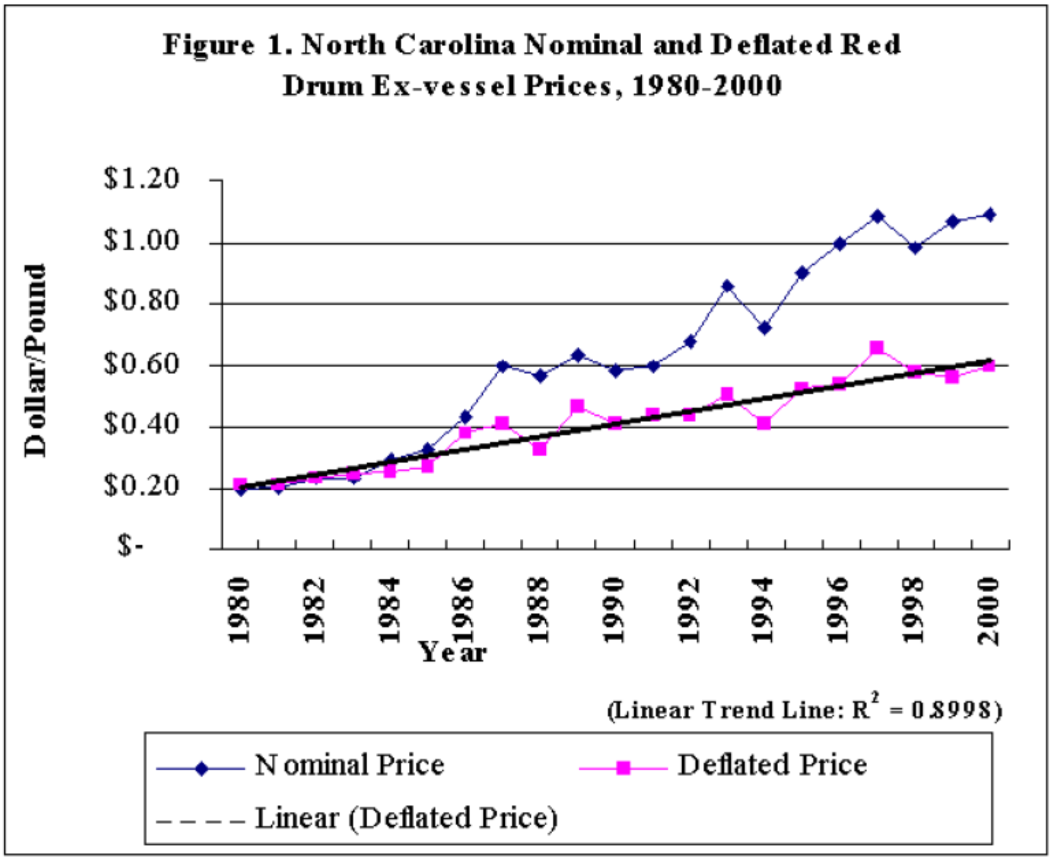

Figure 5.3.4-4. North Carolina nominal and deflated red drum ex-vessel prices, 1980-2000.

There is no recent research on the red drum marketing (e.g. retail price trend analysis, import trends, market structure, etc) in the United States. Except for commercial aquaculture operations, the lack of available market studies on red drum is partly indicative of the lack of interest in developing markets for red drum due to current regulatory constraints on directly harvesting and/or marketing red drum in the U.S. It does appears that there is at least a regional demand for red drum in the Gulf states because anecdotal information indicates that some of the red drum caught in North Carolina are sold in the Gulf states. A small amount of red drum is still landed in the Gulf states, about 38,000 pounds in 2000 at a nominal ex-vessel price of $1.52.

Table 5.3.4-8. Average deflated ex-vessel prices of red drum landings by gear in the Atlantic states, 1980-2000.

Gear Group	Average	Maximum	Minimum
"Combined Gear"*	0.69	0.79	0.57
Gill Nets	0.42	0.65	0.22
Seines	0.40	0.65	0.22
Hand Gear	0.70	1.05	0.47
Other	0.51	0.71	0.18
Pots & Traps	0.53	0.78	0.37
Pound Nets	0.38	0.54	0.18
Trawl	0.35	0.79	0.13

"Combined Gear" - category used for all Florida red drum landings in the 1980s; * Commercial harvesting was disallowed in
Florida after 1988
Gill nets - includes runaround, anchor and other gill nets
Seines - includes beach, common and long haul seines
Hand Gear - includes hand lines, spears (gigs), rakes and rod and reel
Other - all other gear
Pots & Traps - includes fish and crab traps
Trawls - includes shrimp, finfish and crab otter trawls

Recreational fishery

Starting in 1999, a recreational fishing expenditure survey was conducted in the Southeast region as an "add-on" to the NMFS Marine Recreational Fisheries Statistics Survey (MRFSS) (Genter et al. 2001).

Angler daily trip expenditures were estimated for each fishing mode by resident group (i.e. non-resident and state resident) within each state including North Carolina, South Carolina, Georgia, and Florida. For example, resident private boat anglers fishing in North Carolina, South Carolina, Georgia, and on the east coast of Florida, averaged $71, $36, $161, and $37, respectively. Non-resident anglers averaged $92, $67, $78, and $141, when saltwater fishing in North Carolina, South Carolina, Georgia, and along the east coast Florida, respectively (Genter et al. 2001).

Expenditures related to anglers targeting a given species such as red drum were not estimated in the above study. Southwick Associates (2001) did prepare a preliminary estimate of red drum expenditures by red drum anglers in Virginia, the Carolinas, Georgia, and Florida by applying the average expenditure to the number of red drum targeting trips in a given state (Table 5.3.4-9). On a per-trip basis, largest expenditures are reported for resident activity in Florida, South Carolina and North Carolina (Table 5.3.4-9). The average expenditures are significantly higher when equipment items are included compared to trip-related costs only. Equipment expenditures are primarily comprised of boat and tackle costs. The large difference between trip-related and equipment expenditures is also seen in the U.S. Fish and Wildlife Service's 1996 National Survey (USFWS 1997), but was not as prevalent in the 1991 National Survey when the general economy was not as robust as in 1996 and 1999. It can be speculated that increased expenditures for equipment by red drum and other anglers may be driven in part by a strong economy as well as other factors such as fish population, changing angler preferences (i.e. flats boats), etc.

Based upon these preliminary estimates, 1999 expenditures by all anglers was over $1.3 billion, and resident and non-resident anglers targeting red drum in 1999 were $75.7 million and $1.26 billion, respectively. Within the South Atlantic states, Florida had the highest estimated total expenditure by non-resident anglers, $59.2 million, followed by North Carolina, $10.4 million; South Carolina, $4.0 million; and Georgia, $111,000. Estimated resident angler expenditures within the South Atlantic states were $1.1 billion, $78.8 million, $32.1 million, and $11.1 million for Florida, South Carolina, North Carolina, and Georgia, respectively. For the South Atlantic states, estimated red drum angler expenditures represented over 20 % of all marine angler expenditures in the South Atlantic states as reported by Genter et al. 2001. The economic "importance" and impacts of these angler expenditures and related implications will be discussed in Sections 1.5.3.1 and 1.5.3.2. (sections reference ASMFC Red Drum Amendment 2)

The NMFS also conducted an add-on survey to the MRFSS in the southeast region during 1997. The purpose of the add-on survey was to obtain socio-demographic, economic and fishing behavioral information on recreational anglers throughout the southeastern United States (Holiman 2000).

Summarized information on the demographic and economic characteristics of the recreational fishery in North Carolina was also provided in the FMP (NCDMF 2001) for 1997-1998. The majority (95.4%) of recreational anglers targeting red drum in North Carolina waters in 1997 were white and predominantly male (83.5%) and averaged 18.2 years of experience in recreational fishing. The majority (68%) of North Carolina red drum anglers surveyed was between 26 and 55 years of age and about 73% of them were employed, earning between $15,000 to over $175,000 per year. Slightly more than half reported earning over $45,000 per year.

Table 5.3.4-9. Red drum target effort trips in the South Atlantic by state for the period 1985-2000. Figures are thousands of trips (Source: MRFSS data as reported by Holiman 1999 and Southwick 2001).

Year	North Carolina	South Carolina	Georgia	East Florida	Total
1985	3,380.36	1,571.87	438.86	9,926.71	15,317.80
1986	2,977.06	1,447.73	639.43	9,840.15	14,904.37
1987	3,861.94	1,648.12	751.35	10,686.78	16,948.19
1988	4,762.89	1,906.13	666.72	11,485.19	18,820.93
1989	3,848.90	1,080.63	625.89	10,805.93	16,361.35
1990	3,867.93	931.06	705.44	8,067.60	13,572.03
1991	3,762.39	1,796.21	740.82	11,086.64	17,386.06
1992	4,372.00	1,457.23	572.15	10,340.03	16,741.41
1993	4,716.08	1,776.21	673.46	9,630.11	16,795.86
1994	5,170.14	1,987.30	955.82	11,815.06	19,928.32
1995	5,106.67	1,530.25	781.72	11,617.80	19,036.44
1996	4,741.82	1,434.08	617.36	10,525.86	17,319.12
1997	4,891.51	1,606.38	575.87	11,298.96	18,372.72
1998	4,461.46	1,714.09	571.86	10,089.81	16,837.22
1999	4,555.04	1,213.32	472.58	8,194.17	14,435.11
2000	6,090.99	1,276.87	763.93	11,162.94	19,294.73
Total	70,567.18	24,377.50	10,553.26	166,573.72	272,071.66

Although marine angler expenditures at the state and county level are useful, economists do not consider expenditures and related economic impacts to be the best approach for determining the economic value of the recreational fishing experience. From an economic perspective, the appropriate approach to quantifying the economic value of recreational fishing is based upon consumer surplus (Edwards 1991).

In general, consumer surplus or welfare is the value of the trip over and above the actual expenditure on the trip. For non-market goods, like shore or private boat fishing, consumer surplus can be directly estimated by asking anglers what they are willing to pay or be compensated for changes in quantity or quality of their fishing experience (SAFMC 1990b). Consumer surplus can also be indirectly approximated using a specialized travel cost model, Random Utility Models (RUMs), which is used to estimate angler site selection patterns based on individual trip costs and other site characteristics including fish catch rates. A RUM oriented valuation of marine recreational fishing for private boat angler was done by Haab et al. (2000) using data collected during the 1997 MRFSS add-on in the Southeastern states. Controlling for other site selection characteristics, they estimated the marginal value of an increase in historical catch and keep (harvest) by one additional fish harvested in a given state. In the South Atlantic states, the estimated value of one additional red drum caught per trip was the highest for South Carolina ($5.13), followed by Florida's east coast ($3.39), Georgia ($1.88), and North Carolina ($.36). It is assumed that a reduction in the number of red drum that could be caught and retained by the angler due to more stringent bag limits would have a similar magnitude in value change per fish for an angler. The loss of red drum fishing opportunities per trip for the following South Atlantic states was also estimated: South Carolina ($20.79), Florida's east coast ($8.73), Georgia ($3.04), and North Carolina ($1.87). For example, if "elimination of access" to North Carolina's red drum recreational fishery occurred, it would result in a consumer surplus or welfare loss of almost $232,000 based upon 124,053 annual red drum targeting trips, i.e. the value of red drum above angler expenditures (Haab et al. 2000).

Besides the specifics of eliminating "access", there are other qualifiers to this estimate. The RUM analysis will tend to overestimate losses from reduction in catch and keep rates because it does not account for switching to other species by anglers (Haab et al. 2000). In addition, values associated with catch and releases vs. retention were not addressed, although the importance of red drum catch and retention in fishing success has been debated by researchers (e.g., Duda 1993).

Non-Consumptive Factors

Non-consumptive considerations include non-consumptive use values and non-use values. Consumptive use values are associated with capture fisheries including catch-release fishing while non-consumptive use values are usually associated with "eco-tourism." A field trip to view the schooling of juvenile red drum in their estuarine habitat or a fish-watching hobbyist visiting an aquarium to watch large adult red drum in a tank are examples of activities that generate non-consumptive use value related to red drum. In contrast, "non-users" may also derive benefits of some part of the environment, such as red drum, based upon the knowledge that actions have been or will be taken to enhance and/or preserve a portion of the environment (Russell 2001). Economists also divide non-use value into two categories, bequest value and "pure" existence value. As the name implies, bequest value is based upon concern for future generation use or non-use of natural resources while existence value is oriented toward current generations. Consequently, total value (TV) of a resource from an economic perspective can be categorized into the three components as adapted from Hanley & Spash (1993):

$$TV = CS + XV + BV$$

where CS is consumer surplus (i.e. use value) including expected CS, XV is existence value, and BV is bequest value. Estimating total value and/or component values can be problematic, but in general, these values can be estimated two major methods. The indirect methods attempt to analyze markets or other behavioral information (e.g. fishing access site selection by anglers) in order to estimate willingness to pay (WTP) and/or willingness to accept (WTA) changes in environmental quality like catch and retention rates (Russell 2001). Random Utility Models or RUMs are one example of an indirect method, which can be used to estimate changes in consumer surplus related to red drum fishing. In contrast, the direct method is limited to one methodology, the Contingent Valuation Method (CVM).

CVM is based upon directly asking a relevant sample of consumers, not necessarily users of a resource, carefully constructed hypothetical questions about environment goods (e.g. red drum) in order to estimate WTP or WTA related to changes in a portion of the environment (Russell 2001). Both approaches have strengths and weaknesses, but the CVM approach is the only method for estimating nonuse values (Hanley & Spash 1993).

Pace (1995) estimated the total value of stocking or "enhancing" red drum stocks in South Carolina (SC) by surveying a sample of SC anglers and respondents in sample of all SC households using a CVM oriented mail questionnaire in 1994. Pace (1995) pooled angler and non-angler household, but the weighting of the sample results are skewed toward many of the non-angler respondents which have little or no interest in recreational fishing or other uses (e.g. "fish watching"). Consequently, it is assumed that their responses are a rough approximation of nonuse values (benefits) related to stocking red drum in South Carolina. Pace (1995) reported that the average, annual WTP per household (1994 dollars) was $1.73 for red drum stocking with annual aggregate value of about $2.2 million based on total SC households in 1994. The average of the WTP value seems reasonable because it has similar magnitude as reported by Haab et al. (2000) for red drum anglers as approximated using RUMs. Regardless, the preservation and enhancement of red drum stocks can also generate benefits for non-users, not just anglers.

5.3.5 Weakfish and other Sciaenids

5.3.5.1 Description of fishing practices, vessels and gear

Current Status of the Weakfish Fishery

The majority of commercially and recreationally caught weakfish are landed from state waters. The dominant commercial gears used include gill nets, pound nets, haul seines, and trawls. The majority of commercial landings occur in the fall and winter months, presumably as the fish congregate to migrate. The recreational fishery catches weakfish using live or cut bait, jigging, trolling, and chumming. Recreational harvests typically peak in the warmer months (May through October) when effort tends to be greatest.

Typically recreational landings are recorded in numbers and commercial landings are recorded in pounds. However, Table 5.3.5-2uses recreational landings in pounds to compare the landings of the fisheries. Both commercial and recreational landings fell consistently from 2000 to 2004, reaching all-time lows. In 2005, commercial landings continued to decrease, while recreational landings increased 84% from 2004.

Commercial Fishery

The NMFS compiles commercial weakfish landings. The data are cooperatively collected by the NMFS and state fishery agencies from state mandated trip-tickets, landing weigh-out reports from seafood dealers, federal logbooks, shipboard and portside interviews, and biological sampling of catches. The NMFS data were not available for 2005 at the time of this report, thus the 2005 landings rely on preliminary data from annual state compliance reports. Massachusetts had no preliminary data to report and no estimate is included in the total.

The commercial weakfish fishery occurs during the fall and winter as the species migrates from estuaries to over-wintering grounds in the South Atlantic (Hogarth et al. 1995). Weakfish are taken primarily by trawls, pound nets, gill nets, and haul seines. Weakfish landings were dominated by the trawl fishery from the 1950's through the mid - 1980's, when gill net landings began to account for the majority of the landings. Gill net landings in the latter half of the 1990's were about double that of the trawl fishery.

From 2000 to 2003, there was an increasing trend of the commercial fishery accounting for a higher percentage of the total catch (Table 5.3.5-1). However, this trend appears to have stopped in 2004. In 2005, commercial landings contributed less than 50% of the total landings for the first time in the time series (1982-present). Coastwide commercial weakfish landings have ranged from a time series high of 21.2 million pounds in 1986 to a low of 1.3 million pounds in 2005.

Table 5.3.5-1. Amendment 4 Control Rule

	Fishing Mortality Rate	Female Spawning Stock Biomass
Target	$F_{30\%} = F = 0.31$	X
Threshold	$F_{20\%} = F = 0.50$	$SSB_{20\%}$ = 31.8 million pounds

Table 5.3.5-2. Comparison of Atlantic coast commercial and recreational weakfish landings

Year	Recreational Landings (pounds)	Commercial Landings (pounds)	Total Pounds	% Total as Commercial
1982	8,285,323	19,478,274	27,763,597	70%
1983	11,730,620	17,475,003	29,205,623	60%
1984	7,013,779	19,773,587	26,787,366	74%
1985	5,489,027	16,953,357	22,442,384	76%
1986	10,141,785	21,187,973	31,329,758	68%
1987	6,749,894	17,072,159	23,822,053	72%
1988	6,331,649	20,526,402	26,858,051	76%
1989	2,177,234	14,162,178	16,339,412	87%
1990	1,347,259	9,438,190	10,785,449	88%
1991	2,130,564	8,692,760	10,823,324	80%
1992	1,398,977	7,453,788	8,852,765	84%
1993	1,102,338	6,853,579	7,955,917	86%
1994	1,795,515	6,190,522	7,986,037	78%
1995	1,855,546	7,098,658	8,954,204	79%
1996	2,925,391	6,940,038	9,865,429	70%
1997	3,692,716	7,297,783	10,990,499	66%
1998	4,044,973	8,419,604	12,464,577	68%
1999	3,143,428	6,905,158	10,048,586	69%
2000	4,154,793	5,400,529	9,555,322	57%
2001	2,722,629	4,999,539	7,722,168	65%
2002	2,192,603	4,772,978	6,965,581	69%
2003	864,960	2,001,271	2,866,231	70%
2004	860,086	1,523,919	2,384,005	64%
2005	1,584,547	1,315,859	2,900,406	45%

*Commercial landings for 2005 are preliminary. Massachusetts landings are not included in the coastwide total. One hundred pounds was included for Georgia's commercial landings; the state reported "confidential but no more than 100 lbs."

North Carolina, Virginia, and New Jersey have dominated commercial weakfish landings since 1950. North Carolina has annually landed the most weakfish since 1982 and Virginia has consistently landed the second most since 1993. North Carolina has accounted for over half of all the weakfish commercially landed since 1982.

Recreational Fishery

Recreational catch statistics are collected by the NMFS in the Marine Recreational Fisheries Statistics Survey (MRFSS). Effort data is collected through telephone interviews. Catch expansions are based on angler interviews and biological sampling conducted by trained interviewers stationed at fishing access sites.

Recreational landings hit a time series high of 11.7 million pounds in 1983. Landings were relatively high from 1983-1988, but abruptly fell in 1989. Annual recreational landings fluctuated between 1.1 million and 4.1 million pounds from 1993 to 2002, but fell to approximately 864,000 pounds in 2003. The lowest recreational landings on record occurred in 2004 (860,065 pounds). Recreational landings rebounded to over 1.5 million pounds in 2005, with New Jersey taking over 1.1 million pounds (~72% of recreationally landed weakfish). North Carolina is a distant second at 157,018 pounds (~10% of recreationally landed weakfish). The number of fish released alive by anglers has remained above 1 million fish since 1993, peaking at over 5 million in 1996, and decreasing to ~1.8 million fish in 2005.

Recreational landings from the EEZ account for only about 13% of the total coastwide recreational landings by pounds since 1982. From 1995 to 2005, recreational harvest in the EEZ has contributed less than 5.3% to each year's recreational landings, and only 1.8% in 2005.

Since 1982, over half of the total recreational harvest in pounds has come from inshore saltwater and brackish water bodies such as bays, estuaries, and sounds. In 2005, these areas contributed 73.6% of the recreational landings.

Current Status of the Spot Fishery

Spot support commercial fisheries along the Atlantic coast, particularly from the Chesapeake southward. They are harvested by a variety of commercial gear including haul seines, pound nets, gillnets, and trawls. Commercial catches have fluctuated widely since 1930 with no apparent long-term trends. Landings peaked in 1952 at 14.5 million pounds, and have since ranged between 3.9 and 12.7 million pounds. Since 1983, commercial landings on the Atlantic coast have remained steady, ranging from four to nine million pounds. Commercial landings were 4.37 million pounds in 2005.

Spot is a popular recreational species that is sought by anglers from Delaware Bay to northern Florida. Most of the Atlantic recreational harvest is taken within three miles of the coast, from shore or by private or rental boats rather than by party or charter boats. The recreational catch of spot has fluctuated from a high of 6.9 million pounds in 1981 to a low of 1.6 million pounds in 1999. In 2005, 3.6 million pounds were landed, the highest number in almost a decade.

Spot are short-lived and year-to-year fluctuations in landings can be expected since the catch in most years consists of a single year class. Moreover, year class abundance is thought to be determined by environmental conditions that prevail on the spawning and nursery areas in any particular year. Changes in fishing effort, habitat degradation, and economic conditions may also affect the quantities of fish caught in any year.

2006 ASMFC FMP update
Total landings of spot in 2005 were estimated at 7,924,737 pounds. The commercial fishery removed approximately 55 percent of this total, and the recreational fishery removed 45 percent.

The commercial fishery has consistently landed more pounds of spot than the recreational fishery since at least 1981; however, the proportion attributable to the commercial fishery in 2005 was the lowest in the time series.

Commercial landings of spot have fluctuated between 3.8 and 14.5 million pounds from 1950-2005. During this time series, landings have been over 10 million pounds thirteen times, four of those occurring during the peak of landings from 1972-75, and the last occurring in 1982. The 2005 landings were approximately 4.4 million pounds, the lowest since 1969 (Figure 5.3.5-1). Small spot are a major component of the bycatch in seine, fish/shrimp trawl, and pound net fisheries in the Chesapeake and in North Carolina, as well as a part of the bycatch of the South Atlantic shrimp trawl fishery.

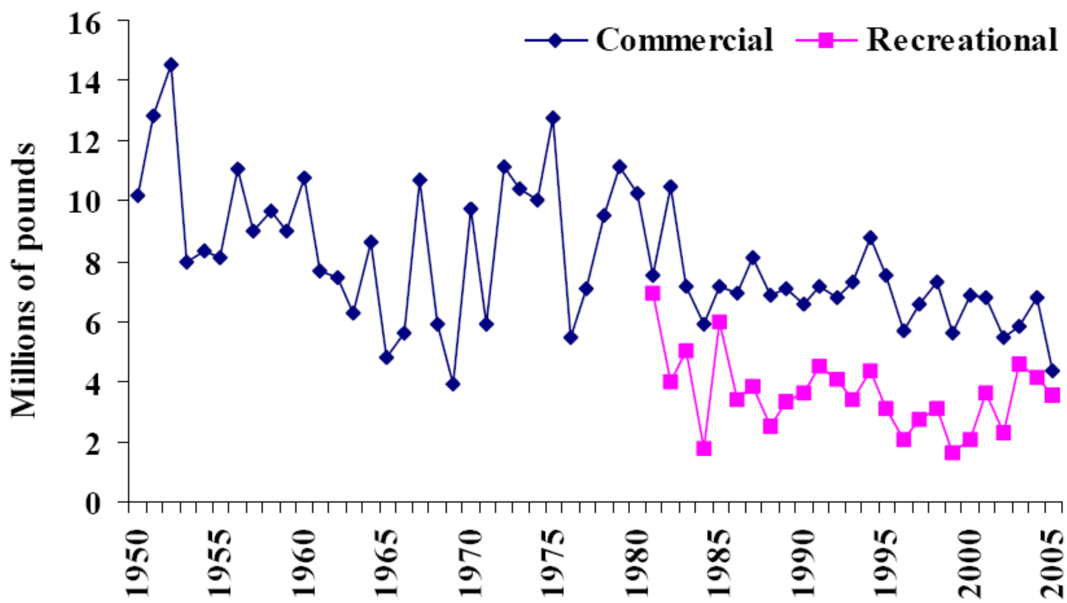

Figure 5.3.5-1. Spot commercial and recreational landings (pounds), 1950-2005

Between 1981 and 2005, the recreational harvest (A + B1 fish) of spot from along the Atlantic coast has varied between 3.6 million fish and 20.1 million fish, but has not exceeded 10 million fish since 1994. From there, spot landings declined steadily to the low point in 1999, after which landings increased gradually (Figure 5.3.5-2). The recreational harvest in 2005 was 8.8 million fish (3.5 million pounds), an increase in the number of fish, yet a decrease in pounds from 2004. The estimated number of spot released annually by recreational anglers from 1981 has remained relatively constant, ranging from 2.0 to 6.3 million fish with the exception of 1981 (11.1 million fish), 1990 (7.3 million fish), and 1991 (10.6 million fish). The number released alive in 2005 was

5.9 million fish, a nearly two-fold increase from the 3.1 million fish released alive in 2004.

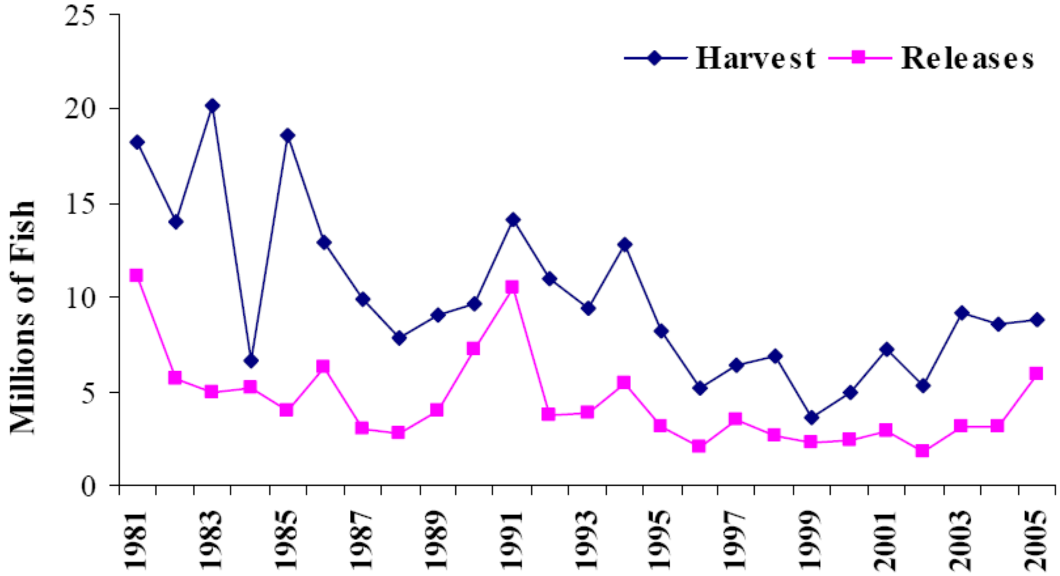

Figure 5.3.5-2. Spot recreational harvest and releases (numbers of fish), 1981-2005

Current Status of the Atlantic Croaker Fishery

Atlantic coast commercial landings of croaker have varied from one million pounds in 1970 to 64 million pounds in 1945. Commercial landings increased steadily each year from a low of 3.7 million pounds in 1991 to more than 28 million pounds in 2003. Commercial landings decreased in 2004 to approximately 25.5 million pounds coastwide, and again in 2005 to 22.5 million pounds; however, coastwide commercial landings have remained above 20 million pounds since 1996 (Figure 5.3.5-3). While commercial fishermen from New Hampshire south have landed Atlantic croaker in at least one year since 1960, the majority of landings come from the mid-Atlantic states (New Jersey through North Carolina) and Florida. Commercial landings from the remaining states are small and sporadic or only a recent component. Virginia and North Carolina have dominated the commercial harvest since 1960.

Atlantic croaker is the major component of the North Carolina and Virginia “scrap fishery”. A number of regulations instituted by North Carolina, such as banned flynet fishing south of Cape Hatteras, the introduction of BRDs in shrimp trawls, incidental finfish limits taken by shrimp and crab trawls in inside waters, minimum mesh size restrictions in trawls and culling panels in long haul seines may have indirectly reduced catches of juvenile croaker and changed the size and age distributions of the harvest. In the last stock assessment, aggregate, unculled (“scrap”) bait fisheries landings data were included for North Carolina and Virginia, and at-sea discard data was included from gill net and trawl fisheries. Scrap landings and discards were combined in the model. Between 1973 and 1995, scrap/discards accounted for an average 20% of removals, and from 1996 to 2002, an average 3% of removals. In Georgia, trawl-caught croaker is sold as unsorted mixed fish along with spot, whiting, and small flounder, therefore, commercial landings are a tenuous measurement of croaker landings there. Small croaker were previously a major part of the bycatch of the south Atlantic shrimp trawl fishery, however the use of TEDs and BRDs has reduced this bycatch.

Recreational landings are from the National Marine Fisheries Service Marine Recreational Fishery Statistics Survey (MRFSS). From 1981-2005, recreational landings of Atlantic croaker (Type A+B1 in numbers) from New Jersey through North Carolina have varied between 1.3 million pounds (1981) and 11 million pounds (2001), with landings showing a strong linear increase over this period (Figure 5.3.5-4).The recreational harvest in 2005 was 11.6 million fish (10.6 million pounds) (Tables 4 and 5). By number of fish, this is the third highest recreational landings for the time series, and the second highest by pounds. The majority of the landings are from Virginia (~68% by pounds). The increased landings in recent years have been at the northern range of the fishery (New Jersey to Virginia). The number of recreational releases in 2005 was estimated at 13.3 million fish, an increase from 2004 (Figure 5.3.5-4).

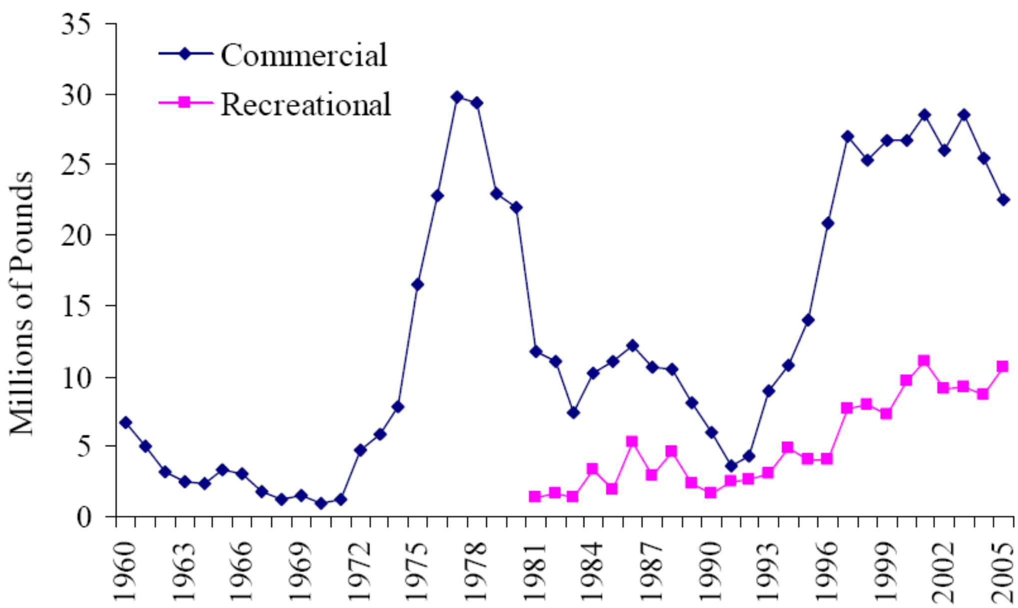

Figure 5.3.5-3. Atlantic croaker commercial and recreational harvest (pounds) (NMFS Office of Science & Technology 2006; State Fishery Agencies, pers. com. 2006).

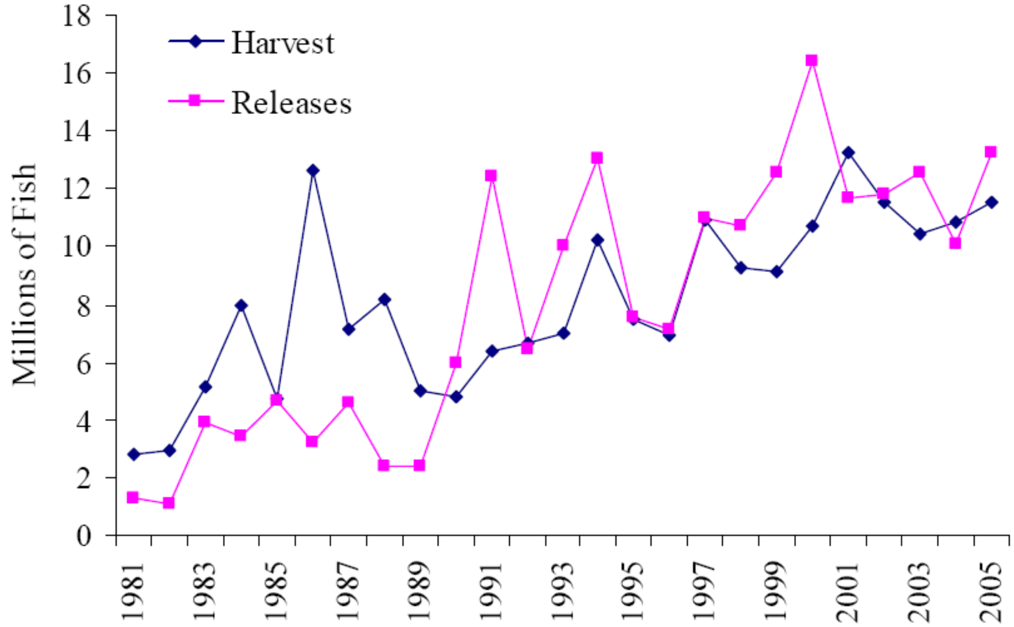

Figure 5.3.5-4. Atlantic croaker recreational harvest (A+B1 fish) and releases (B2 fish), 1981-2005 (NMFS Office of Science & Technology 2006).

Allowable gear

Allowable gear for the commercial harvest of weakfish in the EEZ includes trawl, gillnet, hook-and-line and rod and reel. Weakfish may be harvested recreationally using hook-and-line and spear.

5.3.5.2 Economic and social description

Weakfish Fishery

The Atlantic commercial weakfish fishery is prosecuted between Massachusetts and Florida. There are, however, limited commercial landings in the states of Maine, South Carolina, and Georgia. Maine reported landings of five pounds in 1995; South Carolina had reported landings in 1982 and 1989; and Georgia reported landings, except for 1988 and 1989, between 1982 and 1990. There are no reported landings for New Hampshire. Between 1950 and 2000, total Atlantic Coast landings (Maine through east coast of Florida) declined by 51,021 pounds per year or at the annual rate of 0.64% per year. In 1950, total landings equaled 7.99 million pounds; in 2000, landings equaled 5.38 million pounds ((Figure 5.3.5-4). During the 1970s, however, landings dramatically increased and exceeded 10.0 million pounds in each year until 1990. Between 1990 and 2000 landings decreased from 9.44 to 5.38 million pounds or by nearly 43.0 percent.

The ex-vessel value or first sale value (also referred to as dockside value) followed the same pattern as landings ((Figure 5.3.5-4). In 1950, the ex-vessel value equaled $5.74 million (in 2001 constant dollar values), but declined to $3.78 million in 2000. The decline represented an annual decrease of $38,486 or an annual rate of 0.67 percent.

Between 1978 and 1989, the annual ex-vessel value regularly exceeded $10.0 million per year.
North Carolina has traditionally had the highest level of landings of weakfish (Table 6). On an average annual basis, New Jersey ranks second in terms of landings, and Virginia ranks third. Landings of weakfish in the three states, combined, accounted for 87.9% of the total landings of weakfish between 1980 and 2000 (Table 6). In terms of total ex-vessel or dockside value, North Carolina has traditionally ranked first; Virginia and New Jersey rank second and third, respectively (Table 10). Between 1980 and 2000, all states, except Rhode Island and Connecticut experienced declines in ex-vessel value.

The ex-vessel prices of weakfish have varied substantially over time and among the states (Tables 10 and 11). Between 1980 and 2000, the lowest constant dollar price occurred in 1980. Connecticut, Rhode Island, and New York have generally had the highest ex-vessel prices per pound. North Carolina has typically received the lowest ex-vessel price per pound. The price differences are likely related to product size, market demand, and seasonality of product. Weakfish are generally locally marketed, and prices, therefore, likely reflect local market conditions. In addition, weakfish are highly perishable, and thus, cannot easily be processed and shipped to distant markets.

In describing the economic aspects of a commercial fishery, it is common to describe the size of the fishery, the number of vessels involved, the number of individuals engaged in the fishery, and economic returns. In the case of the weakfish fishery, data necessary for providing a detailed economic description are not available. For the most part, the weakfish fishery is prosecuted in state waters, and few states collect the information required for an extensive economic overview.
Commercial fishermen indicate that there is a varying degree of dependence on weakfish based on the location/port and the gear type used. For some gillnet fishermen in the northern states, weakfish represents one third of the economic value of their total annual catch, while others state that it is one of the three primary species they target during the year. Others suggested that it only represents 10% of their annual catch in terms of value. However, these fish are targeted and caught at a time that helps them “make it through the year.”

Some fishermen have suggested that while they currently target weakfish only minimally, historically it was a sought-after species. This follows a reported trend among fishermen who vary their targeted species based on environmental changes or reductions in the number of fish they see when on the water. The fact that 10 years ago some fishermen targeted weakfish only minimally was more a reflection on the condition of the stock and not the desire for the species.

5.3.6 Bluefish

5.3.6.1 Description of fishing practices, vessels and gear

(MAFMC, 2006)
Bluefish have been commercially harvested in the U.S. for centuries. Bigelow and Schroeder (1953) concluded bluefish were plentiful at the time that New England was

first settled based on the accounts by an author in 1672. However, the abundance of bluefish in southern New England waters has fluctuated periodically since then. An interesting recent account describes the "mosquito fleet" which operated out of Charleston, South Carolina, throughout the nineteenth and first half of the twentieth century (Bishop et al. 1994). This fleet of vessels 20 to 35 feet in length sailed daily from Charleston, out of sight of land with no navigational aids, and provided fresh bluefish, among other species, to the residents, a feat which won the respect and admiration of the community.

In more recent times, total coastwide bluefish landings (commercial and recreational) have averaged 86 million lbs (1981-1989), with commercial landings comprising roughly 17% of the total landings during that time. Since 1981, commercial landings have averaged about 13 million lbs. However, commercial landings declined 44% from a peak of 16.5 million lbs in 1981 to only 9.3 million lbs in 1996.

Bluefish are pursued in both state and EEZ waters by a variety of commercial gears. Coastwide (1987-1996 combined) most bluefish (48%) were landed by gill nets (all types combined) followed by otter trawls (19%). Fish pound nets accounted for 7% of the commercial catch followed by hand and troll lines (6%) and haul seines (3%) during the same time period.

During the period 1976-1987, beach haul seines harvested a significant portion of bluefish in New York and South Carolina. The quantities of bluefish harvested by this gear during 1987-1996 declined considerably relative to earlier years, with measurable landings only in New York, Maryland, Virginia, and North Carolina. The states of Maryland and South Carolina had more bluefish landed commercially by hand lines from 1987 to 1996 than any other gear type. Fish otter trawls were predominant in Rhode Island, Connecticut, and New York. Some type of gill net caught significant amounts of bluefish in all states except Connecticut, South Carolina, Georgia and Florida. Almost all of the bluefish in Maine and New Hampshire were caught by gill nets and this gear type was also predominant in Delaware waters. Runaround gill nets were predominant in New Jersey.

Since 1985, gill nets (all types combined) and otter trawls have been the predominant gear types while the other major gear types (haul seines, paired trawls, purse seines, pound nets, troll and hand lines) has remained relatively consistent at low levels or have declined in importance

.

Seasonally, most bluefish were harvested commercially from May through October. Average monthly landings for the period 1987-1996 peaked at 1.2 million lbs in October. Most bluefish were caught during the fall months from September through November.

Bluefish are very important in the Atlantic coast recreational fishery. Wilk (1980) noted that no other species on the Atlantic coast is as abundant throughout such a wide range and variety of habitats as bluefish. MRFSS data indicate that since 1981 recreational bluefish landings averaged 50 million lbs, ranging from 95 million lbs in 1981 to 14 million lbs in 1995. In 1996, bluefish recreational landings were approximately 15 million lbs. In 1987, bluefish were the fish most sought by marine anglers in the North Atlantic, second only to summer flounder in the Mid-Atlantic, and fourth in preference for anglers in the South Atlantic (MAFMC 1990a). During 1987, bluefish comprised 34% by weight of all species caught by recreational fishermen along the Atlantic coast (MAFMC 1990a). The 1979 to 1987 recreational catch represented a substantial increase over the 1960 to 1970 recreational harvest when bluefish averaged approximately 10% of all species caught by marine anglers along the Atlantic coast.

Bluefish were the predominant species (by number) harvested by anglers in 1987. After reaching a secondary peak in 1986, recreational bluefish landings began to decline. The decline in bluefish recreational catch and landings continued over the last decade. MRFSS data indicate that anglers caught an estimated total of 27.6 million bluefish in 1987, with the numbers declining to a low of 9.9 million in 1993. Numbers increased to approximately 12 million in 1994, but then decreased to 10.5 million in 1995 and, in 1996, decreased again to a low of 9.9 million. The weight of bluefish landed by anglers declined from about 77 million lbs in 1987 to just less than 15 million lbs in 1996. The average weight of the bluefish landed has fluctuated during the years 1987 through 1996 between a low of 2.7 pounds (1994) and a high of 4.9 pounds (1988). The percent of the catch released by anglers has continued to increase from the 24 % reported for 1987 to 54 % in 1996.

An analysis of the recreational landings by subregion indicates more bluefish by weight were landed in the Mid-Atlantic than in the North and South Atlantic every year from 1987 to 1996, except for 1993 and 1994 when North Atlantic landings were highest. In most years, and on average, the weight of the Mid-Atlantic landings (average 55.7%) exceeded those from the North Atlantic (average 33.1%) and South Atlantic (average 11.2%) regions.

Current status of the fishery (Source: ASMFC, 2006)

Recreational catch of bluefish has averaged over 41 million pounds since 1981 although catch declined steadily over the time period. In 2004, recreational anglers along the Atlantic Coast landed 6,939 bluefish. Most of the recreational activity occurs from July to October, when almost 70% of the bluefish harvest is taken. Most of the recreational catch of bluefish is taken in the North and Mid-Atlantic states (New York to Virginia). Recreational landings hit a low of 3,682 fish in 1999 but has averaged over 5,900 fish since 1999 (Table 5.3.6-1).

Table 5.3.6-1. Estimated number of bluefish caught and the estimated number of bluefish landed by marine recreational fishermen each year, 1981 to 2004.

Year	Catch ('000)	Landings ('000)
1981	31,261	23,888
1982	27,220	23,724
1983	30,137	24,884
1984	26,508	20,798
1985	22,474	19,246
1986	30,411	24,441
1987	27,603	21,076
1988	13,365	9,905
1989	18,637	13,600
1990	16,446	11,365
1991	18,292	11,943
1992	11,440	7,158
1993	9,925	5,725
1994	11,920	5,768
1995	10,494	5,168
1996	9,521	4,205
1997	12,574	5,413
1998	9,204	4,202
1999	11,488	3,682
2000	16,260	4,897
2001	20,412	6,663
2002	15,217	5,300
2003	14,679	5,888
2004	18,679	6,939

Commercial landings decreased from 16.5 million pounds (lbs) in 1981 to 7.3 million lbs in 1999. Commercial landings have been regulated by quota since implementation of Amendment 1 in 2000. Since implementation of Amendment 1, landings have varied with a low of 6.8 million pound landed in 2002. Preliminary landing estimates for 2004 increased to 7.2 million pounds.

Allowable gear

Allowable gear for the commercial harvest of bluefish in the EEZ includes Trawl, gillnet, longline, handline, hook and line, rod and reel, bandit gear, cast net, pot, trap, lampara net and spear. Allowable recreational gear includes rod and reel, handline, spear, hook and line, hand harvest, bandit gear, powerhead, gillnet, cast net.

5.3.6.2 Economic and social description

(sections below from the 2007 bluefish specifications document – except as indicated from Amendment 1 to the Bluefish FMP)

Commercial fishery

In 2005, the value of bluefish landings was approximately $2.3 million. Average ex-vessel price of bluefish was $0.33/lb in 2005. On average (1985-1994), the ex-vessel value of bluefish commercial landings from state waters was about twice that from the Exclusive Economic Zone (EEZ) waters.

Bluefish comprised 0.17% and 0.59% of the total ex-vessel value and pounds of all finfish and shellfish species landed along the Atlantic coast of the U.S. in 2004, respectively. The contribution of bluefish to the total value of all finfish and shellfish vary by state, ranging from less than 0.01% in Maine, South Carolina, and Georgia to approximately 1% in New York. The contribution of bluefish to the total pounds landed of all finfish and shellfish vary by state, ranging from less than 0.01% in each Maine, South Carolina, and Georgia to approximately 4% in New York. Relative to total landings value, bluefish were most important in North Carolina and New York, contributing the largest percentage of ex-vessel value of all commercial landings in those states (Table 5.3.6-2). This contribution has not changed considerably from the previous fishing year (i.e., 2004), and it is not expected to change considerably in 2007.

Table 5.3.6-2. The percentage contribution of bluefish to the commercial landings and value of all species combined from Maine through East Coast of Florida, 2005 (Source: NMFS Dealer Weighout data and South Atlantic General Canvass data).

State	Pounds of Bluefish as a Percentage of all Species	Value of Bluefish as a Percentage of all Species
ME	< 0.01%	< 0.01%
NH	0.11%	0.10%
MA	0.14%	0.06%
RI	0.54%	0.20%
CT	0.23%	0.04%
NY	4.17%	1.01%
NJ	0.57%	0.27%
DE	0.63%	0.17%
MD	0.27%	0.12%
VA	0.10%	0.07%

NC	6.60%	1.10%
SC	< 0.01%	< 0.01%
GA	< 0.01%	< 0.01%
FL (East Coast)	0.42%	0.11%
Total	0.59%	0.17%

The economic impact of the commercial bluefish fishery relative to employment and wages is difficult to determine. According to NMFS, commercial fishermen in the western Atlantic landed approximately 1.62 billion lb of fish and shellfish in 2004. Those landings have been valued at approximately $1.33 billion. Total landed value ranged from approximately $14 million in Georgia to $367 million in Maine. However, it can be assumed that only a small amount of the region's fishing vessel employment, wages, and sales are dependent on bluefish since the relative contribution of bluefish to the total value and poundage of all finfish and shellfish is very small.

NMFS VTR data indicate that a total of 11,786 commercial trips targeting bluefish (bluefish ≥ 50% of total catch) resulted in landings of 4.3 million lb from Maine to North Carolina in 2005. Landings from directed trips are approximately 60% of total commercial landings for 2005 (i.e., 7.026 million lb in Table 5.3.6-3). Two major gear types accounted for over 90.3% of the total commercial catch: gillnets and bottom otter trawls. Gillnets comprised 35.0% of the total trips that landed bluefish and 60.2% of the catch, while bottom otter trawls comprised 41.6% of the trips and 30.1% of the catch.

Table 5.3.6-3. Bluefish commercial and recreational landings (‘000 lb), 1981-2005.

Year	Comm	Rec	Total	% Comm	% Rec

Description of the Areas Fished

The Northeast Region is divided into 46 statistical areas for Federal fisheries management. Eight of these areas comprised at least 5 percent of the total commercial bluefish catch in 2005, and collectively accounted for 71.41% of the commercial trips that caught bluefish and 77.1% of the bluefish catch. These eight areas include 635, 611, 636, 613, 612, 614, 615, 623; the percentages associated with each area are provided in Table 5.3.6-4. It may be noted that the vessel log database used to characterize the distribution of commercial harvest does not extend outside of the Northeast Region (i.e., to SC, GA, FL).

Table 5.3.6-4. Statistical areas that accounted for at least 5 percent of the bluefish catch and/or trips in 2005, NMFS VTR data.

Statistical Area	Catch (percent)	Trips (percent)
635	14.0%	2.3%
611	11.9%	26.7%
636	11.8%	1.0%
613	11.5%	14.2%
612	11.2%	12.3%
614	5.7%	4.8%
615	5.5%	2.6%
623	5.5%	0.2%

Processing sector, marketing and consumption (from MAFMC Am 1 to the bluefish FMP)
Bluefish is primarily a fresh fish product. It is generally iced both on board the vessel and at the dock during unloading before it is shipped to market. The limited extent of the fresh fish market has been one of the major factors constraining the commercial harvest of bluefish. Should methods become available to maintain a quality product over longer periods of time, and current efforts to develop markets in the central portions of the country prove successful, the demand for bluefish and bluefish products could increase. At a local level, demand for bluefish by processors is relatively low, and the market can be saturated quickly. When this occurs, the price for bluefish drops to a low level and, consequently, fishermen target other species (MAFMC 1990a).

A relatively small amount of bluefish is filleted and smoked each year. Slightly more than 2% of bluefish landed in 1983 were processed in this manner (MAFMC 1990a). A number of inquires to NMFS indicated interest in processing bluefish increased in 1986 and 1987 (R. Ross pers. comm.). Most of these inquires concern cured bluefish or bluefish pate rather than fillets. A decrease in New England groundfish stocks and an increase in consumer demand for fish may explain this increased interest.

The price per pound of processed bluefish varies by product type. A telephone survey conducted in 1987 (MAFMC 1990a) indicated that fresh fillets were the most common form of processed bluefish product along the Atlantic coast (averaged $1.43 per pound, wholesale, in constant 1985 dollars). Frozen fillets averaged $0.96 per pound whereas smoked bluefish averaged $3.62 per pound. Smoked bluefish comprised an average of 14% of the total value of the output from the plants that processed them while the fresh and frozen fillets averaged 2% and 1%, respectively.

Along the Atlantic coast between 1992 and 1996, an average of 307,410 lbs of bluefish was processed with an average value of $649,973 (in nominal dollars) (Koplin pers. comm.). The largest volume of bluefish was processed in 1992 at 481,274 lbs ($732,302), and the smallest amount processed was in 1995 (186,591 lbs valued at $493,417). The bulk of the bluefish processing from 1987 to 1996 took place in the New England area. The number of processing plants handling bluefish between 1992 and 1996 along the Atlantic coast averaged 13; total employment at these plants averaged 324 people, and bluefish comprised an average of 2.5% of the total output value and 1.7% of the total output weight.

Recreational fishery

The fishery for bluefish is one of the most important recreational fisheries on the Atlantic Coast. For example, during the period 1981 to 1996, bluefish accounted for 29% of the Atlantic coast recreational harvest of finfish by weight (the greatest of any species), ranging from 42% in 1981 to 11% in 1995. From 1996 to 2004, bluefish comprised an average of 10% of total recreational landings, with a low of 7% in 2000 and a high of 12% in both 1998 and 2004. In 2005, bluefish accounted for over 13% of the Atlantic coast recreational harvest of finfish by weight. MRFSS data indicate that the average number of overall recreational fishery participants was relatively constant (~ 5 million) from 1985 – 1999 but has shown a positive trend in recent years, topping off at a little less than 8 million in 2005. This positive trend is consistent with the recent increases in bluefish recreational landings.

During the 1980s, a significant portion of Mid-Atlantic recreational participants depended upon bluefish, particularly those fishing from party/charter vessels. For example, in 1985 party/charter boats in the Mid-Atlantic region landed a total of 22.2 million lb of fish, over half of which were bluefish (12.3 million lb). In 1990, a Council survey was conducted of party and charter boat owners between Maine and Virginia. The survey indicated that bluefish ranked first in the catch and was the second most desired species for party boat owners, while for charter boats, bluefish ranked third in terms of desirability and second in terms of success rate. No survey exists for the more recent time-frame; however, from 1996 – 2005, the proportion of party and charter trips that targeted bluefish has remained relatively constant.

MRFSS catch data by mode indicates that 51% of bluefish were caught by private and rental boats between 1995 and 2004 (Table 5.3.6-5). In addition to private and rental boats, 43% of bluefish were caught from shore and 6% from party and charter boats (Table 5.3.6-5) from 1995 to 2004.

Table 5.3.6-5. The percentage (%) of bluefish caught and landed by recreational fishermen for each mode, Maine through Florida, 1995-2004 (Source: MRFSS).

Mode	Catch (Number A+B1+B2)	Landing (Weight A+B1)
Shore	43	20
Party/Charter	6	21
Private/Rental	51	59

Trends in directed fishing for bluefish from 1991 to 2006 are provided in Table 5.3.6-6. The lowest annual estimate of directed trips was 1.3 million in 2000; the highest annual estimate of directed trips was 5.8 million trips in 1991. In 2003, anglers targeted bluefish in 2.1 million trips bluefish. MRFSS estimates of directed effort since 2003 are not yet available.

Table 5.3.6-6. Number of bluefish recreational fishing trips, recreational harvest limit, and recreational landings from 1991 to 2006.

Year	Number of Fishing Trips[a]	Recreational Harvest Limit ('000 lb)	Recreational Landings ('000 lb)[b]
1991	5,811,446	None	32,997
1992	4,261,811	None	24,275
1993	3,999,487	None	20,292
1994	3,414,337	None	15,541
1995	3,409,966	None	14,307
1996	2,523,984	None	11,746
1997	2,021,713	None	14,302
1998	1,838,525	None	12,334
1999	1,316,939	None	8,253
2000	1,279,035	25,745	10,606
2001	1,914,480	28,258	13,230
2002	1,880,539	16,365	11,371
2003	2,099,771	26,691[c]	13,136
2004	n/a	21,150[c]	15,146

2006	n/a	16,473[c]	n/a

[a]Number of fishing trips as reported by anglers in the intercept survey indicating that the primary species sought was bluefish, North Atlantic, Mid-Atlantic, and South Atlantic regions combined. Estimates are not expanded. MRFSS Data.
[b]Atlantic coast from Maine through Florida's east coast.
[c]Adjusted for RSA.
n/a = Data not available.

Because of the importance of bluefish to recreational anglers, a change in expenditures by bluefish anglers would be expected to impact the sales, service, and manufacturing sectors for the overall recreational fishing industry. The total value recreational anglers place on the opportunity to fish can be divided into actual expenditures and a non-monetary benefit associated with satisfaction. In other words, anglers incur expenses to fish (purchases of gear, bait, boats, fuel, etc.), but do not pay for the fish they catch or retain nor for the enjoyment of many other attributes of the fishing experience (socializing with friends, being out on the water, etc.). Despite the obvious value of these fish and other attributes of the experience to anglers, no direct expenditures are made for them, hence the term "non-monetary" benefits. In order to determine the magnitude of non-monetary benefits, a demand curve for recreational fishing must be estimated. In the case of bluefish, as with many recreationally sought species, a demand curve is not available. Part of the problem in estimating a demand curve is due to the many and diverse attributes of a recreational fishing experience: socializing, weather, ease of access and site development, catch rates, congestion, travel expenditures, and costs of equipment and supplies, among others. A recreational angler's willingness-to-pay for bluefish must be separated from the willingness-to-pay for other attributes of the experience. Holding all other factors constant (expenditures, weather, etc.), a decrease in the catch (or retention rate) of bluefish would decrease demand and an increase in the catch (or retention rate) should increase demand. Each change will have an associated decrease/increase in expenditures and non-monetary benefits.

Recreational fishing contributes to the general well being of participants by affording them with opportunities for relaxation, experiencing nature, and socializing with friends. The potential to catch and ultimately consume fish is an integral part of the recreational experience, though studies have shown that non-catch related aspects of the experience are often as highly regarded by anglers as the number and size of fish caught. Since equipment purchase and travel-related expenditures by marine recreational anglers have a positive effect on local economies, the maintenance of healthy fish stocks is important to fishery managers.

Economic impact of the recreational fishery

Anglers' expenditures generate and sustain employment and personal income in the production and marketing of fishing-related goods and services. In 1998, saltwater anglers from Maine through Virginia spent an estimated $903.3 million on trip-related goods and services (Steinback and Gentner 2001). Private/rental boat fishing comprised the majority of these expenditures ($561.8 million), followed by shore fishing ($259.8 million) and party/charter fishing ($81.7 million). Survey results indicate that the average trip expenditure in 1998 was $47.42 for anglers fishing from a private/rental boat, $32.48 for shore anglers, and $67.12 for anglers that fished from a party/charter boat. Adjusted average expenditures in 2005 dollars are $81.93 for party/charter boat trips, $57.80 for private/rental boat trips, and $39.64 for shore trips.1 Trip-related goods and services included expenditures on private transportation, public transportation, food, lodging, boat fuel, private boat rental fees, party/charter fees, access/boat launching fees, equipment rental, bait, and ice. Unfortunately, estimates of trip expenditures specifically associated with bluefish were not provided in the study. However, if average trip expenditures are assumed to be constant across fishing modes, estimates of the expenditures associated with bluefish can be determined by multiplying the proportion of total trips that targeted bluefish by mode (expanded estimates) by the total estimated trip expenditures from the Steinback and Gentner study. According to this procedure, anglers fishing for bluefish from Maine through Virginia spent an estimated $104.69 million on trip-related goods and services in 2005. Approximately $37.26 million was spent by anglers fishing aboard private/rental boats, $60.50 million by those fishing from shore, and $6.93 million by anglers fishing from party/charter boats. Apart from trip-related expenditures, anglers also purchase fishing equipment and other durable items that are used for many trips (i.e., rods, reels, clothing, boats, etc.). Although some of these items may be purchased with the intent of targeting/catching specific species, the fact that these items can be used for multiple trips creates difficulty when attempting to associate durable expenditures with particular species. Therefore, only trip-related expenditures were used in this assessment.

The bluefish expenditure estimates can be used to reveal how anglers' expenditures affect economic activity such as sales, income, and employment from Maine through Virginia. During the course of a fishing trip, anglers fishing for bluefish purchase a variety of goods and services, spending money on transportation, food, boat fuel, lodging, etc. The sales, employment, and income generated from these transactions are known as the direct effects of anglers' purchases. Indirect and induced effects also occur because businesses providing these goods and services also must purchase goods and services and hire employees, which in turn, generate more sales, income, and employment. These ripple effects (i.e., multiplier effects) continue until the amount remaining in a local economy is negligible. A variety of analytical approaches are available for determining these impacts, such as input-output modeling. Unfortunately, a model of this kind was not available. Nonetheless, the total sales impacts can be approximated by assuming a multiplier of 1.5 to 2.0 for the Northeast Region. Given the large geographical area of the Northeast Region, it is likely that the sales multiplier falls within those values. As such, the total estimated sales, income and employment generated from anglers that targeted bluefish in 2005 was likely to be between $157.04 million ($104.69 million * 1.5) and $209.38 million ($104.69 million * 2.0) from Maine through Virginia. A similar procedure could be used to calculate the total personal income, value-added, and employment generated from bluefish anglers' expenditures, but since these multiplier values have been quite variable in past studies, no estimates were provided here.

For-hire recreational fishery

(from MAFMC Amendment 1 to the bluefish FMP)
Vessel trip report data (VTR) has been collected by NMFS since 1994 for the recreational and commercial fisheries. In the recreational fishery, this data is collected from party/charter vessels that have permits to operate in federal waters as required by the FMPs or amendments for Summer Flounder, Scup, Black Sea Bass, Northeast Multispecies, and Atlantic Mackerel, Butterfish, and Squids.

Party and charter vessels with a federal permit are required to report all their activities regardless of location (e.g., federal or state waters) when they engage in a fishery for one or more of the species mentioned above. As such, these vessels are required to report all their catches, including bluefish. If a party/charter vessel does not have federal permit as specified above and operates exclusively in nonfederal waters, it is exempt from reporting and this activity is not included in the VTR data system (Power pers. comm.).

Vessel trip reporting data indicate that bluefish contributed over 13% of the total catch (by number) made by party/charter vessels in 1996. The contribution of bluefish to the total catch of party/charter vessels fluctuated throughout the year, ranging from 0% in January, February, March, April, and December to 20% in August, with the largest proportion of bluefish caught to other species caught occurring from June through

August. Analysis of the recreational landings by state indicates that bluefish contributed with less than 1% of the total catch of party/charter vessels in Delaware and Maryland, and over 67% in Connecticut.

Social Description
Ports and communities that are dependent on bluefish are fully described in the 2002 Bluefish Specification Document (section 4.3; MAFMC 2001) and are available via the internet at http://www.nero.noaa.gov/ro/doc/nr02.htm.

NMFS dealer data from 2005 were used to rank fishing ports in order of importance for bluefish commercial landings. Ten ports qualified as "top bluefish ports", i.e., those ports where 100,000 pounds or more of bluefish were landed. Wanchese, NC was by far the most important commercial bluefish port with over 2.1 million lb landed, which is more than four times the landings from the second ranked port (Belford, NJ; 493 thousand lb).

The ranking of recreational fisheries landings (numbers of fish) by state in 2005 is provided in Table 5.3.6-7.

Table 5.3.6-7. MRFSS preliminary estimates of 2005 recreational harvest and total catch for bluefish.

State	Harvest (A+B1)		Catch (A+B1+B2)
	Pounds of Fish	Number of Fish	Number of Fish
ME	81,284	18,662	68,150
NH	63,437	11,296	50,024
MA	2,289,770	568,294	2,330,056

FL	752,878	547,891	958,157

Wanchese, North Carolina (this section excerpted from the MAFMC's Am. 1 to the Bluefish FMP, 1998)
"Wanchese has traditionally been a fishing community with commercial fishing operations since the late 1800s. Many of the current residents of Wanchese are descendants of people who settled here in the late 1600s and early 1700s." Many of the fishers are small, independent owner operators. "Informants have estimated that fifty percent of the men in Wanchese are in a marine related career." Wanchese has never developed the strong tourism sector seen in nearby areas. Because of the periodic shallowness of Oregon Inlet, many of its larger trawlers stay in Hampton, Virginia or New Bedford, Massachusetts during the winter. "Wanchese is also the site of the Wanchese Seafood Industrial Park (WSIP) which was developed in the 1970s to be a major site for seafood processing activities. However, because of the uncertain nature of Oregon Inlet and the general decline in fisheries since the 1970s, very few businesses actually operate in WSIP. The catch is either sold at retail markets locally or it is packed in ice and sent to other markets. At least one of the Wanchese commercial fishing and packing operations has expanded to other ports such as Hampton, Virginia and New Bedford, Massachusetts." In recent years, some New Bedford vessels have moved south to base in Wanchese in response to shortages of groundfish and scallops in New England.

Much of Wanchese ocean fishing occurs in the winter months (November-April). However, the boats in Wanchese fish all year round. Bluefish is predominantly caught with ocean gill nets which fish up to ten miles offshore and in the area of Ocracoke to Currituck Light. Other species include weakfish, dogfish and Atlantic croaker between the first of November and the end of April. There are a half dozen fish houses and other marine-related businesses that handle species other than crabs, and a couple that handle crabs exclusively. McCay et al. (1993) reported that summer flounder (21%) was the most important species in Dare County in terms of landed value in 1991. The value of all species landed in Dare County was over $11 million in 1991. Blue crabs (hard) are second in importance (11%), followed by weakfish (9%). Other species of volume in Dare County in 1991 were bluefish (4.02%), sea basses (3.41%), dogfish (1.00%), tilefish (0.53%), scup (0.41%), butterfish (0.31%), squid (0.29%), and Atlantic mackerel (0.12%).

Generally, the boats that are owned by local companies are operated by hired captains. However, these boats may be operated by a relative in some instances. Independent boats are usually owner-operated, with family members often serving as crew. "The crew on these vessels are mostly local; 75-80% are from within the area. All are paid with some variation of a share system." The crews are mostly 18 to 40 years of age; captains are usually older, with some over 65. Most crew members are white, though there are some black fishers including black captains. Sometimes, members of a family will own boats and fish houses. In the fish houses, most of the work force are black women, except for the crab houses where Latino workers are more common."

Recreational fishers use the inshore, offshore, and sound waters around Wanchese in Dare County. Those fishing from boats do not predominantly target bluefish. Bluefish are targeted by pier and surf fishers, who are primarily local residents and residents of nearby counties. Other species targeted by pier and surf fishers are flounder, Kingfish or sea mullet, triggers, puffers, skates, rays, spot, pigfish, and pinfish.

Federally Permitted Vessels (from the 2007 bluefish specifications document)
NMFS Federal permit data indicate that a total of 3,441 commercial and 900 recreational (party/charter) bluefish permits were issued in 2005. Among these, 478 vessels had both commercial and recreational bluefish permits.

A subset of federally-permitted vessels was active in 2005. Dealer reports indicate that 669 vessels with commercial bluefish permits actually landed bluefish (19.4% of the permitted fleet); and VTR data show 233 party/charter vessels catching bluefish (25.9% of the permitted fleet).

Dealers (from the 2007 bluefish specifications document)
According to NMFS permit data, 417 dealers had Federal bluefish permits in 2005. Dealer reports, however, indicate that only 156 of these dealers (37.4%) actually bought bluefish. The distribution of permitted and active dealers by state is provided in Table 17. While employment data for these dealers are not available, dealer reports indicate that gross revenues from the purchase of bluefish in 2005 were $2.27 million.

5.3.7 Summer Flounder

5.3.7.1 Description of fishing practices, vessels and gear

Summer flounder support an extensive commercial fishery along the Atlantic Coast, principally from Massachusetts through North Carolina. Landings from Maine through North Carolina, have fluctuated widely over the last six decades (Table 38), increasing from slightly less than 10 million pounds per year prior to World War II to an average of around 20 million pounds during the 1950's and early 1960's. Landings consistently decreased during the 1960's to a low of 6.7 million pounds in 1969. Commercial landings increased in the mid 1970's until 1989, due to increased levels of effort in the southern winter trawl fishery (MAFMC 1993). Landings of summer flounder from Maine to North Carolina peaked in 1979 at nearly 40 million pounds (Table 38). Reported landings were 32.3 million pounds in 1988 and less than 18 million pounds in 1989, and further decreased in 1990 to about 9 million pounds, a decline of 71% from 1988 (Table 38).

In 1993, the first year that a coastwide quota was implemented, commercial landings were 12.8 million pounds, slightly in excess of the quota for that year. Commercial landings increased to 15.4 million pounds in 1995 and then dropped to 8.8 million pounds in 1997. Commercial landings were 10.7 million pounds in 1999.

From 1990 to 1999 the state of North Carolina had the highest commercial landings of summer flounder, accounting for 25% of the 1990 to 1999 mean, followed by Virginia (24%), New Jersey (17%), and Rhode Island (15%; Table 38). The states of Maine,

Delaware, and Maryland, accounted for less than 1% each of the 1990 to 1999 mean. The state of New Hampshire had no summer flounder landings from 1990 to 1999.
Most commercial landings are made from otter trawl vessels (93%) and sea scallop dredges (2%), as based on 1990 to 1999 NMFS Weighout Data (Table 39). From 1990 to 1999 combined, otter trawls caught 117 million pounds of summer flounder, while sea scallop dredges caught 2.5 million pounds. Hand lines, pound nets, and unknown combined gears were the only other gear that averaged more than 1 million pounds for the time period. Small catches of summer flounder were also made with haul seines, floating traps, gillnets, pots/traps, and midwater/pair trawls (Table 39).
From 1990 to 1999, the majority of the summer flounder were landed annually by commercial fishermen using otter trawls in all states except Delaware (Table 40). Three gear types accounted for 97% of the Delaware landings, pots/traps, gillnets, and hand lines.

Due to a change in reporting requirements, the reporting of commercial landings by distance from shore is inconsistent from 1994-1998. Therefore, only 1999 landings are presented by distance from shore in this document. Earlier landings by distance from shore are presented in Amendment 10. In 1999, 73.8% of the commercial landings of summer flounder came from the EEZ (Table 12). Delaware had the lowest landings (12.5%) in the EEZ, while Virginia had the highest landings (92.3%) in the EEZ. The remainder of the states caught the majority of their landings in the EEZ (Table 12).

Approximately 37% of the commercial summer flounder landings from 1990 to 1999 were caught in January and February (Table 41). Less than 10% of the landings for this time period were caught in each month from March through December. The lowest landings occurred April through August.

Summer flounder is one of the mainstays of the sport fishery along the Atlantic coast. The use of live bait is common, but summer flounder are also taken on jigs, small spoons, and spinners. Although not as strong a fighter per pound as some other sport fishes, the summer flounder provides lively action, especially on light tackle (MAFMC 1993). From 1980 to 1989 summer flounder landings ranged from a high of 38.2 million pounds in 1980 to a low of 3.2 million pounds in 1989. Recreational landings of summer flounder in 1999, at about 8.4 million pounds, were 36% below the historical 1980-1999 average of 17.4 million pounds and only slightly below the 1990-1999 average of 8.6 million pounds (Table 42). In 1999 the recreational sector accounted for 44% of the total landings. Historically recreational summer flounder landings accounted for 61% of the average total landings from 1980-1999, and 59% of the average total landings from 1990 to 1999 (Table 42).

Recreational catch and landings have fluctuated since recreational harvest limits were implemented under Amendment 2 regulations in 1993 (Table 43). Landings increased to 8.8 million pounds in 1993 from the 1992 level of 7.15 million pounds (Table 43). From 1994 to 1999, recreational landings ranged from 5.4 million pounds (1995) to 12.5 million pounds (1998). Recreational landings in 1999 were estimated to be 8.4 million pounds. In 1980 summer flounder recreational catch was at its highest with 28.4 million fish. It declined to a low of 2.7 million fish in 1989 and has been increasing since. In 1999 summer flounder recreational catch totaled 21.4 million fish.

Summer flounder recreational data indicate that in only two of the last eight years (1994 and 1995) have recreational landings been less than the recreational harvest limits (Table 44). In 1998 and 1999, recreational landings of summer flounder were 12.5 million lb and 8.4 million lb, respectively. The summer flounder recreational landings in 1998 and 1999 were 5.07 million lb and 0.96 million lb over the recreational harvest limit for those years, respectively.
The method of estimating trips for specific species is potentially biased since MRFSS interviewers ask anglers, upon completion of their trip, which species they targeted. This approach may cause anglers to report the species they caught, regardless of the species they originally sought. Over the past 10 years, recreational trips directing for summer flounder in the Mid-Atlantic, New England, and South Atlantic Regions, have fluctuated between a low of 3.6 million trips in 1990 to a high of 5.8 million trips in 1994, the second year with a recreational harvest limit (Table 44). In 1999, there was an estimated 4.2 million trips directing for summer flounder.

From 1990 to 1999, New Jersey landed the largest percentage of catch by number (42.9%), followed by New York (18.8%), Virginia (14.8%), and North Carolina (5.8%). The remaining states all caught less than 5% each (Table 45).

MRFSS estimates from 1990 to 1999 indicate that more than 90% of the recreational summer flounder landings occurred in state waters (inland waters and ocean water <= 3 miles combined) in the North Atlantic and Mid-Atlantic subregions and in North Carolina (Table 46).

From 1990 to 1999, recreational fishermen in private/rental boats, accounted for 92.2%, 84.0%, and 75.9% of the landings in the New England Region, Mid-Atlantic Region, and North Carolina, respectively. The party/charter boat industry accounted for the second highest percent (11.6%) of recreational summer flounder landings in the Mid-Atlantic Region, as compared to only 2.4% and 0.4% of the landings in the New England Region and North Carolina (Table 47). Fishermen fishing from shore were the second highest in both the New England Region (54.9%) and North Carolina (23.7%; Table 47).

VTR data for party/charter boats is only available from 1996 and later, when the requirement for a federal permit holder to submit a vessel logbook was implemented. VTR data indicate that summer flounder contributed almost 13% of the total catch (by number) made by party/charter vessels for the 1996-1999 period (Table 48). The contribution of summer flounder to the total catch of party/charter vessels fluctuated throughout the year, ranging from less than 1% in January, February, March, April, and December to 24% in July. The largest proportion of summer flounder was caught from May through September (Table 48). Analysis of the VTR party/charter data by state indicates that the proportion of summer flounder in the total catch ranged from less than 1% in Maine, New Hampshire, Massachusetts, and Maryland to 34% in New York (Table 48).

Current status of the fishery

(Source: ASMFC 2006)
During the late 1980's landings declined dramatically, reaching a low of 9.3 million pounds in the commercial fishery in 1990 and 3.2 million pounds in the recreational fishery in 1989. Following this record low, the commercial landings showed an increasing trend through 1995, but have varied without trend through 2005. For the past four years commercial landings have been over 13.8 million pounds, with 2005 landings at 17.14 million pounds.

Recreational landings in 1997 were 11.9 million pounds, double the estimate for 1995). The landings continued to increase through 2000, 16.5 million pounds. In 2002 landings dropped to 8.0 million pounds, but then increase to 11.6 million pounds in 2003. Landings have since declined to 10.02 million pounds in 2005. New York, New Jersey, and Virginia dominated the recreational fishery by landings again in 2005.

Combined commercial and recreational landings were 27.16 million pounds in 2005.

Allowable gear

Summer flounder may be harvested commercially in the EEZ using trawl, longline, handline, rod and reel, pot, trap, gillnet and dredge. They may be harvested recreationally using rod and reel, handline, pot, trap and spear.

5.3.7.2 Economic and social description

Commercial fishery

Commercial landings of summer flounder have decreased approximately 75% from 37.8 million pounds in 1984 to 9.3 million pounds in 1990. Commercial landings in 1992 were 16.6 million pounds, and then decrease to 8.8 million pounds in 1997. In 1998 and 1999, commercial landings were above the 1997 landings. In 1999, commercial landings were 10.7 million pounds or 4% below the 1998 level and 15% below the 1990-1999 mean. The commercial share averaged about 60% of the combined total landings of summer flounder from 1990-1999 (Table 42). Preliminary landings data indicates that 11.2 million pounds of summer flounder were landed in 2000.

The ex-vessel value of summer flounder landings has increased from about $19 million in 1991 to a peak $28 million in 1995 (Table 69). Ex-vessel value dropped to $21.1 and $16.5 million in 1996 and 1997, respectively. The sharp decrease in summer flounder value in 1996 and 1997 from the 1995 level was the result of a sharp decline in landings of approximately 7 and 12 million pound, respectively. Between 1998 and 2000, summer flounder ex-vessel value has ranged from $18.4 to $19.8 million. Inflation adjusted prices (2000 dollars) have ranged from $1.57 to $1.96 per pound for the 1991 to 2000 period (Table 69).

The value of summer flounder landings relative to the value of total landings in 1999 and 2000 are presented in Table 70. In 2000, the contribution of summer flounder landings to the value of total landings varied for each state from 1% or less (Maine, New Hampshire, Massachusetts, Delaware, and Maryland) to about 12% in North Carolina. The overall contribution of summer flounder landings to the total ex-vessel value from Maine to North Carolina was about 1.6%.

While some states experienced small percentage changes in the contribution of summer flounder value to the value of total landings from 1999 to 2000, the aggregate contribution associated with this species from Maine to North Carolina was virtually unchanged. At $1.96/lb, the average price (all sizes) of summer flounder reached a record high in inflation adjusted (2000) dollars in 1995 (Table 69). Adjusted prices for summer flounder have ranged from $1.57 to $1.96 per pound for the 1991 to 2000 period. In 2000, highest prices were received in the northern States with Maine, Connecticut and New York as the leaders at $3.12, $2.63, and $2.47 per pound, respectively. Coastwide, the average price of summer flounder was $1.65 per pound in 2000 (Table 71).

Monthly landing and price data for flounder indicates that a supply - price relationship is observable on a monthly basis. Months with highest average ex-vessel prices tend to coincide with months of lowest landings, normally in June, July, and August (Table 72). Prices received for summer flounder originating in state waters for the 1999-2000 period were generally higher than for EEZ waters (Table 73) and tracked the seasonal supply relationship for 1991-2000 (Table 72). The 2000 coastwide average ex-vessel price per pound for jumbo was $2.07, $1.67 for large, $1.39 for medium, $1.40 for small, and $2.08 for unclassified landings (Table 74). The average price per pound for peewees was $3.86 in 2000, however, only a few hundred pounds of summer flounder belonging to this category were landed and this does not represent a typical price pattern. As a general rule, price premiums for larger flounder reflect higher yielding fillet weight.

Processing, marketing, and consumption

Almost all summer flounder are sold in fresh form. The catch is generally iced at the dock and then shipped to market. The major central wholesale market for fresh fish in the Mid-Atlantic region is the Fulton Fish Market.

The number of processing plants handling summer flounder from Maine through North Carolina has varied from 10 in 1990 to 4 in 1999. The value of the summer flounder processed by these plants has varied from $2.1 million in 1990 to over $2.5 million in 1999. In addition, 91 plants reported handling unclassified flounders in 1990 (valued at $42.3 million) and 35 plants in 1999 (valued at $30.8 million) from Maine through North Carolina. The bulk of the plants handling unclassified flounders in 1999 were located in Massachusetts (20) followed by North Carolina (5), and Maine (4). Maryland, New Jersey, Pennsylvania, Rhode Island, and Virginia had a combined total of 6 plants handling unclassified summer flounder in 1999 (NMFS Unpublished processing survey data).

Summer flounder prices per pound for each size category vary from processor to processor and from day to day for each processor. The prices react to the market supply of summer flounder, other flounders available, imports, and wholesale/retail demand. The size categories of summer flounder are likewise not fixed. In the areas where more summer flounder less than 14" are landed there, is a greater tendency to refer to smaller fish as mediums, than in areas where fewer summer flounder less than 14" are landed. The exact lengths which comprise a size category are known to vary from processor to processor and day to day. This variation in price leaves the fisherman with some sense of uncertainty in terms of what he will receive for his catch. Such uncertainty, however, is common in the fishing business.

A study conducted in New England in 1982 (Hu et al. 1983) showed that labor costs would be reduced approximately $0.05 per pound by filleting large flounder instead of small flounder. This is the result of more fillet weight per flounder and the reduced time involved in the fillet process. The species of flounder examined and the size differences were not mentioned.

Economic impact of the commercial fishery

A study by the National Fisheries Education and Research Foundation estimated sales, employment, and wage impacts for flounder harvesting, processing and distribution in the Mid-Atlantic region for 1986 (NFERF 1989). Since summer flounder comprised 84% of the total flounder landings in this region in 1986, specific estimates for summer flounder can be derived from the estimates for total flounders.

Cumulative direct impacts of the Mid-Atlantic summer flounder fishery (Table 104) amounted to 2,290 person-years of employment, $21.6 million in income, and $50.2 million in output (sales). Over 60% of the employment was generated in the food service sector. Harvesting and processing made up most of the remainder, each accounting for just under 15%. Income per person-year was highest in the harvesting and distribution sectors and lowest for processing and food service, probably related to the labor intensive nature of the two latter sectors. Value of output was high for harvesting, processing and food service, indicating the large markup in these sectors. In 2000, summer flounder contributed 1.6% of the total value of all finfish and shellfish landed from Maine to North Carolina (Table 70).

International trade

No summer flounder are imported into the US since the species occurs primarily along the US Atlantic coast. However, imports of several other species of flatfish are substitutes for summer flounder in the market place. These imports compete with and affect the price of summer flounder, winter flounder, yellowtail flounder, and other domestic flatfish species (Wang 1984).

Flat fish imports (excluding halibut) for all product forms decreased from 68.2 million pounds in 1995 to 35.0 million in 2000. However, the value of those imports increased from $139.0 in 1995 to $147.4 in 2000 (NMFS trade data).

Imports of summer flounder have slightly increased for the 1995 to 2000 period. The quantity of summer flounder (all product forms) that entered the US increased from 9.4 million pounds ($42.4 million) in 1995 to 9.7 million pounds ($44.3 million) in 2000. By product type, “frozen fillets” contributed to the bulk of the imports in 2000 with over 52% of the total poundage and 63% of the total value, followed by “whole fresh” (29%, 12%), “fresh fillets” (11%, 17%), “frozen fillet blocks >4.5 kg” (6%, 7%), and “whole frozen” (2%, 1%). Canada and Argentina contributed with the bulk of the summer flounder shipped into the US in 2000. Canada contributed with 50% of the total volume and 37% of the total value of all summer flounder that entered the US last year, and Argentina contributed with 27% of the total volume and 36% of the total value.

The value of imported flatfish products can vary widely depending on the species, whether fresh or frozen, overall quality, and the level of value added through filleting, etc. Belgium and the Netherlands in particular specialize in high value species and products. The average value of Belgium’s and Netherlands' flatfish exports to the US was $10.65/lb and 6.83/lb in 2000, versus Pakistan $1.01/lb, and $4.21 per lb. for all countries combined. The value of summer flounder that enters the US also varies by product form. The average value of summer flounder (all product forms) that entered the country in 2000 was $4.56/lb. In 2000, the most valuable summer flounder product form was “fresh fillets” at $7.23/lb, followed by “frozen fillets” ($5.56/lb), “frozen fillet blocks >4.5 kg” ($5.11/lb), “whole frozen” ($2.02/lb), and “whole fresh” $1.88/lb.

Total US commercial production flounders was estimated at 331 million pounds in 1999, with an average ex-vessel value of $0.27/lb (Fisheries of the USA, 2000). Slightly more than 3.2% (10.6 million pounds) of this domestic harvest was made up of summer flounder, with an average price of $1.83/lb: more than six times the nation's average. When compared with just the more valuable Atlantic coast flounders (winter, summer, and yellow tail flounders), summer flounder comprised 35% of the 1999 landings and 44% of the value.

Japan continues to be the most important export market for summer flounder. Exports of summer flounder are difficult to determine as summer flounder gets lumped under a variety of export codes and it is impossible to identify in the U.S. export data (Ross pers. comm.). However, export of US summer flounder to Japan has been reported to vary from approximately 800 to 1,800 mt in 1993-1997 (Asakawa pers. comm.). Fresh whole U.S. fluke or summer flounder is generally exported to Japan for raw (sashimi) consumption. Fresh U.S. summer flounder is used as a substitute for Japanese “hirame” (bastard halibut – *Paralichthys olivaceus*), and normally imported whole fresh and sold through seafood auction markets to restaurants. They are usually consumed raw for sashimi or sushi toppings in Japan. While U.S. summer flounder is well established in some major action markets, daily prices may fluctuate depending on the total quantity of domestic and imported hirame (including U.S. summer flounder) delivered to auction on a given day. Depending on quality, auction prices for fresh U.S. summer flounder may vary from around 1,000 to 3,000 yen/kilo ($3.13 to 9.40/lb at 145 yen/$ 1.00) depending on size, quality and market conditions (Asakawa pers. comm.). Frozen summer flounder may not be considered to be of the same quality, and is unlikely to become substitute for unfrozen summer flounder. Nevertheless, properly handled frozen summer flounder may receive wholesale prices of 400-900 yen/kilo ($1.73-3.90/lb) or higher (Asakawa pers. comm.). The recent economic crisis in Japan could potentially hamper exports of seafood commodities to that country. Furthermore, future devaluation of the yen would result in reduced revenues for exporters of summer flounder to Japan.

Activity at the port level indicate that 54% of the total fluke commercial landings occurred in seven ports: Point Judith, Rhode Island; Cape May and Point Pleasant, New Jersey; Newport News and Hampton, Virginia; and Wanchese and Beaufort, North Carolina. The contribution of summer flounder to ports with 10% or more summer flounder dependence (value) is presented in Table 90. Of the seven ports accounting for the bulk of the summer flounder landings in 1999, only Beaufort (18.95%), Wanchese (13.26%), and Hampton (10.87%) had 10% or more revenue dependence on summer flounder (Table 90).

Recreational fishery

Recreational fishermen caught over 24 million summer flounder in 2000, the highest annual level of the past decade (Table 105). Landings in 2000 were also substantially higher than the ten year average in terms of numbers (7.5 million fish) and weight (15.8 million pounds). However, recreational fishermen released a slightly lower proportion of summer flounder alive (31%) than the 10 year average of 32%.

In 2000, over 90% of the summer flounder landed by weight in the North and Mid-Atlantic were caught in state waters (Table 106). Landings by North and Mid-Atlantic fishermen fishing in state waters have consistently exceeded EEZ landings throughout the past decade, accounting for over 93% of total landings, on average, during the past 10 years.

The participation of summer flounder anglers by region and mode indicates that from 1991 to 2000, 8% of the summer flounder (by number) were caught from party or charter vessels (Table 107). Anglers' expenditures aboard party and charter boats benefits the party and charter industry as well as other businesses in the coastal communities.
In addition to party and charter vessels, 10% of the summer flounder were caught from shore, and 82% from private/rental boats (Table 107). Furthermore, private and rental boat fishermen also accounted for over 80% of the summer flounder landings (by number) and over 80% of the summer flounder released alive, on average, during the past decade. Ownership of a private vessel involves sizable investment and maintenance costs, thus contributing greatly to measures of economic impact. Private vessels are also used for non-fishing purposes; and are used to fish for many different species. Expenditure and cost data must be prorated for summer flounder trips to account for multipurpose use.

Anglers fishing in New Jersey were responsible for over 45% of the average annual total summer flounder landings from Maine to North Carolina during the past decade (Table 108). Recreational landings in New Jersey, New York, and Virginia accounted for 76% of the total annual landings (by number) during this time period.

NMFS estimated that in 2000, a total of 33.228 million day trips were taken by marine recreational anglers along the Atlantic coast from Maine to North Carolina (Personal communication from NMFS, Fisheries Statistics and Economics Division). An estimated 16.7% of these anglers indicated that they preferred or sought summer flounder as the primary target species. That is, an estimated 5.56 million angler trips (all modes) were nominally directed at summer flounder from Maine to North Carolina in 2000.

Economic impact of the recreational fishery

Anglers' expenditures generate and sustain employment and personal income in the production and marketing of fishing-related goods and services. In 1998, saltwater anglers from Maine to Virginia spent an estimated $1.136 billion on trip-related goods and services (Steinback and Gentner 2001). Trip-related goods and services included expenditures on private transportation, public transportation, food, lodging, boat fuel, party/charter fees, access/boat launching fees, equipment rental, bait, and ice.

Unfortunately, estimates of trip expenditures specifically associated with summer flounder were not provided in the study. However, if average trip expenditures are assumed to be constant across all fishing trips, an estimate of the expenditures associated with summer flounder can be determined by multiplying the proportion of total trips that targeted summer flounder (16.7%) by the total estimated trip expenditures from the Steinback and Gentner study ($1.136 billion). According to this procedure, anglers fishing for summer flounder from Maine to Virginia spent an estimated $200.412 million on trip-related goods and services in 2000.1 Apart from trip-related expenditures, anglers also purchase fishing equipment and other durable items that are used for many trips (i.e., rods, reels, clothing, boats, etc.).

Although some of these items may be purchased with the intent of targeting/catching specific species, the fact that these items can be used for multiple trips creates difficulty when attempting to associate durable expenditures with particular species. Therefore, only trip-related expenditures were used in this assessment.

The summer flounder expenditure estimate can be used to reveal how anglers' expenditures affect economic activity such as sales, income, and employment from Maine to Virginia. During the course of a fishing trip, summer flounder anglers purchase a variety of goods and services, spending money on transportation, food, boat fuel, lodging, etc. The sales, employment, and income generated from these transactions are known as the direct effects of anglers' purchases.
Indirect and induced effects also occur because businesses providing these goods and services also must purchase goods and services and hire employees, which in turn, generate more sales, income, and employment. These ripple effects (i.e., multiplier effects) continue until the amount remaining in a local economy in negligible. A variety of analytical approaches are available for determining these impacts, such as input-output modeling. Unfortunately, a model of this kind was not available. Nonetheless, the total sales impacts can be approximated by assuming a multiplier of 1.5 to 2.0 for the Northeast Region. Given the large geographical area of the Northeast Region, it is likely that the sales multiplier falls within those values. As such, the total estimated sales

generated from anglers that targeted summer flounder in 2000 was likely to be between $300.618 million ($200.412 million * 1.5) and $400.824 million ($200.412 million * 2.0) from Maine to Virginia. A similar procedure could be used to calculate the total personal income and employment generated from summer flounder anglers' expenditures, but since these multiplier values have been quite variable in past studies, no estimates were provided here.

Value of the fishery to anglers

The value that anglers place on the recreational fishing experience can be divided into actual expenditures and non-monetary benefits associated with satisfaction (consumer surplus). Anglers incur expenses for fishing (purchase of gear, bait, boats, fuel, etc.), but do not pay for the fish they catch or for the enjoyment of many other attributes of the fishing experience (socializing with friends, contact with nature, etc.). Despite the obvious value of these attributes of the experience to anglers, no direct expenditures are made for them, hence the term "non-monetary" benefits.

Behavioral models that examine travel expenditures, catch rates, accessibility of fishing sites, and a variety of other factors affecting angler enjoyment can be used to estimate the "non-monetary" benefits associated with recreational fishing trips. Unfortunately, a model of this kind does not exist for summer flounder. Data constraints often preclude researchers from designing species-specific behavioral models. However, a recent study by Hicks, et. al. (1999) estimated the value of access across states in the Northeast region (that is, what people are willing to pay for the opportunity to go marine recreational fishing in a particular state in the Northeast) and the marginal value of catching fish (that is, what people are willing to pay to catch an additional fish). Table 117 shows, on average, the amount anglers in the Northeast states (except for North Carolina which was not included in the study) are willing to pay for a one-day fishing trip. The magnitude of the values in Table 117 reflect both the relative fishing quality of a state and the ability of anglers to choose substitute sites. The willingness to pay is generally larger for larger states, since anglers residing in those states may need to travel significant distances to visit alternative sites. Several factors need to be considered when examining the values in Table 117.

First, note that Virginia has relatively high willingness to pay estimates given its relative size and fishing quality characteristics. In this study, Virginia defines the southern geographic boundary for a person's choice set, a definition that is arbitrary in nature. For example, an angler in southern Virginia is likely to have a choice set that contains sites in North Carolina. The regional focus of the study ignores these potential substitutes and therefore the valuation estimates may be biased upward (Hicks, et. al. 1999). Second, the values cannot be added across states since they are contingent upon all of the other states being available to the angler. If it was desirable to know the willingness to pay for a fishing trip within Maryland and Virginia, for example, the welfare measure would need to be recalculated while simultaneously closing the states of Maryland and Virginia.

Assuming the average willingness to pay values shown in Table 117 are representative of trips that targeted summer flounder, these values can be multiplied by the number of trips that targeted summer flounder by state (from the MRFSS data) to derive welfare values for summer flounder.

Table 118 shows the aggregate estimated willingness to pay by state for anglers that targeted summer flounder in 2000 (i.e., the value of the opportunity to go recreational fishing for summer flounder). New York, New Jersey, and Virginia were the states with the highest estimated willingness to pay for summer flounder day trips. Once again, note that the values cannot be added across states since values are calculated contingent upon all of the other states being available to the angler.

In the Hicks et. al. (1999) study the researchers also estimated welfare measures for a one fish change in catch rates for 4 different species groups by state. One of the species groups was "flat fish," of which summer flounder is a component. Table 119 shows their estimate of the welfare change associated with a one fish increase in the catch rate of all flat fish by state. For example, in Massachusetts, it was estimated that all anglers would be willing to pay $5.03 (the 1994 value adjusted to its 2000 equivalent) extra per trip for a one fish increase in the expected catch rate of all flat fish. The drawback to this type of aggregation scheme is that the estimates relate to the marginal value of the entire set of species within the flat fish category, rather than for a particular species within the grouping. As such, it is not possible to estimate the marginal willingness to pay for a one fish increase in the expected catch rate of summer flounder from the information provided in Table 119.

However, it is possible to calculate the aggregate willingness to pay for a 1 fish increase in the catch rate of flat fish across all anglers. Assuming that anglers will not adjust their trip taking behavior when flat fish catch rates at all sites increase by one fish, the estimated total aggregate willingness to pay for a one fish increase in the catch rate of flat fish in 2000 was $154.843 million (total trips (33.228 million) x average per trip value ($4.66)). This is an estimate of the total estimated welfare gain (or loss) to fishermen of a one fish change in the average per trip catch rate of all flat fish. Although it is unclear how much of this welfare measure would be attributable to summer flounder, the results show that flat fish in general, in the Northeast, are an extremely valuable resource.

Although not addressed here, recreational fishing participants and non-participants may also hold additional intrinsic value out of a desire to be altruistic to friends and relatives who fish or to bequeath a fishery resource to future generations. A properly constructed valuation assessment would include both use and intrinsic values in the estimation of total net economic value. Currently, however, there have been no attempts to determine the altruistic value (i.e., non-use value) of summer flounder in the Northeast.

5.3.8 Horseshoe Crab

5.3.8.1 Description of fishing practices, vessels and gear

(Source: http://www.dnr.state.md.us/education/horseshoecrab/fhistory.html)

A commercial fishery for horseshoe crabs has existed since the 19th century. Early on, horseshoe crabs were harvested primarily for fertilizer and animal feed. Typically, crabs were collected by hand on beaches during the spawning season or by pound nets. Huge numbers were collected during the spawning season as the crabs became concentrated on mid-Atlantic beaches. In fact, between the 1870's and 1920's, annual harvests in the Delaware Bay averaged over one million crabs.

This fishery eventually declined for several reasons. First, competition from chemical fertilizers developed starting in the 1930s. Second, the horseshoe crab population declined. And lastly, the public complained about the odor caused by large numbers of dead horseshoe crabs processed at fertilizer and animal feed factories. In the 1950s to the 1980s, reported commercial harvests were almost non-existent. However, no mandatory reporting requirements existed for horseshoe crabs during this period. Commercial harvesting of the crabs continued throughout this time period but not reported. These harvests appear to have been localized and limited because horseshoe crab populations steadily recovered.

Since the 1980s several new fisheries have developed for horseshoe crabs. Horseshoe crabs are harvested as bait to catch American eel (*Anguilla rostrata*), channel whelk (*Busycotypus canaliculatus*) and knobbed whelk (*Busycon carica*) in Maryland and the rest of the mid-Atlantic region. Increased demand in these fisheries led to a dramatic increase in the horseshoe crab harvest during the 1990s and led to coast-wide management of horseshoe crabs.

In the American eel fishery unique chemical odors emitted by egg-laden female horseshoe crabs strongly attract the eels to an eel pot. It is because of this strong attraction that eels prefer female horseshoe crabs to other types of bait. The eel pot fishery only uses female horseshoe crabs as bait. Male crabs do not emit the same chemical odors as the females and are not used. To catch the whelk, the horseshoe crab is used as bait, divided into quarters, placed in a conch trap and placed offshore on the bottom. Whelks smell the horseshoe crab bait and enter the trap to feed. Periodically, the waterman will check each trap and harvest the whelks he finds. This fishery uses both male and female crabs as bait to catch whelk. The fishery for whelk grew out of increasing overseas demand for this mollusk. Starting in the 1990s, expansion of the whelk fishery led to dramatic increases in horseshoe crab harvests. The whelk harvest goes primarily to regional processing plants or is directly exported to European food markets.

(excerpt for the ASMFC's species profile factsheet for horseshoe crab):
Horseshoe crabs are also collected by the biomedical industry to support the production of Limulus Amoebocyte Lysate (LAL), a clotting agent that aids in the detection of human pathogens in patients, drugs, and intravenous devices. No other procedure has the same accuracy as the LAL test. The current estimate of medical usage is between 250,000 and 300,000 horseshoe crabs per year on the Atlantic coast. While crabs are bled and released live generally within 72 hours of capture, up to 15 percent do not survive the procedure.

Current status of the fishery

Bait Fishery (ASMFC 2006)
Reported coastwide bait landings in 2006 remained below the quota established under Addendum III and IV (Table 1, Figure 1). Bait landings increased for the third consecutive year, but also remained below one million crabs for the third consecutive year.

An alternative bait/gear workshop conducted under the auspices of ASMFC in 1999 introduced the concept of using bait savings devices (bait bags) in whelk (conch) pots. Free bait bags were distributed to whelk potters in the Mid Atlantic and southern New England regions through a state, federal, and NGO partnership. National Marine Fisheries Service funded the acquisition of the bait bags. The Ecological Research and Development Group (ERDG), Delaware, Maryland, New Jersey, Virginia, New York, Connecticut, Rhode Island and Massachusetts assisted in the distribution of the bags. The reductions in reported bait landings in excess of the 25% reductions required under Addendum I were largely attributed to the success of this program, with the widespread use of the devices by the commercial fishery. Massachusetts fishermen have been using bait cups in conch traps with success. The cups use about a 10th of a crab and can be fished for 2-3 days the relatively cold waters.

Reported coastwide landings since 1998 showed more male than female horseshoe crabs were annually harvested; though, a large proportion of the reported landings in 1998 and 1999 were unclassified. Unclassified landings accounted for less than 12% of the reported landings since 2000. The American eel pot fishery prefers egg-laden female horseshoe crabs as bait, while the whelk (conch) pot fishery is less dependent on females. The hand, trawl and dredge fisheries accounted for over 90% of the 2006 reported commercial horseshoe crab bait landings by gear type. This is consistent with the distribution of landings by gear since 1998. Although the hand fishery accounted for most of the coastwide harvest and was typically the most prominent method of take in most states, the trawl and dredge fisheries accounted for over 45% of the reported landings by gear in 2006. The dredge fishery accounted for 52% of the Delaware landings and 82% of the Virginia landings. The trawl fishery accounted for over 99% of Maryland's horseshoe crab bait landings.

The dominance of the hand fishery was reflected in the seasonal distribution of landings. Most of the coastwide harvest since 1998 came during May and June as crabs come ashore to spawn and, thus, were readily available to the fishery. There is typically a secondary mode I monthly landings during the late summer or fall. This secondary peak coincides with an increased demand for horseshoe crabs in the conch pot fishery.

Biomedical Fishery
The horseshoe crab is an important resource for research and manufacture of materials used for human health. There are four companies along the Atlantic Coast that process

horseshoe crab blood for use in manufacturing Limulus Amoebocyte Lysate (LAL): Associates of Cape Cod, Massachusetts; Cambrex Bioscience, Maryland; Wako Chemicals, Virginia; and Endosafe, South Carolina. There is one company that bleeds horseshoe crabs but does not manufacture LAL: Limuli Labs, New Jersey. Addendum III requires states where horseshoe crabs are collected for biomedical use to collect and report harvest data and characterize mortality.

The Plan Review Team annually calculates total coastwide harvest and estimates mortality. It was reported that 367,914 crabs (including crabs harvested as bait) coastwide were brought to biomedical companies for bleeding in 2006 (see table below). A total of 58,625 crabs were harvested as bait and counted against state quotas. These crabs were not included in the mortality estimates below. It was reported for 2006 that 309,289 crabs were harvested for biomedical purposes only. Crabs were rejected prior to bleeding because of mortality, minor injuries, and slow movement. Based on state reports, approximately 1.5% of crabs harvested and brought to bleeding facilities were rejected because of death or serious injury. The PRT estimates a mortality of 4,639 crabs prior to bleeding.

Table 5.3.8-1. Number of crabs harvested for biomedical purposes.

Year	*2004*	*2005*	*2006*
Number of crabs brought to biomedical facilities (bait and biomedical crabs)	343,126	323,149	367,914
Number of biomedical-only crabs harvested (not counted against state bait quotas)	292,760	283,720	309,289
Estimated mortality of biomedical-only crabs prior to bleeding	4,391	4,256	4,639
Number of biomedical-only crabs bled	275,194	270,496	296,958
Estimated mortality of biomedical-only crabs during or after bleeding	41,279	40,574	44,543
Total estimated mortality on biomedical crabs not counted against state bait quotas	45,670	44,830	49,182

The highest estimate of crab mortality from the bleeding process in the literature is 15% (Thompson 1998). Using the number of biomedical-only crabs and the estimated mortality rate during or after the bleeding process, the PRT calculated an estimated mortality of 44,543 crabs. The total coastwide mortality estimate of crabs not counted against state quotas is 49,182 crabs for 2006.

The 1998 FMP establishes a mortality threshold of 57,500 crabs, where if exceeded the Board is required to consider action. The PRT recommends that the Board not consider action at this time but that it continues to monitor biomedical use of crabs closely. It appears that use of horseshoe crabs has increased slightly since the original FMP was approved. However, more crabs that were harvested for bait were bled in biomedical facilities in 2006, thereby keeping mortality under the threshold. While monitoring of biomedical harvest and use of crabs has improved under Addendum III to the FMP, inconsistencies remain in reporting among the states. The PRT plans to work with the states that report biomedical landings to continue to standardize reporting.

Allowable gear

5.3.8.2 Economic and social description

Commercial Fishery

Between the 1850s and the 1920s, over 1 million horseshoe crabs were harvested annually for fertilizer and livestock feed (Shuster 1982; Shuster and Botton 1985). Reported harvests in the 1870s were 4 million horseshoe crabs annually, and 1.5 to 1.8 million horseshoe crabs annually between 1880s and 1920s (Finn et al. 1991). Shuster (1960) reports that in the late 1920s and early 1930s 4 to 5 million crabs were harvested annually. Shuster (1960) reports over 1 million crabs were harvested during the 1940s and 500,000 to 250,000 horseshoe crabs were harvested in the 1950s. By the 1960s, only 42,000 horseshoe crabs were reported to be harvested annually (Finn et al., 1991).

Early harvest records are suspect due to under-reporting. The period of time between 1950 and 1960 is considered the nadir of horseshoe crab abundance. The substantial commercial-scale harvesting of horseshoe crabs ceased in the 1960s (Shuster, 1996).

Bait Fishery

Currently, horseshoe crabs are commercially harvested for use as American eel, conch (or whelk), and catfish bait along certain portions of the Atlantic coast. The horseshoe crab fishery is unique in that crabs can be easily harvested during their spawning season and can be caught with a minimal financial expense. The eel fishery is highly dependent on sustained populations of horseshoe crabs and prefers female horseshoe crabs with eggs.

The conch fishery also is dependent on horseshoe crabs, but uses both male and female horseshoe crabs. Commercial landings data for horseshoe crabs (i.e., metric tons, pounds, and price) are collected by the NMFS by state, year, and gear type. Commercial landings data may include harvest for both the bait and biomedical fisheries.

However, the NMFS data are relatively incomplete and disjunct. For example, in several years that NMFS reports no landings in states such as Delaware, state biologists report that landings did occur (Michels, pers. comm., 1997). In 1994 and 1995, the NMFS reported Maryland's harvest at 232,000 and 117,000 pounds, respectively. Based on State landing records, actual Maryland harvest was approximately 1 million pounds during these years (O'Connell, pers. comm., 1998). In many cases, horseshoe crabs are harvested and used directly by eel fishers, whelk fishers, or catfish fishers without going through a dealer (where NMFS gets much of its information) or arrangements are made for harvesters to sell directly to such fisheries without going to dealers. Since such private sales are not reported, NMFS fishery statistics underestimate the catch. Based on NMFS data, commercial harvest from the northeastern Atlantic coast has ranged between 10,000 pounds (in 1969) to over 5.0 million pounds (in 1996) (NMFS, 1998).

Since 1988, commercial landings have averaged 1,436,808 pounds. Botton and Ropes (1987b) estimated the total number of horseshoe crabs harvested by comparing the total number of pounds landed with the average weight of an adult horseshoe crab, which is approximately 4 pounds. However, the NMFS used a different conversion factor to estimate the number of pounds landed (e.g., 2.6 pounds per crab). The total average horseshoe crab catch (animals/year) for the Atlantic Coast (assuming an adult horseshoe crab is 4 pounds) has increased from 476,515 in 1993 to 1,288,408 in 1996 (NMFS, 1998). This increase is similar to increases reported by Michels (unpublished data, 1997) for the Delaware Bay harvest, which ranged from 330,333 in 1993 to 896,540 in 1996. However, Michels (unpublished data, 1997) did not include the Maryland harvest (which can be substantial). These statistics provide further evidence that the NMFS data represent an underestimate of actual harvest. Regardless of the data set used, all data show a significant increase in harvest between 1990 and 1996.

The SAS and the PRP concluded that commercial landings data show a substantial increase in reported harvest during the 1990s (Atlantic States Marine Fisheries Commission, 1998a; 1998b). This increase could be, in part, a function of increased harvest reporting efficiency. The states of Delaware, Maryland, New Jersey, and New York represent the largest harvest of horseshoe crabs recently. Estimates in Delaware, Maryland, New Jersey, New York, and Rhode Island indicate a rapid increase in fishery growth, based primarily on use as bait for the American eel and whelk fisheries and the shift in pressure from declining traditional fisheries (Michels, unpublished data, 1997; NMFS, 1998; Thompson, 1998). However, the States of Connecticut, Massachusetts, North Carolina, and Virginia indicate declines in current harvest compared with harvest in the late 1970s and early 1980s (NMFS, 1998).

Based on reported landings in New Jersey alone, horseshoe crab harvests have increased in the last three years from approximately 250,000 in 1993 to over 600,800 in 1996. The Delaware Division of Fish and Wildlife (1997) reports increases in landings between 1990 (under 250,000 pounds) and 1997 (over 1,500,000 pounds). The Delaware Division of Fish and Wildlife (1997) also reports increases in effort as represented by issuance of beach collection permits, which increased from 18 in 1991 to 131 in 1997.

However, prior to 1991 little or no reporting occurred within the Delaware Bay. Thus, the increase in horseshoe crab harvest during the 1990s may be partly related to mandatory reporting requirements. Primary harvest was identified in Rhode Island, New Jersey, Delaware, Maryland, and Virginia. Little to no harvesting of horseshoe crabs was reported in Maine, New Hampshire, or Connecticut (Botton and Ropes, 1987b).

The Chesapeake Bay in Maryland and Virginia likely has a substantial harvest, but without quantitative studies, the catch remains under-reported. Maryland has been responsible for 23 to 78 percent of the total commercial catch of horseshoe crabs from the northeastern Atlantic coast since 1980 (NMFS, 1998). Maryland averaged 357,000 pounds between 1981 and 1991 from a small directed ocean fishery and bycatch from the clam fishery. Since 1992, harvest has increased significantly in Maryland with 2.6 million pounds landed in 1996. Maryland's fishery is primarily an offshore trawl fishery;

more than 95 percent of the harvest occurs from July through November. In 1996, 96 percent of Maryland's harvest was from waters outside of 1 mile (52 percent from State waters [1-3 miles] and 44 percent from federal waters [3+ miles]), 3 percent from the coastal bays, and <1 percent from the Chesapeake Bay (O'Connell, pers. comm., 1998).

In Virginia, horseshoe crab harvest averaged 190,000 pounds between 1980 and 1988. With a ban on trawling in state waters since 1989, horseshoe crab landings have decreased considerably, averaging 22,000 pounds (Butowski 1994) and only increasing to 86,294 pounds in 1996 (NMFS 1998). Demand has increased in Virginia as indicated by whelk landings, which have increased from 75,000 pounds in 1994 to 750,000 pounds in 1995 (Petrocci 1997).

Reported dockside value from the northeastern Atlantic coast has ranged between $289 (1967) and $1,541,260 (1996). Fishery statistics (Table 5.3.8-2) for the period 1970 through 1997 indicate a variable fishery. As previously identified, fishery statistics probably underestimate the catch of horseshoe crabs, because the sale of crabs for bait is often arranged between private individuals (i.e., unreported in NMFS landing statistics) rather than through centralized dealers (Botton and Ropes 1987b).

In 1997, the majority (85 percent) of horseshoe crabs in Delaware were landed by hand harvest, while dredge harvest made up approximately 15 percent (Delaware Division of Fish and Wildlife, 1997). Between 1991 and 1996 the majority of the horseshoe crabs were landed by hand-harvest (63 percent) compared to dredging (37 percent) (Delaware Division of Fish and Wildlife, 1997), except for 1991 when the dredge harvest dominated the catch (56 percent). The increased harvest noted in Delaware mirrored increases in the number of hand-collection permits issued (Delaware Division of Fish and Wildlife, 1997). NMFS data compiled by Delaware Division of Fish and Wildlife (1997) identified that among the northeastern and mid-Atlantic States, Maryland, New Jersey, and

Delaware harvest the majority of horseshoe crabs (36, 31, and 14 percent, respectively). The shrimp trawl fishery in the South Atlantic Bight may contribute to horseshoe crab mortality via bycatch (Thompson, 1998), but the amount of bycatch harvest remains unreported. The amount of horseshoe crab bycatch has become very small, since the use of turtle excluder devices became mandatory in the shrimp trawl fishery (Cupka, pers. comm., 1998).

Table 5.3.8-2. Atlantic states landings for horseshoe crab for the period 1970 - 1997. Source: National Marine Fisheries Service (1998). Note: National Marine Fisheries Service data is an underestimate of the true coastwide harvest due to the lack of mandatory reporting in all states. Note: All dollars are 1992 dollars, adjusted by the implicit price deflator (GDP). All life stages are included.

ATLANTIC STATES LANDINGS (MAINE - FLORIDA)		
Year	Pounds	Value (in $1000s)
1970	15,900	7.79
1971	11,900	3.01
1972	42,000	2.63
1973	88,700	5.54
1974	16,700	6.90
1975	62,800	18.90
1976	2,043,100	63.96
1977	473,000	16.58

1997	6,146,487	1228.56

Biomedical Fishery
Scientists have used horseshoe crabs in eye research, surgical sutures wound dressing development, and detection of bacterial endotoxins in drugs and intravenous devices (Hall 1992). Limulus Amoebocyte Lysate (LAL), a clotting agent in horseshoe crab blood, has made it possible to detect human pathogens such as spinal meningitis and gonorrhea in patients, drugs, and all intravenous devices. In 1964, researchers discovered that horseshoe crab blood coagulates in the presence of minute quantities of gram-negative bacterial endotoxin and the LAL industry was initiated. By 1979, the U.S. Food

and Drug Administration (FDA) issued draft guidelines for the use of LAL as an end-product pyrogen test for endotoxin in medical devices and injectable drugs. The LAL test is currently the worldwide standard for screening medical equipment for bacterial contamination; any drug produced by a pharmaceutical company must pass an LAL screening. No other known procedure has the same accuracy as the LAL test. If LAL became unavailable, it could take years to find a universally accepted replacement. To obtain LAL, manufacturing companies catch primarily adult horseshoe crabs, collect a portion of their blood, and then release them alive.

In 1989, the FDA reported that 130,000 horseshoe crabs were used in the biomedical industry. The current estimate of medical usage is between 200,000 and 250,000 horseshoe crabs per year on the Atlantic Coast (Swan pers. comm. 1998; McCormick pers. comm. 1998). The FDA mandates conservation by requiring the return of horseshoe crabs to the environment. Most labs return bled crabs to their habitat within 72 hours of capture, but may or may not release crabs at the collection site (Botton 1995).

Approximately 10 percent of the crabs do not survive the bleeding procedure, which comprises a source of mortality that is not included in the commercial catch statistics (Rudloe 1983). Based on a tagging and controlled mortality study, Thompson (1998) reported similar post-processing mortality of horseshoe crabs (10 to 15 percent). Mortality due to the bleeding procedure may be lower (e.g., 0 to 4 percent), depending on the biomedical facility (Swan pers. comm. 1998), but the mortality associated with collection, shipping, and handling remains unknown. This mortality is minimal compared to that from the commercial bait fishery.

In South Carolina, live horseshoe crabs may be taken only for use in LAL production, with animals returned to natural habitat after bleeding. Landings in South Carolina by hand-harvest and trawl have increased since the late 1980s. The annual reported harvest in South Carolina has increased over 300 percent since reporting requirements were established in 1991 (Thompson 1998). Presumably, this increase in harvest was driven by the biomedical industry’s demand for more horseshoe crabs.

Horseshoe crabs are used also to make chitin filament for suturing (Hall 1992). Since the mid-1950s medical researchers have known that chitin-coated suture material enhanced healing time by 35-50 percent. Currently, horseshoe crabs are harvested on a limited basis to manufacture chitin-coated suture material and chitin wound dressings (Hall 1992). Horseshoe crab blood is also beneficial in cancer research; the LAL could lead to controlled cancer therapy. Endotoxins and other substances in horseshoe crab blood may have the potential for diagnosing leukemia.

Social environment

(excerpt from Horsheshoecrab.org)

Horseshoe crabs are the primary bait for the American eel and conch fisheries in many mid-Atlantic States. In Maryland, the estimated value of the horseshoe crab fishery in 1996 for 10 horseshoe crab harvesters was $398,596 (Maryland Department of Natural Resources 1998). Also in 1996, one Maryland seafood dealer, supplying horseshoe crabs to 20 American eel and 25 conch harvesters, estimated that the value of horseshoe crabs for these fisheries was $151,200. Horseshoe crab prices vary and are reported to be between $0.65 to $0.75 per animal (Maryland Department of Natural Resources 1998).

In 1997, American eel and conch harvesters in Delaware used an average of 4,714 and 20,502 horseshoe crabs per season per harvester, respectively. In New Jersey, American eel and conch harvesters used an average of 4,005 and 22,654 horseshoe crabs per season per harvester, respectively (Munson 1998). Many conch and American eel harvesters in New Jersey and Delaware harvest their own bait, supplying 18 to 65 percent of their bait needs (Munson 1998). While only nine percent of the fishing income (of respondents in the Delaware Bay Watermen's study) is attributable to the direct sale of horseshoe crabs, an average of 58 percent of the eel and conch fishing income depends on using horseshoe crabs as bait (Munson 1998). American eel harvesters in the Delaware Bay area report that approximately 21 percent of their total fishing income is attributable to eeling, while conch harvesters report that an average of 53 percent of their total fishing income depends on the conch fishery (Munson 1998). In 1996, the commercial harvest of horseshoe crabs was estimated to be a $1.5 million industry.

Horseshoe crabs are vital to medical research and the pharmaceutical products industry. The worldwide market for LAL is currently estimated to be approximately $50 million per year. This estimate is based on bleeding 250,000 horseshoe crabs per year, generating approximately $200 in revenue per crab for the biomedical industry. The biomedical industry either directly collects horseshoe crabs on spawning beaches or purchases horseshoe crabs for as much as $3.00 per crab. The biomedical industry pays approximately $375,000 per year for horseshoe crabs based on an estimate of 250,000 horseshoe crabs harvested at an average price of $1.50 per crab.

Eco-tourism is critical to the economies of many states, including New Jersey and Delaware, and it depends on the abundance and health of the ecosystems within the region. In 1988, over 90,000 “birders” spent $5.5 million in Cape May, New Jersey (Kerlinger and Weidner 1991) to watch the interaction between spawning horseshoe crabs and migrating shorebirds. In 1996, approximately 606,000 people in New Jersey and Delaware took trips away from their residence (traveling more than one mile) for the primary purpose of watching wildlife. Of these people, 409,000 individuals specifically stated that they were watching shorebirds (U.S. Bureau of Census and USFWS, 1998).

In 1996, New Jersey and Delaware wildlife watchers spent between nine and 12 days per year (on average) away from home (traveling more than one mile) watching wildlife (U.S. Bureau of Census and USFWS, 1998). In New Jersey and Delaware, total expenditures, including food, lodging, transportation, and equipment in 1996 for the primary purpose of wildlife watching was $639,992,000 (USFWS, 1998). The type of wildlife watched was not identified in this survey. The 1996 regional economic impact resulting from expenditures by wildlife watchers in New Jersey and Delaware was the creation of 15,127 jobs and the generation of a total household income of $399 million (USFWS, 1998).

5.3.8.3 Bycatch

Little is known about bycatch in the horseshoe crab trawl fishery. Although bycatch monitoring programs have been developed for many fisheries (NOAA 2003), to date no studies have attempted to identify or quantify bycatch in the horseshoe crab trawl fishery. The gear used in the horseshoe crab trawl fishery is much different than that used in other fisheries; the benthic gear is equipped with heavy ground gear to effectively catch horseshoe crabs. Therefore, monitoring programs developed for other fisheries may not accurately portray bycatch in the horseshoe crab trawl fishery.

In 2001, a benthic trawl survey was developed and initiated by the Horseshoe Crab Research Center (HCRC) at Virginia Tech (Hata and Berkson 2004). Species composition data were collected aboard the HCRC trawl survey in the fall of 2005 and 2006 to identify species that are susceptible to the trawl gear used in the horseshoe crab trawl fishery (Graham et al., in review). Sites between the eastern tip of Long Island, New York, USA (71° 50'W and 41° 04'N) and the southern tip of the Delmarva Peninsula, Virginia, USA (75° 55'W and 37° 05'N) were sampled using the trawl gear that is commonly used in the commercial fishery (n = 156 sites) (Graham et al., in review).

Over two fall seasons, 76 different taxa were identified as susceptible to the trawl gear (n = 60 taxa in 2005, n = 69 taxa in 2006), including 47 finfish species from 33 families (Table 5.3.8-3) (Graham et al., in review). The majority of biomass was comprised of skates (49%) and horseshoe crabs (33%) (Graham et al., in review). Catch per unit effort was greatest for little/winter skate (*Leucoraja* spp.), horseshoe crab, and clearnose skate (*Raja eglanteria*) (Graham et al. in review). Clearnose skate, horseshoe crab, summer flounder (*Paralichthys dentatus*), spider crab (*Libinia* spp.), and windowpane flounder (*Scophthalmus aquosus*) were most commonly caught throughout the study area (Graham et al., in review). Of the 76 taxa caught, some taxa may be especially sensitive to removal as bycatch (Table 5.3.8-4) (Graham et al., in review). Some species that were caught have low population sizes and life history characteristics do not allow quick recovery of their populations (Graham et al., in review). Other species are currently unmanaged, possibly allowing populations to decline without detection (Graham et al., in review). The majority of species have potential to exhibit heavy harvest elsewhere, as most support commercial and recreational fisheries (Graham et al., in review). It is important to quantify bycatch of all species in the horseshoe crab trawl fishery so management strategies can be adapted accordingly (Graham et al., in review).

Species composition among sites differed based on location and bottom water temperature, suggesting that these variables can be used to predict potential bycatch species during other seasons (Graham et al., in review). Species composition shifted at Atlantic City, New Jersey with species composition at northern sites (i.e., sites north of Atlantic City) being much different than at southern sites (i.e., sites south of Atlantic City, New Jersey) (Table 5.3.8-3(Graham et al., in review). Species caught during the HCRC trawl survey were also common to their preferred temperature ranges; therefore, researchers may be able to use species' preferred temperature ranges in conjunction with water temperature data to determine which bycatch species will be caught throughout the year (Graham et al., in review).

This study provides crucial information about bycatch in the horseshoe crab trawl fishery; however, it is important to point out the differences between collection methods of the HCRC trawl survey and the commercial fishery. The HCRC trawl survey sites were randomly selected (based on the methods of Hata and Berkson, 2004), whereas commercial fishers often target sites that are high in horseshoe crab abundance. HCRC survey sites were also only sampled in the fall, while commercial fishing has potential to occur year round depending on current regulations. Also, HCRC survey sites were only towed for fifteen minutes, unlike commercial tows which may last for much longer (i.e., > 1 hour). Due to these differences between the HCRC survey and the commercial fishery, data should be collected aboard commercial fishing vessels to confirm these results and further identify and quantify bycatch in the horseshoe crab trawl fishery. Lastly, it is important to emphasize that commercial fishers use trawl gear to collect horseshoe crabs for bait and biomedical companies. Many times, biomedical companies are given more lenient harvest regulations because horseshoe crabs are returned to the water after they are bled, and experience relatively low mortality. Although mortality of horseshoe crabs is relatively low, harvest methods still have potential to catch many individuals as bycatch and regulations should be set accordingly to minimize bycatch.

Table 5.3.8-3. (from Graham et al., in review). Catch per unit effort (CPUE) and percent occurrence for all taxa caught during the Horseshoe Crab Research Center trawl survey (2005 and 2006).

		Catch per Unit Effort (ind/km)		Percent occurrence

5.3.9 Highly Migratory Pelagics

5.3.9.1 Description of fishing practices, vessels and gear

Pelagic longline fishery

The U.S. pelagic longline fishery for Atlantic HMS primarily targets swordfish, yellowfin tuna, and bigeye tuna in various areas and seasons. Secondary target species include dolphin, albacore tuna, pelagic sharks (including mako, thresher, and porbeagle sharks), as well as several species of large coastal sharks. Although this gear can be modified (e.g., depth of set, hook type, etc) to target swordfish, tunas, or sharks, it is generally a multi-species fishery. These vessel operators are opportunistic, switching gear style and making subtle changes to target the best available economic opportunity of each individual trip. Pelagic longline gear sometimes attracts and hooks non-target finfish with little or no commercial value, as well as species that cannot be retained by commercial fishermen due to regulations, such as billfish. Pelagic longlines may also interact with protected species such as marine mammals, sea turtles, and seabirds. Thus, this gear has been classified as a Category I fishery with respect to the Marine Mammal Protection Act. Any species (or undersized catch of permitted species) that cannot be landed due to fishery regulations is required to be released, whether dead or alive. Pelagic longline gear is composed of several parts (see Figure 5.3.9-1) (NMFS, 1999).

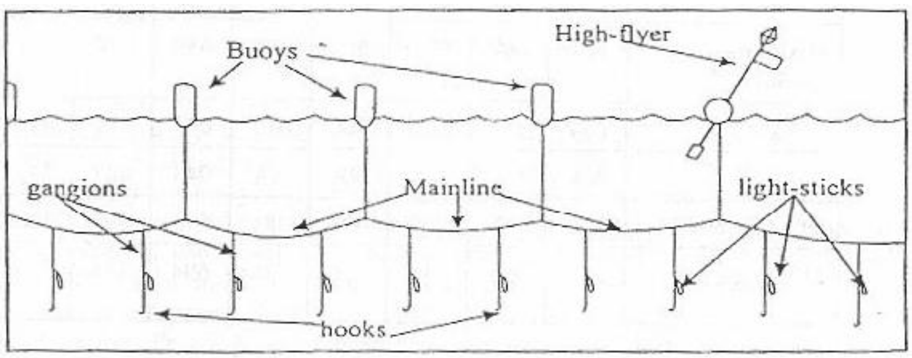

Figure 5.3.9-1. Typical U.S. Pelagic Longline Gear. Source: Arocha 1996 Note: As of April 1, 2001, (66 FR 17370) a vessel is considered to have pelagic longline gear on board when a power-operated longline hauler, a mainline, floats capable of supporting the mainline, and leaders (gangions) with hooks are on board.

The primary fishing line, or mainline of the longline system, can vary from five to 40 miles in length, with approximately 20 to 30 hooks per mile. The depth of the mainline is determined by ocean currents and the length of the floatline, which connects the mainline to several buoys, and periodic markers which can have radar reflectors or radio beacons attached.

Each individual hook is connected by a leader, or gangion, to the mainline. Lightsticks, which contain chemicals that emit a glowing light, are often used, particularly when targeting swordfish. When attached to the hook and suspended at a certain depth, lightsticks attract baitfish, which may, in turn, attract pelagic predators (NMFS, 1999).

When targeting swordfish, pelagic longline gear is generally deployed at sunset and hauled at sunrise to take advantage of swordfish nocturnal near-surface feeding habits (NMFS, 1999). In general, longlines targeting tunas are set in the morning, deeper in the water column, and hauled in the evening. Except for vessels of the distant water fleet, which undertake extended trips, fishing vessels preferentially target swordfish during periods when the moon is full to take advantage of increased densities of pelagic species near the surface. The number of hooks per set varies with line configuration and target species (Table 5.3.9-1) (NMFS, 1999). The pelagic longline gear components may also be deployed as a trolling gear to target surface feeding tunas. Under this configuration, the mainline and gangions are elevated and actively trolled so that the baits fish on or above the water's surface. This style of fishing is often referred to as "green-stick fishing," and reports indicate that it can be extremely efficient compared to conventional fishing techniques.

Table 5.3.9-1. Average Number of Hooks per Pelagic Longline Set, 1999-2004. Source: Data reported in pelagic longline logbook.

Target Species	1999	2000	2001	2002	2003	2004
Swordfish	521	550	625	695	712	701
Bigeye Tuna	768	454	671	755	967	400
Yellowfin Tuna	741	772	731	715	723	696
Mix of tuna species	NA	638	719	767	764	779
Shark	613	621	571	640	970	1,046
Dolphin	NA	943	447	542	692	1,033
Other species	781	504	318	300	865	270
Mix of species	738	694	754	756	750	777

Figure 5.3.9-2 illustrates basic differences between swordfish (shallow) sets and tuna (deep)longline sets. Swordfish sets are buoyed to the surface, have few hooks between floats, and are relatively shallow. This same type of gear arrangement is used for mixed target sets. Tuna sets use a different type of float placed much further apart. Compared with swordfish sets, tuna sets have more hooks between the floats and the hooks are set much deeper in the water column. It is believed that because of the difference in fishing depth, tuna sets hook fewer turtles than the swordfish sets. In addition, tuna sets use bait only, while swordfish fishing uses a combination of bait and lightsticks. Compared with vessels targeting swordfish or mixed species, vessels specifically targeting tuna are typically smaller and fish different grounds.

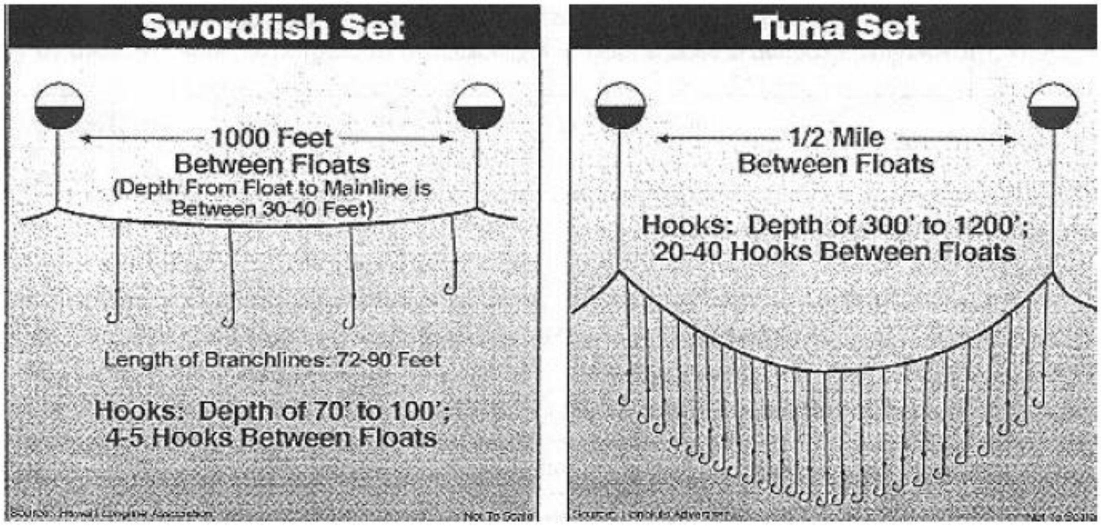

Figure 5.3.9-2 . Different Pelagic Longline Gear Deployment Techniques. Source: Hawaii Longline Association and Honolulu Advertiser. NOTE: This figure is only included to show basic differences in pelagic longline gear configuration and to illustrate that this gear may be altered to target different species.

<u>The South Atlantic – Florida East Coast to Cape Hatteras Swordfish Fishery</u>
Historically, South Atlantic pelagic longline vessels targeted swordfish year-round, although yellowfin tuna and dolphin fish were other important marketable components of the catch. In 2001 (65 FR 47214, August 1, 2000), the Florida East Coast closed area (year-round closure) and the Charleston Bump closed area (February through April closure) became effective.

Prior to these closures, smaller vessels used to fish short trips from the Florida Straits north to the bend in the Gulf Stream off Charleston, South Carolina (Charleston Bump). Midsized and larger vessels migrate seasonally on longer trips from the Yucatan Peninsula throughout the West Indies and Caribbean Sea, and some trips range as far north as the Mid-Atlantic coast of the United States to target bigeye tuna and swordfish during the late summer and fall. Fishing trips in this fishery average nine sets over 12 days. Home ports (including seasonal ports) for this fishery include Georgetown, South Carolina; Charleston, South Carolina; Fort Pierce, Florida; Pompano Beach, Florida; and Key West, Florida. This sector of the fishery consists of small to mid-size vessels, which typically sell fresh swordfish to local high-quality markets (NMFS 1999).

<u>Management of the U.S. Pelagic Longline Fishery</u>
The U.S. Atlantic pelagic longline fishery is restricted by a limited swordfish quota, divided between the North and South Atlantic (separated at 5°N. Lat). Other regulations include minimum sizes for swordfish, yellowfin, bigeye, and bluefin tuna, limited access permitting, bluefin tuna catch requirements, shark quotas, protected species incidental take limits, reporting requirements (including logbooks), and gear and bait requirements. Current billfish regulations prohibit the retention of billfish by pelagic longline vessels, or the sale of billfish from the Atlantic Ocean. As a result, all billfish hooked on pelagic

longlines must be discarded, and are considered bycatch. This is a heavily managed gear type and, as such, is strictly monitored.

Because it is difficult for pelagic longline fishermen to avoid undersized fish in some areas, NMFS has closed areas in the Gulf of Mexico and along the east coast. The intent of these closures is to decrease bycatch in the pelagic longline fishery by closing those areas with the highest rates of bycatch. There are also time/area closures for pelagic longline fishermen designed to reduce the incidental catch of bluefin tuna and sea turtles. In order to enforce time/area closures and to monitor the fishery, NMFS requires all pelagic longline vessels to report positions on an approved vessel monitoring system (VMS).

In June 2004, NMFS conditionally re-opened the Northeast Distant Statistical Reporting Area (NED)to pelagic longline fishing. NMFS limited vessels with pelagic longline gear onboard in that area, at all times, to possessing onboard and/or using only 18/0 or larger circle hooks with an offset not to exceed ten degrees. Only whole mackerel and squid baits may be possessed and or utilized with allowable hooks. In August of 2004, NMFS limited vessels with pelagic longline gear onboard, at all times, in all areas open to pelagic longline fishing, excluding the NED, to possessing onboard and/or using only 16/0 or larger non-offset circle hooks and/or 18/0 or larger circle hooks with an offset not to exceed ten degrees. Only whole finfish and squid baits may be possessed and/or utilized with allowable hooks. All pelagic longline vessels must possess and use sea turtle handling and release gear in compliance with NMFS careful release protocols.

Permits

The 1999 FMP established six different limited access permit types: (1) directed swordfish, (2) incidental swordfish, (3) swordfish handgear, (4) directed shark, (5) incidental shark, and (6) tuna longline. To reduce bycatch in the pelagic longline fishery, these permits were designed so that the swordfish directed and incidental permits are valid only if the permit holder also holds both a tuna longline and a shark permit.

Similarly, the tuna longline permit is valid only if the permit holder also holds both a swordfish (directed or incidental, not handgear) and a shark permit. This allows limited retention of species that might otherwise have been discarded.

As of February 1, 2006, approximately 214 tuna longline limited access permits had been issued. In addition, approximately 191 directed swordfish limited access permits, 86 incidental swordfish limited access permits, 240 directed shark limited access permits, and 312 incidental shark limited access permits had been issued. Vessels with limited access swordfish and shark permits do not necessarily use pelagic longline gear, but these are the only permits that allow for the use of pelagic longline gear in HMS fisheries.

Monitoring and Reporting

Pelagic longline fishermen and the dealers who purchase HMS from them are subject to reporting requirements. NMFS has extended dealer reporting requirements to all swordfish importers as well as dealers who buy domestic swordfish from the Atlantic.

These data are used to evaluate the impacts of harvesting on the stock and the impacts of regulations on affected entities.

Commercial HMS fisheries are monitored through a combination of vessel logbooks, dealer reports, port sampling, cooperative agreements with states, and scientific observer coverage. Logbooks contain information on fishing vessel activity, including dates of trips, number of sets, area fished, number of fish, and other marine species caught, released, and retained. In some cases, social and economic data such as volume and cost of fishing inputs are also required.

Recent Catch and Landings

U.S. pelagic longline catch (including bycatch, incidental catch, and target catch) is largely related to these vessel and gear characteristics, but is summarized for the whole fishery in Table 5.3.9-2. U.S. pelagic longline landings of Atlantic tunas and swordfish for 1999 – 2004 are summarized in Table 5.3.9-3. Additional information related to landings can be found in Section 3.4.6 of the Consolidated Atlantic Highly Migratory Species Fishery Management Plan.

From May 1992 through December 2000, the Pelagic Observer Program (POP) recorded a total of 4,612 elasmobranchs (15 percent of the total catch) caught off the southeastern U.S. coast in fisheries targeting tunas and swordfish (Beerkircher et al. 2004). Of the 22 elasmobranch species observed, silky sharks were numerically dominant (31.4 percent of the elasmobranch catch), with silky, dusky, night, blue, tiger, scalloped hammerhead, and unidentified sharks making up the majority (84.6 percent) (Beerkircher et al. 2004).

Purse seine fishery

Purse seine gear consists of a floated and weighted encircling net that is closed by means of a drawstring; know as a purseline, threaded through rings attached to the bottom of the net.

The efficiency of this gear can be enhanced by the assistance of spotter planes used to locate schools of tuna. Once a school is spotted, the vessel, with the aid of a smaller skiff, intercepts and uses the large net to encircle it. Once encircled, the purseline is pulled, closing the bottom of the net and preventing escape. The net is hauled back onboard using a powerblock, and the tunas are removed and placed onboard the larger vessel.

Vessels using purse seine nets have participated in the U.S. Atlantic tuna fishery continuously since the 1950s; although a number of purse seine vessels did target and land bluefin tuna off the coast of Gloucester, MA as early as the 1930s. In 1958, continued commercial purse seining effort for Atlantic tunas began with a single vessel in Cape Cod Bay and expanded rapidly into the region between Cape Hatteras and Cape Cod during the early 1960s. The purse seine fishery between Cape Hatteras and Cape Cod was directed mainly at small and medium bluefin tuna, yellowfin tuna, and at skipjack tuna, primarily for the canning industry. North of Cape Cod, purse seining was directed at giant BLUEFIN TUNA. High catches of juvenile BLUEFIN TUNA were sustained throughout the 1960s and into the early 1970s. These high catch rates by U.S. purse seine vessels are believed to have played a role in the decline in abundance during subsequent years. Currently these purse seine vessels focus their effort on giant bluefin tuna, versus other tunas, due to the international market that developed for giant bluefin tuna in the late 1970s. These fresh caught bluefin tuna are primarily flown directly to Japan for processing into sushi or sashimi. By the late 1980s, high ex-vessel prices and the increased importance of the Japanese market had increased effort on all size classes of bluefin tuna. In 1992, NMFS responded by banning the sale of school, large school, and small medium bluefin tuna (27 inches to less than 73 inches curved fork length).

A limited entry system with non-transferable individual vessel quotas (IVQs) for purse seining was established in 1982, effectively excluding any new entrants into this category. Equal baseline quotas of bluefin tuna are assigned to individual vessels by regulation; the IVQ system is possible given the small pool of ownership in this sector of the fishery. Currently, only five vessels comprise the Atlantic tuna purse seine fleet and in 1996 the quotas were made transferable among the five vessels.

Vessels that are participating in the Atlantic tunas purse seine fishery are required to target the larger size class bluefin tuna, more specifically the giant sized class (81 inches or larger) and are granted a tolerance limit of 15 percent by weight, of the total amount of giant bluefin tuna landed during a season. These vessels may commence fishing starting on July 15 of each year and may continue through December 31, provided the vessel has not fully attained its IVQ. Over the last few years, the purse seine category has not fully harvested its allocated quota. This can be attributed to a number of different reasons outside of the industry's or NMFS' control, such as lack of availability or schools being comprised of mixed size classes. NMFS has issued several Exempted Fishing Permits (EFPs) to this sector of the fishery and will continue to assess current regulations and their impact on providing reasonable opportunities to harvest available quota.

Recent Catch and Landings

Table 5.3.9-4 shows purse seine landings of Atlantic tunas from 1999 through 2004. Purse seine landings typically make up approximately 20 percent of the total annual U.S. landings of bluefin tuna (about 25 percent of total commercial landings), but account for only a small percentage, if any, of the landings of other HMS. In the 1980s and early 1990s, purse seine landings of yellowfin tuna were often over several hundred metric tons. Over 4,000 mt ww of yellowfin tuna were recorded landed in 1985. In recent years, via informal agreements with other sectors of the tuna industry, the purse seine fleet has opted not to direct any effort on HMS other than bluefin tuna.

Table 5.3.9-4. Domestic Atlantic Tuna Landings for the Purse Seine Fishery: 1999-2004 (mt ww). Northwest Atlantic Fishing Area. Source: U.S. National Report to ICCAT: 2005.

Species	1999	2000	2001	2002	2003	2004
Bluefin Tuna	247.9	275.2	195.9	207.7	265.4	31.8
Yellowfin Tuna	0	0	0	0	0	0
Skipjack Tuna	0	0	0	0	0	0

Commercial handgear fishery

Commercial handgears, including handline, harpoon, rod and reel, and bandit gear are often used to fish for Atlantic HMS by fishermen on private vessels, charter vessels, and headboat vessels. Rod and reel gear may be deployed from a vessel that is at anchor, drifting, or underway (i.e., trolling). In general, trolling consists of dragging baits or lures through, on top of, or even above the water's surface. While trolling, vessels often use outriggers, kites, or green-sticks to assist in spreading out or elevating baits or lures and to prevent fishing lines from tangling. Operations, frequency and duration of trips, and distance ventured offshore vary widely. Most of the vessels are greater than seven meters in length and are privately owned by individual fishermen.

The handgear fisheries are typically most active during the summer and fall, although in the South Atlantic and Gulf of Mexico fishing occurs during the winter months. Fishing usually takes place between eight and 200 km from shore and for those vessels using bait, the baitfish typically includes herring, mackerel, whiting, mullet, menhaden, ballyhoo, butterfish, and squid.

The commercial handgear fishery for bluefin tuna occurs mainly in New England, and more recently off the coast of southern Atlantic states, such as Virginia, North Carolina and South Carolina, with vessels targeting large medium and giant bluefin tuna. The

majority of U.S. commercial handgear fishing activities for bigeye, albacore, yellowfin, and skipjack tunas take place in the northwest Atlantic. Beyond these general patterns, the availability of Atlantic tunas at a specific location and time is highly dependent on environmental variables that fluctuate from year to year.
Currently the U.S. Atlantic tuna commercial handgear fisheries are managed through an open access vessel permit program. Vessels that wish to sell their Atlantic tunas must obtain a commercial handgear permit in one of the following categories: General (rod and reel, harpoon, handline, bandit gear), Harpoon (harpoon only), or Charter/Headboat (rod and reel and handline).

These vessels may also need permits from the states they operate out of in order to land and sell their catch. All commercial permit holders are encouraged to check with their local state fish/natural resource management office regarding these requirements.

Permitted vessels are also required to sell their Atlantic tunas to federally permitted Atlantic tuna dealers. As the Atlantic tunas dealer permits are issued by the Northeast Region Permit Office, vessel owner/operators are encouraged to contact the permitting office directly, either by phone at (978) 281-9438 or via the web at http://www.nero.noaa.gov/ro/doc/vesdata1.htm, to obtain a list of permitted dealers in their area.

Vessels that are permitted in the General and Charter/Headboat categories commercially fish under the General category rules and regulations. For instance, regarding bluefin tuna, vessels that possess either of the two permits mentioned above have the ability to retain a daily bag limit of zero to three bluefin tuna, measuring 73 inches or greater curved fork length per vessel per day while the General category bluefin tuna fishery is open. The General category bluefin tuna fishery opens on June 1 of each year and remains open until January 31 of the subsequent year, or until the quota is filled. Vessel owner/operators should check with the agency via websites (www.hmspermits.gov) or telephone information lines (1-888-872-8862) to verify the bluefin tuna retention limit on any given day. The General category bluefin tuna quota is approximately 47 percent of the U.S. quota and equates to a base line allocation of approximately 690 mt.

Vessels that are permitted in the Harpoon category fish under the Harpoon category rules and regulations. For instance, regarding bluefin tuna, vessels have the ability to keep two bluefin measuring 73 inches to less than 81 inches curved fork length per vessel trip per day while the fishery is open. There is no limit on the number of bluefin tuna that measure longer than 81 inches curved fork length, as long as the Harpoon category season is open. The Harpoon category season also opens on June 1 of each year and remains open until November 15, or until the quota is filled. The Harpoon category bluefin tuna quota is approximately 3.9 percent of the U.S. quota and equates to a base line allocation of approximately 57 mt.

U.S. commercial swordfish fishing in the Atlantic Ocean is reported to have begun in the early 1800s as a harpoon fishery off the coast of New England. This fishery traditionally consisted of harpoon vessels operating out of Rhode Island and Massachusetts where they took extended trips for swordfish north and east of the Hudson Canyon and particularly off Georges Bank, and could land as many as 20 to 25 large swordfish over a ten-day period. These fish primarily consisted of large fish that finned on the surface and were available to the harpoon gear, some weighing as much as 600 lbs dw, but averaging about 225 to 300 lbs dw at the turn of the century. Because of the limited effort directed towards large fish, the stock was sufficient to support a sustainable seasonal swordfish fishery for more than 150 years. Most swordfish caught in the United States in the early 1900s were harvested with harpoons; harpoon landings declined from the 1940s through the 1960s. Due to a decreased availability of the large swordfish in the northeast this fishery has essentially ceased to exist. However, a recently emerging swordfish handgear fishery, both commercial and recreational, has appeared to develop off the east coast of Florida. This fishery is essentially prosecuted at night with rod and reel or handline gear. Some vessels participating in this fishery are currently utilizing individual handlines attached to free-floating buoys. This fishery has been operating under the current regulations, which require that handlines be restricted to no more than two hooks and be released and retrieved by hand. The current regulations do not limit the number of individual handlines/buoys that may be possessed or deployed.

Currently the U.S. commercial swordfish fishery is managed through limited access vessel permits. Vessels that possess a limited access handgear permit must abide by the minimum size limits for swordfish (i.e., 29 inches form cleithrum to caudal keel; 47 inches lower jaw fork length; or 33 lbs dressed weight) and seasonal retention limits. When the directed swordfish fishery is open, permitted handgear vessel do not have a possession limit. However, during a directed fishery closure, permitted handgear vessels may land two swordfish per trip, provided these two fish were not taken with harpoon gear. Fishermen with a commercial handgear swordfish permit are required to report fishing activities in an approved logbook within 48 hours of each day’s fishing activities for multi-day trips, or before offloading for one-day trips, and submit the logbook within seven days of offloading.

The shark commercial handgear fishery plays a very minor role in contributing to the overall shark landing statistics. For further information regarding the shark fishery refer to Section 3.4.5. Economic and social aspects of all the domestic handgear fisheries are described later in this document (Section 3.5 and Chapter 9.0 respectively).

<u>Recent Catch and Landings</u>

The proportion of domestic HMS landings harvested with handgear varies by species, with Atlantic tunas comprising the majority of commercial landings. Commercial handgear landings of all Atlantic HMS (other than sharks) in the United States are shown in Table 5.3.9-5.

In 2004, bluefin tuna commercial handgear landings accounted for approximately 42 percent of the total U.S. bluefin tuna landings, and almost 75 percent of commercial bluefin tuna landings. Also in 2004, four percent of the total yellowfin catch, or nine percent of the commercial yellowfin catch, was attributable to commercial handgear. Commercial handgear landings of skipjack tuna accounted for approximately ten percent of total skipjack landings, or about 30 percent of commercial skipjack landings. For albacore, commercial handgear landings accounted for approximately one percent of total albacore landings, or about six percent of commercial albacore landings. Commercial handgear landings of bigeye tuna accounted for approximately one percent of total bigeye landings and one percent of total commercial bigeye landings. Updated tables of landings for the commercial handgear fisheries by gear and by area for 1999 – 2004 are presented in the following tables.

Bottom longline

In 1993, NMFS implemented the FMP for Sharks of the Atlantic Ocean, which established three management units: large coastal sharks (LCS), small coastal sharks (SCS), and pelagic sharks. At that time, NMFS identified LCS as overfished, and implemented commercial quotas for LCS and established recreational harvest limits for all sharks. In 2003, NMFS amended the measures enacted in the 1999 FMP based on the 2002 LCS and SCS stock assessments, litigation, and public comments. Implementing regulations for Amendment 1 to the 1999 FMP were published on December 24, 2003 (68 FR 74746). Management measures enacted in the amendment included: re-aggregating the large coastal shark complex, using maximum sustainable yield (MSY) as a basis for setting commercial quotas, eliminating the commercial minimum size restrictions, establishing three regional commercial quotas (Gulf of Mexico, South Atlantic, and North Atlantic) for LCS and SCS management units, implementing trimester commercial fishing seasons effective January 1, 2005, imposing gear restrictions to reduce bycatch, and a time/area closure off the coast of North Carolina effective January 1, 2005.

As a result of using MSY to establish quotas, and implementing a new rebuilding plan, the overall annual landings quota for LCS in 2004 was established at 1,017 metric tons (mt) dressed weight (dw). The overall annual landings quota for SCS was established at 454 mt dw and the pelagic, blue, and porbeagle shark quotas were established at 488 mt dw, 273 mt dw, and 92 mt dw, respectively.

The regional quotas which were established in Amendment 1 to the 1999 HMS FMP for LCS and SCS were intended to improve overall management of the stocks by tailoring quotas to specific regions based on landings information. These quotas were based upon average historical landings (1999 – 2001) from the canvass and quota monitoring databases. The canvass database provides a near-census of the landings at major dealers in the southeast United States (including state landings) and the quota monitoring database collects information from dealers in the South Atlantic and Gulf of Mexico.

On November 30, 2004, NMFS issued a final rule (69 FR 69537), which established, among other things, new regional quotas based on updated landings information from 1999 –2003. This final rule did not change the overall quotas for LCS, SCS, and pelagic sharks established in Amendment 1 to the 1999 HMS FMP, but did revise the percentages allocated to each of the regions. The updated information was based on several different databases, including the canvass and quota monitoring databases, the Northeast Commercial Fisheries Database (CFDBS), and the snapper grouper logbook.

The new regional quotas and trimester seasons for the commercial Atlantic shark fishery became effective January 1, 2005. Commercial shark fishing effort is generally concentrated in the southeastern United States and Gulf of Mexico (Cortes and Neer, 2002). During 1997 – 2003, 92 – 98 percent of LCS, 38 – 49 percent of pelagic sharks, and nearly all SCS (80 – 100 percent) came from the southeast region (Cortes, pers. comm.). McHugh and Murray (1997) found in a survey of shark fishery participants that the largest concentration of bottom longline fishing vessels is found along the central Gulf coast of Florida, with the John’s Pass - Madeira Beach area considered the center of directed shark fishing activities. Consistent with other HMS fisheries, some shark fishery participants move from their homeports to other fishing areas as the seasons change and fish stocks move.

The Atlantic bottom longline fishery targets both LCS and SCS. Bottom longline is the primary commercial gear employed in the LCS and SCS fisheries in all regions. Gear characteristics vary by region, but in general, an approximately ten-mile long bottom longline, containing about 600 hooks, is fished overnight. Skates, sharks, or various finfishes are used as bait. The gear typically consists of a heavy monofilament mainline with lighter weight monofilament gangions. Some fishermen may occasionally use a flexible 1/16 inch wire rope as gangion material or as a short leader above the hook.

Recent Catch and Landings Data

The following section provides information on shark landings as reported in the shark bottom longline observer program. For recent catch and landings data for the shark fishery as a whole, which includes landings from bottom longline and other gears combined, please refer to Section 3.4.7.

In January 2002, the observer coverage requirements in the shark bottom longline fishery changed from voluntary to mandatory participation if selected. NMFS selects approximately 40 - 50 vessels for observer coverage during each season. Vessels are randomly selected if they have a directed shark limited access permit, have reported landings from sharks during the previous year, and have not been selected for observer coverage during each of the three previous seasons.

The U.S. Atlantic commercial shark bottom longline fishery has been monitored by the University of Florida and Florida Museum of Natural History, Commercial Shark Fishery Observer Program (CSFOP) since 1994. In June 2005, responsibility for the observer program was transferred to the Southeast Fisheries Science Center's Panama City Laboratory. The observer program trains and places the observers aboard vessels in the directed shark bottom longline fishery in the Atlantic and Gulf of Mexico to collect data on the commercial shark fishery and thus improve overall management strategies for the fishery. Observers provide baseline characterization information, by region, on catch rates, species composition, catch disposition, relative abundance, and size composition within species for the large coastal and small coastal shark bottom longline fisheries.

During 2003, six observers logged 263 sea days on shark fishing trips aboard 20 vessels in the Atlantic from North Carolina to Florida and in the eastern Gulf of Mexico off Florida. The number of trips taken on each vessel ranged from one to five and the number of sea days each observer logged ranged from nine to 35. Observers documented the catches and fishing effort on approximately 150 longline sets that fished 103,351 hooks.

During 2004, five observers logged 196 sea days on 56 shark fishing trips aboard 11 vessels. Observers documented the catches and fishing effort during 120 longline sets that fished 90,980 hooks.

Data from the shark observer program between 2000 and 2002 show that LCS comprised 66.2 percent of the total catch (Burgess and Morgan, 2002). During 2003, LCS comprised 68.4 percent of the total catch, and in 2004 LCS comprised 66.7 percent of the total catch. Sandbar sharks dominated the observed catches with 30.6 percent of total LCS catch in 2003 and 26.6 percent in 2004 (Table 3.52). The overall catch and disposition of species for 2004 is listed in Table 3.53. Regional differences in sandbar shark abundance were evident. For example, in the Carolina region, sandbar sharks comprised 67.4 percent of the total catch and 77.2 percent of the large coastal shark catch. In the Florida Gulf region, sandbar sharks comprised 62.0 percent of the total catch and 66.5 percent of the large coastal catch, whereas in the Florida East Coast region, sandbar sharks comprised only 17.2 percent of the total observed catch, and 37.1 percent of the large coastal shark catch (Burgess and Morgan, 2003). Blacktip sharks comprised 13.9 percent of total observed catch and 20.3 percent of the large coastal catch (Burgess and Morgan, 2002). Tiger sharks comprised 7.5 percent of the total observed catch and 11.0 percent of the large coastal shark catch. A majority of tiger sharks (71.7 percent) and nurse sharks (98.8 percent) were tagged and released.

During 2003, shark observer program data indicate that SCS comprised 28.0 percent of the total observed catch (Burgess and Morgan, 2003; Burgess and Morgan 2004). Atlantic sharpnose shark dominated the SCS catch (80.3 percent). The remainder of the small coastal catch consisted of blacknose sharks (5.5 percent), bonnethead (0.03 percent), and finetooth (0.02 percent)(Table 3.52). In previous seasons, the Atlantic sharpnose shark was the most frequently caught shark in the Florida East Coast region and accounted for 51.6 percent of the total observed catch, and 96.0 percent of the small coastal catch in that region (Burgess and Morgan, 2002).

Bottom longlining for sharks has relatively low observed bycatch rates. Historically, finfish bycatch has averaged approximately five percent in the bottom longline fishery. Finfish bycatch for the bottom longline fishery includes, but is not limited to, skates, rays, cobia, redfish, bluefish, and great barracuda. During the second semi-annual season of 2003, observer data indicate that approximately 4,320 sharks were caught compared to 432 other fish, four invertebrates, and three sea turtles (Burgess and Johns, 1999). In terms of bycatch rates, observed shark catches constitute 91 percent of the 4,759 total animals caught, with other fish comprising 10 percent, invertebrates less than .01 percent, and sea turtles less than .01 percent. For more information on bycatch see Section 3.8.

Gillnet fishery

The southeast shark gillnet fishery is comprised of several vessels based primarily out of ports in northern Florida (South Atlantic Region) that use nets typically 456 to 2,280 meters long and 6.1 to 15.2 meters deep, with stretched mesh from 12.7 to 22.9 cm. This fishery is currently prohibited in the state waters off South Carolina, Georgia, and Florida, thereby forcing some of these vessels to operate in deeper waters under Federal jurisdiction, where gillnets are less effective. The entire process (set to haulback) takes approximately 9 hours (Carlson and Baremore 2002a).

The 2005 Directed Shark Gillnet Fishery Observer Program report described the gear and soak time deployed by drift gillnet, strike gillnet, and sink gillnet fishermen. Set duration was generally 0.3 hours and haulback averaged 2.9 hours. The average time from setting the net through completion of haulback was 10.2 hours. The most frequently used mesh size for drift gillnets was 12.7 cm. Strikenetters use the largest mesh size (22.9 cm) and the set times were 2.7 hours. Sink gillnets used to target sharks generally use 17.8 cm mesh size and were soaked for approximately 0.8 hours. This gear was also observed being deployed to target non-HMS (kingfish or Spanish mackerel); using a stretched mesh size of 7.6 cm, to comply with mesh size regulations for the Spanish mackerel fishery, and soaked for approximately 5.9 hours (Carlson and Bethea 2006).

In the southeast shark gillnet fishery, NMFS modified the requirement to have 100 percent observer coverage at all times on March 30, 2001 (66 FR 17370), by reducing the level required to a statistically significant level outside of right whale calving season (100 percent observer coverage is still required during the right whale calving season from November 15 through March 31). This modification of observer coverage reduced administrative costs while maintaining statistically significant and adequate levels of coverage to provide reasonable estimates of sea turtle and marine mammal takes outside the right whale calving season. The level of observer coverage necessary to maintain statistical significance will be reevaluated annually and adjusted accordingly.

Additionally, in 2001, NMFS established a requirement to conduct net checks every two hours to look for and remove any protected species.

Recent Catch and Landings

The following section provides information on shark landings as reported in the shark gillnet observer program. For recent catch and landings data for the shark fishery as a whole, which includes landings from gillnet, bottom longline, and other gears combined, please refer to Section 3.4.7. A total of 24 driftnet sets were observed on five vessels from February through September, 2004. Driftnet vessels carried nets ranging in length from 547.2 – 2736 m; depths from 7.6 – 13.7 m and stretched mesh sizes from 12.7 – 22.9 cm. The most frequently used mesh size was 12.7 cm. For all observed driftnet sets, set duration averaged 0.4 hrs. Sets were made in seawater averaging 15.4 m deep.

Haulback and processing of the catch averaged 3.4 hrs. Average soak time for the driftnet (time net was first set minus time haulback began) was 10.8 hrs. The observed driftnet catch consisted of nine species of sharks. Three species of sharks made up 92.9 percent (by number) of the observed shark catch (Table 3.57). These species were the Atlantic sharpnose shark, blacknose shark, and finetooth shark. By weight, the shark catch was made up of Atlantic sharpnose shark, (55.3 percent), blacknose shark (17.1 percent), blacktip shark (10.7 percent), and finetooth shark (10.3 percent). Total observed catch composition (percent of numbers caught) was 79.0 percent sharks, 20.7 percent teleosts, 0.3 percent rays, and 0.03 percent protected species (i.e., marine mammals, sea turtles, sawfish).

Recreational fishery

Atlantic tunas, sharks, swordfish, and billfish are all targeted by domestic recreational fishermen using rod and reel gear. The recreational swordfish fishery had declined dramatically over the past twenty years, but recent information indicates that the recreational swordfish fishery is rebuilding in the Mid-Atlantic Bight, and off the east coast of Florida. Effective March 1, 2003, an HMS Angling category permit has been required to fish recreationally for any HMS managed species (Atlantic tunas, sharks, swordfish, and billfish) (67 FR 77434, December 18, 2002). Prior to March 1, 2003, the regulations only required vessels fishing recreationally for Atlantic tunas to possess an Atlantic Tunas Angling category permit.

Recreational fishing for Atlantic HMS is managed primarily through the use of minimum size limits and bag limits. Recreational tuna fishing regulations are the most complex and include a combination of minimum sizes, bag limits, limited season-based quota allotment for bluefin tuna, and reporting requirements (depending upon the particular species and vessel type).

The recreational swordfish fishery has been managed through the use of a minimum size requirement and landings requirement (swordfish may be headed and gutted but may not be cut into smaller pieces). However, regulations effective March 2003 (68 FR 711) established a recreational retention limit of one swordfish per person up to three per vessel per day. Regardless of the length of a trip, no more than the daily limit of North Atlantic swordfish can be possessed onboard a vessel.

The recreational shark fishery is managed using bag limits, minimum size requirements, and landing requirements (sharks must be landed with head and fins attached). Additionally, the possession of 19 species of sharks is prohibited.

Atlantic blue and white marlin have a combined landings limit (i.e., a maximum of 250 fish that can be landed per year); however, the primary management strategy for the recreational billfish fishery is through the use of minimum size limits. There are no recreational retention limits for Atlantic sailfish, blue marlin, and white marlin. Recreational anglers may not land longbill spearfish.

ICCAT has made several recommendations to recover billfish resources throughout the Atlantic Ocean that are discussed in detail in Section 3.1.2 of the Consolidated Atlantic Highly Migratory Species Fishery Management Plan (2006).

Recent Catch and Landings Data

The recreational landings database for HMS consists of information obtained through surveys including the Marine Recreational Fishery Statistics Survey (MRFSS), Large Pelagic Survey (LPS), Southeast Headboat Survey (HBS), Texas Headboat Survey, and Recreational Billfish Survey Tournament Data (RBS). Descriptions of these surveys, the geographic areas they include, and their limitations, are discussed in Section 2.6.2 of the 1999 FMP and Section 2.3.2 of the 1999 Billfish Amendment (REF?).

Reported domestic landings of Atlantic bluefin tuna (1983 through 1998) and BAYS tuna (1995 through 1997) were presented in Section 2.2.3 of the 1999 FMP. As landings figures for 1997 and 1998 were preliminary in the 1999 FMP, updated landings for recreational rod and reel fisheries are presented in Table 3.41 through 2004. Recreational landings of swordfish are monitored by the LPS and the MRFSS. However, because swordfish landings are considered rare events, it is difficult to extrapolate the total recreational landings from dockside intercepts.

An ad hoc committee of NMFS scientists reviewed the methodology and data used to estimate recreational landings of Atlantic HMS during 2004. The Committee was charged with reviewing the 2002 estimates of U.S. recreational landings of bluefin tuna, white marlin and blue marlin reported by NMFS to ICCAT. The committee was also charged with recommending methods to be used for the estimation of 2003 recreational fishery landings of bluefin tuna and marlin. Although the Committee discovered and corrected a few problems with the raw data from the LPS and the estimation program used to produce the estimates, the Committee concluded that the estimation methods for producing the 2002 estimates were consistent with methods used in previous years. The report of the Committee is available at: http://www.nmfs.noaa.gov/sfa/hms/Tuna/2002-2003_Bluefin-Marlin_Report-120304.pdf.

Atlantic Billfish Recreational Fishery

Due to the rare nature of billfish encounters and the difficulty of monitoring landings outside of tournament events, reports of recreational billfish landings are sparse. However, the Recreational Billfish Survey (RBS) provides a preliminary source for analyzing recreational billfish landings. Table 5.3.9-7 documents the number of billfish landed in 1999 – 2004, as reported by the RBS.

Table 5.3.9-7. Preliminary RBS Recreational Billfish Landings in numbers of fish (calendar year). Source: NMFS Recreational Billfish Survey.

Species	1999	2000	2001	2002	2003	2004
Blue Marlin	172	117	75	84	96	110
White Marlin	36	8	22	33	20	25
Sailfish	30	18	11	14	24	9
Swordfish	-	-	0	16	48	168

In support of the sailfish assessment conducted at the 2001 SCRS billfish species group meeting, document SCRS/01/106 developed indices of abundance of sailfish from the U.S. recreational billfish tournament fishery for the period 1973 – 2000. The index of weight per 100 hours fishing was estimated from numbers of sailfish caught and reported in the logbooks submitted by tournament coordinators and NMFS observers under the RBS, as well as available size information. Document SCRS/01/138 estimated U.S. sailfish catch estimates from various recreational fishery surveys.

All recreational, non-tournament landings of billfish, including swordfish, must be reported within 24 hours of landing to NMFS by the permitted owner of the vessel landing the fish. This requirement is applicable to all permit holders, both private and charter/headboat vessels, not fishing in a tournament. In Maryland and North Carolina, vessel owners should report their billfish landings at state-operated landings stations. A landed fish means a fish that is kept and brought to shore. Due to large-scale non-compliance with the call-in requirement, the landings in Table 5.3.9-8 are considered a minimum estimate of the non-tournament landings of billfish.

Table 5.3.9-8. Number of billfish reported to NMFS via call-in system by fishing year, 2002-2005. Source: G. Fairclough pers. comm.

Species	2002*	2003	2004	2005**
Blue Marlin	0	7	2	5
White Marlin	0	1	0	2
Sailfish	3	16	57	58
Swordfish	28	188	314	381

Based on a fishing year of June 1 – May 31.
* Reporting requirement did not go into effect until March 1, 2003
** 2005 landings as of May 16, 2006

Swordfish Recreational Fishery

The recreational swordfish fishery in the North Atlantic Ocean has been steadily expanding in recent years, probably due to increased availability of small swordfish and an increased interest in the sport. Fishermen typically fish off the east coast of Florida and off the coasts of New Jersey and New York. Fish have also occasionally been encountered on trips off Maryland and Virginia. In the past, the New York swordfish fishery occurred incidental to overnight yellowfin tuna trips. During the day, fishermen targeted tunas, while at night they fished deeper for swordfish. This appears to have evolved into a year-round directed fishery off Florida and a summer fishery off of New Jersey. The Florida fishery occurs at night with fishermen targeting swordfish using live or dead bait and additional attractants such as lightsticks, LED lights, and light bars suspended under the boat.

Historically, fishery survey strategies have not captured all landings of recreational handgear-caught swordfish. Although some handgear swordfish fishermen have commercial permits, many others land swordfish strictly for personal consumption. Therefore, NMFS published regulations to improve recreational swordfish monitoring and conservation. A trip limit of one swordfish per person, up to three per vessel, and mandatory reporting of all recreationally-landed swordfish and billfish via a toll-free call-in system became effective on March 2, 2003 (68 FR 711). Accordingly, all reported recreational swordfish landings are counted against the incidental swordfish quota.

Recreational fishing tournaments allow for the collection of a large volume of fishery-dependent data in a relatively short time period. Tournaments also provide a “snapshot” of the recreational fishery at a particular time and location. Analysis of tournament data collected over a period of years could provide valuable information regarding trends in the recreational swordfish fishery. A recent study documented recreational handgear-caught swordfish in three south Florida tournaments (J. Levesque, pers. comm.). The tournaments occurred from July through September 2002, two in Lighthouse Point and the other in Ft. Lauderdale. Data was obtained through direct at-sea observation, dockside interviews with anglers landing swordfish, and a telephone interview with a tournament organizer. A total of 156 vessels and between 468 – 624 individuals participated in the three tournaments.

Tournament caught swordfish reported to the RBS have increased in recent years. There were none reported in 2001, 16 in 2002, 48 in 2003, and 168 in 2004. While total tournament landings of swordfish are still low in terms of numbers of fish, it appears that as swordfish have recovered in the past few years, tournament landings of swordfish have increased.

Shark Recreational Fishery

Recreational landings of sharks are an important component of HMS fisheries. Recreational shark fishing with rod and reel is a popular sport at all social and economic levels, largely because the resource is accessible. Sharks can be caught virtually anywhere in salt water, depending upon the species. Recreational shark fisheries are oftentimes exploited in nearshore waters by private vessels and charter/headboats. However, there is also some shore-based fishing and some offshore fishing. The following tables provide a summary of landings for each of the three species groups.

Amendment 1 to the 1999 Atlantic Tunas, Swordfish, and Shark FMP limited the recreational fishery to rod and reel and handline gear only.

Table 5.3.9-9. Estimates of Total Recreational Harvest of Atlantic Sharks: 1998-2004 (numbers of fish in thousands). Source: 1998-2000 (Cortés, pers. comm.); 2001-2004 (Cortés, 2005a; 2005b). Estimates for 2001-2004 do not include prohibited species.

Allowable gear

5.3.9.2 Economic and social description

Commercial fisheries

In 2003, the total commercial landings at ports in the 50 states by U.S. fishermen were 9.5 billion pounds valued at $3.3 billion. In 2004, the total commercial landings at ports in the 50 states by U.S. fishermen were 9.6 billion pounds and were valued at $3.7 billion. The overall value of landings between 2003 and 2004 had increased by nine percent. The total value of commercial HMS landings in 2004 was $43.9 million (Table 3.77). The 2004 ex-vessel price index indicated that 12 of the 17 finfish species tracked had increasing ex-vessel prices and five species had decreasing ex-vessel prices since 2003. The total edible finfish ex-vessel price index for 2004 was up eight percent from 2003.

The estimated value of the 2004 domestic production of all fishery products was $6.6 billion. This is $909 million less than the estimated value in 2003. The total import value of fishery products was $22.9 billion in 2004. This is an increase of $1.7 billion from 2003. The total import value in 1996 was $13.1 billion. The total export value of fishery products was $13.6 billion in 2004. This is an increase of $1.6 billion from 2003. The total export value in 1996 was $8.7 billion.

Consumers spent an estimated $61.9 billion for fishery products in 2004 including $42.8 billion at food service establishments, $18.9 billion in retail sales for home consumption, and $213.3 million for industrial fish products. The commercial marine fishing industry contributed $31.6 billion to the U.S. Gross National Product in 2004. In 1996, consumers spent an estimated $41.2 billion including $27.8 billion at food service establishments, $13.2 billion for home consumption, and $283.9 billion for industrial fish products. The commercial marine fishing industry contributed $21.0 billion to the U.S. Gross National Product in 1996.

Ex-Vessel Prices

The ex-vessel price depends on a number of factors including the quality of the fish (e.g., freshness, fat content, method of storage), the weight of the fish, the supply of fish, and consumer demand.

Average ex-vessel prices for bigeye tuna have generally increased since 1996. Prices from 2003 to 2004 have increased in all four regions. The gears used also influenced the average price of bigeye tuna.

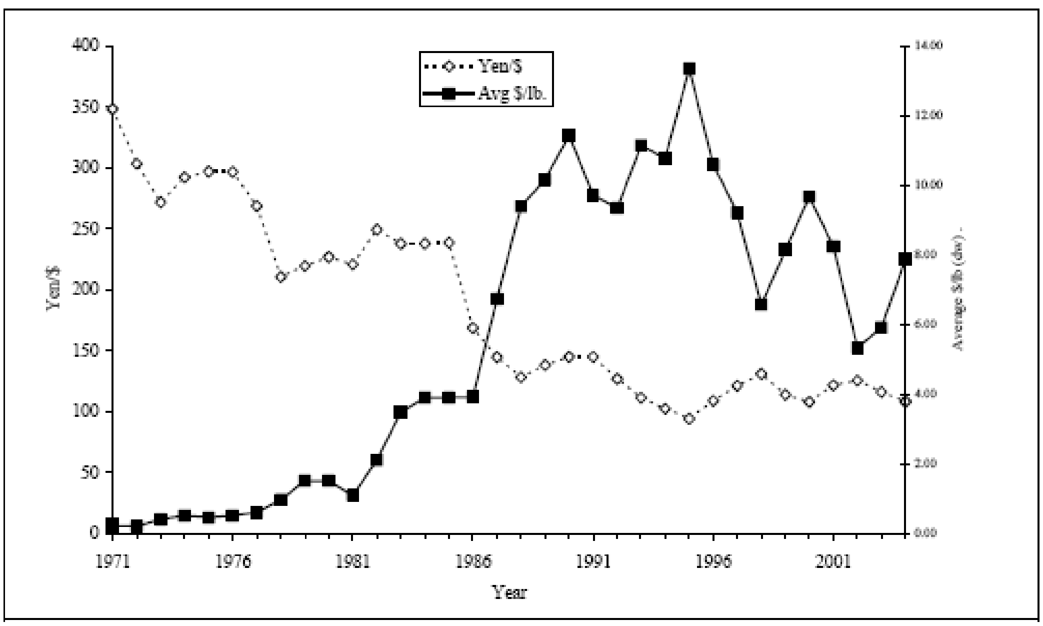

Figure 5.3.9-3. Average Annual Yen/$ Exchange Rate and Average U.S. bluefin tuna. Ex-vessel $/lb (dw) for all gears: 1971-2003. Source: Federal Reserve Bank (www.stls.frb.org) and Northeast Regional Office.

Average ex-vessel prices for bluefin tuna have generally declined since 1996. Since 2002, however, prices increased in all regions except the North Atlantic. The gear used also made a difference in the ex-vessel price. In the North Atlantic and Mid-Atlantic, bluefin tuna caught with handgear had higher average prices than those caught with longline. This trend has been fairly consistent over the years between 1996 and 2004. The ex-vessel prices for bluefin tuna can be influenced by many factors, including market supply and the Japanese Yen/U.S. Dollar (¥/$) exchange rate. Figure 5.3.9-3 shows the average ¥/$ exchange rate, plotted with average ex-vessel bluefin tuna prices, from 1971 to 2003.

The average ex-vessel prices for yellowfin tuna have increased in 2004 in the Gulf of Mexico, Mid-Atlantic and North Atlantic while increasing slightly in the South Atlantic. Yellowfin tuna caught with longline gear had higher average ex-vessel prices than fish caught with other gear types in 2004. The average ex-vessel price for other tunas decreased in all regions except the Gulf of Mexico in 2004. The average price of other tunas is lowest in the South Atlantic compared to other regions. The type of gear used did not appear to consistently influence the average ex-vessel prices of other tuna.

Average ex-vessel prices for swordfish increased in 2004 in all regions. Swordfish caught using handline gear had higher average ex-vessel prices than other gear types, except in the Mid-Atlantic where it was trawls.

The average ex-vessel price for LCS slightly decreased in the Gulf of Mexico in 2004 and North Atlantic. However, prices for LCS increased in the Mid-Atlantic and South Atlantic (Table 5.3.9-14).

The average ex-vessel prices for pelagic sharks increased in the Mid-Atlantic and North Atlantic regions in 2004 (Table 5.3.9-14), while prices decreased in Gulf of Mexico and South Atlantic. The 2004 prices for pelagic sharks are not significantly different than 1996 prices and are actually lower than 1996 when adjusting for inflation. The average ex-vessel prices for small coastal sharks (SCS) rebounded in all regions in 2004 (Table 5.3.9-14). Gear type did not consistently affect ex-vessel price of small coastal sharks in 2004 (Table 5.3.9-14).

<u>Revenues</u>

Table 5.3.9-14 summarizes the average annual revenues of the Atlantic HMS fishery based on average ex-vessel prices and the weight reported landed as per the U.S. National Report (NMFS 2005), the Shark Evaluation Reports, information given to ICCAT (Cortes, 2005), as well as price and weight reported to the NMFS Northeast Regional Office by Atlantic bluefin tuna dealers. These values indicate that the estimated total annual revenue of Atlantic HMS fisheries has decreased 34 percent from approximately $66.4 million in 1996 to approximately $43.9 million in 2004. From 2003 to 2004, the tuna fishery's total revenue decreased significantly. A majority of that decrease can be attributed to reduced commercial landings of bluefin tuna and yellowfin tuna. From 2003 to 2004, the annual revenues from shark decreased by over 21 percent. In contrast, the annual revenues from swordfish from 2003 to 2004 increased by five percent after having been in decline for several years.

<u>Wholesale Market</u>

Currently, NMFS does not collect wholesale price information from dealers. However, the wholesale price of some fish species is available off the web (http://www.st.nmfs.gov/st1/market_news/index.html). As with ex-vessel prices, wholesale prices depend on a number of factors including the quality of the fish, the weight of the fish, the supply of fish, and consumer demand.

As reported by the Fulton Fish Market, Table 5.3.9-12 indicates that the average wholesale price of HMS sold in Atlantic and Gulf of Mexico states generally decreased from 1996 to 2003, except for blacktip shark. Prices have appeared to have rebounded in 2004, breaking from the declining trend. During that same period, the wholesale price of swordfish weighing over 100 pounds decreased 19 percent, swordfish weighing between 50 and 99 pounds decreased 25 percent, and swordfish cuts decreased 15 percent. The wholesale price of blacktip shark increased 27 percent from 1996 to 2003, with most of the increase occurring in 2003. The wholesale price of mako shark decreased 14 percent from 1996 to 2003, however 2003 wholesale prices were up from 2002. The wholesale price of thresher shark has decreased 22 percent from 1996 to 2003. Wholesale yellowfin tuna prices have remained relatively stable from 1996 to 2003. The yellowfin tuna wholesale price of #2 quality fish had decreased eight percent while the price of #2 cuts has increased seven percent from 1996 to 2003. Bigeye tuna wholesale prices from 1999 to 2003 have increased significantly for both high grade cuts and fish.

Table 5.3.9-12. The overall average wholesale price per lb of fresh HMS sold in Atlantic and Gulf of Mexico states as reported by the Fulton Fish Market. Source: NMFS, 2004.

Species	Description	1996 Price/lb	1999 Price/lb	2000 Price/lb	2001 Price/lb	2002 Price/lb	2003 Price/lb	2004 Price/lb

	#2: Cuts	-	$6.00	-	-	-	-	-

Note: #'s indicate quality (1 is highest, 3 is lowest); BTF is by the fish.

Recreational fisheries

Although NMFS believes that recreational fisheries have a large influence on them economies of coastal communities, NMFS has only recently been able to gather additional information on the costs and expenditures of anglers or the businesses that rely on them.

An economic survey done by the U.S. Fish and Wildlife Service2 in 2001 found that for the entire United States 9.1 million saltwater anglers (including anglers in state waters) went on approximately 72 million fishing trips and spent approximately $8.4 billion (USFWS, 2001). Expenditures included lodging, transportation to and from the coastal community, vessel fees, equipment rental, bait, auxiliary purchases (e.g., binoculars, cameras, film, foul weather clothing, etc.), and fishing licenses (USFWS, 2001). Saltwater anglers spent $4.5 billion on trip-related costs and $3.9 billion on equipment (USFWS, 2001). Approximately 76 percent of the saltwater anglers surveyed fished in their home state (USFWS, 2001). The next USFWS survey was conducted in 2006.

Specific information regarding angler expenditures for trips targeting HMS species was extracted from the recreational fishing expenditure survey add-on (1998 in the Northeast, 1999 – 2000 in the Southeast) to the National Marine Fisheries Service's Marine Recreational Fisheries Statistics Survey (MRFSS). These angler expenditure data were analyzed on a per-person per trip-day level and reported in 2003 dollars. The expenditure data include the costs of tackle, food, lodging, bait, ice, boat fuel, processing, transportation, party/charter fees, access/boat launching, and equipment rental. The overall average expenditure on HMS related trips is estimated to be $122 per person per day. Specifically, expenditures are estimated to be $686 per person per day on billfish directed trips (based on a low sample size), $85 on pelagic shark directed trips, $95 on large coastal shark directed trips, $81 on small coastal sharks, and $106 on tuna trips.

The American Sportfishing Association (ASA) also has a report listing the 2001 economic impact of sportfishing on specific states. This report states that all sportfishing (in both Federal and state waters) has an overall economic importance of $116 billion dollars (ASA, 2001). Florida, Texas, North Carolina, New York, and Alabama are among the top ten states in terms of overall economic impact for both saltwater and freshwater fishing (ASA, 2001). Florida is also one of the top states in terms of economic impact of saltwater fishing with $2.9 billion in angler expenditures, $5.4 billion in overall economic impact, $1.5 billion in salaries and wages related to fishing, and 59,418 fishing related jobs (ASA, 2001). California followed Florida with $0.8 billion in angler expenditures, $1.7 billion in overall economic impact, $0.4 billion in salaries and wages, and 15,652 jobs (ASA, 2001). Texas and New Jersey were the next highest states in terms of economic impact (ASA, 2001).

At the end of 2004, NMFS began collecting market information regarding advertised charterboat rates. This preliminary analysis of the data collected includes 99 observations of advertised rates on the internet for full day charters. Full day charters vary from six to 14 hours long with a typical trip being 10 hours. Most vessels can accommodate six passengers, but this also varies from two to 12 passengers. Table 3.79 summarizes the average charterboat rate for full day trips on vessels with HMS Charter/Headboat permits. The average price for a full day boat charter was $1,053 in 2004. Sutton et al., (1999) surveyed charterboats throughout Alabama, Mississippi, Louisiana, and Texas in

1998 and found the average charterboat base fee to be $762 for a full day trip. Holland et al. (1999) conducted a similar study on charterboats in Florida, Georgia, South Carolina, and North Carolina and found the average fee for full day trips to be $554, $562, $661, and $701, respectively. Comparing these two studies conducted in the late 1990s to the average advertised daily HMS charterboat rate in 2004, it is apparent that there has been a significant gain in charterboat rates.

Table 5.3.9-13. Average Atlantic HMS charterboat rates for day trips. Source: NMFS searches for advertised daily charter rates of HMS Charter/Headboat permit holders. (Observations=99)

State	2004 Average Daily Charter Rate
AL	$1,783
CT	$1,500

NY	$1,113
RI	$917
SC	$1,300
TX	$767
VA	$825
Overall Average	**$1,053**

In 2003, Ditton and Stoll published a paper that surveyed the literature regarding what is currently known about the social and economic aspects of recreational billfish fisheries. It was estimated that 230,000 anglers in the United States spent 2,136,899 days fishing for billfish in 1991. This is approximately 3.6 percent of all saltwater anglers over age 16.

The states with the highest number of billfish anglers are Florida, California, North Carolina, Hawaii, and Texas in descending order. Billfish anglers studied in the U.S. Atlantic, Puerto Rico, and Costa Rica fished between 39 and 43 days per year.

Billfish recreational anglers tend to spend a great deal of money on trips. Ditton and Stoll (2003) report that a 1990 study of U.S. total trip costs for a typical billfish angler estimated a mean expenditure of $2,105 per trip for the Atlantic and $1,052 per trip for Puerto Rico. The aggregate economic impact of billfish fishing trips in the U.S. Atlantic is conservatively estimated to be $22.7 million annually.

In addition to the economic impact of recreational billfish angling, Ditton and Stoll (2003) report that using a contingent valuation method they estimated consumer's surplus or net economic benefit to maintain current billfish populations in the U.S. Atlantic to be $497 per billfish angler per year in the U.S. Atlantic and $480 in Puerto Rico. They also estimate that the number of annual billfish anglers in the U.S. Atlantic to be 7,915 and 1,627 in Puerto Rico. The aggregate willingness-to-pay for maintaining current billfish populations is $3.93 million in the U.S. Atlantic and 0.78 million in Puerto Rico. The aggregate direct impact of billfish expenditures is estimated to be $15.13 million for the U.S. Atlantic and $32.40 million for Puerto Rico. Thus, the total aggregate economic value of billfish angler fishing is $19.06 million per year for the U.S. Atlantic and $33.18 million per year for Puerto Rico.

Generally, HMS tournaments last from three to seven days, but lengths can range from one day to an entire fishing season. Similarly, average entry fees can range from approximately $0 to $5,000 per boat (average approximately $500/boat – $1,000/boat), depending largely upon the magnitude of the prize money that is being awarded. The entry fee would pay for a maximum of two to six anglers per team during the course of the tournament. Additional anglers can, in some tournaments, join the team at a reduced rate of between $50 and $450. The team entry fee did not appear to be directly proportional to the number of anglers per team, but rather with the amount of money available for prizes and, possibly, the species being targeted. Prizes may include citations, T-shirts, trophies, fishing tackle, automobiles, boats, or other similar items, but most often consists of cash awards. In general, it appears that billfish and tuna tournaments charge higher entry fees and award more prize money than shark and swordfish tournaments, although all species have a wide range.

Cash awards distributed in HMS tournaments can be quite substantial. Several of the largest tournaments, some of which are described below, are part of the World Billfish Series Tournament Trail whereby regional winners are invited to compete in the World Billfish Series Grand Championship for a new automobile and a bronze sculpture. Other tournament series include the International Game Fish Association (IGFA) Rolex Tournament of Champions, and the South Carolina Governor’s Cup. White marlin is a top billfish species from Cape Hatteras, North Carolina to the eastern tip of Georges Bank from June through October each year. The White Marlin Open in Ocean City, Maryland, which is billed as the “world’s richest fishing tournament,” established a new world record payout for catching a fish when it awarded $1.32 million in 2004 to the vessel catching the largest white marlin. The 21st Annual Pirates Cove Billfish Tournament in North Carolina awarded over $1 million in prizes in 2004, with the top boat garnering over $400,000 for winning in six categories. Total prize money awarded in the Big Rock Tournament in North Carolina has exceeded $1 million since 1998.

Blue marlin, sailfish, and tunas are also often targeted in fishing tournaments, including those discussed above. In 2004, blue marlin was the HMS most frequently identified as a prize category in registered HMS tournaments. Forty-five teams participated in the 2004 Emerald Coast Blue Marlin Classic at Sandestin, Florida, with over $482,000 in cash prizes and the top boat receiving over $58,000. The 34th Annual Pensacola (Florida) International Billfish Tournament indicated that it would award over $325,000 in cash and prizes in 2004. The World Sailfish Championship in Key West, Florida has a

$100,000 guaranteed first prize for 2005. In South Carolina, the Megadock Billfishing Tournament offers a $1,000,000 prize for any boat exceeding the current blue marlin state record. The 2004 Florida Billfish Masters Tournament in Miami, Florida awarded over $123,000 in prize money, with the top boat receiving over $74,000. Sixty-two boats competed in the 2003 Babylon Tuna Club Invitational in Babylon, New York for over $75,000 in cash prizes, and the Mid-Atlantic Tuna Tournament sponsored by the South Jersey Marina in Cape May, New Jersey anticipates awarding over $25,000 in prizes in 2005.

Several tournaments target sharks. Many shark tournaments occur in New England, New York, and New Jersey, although other regions hold shark tournaments as well. In 2004, the 24th Annual South Jersey Shark Tournament hosted over 200 boats and awarded over $220,000 in prize money, with an entry fee of $450 per boat. The "Mako Fever" tournament, sponsored by the Jersey Coast Shark Anglers, in 2004 awarded over $55,000 in prizes, with the first place vessel receiving $25,000. In 2004, the 18th Annual Monster Shark Tournament in Martha's Vineyard, Massachusetts was broadcast on ESPN, and featured a new fishing boat valued at over $130,000 awarded to the winner.

Swordfish tournaments have gained increased popularity in recent years, especially on the east coast of Florida, as the swordfish population has recovered. Events include the Islamorada Swordfish Tournament that began in 2004, and the Miami Swordfish Tournament that began in 2003. Both of these tournaments anticipated awarding over $30,000 in total cash and prizes, assuming that 50 boats would participate.

In addition to official prize money, many fishing tournaments may also conduct a "calcutta" whereby anglers pay from $200 to $5,000 to win more money than the advertised tournament prizes for a particular fish. Tournament participants do not have to enter calcuttas. Tournaments with calcuttas generally offer different levels depending upon the amount of money an angler is willing to put down. Calcutta prize money is distributed based on the percentage of the total amount entered into that Calcutta. Therefore, first place winner of a low level calcutta (entry fee ~$200) could win less than a last place winner in a high level calcutta (entry fee ~$1000). On the tournament websites, it was not always clear if the total amount of prizes distributed by the tournament included prize money from the calcuttas or the estimated price of any equipment. As such, the range of prizes discussed above could be a combination of fish prize money, Calcutta prize money, and equipment/trophies.

Fishing tournaments can sometimes generate a substantial amount of money for surrounding communities and local businesses. Besides the entry fee to the tournament and possibly the calcutta, anglers may also pay for marina space and gas (if they have their own vessel), vessel rental (if they do not have their own vessel), meals and awards dinners (if not covered by the entry fee), hotel, fishing equipment, travel costs to and from the tournament, camera equipment, and other miscellaneous expenses. Fisher and Ditton (1992) found that the average angler who attended a billfish tournament spent $2,147 per trip (2.59 days), and that billfish tournament anglers spent an estimated $180 million (tournament and non-tournament trips) in 1989. Ditton and Clark (1994) estimated annual expenditures for Puerto Rican billfish fishing trips (tournaments and non-tournaments) at $21.5 million. More recently, Ditton, et al., (2000) estimated that the total expenditure (direct economic impact) associated with the 1999 Pirates Cove Billfish Tournament, not including registration fees, was approximately $2,072,518.

The total expenditure (direct economic impact) associated with the 2000 Virginia Beach Red, White, and Blue Tournament was estimated at approximately $450,359 (Thailing et al. 2001). These estimated direct expenditures do not include economic effects that may ripple through the local economy leading to a total impact exceeding that of the original purchases by anglers (i.e., the multiplier effect). Less direct, but equally important, fishing tournaments may serve to generally promote the local tourist industry in coastal communities. In a survey of participants in the 1999 Pirates Cove Billfish Tournament, Ditton, et al., (2000) found that almost 80 percent of tournament anglers were from outside of the tournament's county. For this reason, tourism bureaus, chambers of commerce, resorts, and state and local governments often sponsor fishing tournaments.

Social and cultural environment

This section consolidates all of the community profiles from previous HMS management plans or amendments and updates the community information, where possible. To ensure continuity with the 1999 HMS FMP and previous amendments, if a community was selected and described as being involved with an HMS fishery, the same community was included in this assessment. The communities profiled were originally selected due to the proportion of HMS landings, the relationship between the geographic communities and the fishing fleets, the existence of other community studies, and input from the HMS and Billfish Advisory Panels. The communities selected for detailed study are Gloucester and New Bedford, Massachusetts; Barnegat Light and Brielle, New Jersey; Wanchese, and Hatteras Township, North Carolina; Pompano Beach, Fort Pierce, Madeira Beach, Panama City Beach, and Islamorada, Florida; Boothville/Venice and Dulac, Louisiana; and Arecibo, Puerto Rico. These communities are not intended to be an exhaustive list of every HMS-related community in the United States; rather the objective is to give a broad perspective of representative areas.

The demographic profiles found in the 2006 Consolidated Atlantic Highly Migratory Species FMP have been modified to include the same baseline information for each community profiled; as a result, most of the tables include more information than portrayed in the 1999 HMS FMP and its amendments. The demographic tables still use both 1990 and 2000 Bureau of the Census data for comparative purposes. The descriptive community profiles include the same information provided by the Wilson, et al. (1998) and Kirkley (2005) analyses with some new information provided by Impact Assessment, Inc (2004) on the Gulf of Mexico communities. Unlike the Wilson, et al., (1998) study used in the 1999 HMS FMP, it was not possible to undertake field research for this assessment.

This assessment also reviewed the HMS permit databases to incorporate information about residence. This information was also used to identify additional HMS-related fishing communities that should be profiled in the future. Six GIS maps were generated to identify the communities where angler, charter/headboat, HMS dealers (tunas, shark, and swordfish combined), commercial tuna (all gear categories combined), directed and incidental shark, and swordfish (directed, incidental, and handgear combined) permit holders reside (Figure 9.1 to Figure 9.6 in the 2006 Consolidated FMP). In past community profile and social impact analyses, it was difficult to identify where recreational HMS fishermen were located because no data were available for the number of recreational fishermen, as well as recreational landings by community. Previous social impact assessments report on charter fishing operations, fishing tournaments, and related activities to identify the scope of recreational fishing for each of the communities described. The information provided by the HMS permit databases should facilitate the identification of recreational HMS communities that should be profiled in the future.

For future social impact analyses, the HMS permit databases, landings information, and HMS APs should be consulted to determine the most appropriate community profiles for HMS-related fisheries. The 2005 HMS permit data indicate that several new community profiles should be developed and some of the previously profiled communities may no longer be as significantly involved in the fishery as they were in the past.

Wakefield, Rhode Island should be considered due to the number of commercial tuna and swordfish permit holders in the area. Montauk, New York has a large concentration of charter/headboat, commercial tuna, and HMS dealer permit holders in the community. A large number of Cape May, New Jersey residents hold an HMS angling, charter/headboat, shark and/or swordfish permits. Morehead City, North Carolina is home to a number of HMS angling, charter/headboat, and commercial tuna permit holders. Each of these towns is actively involved with more than one sector of the HMS fisheries and therefore be impacted be any changes to HMS regulations.

5.3.9.3 Bycatch

Pelagic Longline Fishery

NMFS collects data on the disposition (released alive or dead) of bycatch species from logbooks submitted by fishermen in the pelagic longline fishery. Observer reports also include disposition of the catch as well as information on hook location, trailing gear and injury status of protected species interactions. These data are used to estimate post-release mortality of sea turtles and marine mammals based on guidelines for each (Angliss and DeMaster 1998, Ryder et al. 2006).

Marine Mammals

Of the marine mammals that are hooked by U.S. pelagic longline fishermen, many are released alive, although some animals suffer serious injuries and may die after being released. The observed and estimated marine mammal interactions for 1992 – 2005 are summarized in Table 5.3.9-17 and Table 5.3.9-18. Marine mammals are caught primarily during the third and fourth quarters in the Mid-Atlantic Bight (MAB) and Northeast Coastal (NEC) areas (Table 5.3.9-18). In 2005, the majority of observed interactions were with pilot whales in the MAB area (Walsh and Garrison, 2006).

In 2000, there were 14 observed takes of marine mammals by pelagic longlines. This number has been extrapolated based on reported fishing effort to an estimated 403 mammals fleet-wide (32 common dolphin, 93 Risso's dolphin, 231 pilot whales, 19 whales, 29 pygmy sperm whales) (Yeung 2001). In 2001 and 2002, there were 16 and 24 observed takes of marine mammals, respectively. The majority of these interactions were observed in the MAB, followed by the Northeast Distant (NED) research experiment. In 2001, there were an estimated total of 84 Risso's dolphin and 93 pilot whale interactions in the pelagic longline fishery. In 2002, there were an estimated 87 Risso's dolphin and 114 pilot whale interactions in the pelagic longline fishery. In the NED research experiment, an additional four Risso's dolphin and one northern bottlenose whale were recorded with serious injuries during 2001, as well as three Risso's dolphin, one unidentified dolphin, and one unidentified marine mammal in 2002. One striped dolphin was recorded as released alive during the NED experiment in 2001, as well as one Risso's dolphin, one common dolphin, one pilot whale, and one unidentified dolphin in 2002 (Garrison, 2003).

In 2003, there were 28 observed takes of marine mammals in the pelagic longline fishery. The majority of these interactions were observed in the MAB, followed by the NED experimental fishery, and the NEC area. This number has been extrapolated based on reported fishing effort to an estimated 300 mammals fleet wide (49 beaked whales, 16 dolphin, 30 Atlantic spotted dolphin, 46 common dolphin, 105 Risso's dolphin, 32 pilot whales, 22 minke whales). In addition, five Risso's dolphin, one striped dolphin, and one baleen whale were observed captured in the 2003 NED research experiment, with one Risso's dolphin recorded as dead (Garrison and Richards 2004).

There were a total of 12 observed interactions with marine mammals in the pelagic longline fishery in 2004. The majority of these interactions was with pilot whales and was observed in the MAB area. During 2004, the pelagic longline fishery was estimated to have interacted with 108 pilot whales, 49 Risso's dolphins, and seven common dolphins (Garrison, 2005). In 2005, there were a total of 24 observed interactions with marine mammals in the pelagic longline fishery. The majority of these interactions was with pilot whales and was observed in the MAB area. During 2005, the pelagic longline fishery was estimated to have interacted with 294 pilot whales, 42 Risso's dolphin, six common dolphin, five bottlenose dolphin, four Atlantic spotted dolphin, one beaked whale, 13 unidentified marine mammals, three unidentified whales, and three unidentified dolphin (Walsh and Garrison, 2006). NMFS monitors observed interactions with sea turtles and marine mammals on a quarterly basis and reviews data for appropriate action, if any, as necessary. In June 2005, NMFS convened the Pelagic Longline Take Reduction Team (PLTRT) to assess and reduce marine mammal takes, specifically pilot whales and Risso's dolphins, by the pelagic longline fishery. At the time of writing, the Pelagic Longline Take Reduction Plan (PLTRP) was expected to be finalized soon.

Sea Turtles

Currently, many sea turtles are taken in the GOM and NEC areas (Table 5.3.9-16) and most are released alive. In the past, the bycatch rate was highest in the third and fourth quarters.

Loggerhead and leatherback turtles dominate the catch of sea turtles. In general, sea turtle captures are rare, but takes appear to be clustered (Hoey and Moore 1999).

The estimated take levels for 2000 were 1,256 loggerhead and 769 leatherback sea turtles (Yeung, 2001). The estimated sea turtle takes for regular fishing and experimental fishing effort for 2001 - 2005 are summarized in Table 5.3.9-19. The majority of leatherback interactions have occurred in the Gulf of Mexico. Loggerhead interactions are more widely distributed, however, the NEC, FEC, and Gulf of Mexico appear to be areas with high interaction levels each year.

In 2005, the pelagic longline fishery interacted with an estimated 351 leatherback sea turtles and 275 loggerhead sea turtles outside of experimental fishing operations. During 2005, the interactions with leatherback sea turtles were highest in the Gulf of Mexico (179 animals). The majority of loggerhead sea turtle interactions occurred in the NEC, MAB, CAR, SAR, and SAB areas (Walsh and Garrison, 2006). NMFS monitors observed interactions with sea turtles and marine mammals on a quarterly basis and reviews data for appropriate action, if any, as necessary.

As a result of the increased sea turtle interactions in 2001 and 2002, NMFS reinitiated consultation for the pelagic longline fishery and completed a new BiOp on June 1, 2004. The June 2004 BiOp concluded that long-term continued operation of the Atlantic pelagic longline fishery is not likely to jeopardize the continued existence of loggerhead, green, hawksbill, Kemp's ridley, or olive ridley sea turtles, but is likely to jeopardize the continued existence of leatherback sea turtles. The BiOp included a reasonable and prudent alternative (RPA) and an incidental take statement (ITS) for the combined years 2004 – 2006, and for each subsequent three-year period (NMFS, 2004b).

A final rule published in July 2004 (69 FR 40734) prohibited the possession of "J"-style hooks in the pelagic longline fishery and required the possession and use of specific sea turtle release and disentanglement gears, handling and release protocols, as well as requiring the use of specific circle hooks and baits.

NED Research Experiment
Consistent with the conservation recommendation of an earlier, 2001 BiOp, NMFS initiated a research experiment in the Northeast Distant (NED) area in consultation and cooperation with the domestic pelagic longline fleet. The goal was to develop and evaluate the efficacy of new technologies and changes in fishing practices to reduce sea turtle interactions. In 2001, the experiment attempted to evaluate the effect of gangions placed two gangion lengths from floatlines, the effect of blue-dyed bait on target catch and sea turtle interactions, and the effectiveness of dipnets, line clippers, and dehooking devices. Eight vessels participated, making 186 sets, between August and November.

During the course of the research experiment, 142 loggerhead and 77 leatherback sea turtles were incidentally captured and no turtles were released dead. The data gathered during the 2001 experiment were analyzed to determine if the tested measures reduced the incidental capture of sea turtles by a statistically significant amount. The blue-dyed bait parameter decreased the catch of loggerheads by 9.5 percent and increased the catch of leatherbacks by 45 percent. Neither value is statistically significant. In examining the gangion placement provision, the treatment sections of the gear (with gangions placed 20 fathoms from floatlines) did not result in a statistically significant reduction in the number of loggerhead and leatherback sea turtle interactions than the control sections of the gear (with a gangion located under a floatline). The treatment section of the gear recorded an insignificant increase in the number of leatherback interactions. Following an examination of the data, NMFS discovered that the measures had no significant effect upon the catch of sea turtles (Watson et al., 2003).

Dipnets and line clippers were examined for general effectiveness. The dipnets were found to be adequate in boating loggerhead sea turtles. Several line clippers were tested, with the La Force line clipper having the best performance. Several types of dehooking devices were tested, with the work on these devices continuing in the 2002 and 2003 NED research experiment.

In the summer and fall of 2002, NMFS conducted the second year of the research experiment. The use of circle and "J"-hooks, whole mackerel bait, squid bait, and shortened daylight soak time were tested to examine their effectiveness in reducing the capture of sea turtles. The data indicate there were 501 sets made by 13 vessels with 100 percent observer coverage. During the course of the experiment, 100 loggerhead and 158 leatherback sea turtles were captured and 11 were tagged with satellite tags. In addition to the sea turtles, the vessels interacted with one unidentified marine mammal, one unidentified dolphin, one common dolphin, one longfin pilot whale, and four Risso's dolphins; all were released alive (Watson et al. 2003).

In 2003, the research experiment tested a number of treatments to verify the results of the 2002 experiment in addition to testing additional treatments. Data indicate that there were 539 sets made by 11 vessels with 100 percent observer coverage. During the course of the experiment, one olive ridley, 92 loggerhead, and 79 leatherback sea turtles were captured; all were released alive (Foster et al., 2004; Watson et al., 2004). In addition to the sea turtles, the vessels interacted with one striped dolphin, one baleen whale, and five Risso's dolphin resulting in one mortality (Garrison and Richards, 2004).

From 2001 through 2003, NMFS worked with the commercial fishing industry to develop new pelagic longline fishing technology to reduce interaction rates and bycatch mortality of threatened and endangered sea turtles. The cooperative gear technology research investigated line configurations, setting and retrieving procedures, hook types, hook sizes, bait types, and release and disentanglement gears. Ultimately, specific hook designs and bait types were found to be the most effective measures for reducing sea turtle interactions. Large circle hooks and mackerel baits were found to substantially reduce sea turtle interactions over the use of the industry standard "J"-hooks and squid baits. The gears developed to remove hooks and line from hooked and entangled sea turtles are anticipated to reduce post-hooking mortality associated with those interactions not avoided. Since the conclusion of the NED research experiment, NMFS has continued to investigate pelagic longline bycatch mitigation techniques in the Gulf of Mexico, Atlantic Ocean and the Caribbean Sea.

Additionally, NMFS held a series of voluntary workshops for U.S. pelagic longline fishermen providing outreach and training in sea turtle handling and release techniques. NMFS believes that the transfer of this information to other fishing countries will result in significant reductions in interaction rates and post-release mortalities of threatened and endangered sea turtles throughout their ranges.

Seabirds

Gannets, gulls, greater shearwaters, and storm petrels are occasionally hooked by Atlantic pelagic longlines. These species and all other seabirds are protected under the Migratory Bird Treaty Act. Seabird populations are often slow to recover from excess mortality as a consequence of their low reproductive potential (one egg per year and late sexual maturation). The majority of longline interactions with seabirds occur as the gear is being set. The birds eat the bait and become hooked on the line. The line then sinks and the birds are subsequently drowned.

The United States has developed a National Plan of Action in response to the Food and Agriculture Organization of the United Nations (FAO) International Plan of Action to reduce the incidental takes of seabirds (www.nmfs.gov.gov/NPOA-S.html). Although Atlantic pelagic longline interactions will be considered in the plan, NMFS has not identified a need to implement gear modifications to reduce seabird takes by Atlantic pelagic longlines. Takes of seabirds have been minimal in the fishery, most likely due to the setting of longlines at night and/or fishing in areas where birds are largely absent. Observer data from 1992 through 2005 indicate that seabird bycatch is relatively low in the U.S. Atlantic pelagic longline fishery (Table 5.3.9-17). Since 1992, a total of 129 seabird interactions have been observed, with 95 observed killed (73.6 percent). In 2005, a total of four seabirds were observed taken.

Observed bycatch has ranged from one to 18 seabirds observed dead per year and zero to 15 seabirds observed released alive per year from 1992 through 2003. Half of the seabirds observed were not identified to species (n = 59). Of the seabirds identified, gulls represent the largest group (n = 35), followed by greater shearwaters (n = 23), and northern gannets (n = 8) (Table 5.3.9-21). Greater shearwaters experienced the highest mortality (96.2 percent), followed by gulls (80 percent), and unidentified seabirds (67.8 percent). Northern gannets had the lowest mortality rate (12.5 percent).

Preliminary estimates of expanded seabird bycatch and bycatch rates from 1995 – 2004, varied by year and species with no apparent pattern. The estimated number of all seabirds caught and discarded dead ranged from zero to 468 per year, while live discards ranged from zero to 292 per year. The annual bycatch rate of birds discarded dead ranged from zero to 0.0486 birds per 1,000 hooks, while live discards ranged from zero to 0.0303 birds per 1,000 hooks.

Finfish

In the U.S. pelagic longline fishery, fish are discarded for a variety reasons. Swordfish, yellowfin tuna, and bigeye tuna may be discarded because they are undersized or unmarketable (e.g., shark bitten). Blue sharks, as well as other species, are discarded because of a limited markets (resulting in low prices) and perishability of the product. Large coastal sharks are discarded during times when the shark season is closed. Bluefin tuna may be discarded because target catch requirements for other species have not been met. Also, all billfish are required to be released. In the past, swordfish have been discarded when the swordfish season was closed.

Reported catch from 1999 – 2004 for the U.S. pelagic longline fishery (including reported bycatch, incidental catch, and target catch) is summarized in Table 5.3.9-2**.** Additional U.S. landings and discard data are available in the 2005 U.S. National Report to ICCAT (NMFS, 2005).

At this time, direct use of observer data with pooling for estimating dead discards in this fishery represents the best scientific information available for use in stock assessments. Direct use of observer data has been employed for a number of years to estimate dead discards in Atlantic and Pacific longline fisheries, including billfish, sharks, and undersized swordfish. Furthermore, the data have been used for scientific analyses by both ICCAT and the Inter- American Tropical Tuna Commission (IATTC) for a number of years.

Bycatch mortality of marlins, swordfish, and bluefin tuna from all fishing nations may significantly reduce the ability of these populations to rebuild, and it remains an important management issue. In order to minimize bycatch and bycatch mortality in the domestic pelagic longline fishery, NMFS implemented regulations to close areas to this gear type (Figure 5.3.9-4) and has banned the use of live bait by pelagic longline vessels in the Gulf of Mexico.

As part of the bluefin tuna rebuilding program, ICCAT recommends an allowance for dead discards. The U.S. annual dead discard allowance is approximately 68 mt ww. The estimate for the 2004 calendar year was used as a proxy to calculate the amount to be added to, or subtracted from, the U.S. bluefin tuna landings quota for 2005. The 2004 calendar year preliminary estimate of U.S. dead discards, as reported per the longline discards calculated from logbook tallies, adjusted as warranted when observer counts in quarterly/geographic stratum exceeded logbook reports, totaled 72 mt ww. Estimates of dead discards from other gear types and fishing sectors that do not use the pelagic longline vessel logbook are unavailable at this time, and thus, are not included in this calculation. As U.S. fishing activity is estimated to have exceeded the approximate 68 mt ww dead discard allowance by approximately 4.0 mt, the ICCAT recommendation and U.S. regulations state that the United States must account for this excess. Therefore, NMFS shall subtract the amount in excess (approximately 4.0 mt) from the amount of bluefin tuna that can be landed in the subsequent fishing year by those categories accounting for the dead discards.

The 2005 calendar year preliminary dead discard estimate is not yet available. The 2004 calendar year preliminary dead discard estimate, as reported in pelagic longline vessel logbooks and published in 2005 Final Initial Quota Specifications (70 FR 33033, June 7, 2005), totaled 71.8 mt ww. This preliminary estimate has been revised using the longline discards calculated from logbook tallies, adjusted as warranted when observer counts in stratum exceeded logbook reports. The revised 2004 calendar year dead discard estimate is 72.0 mt ww.

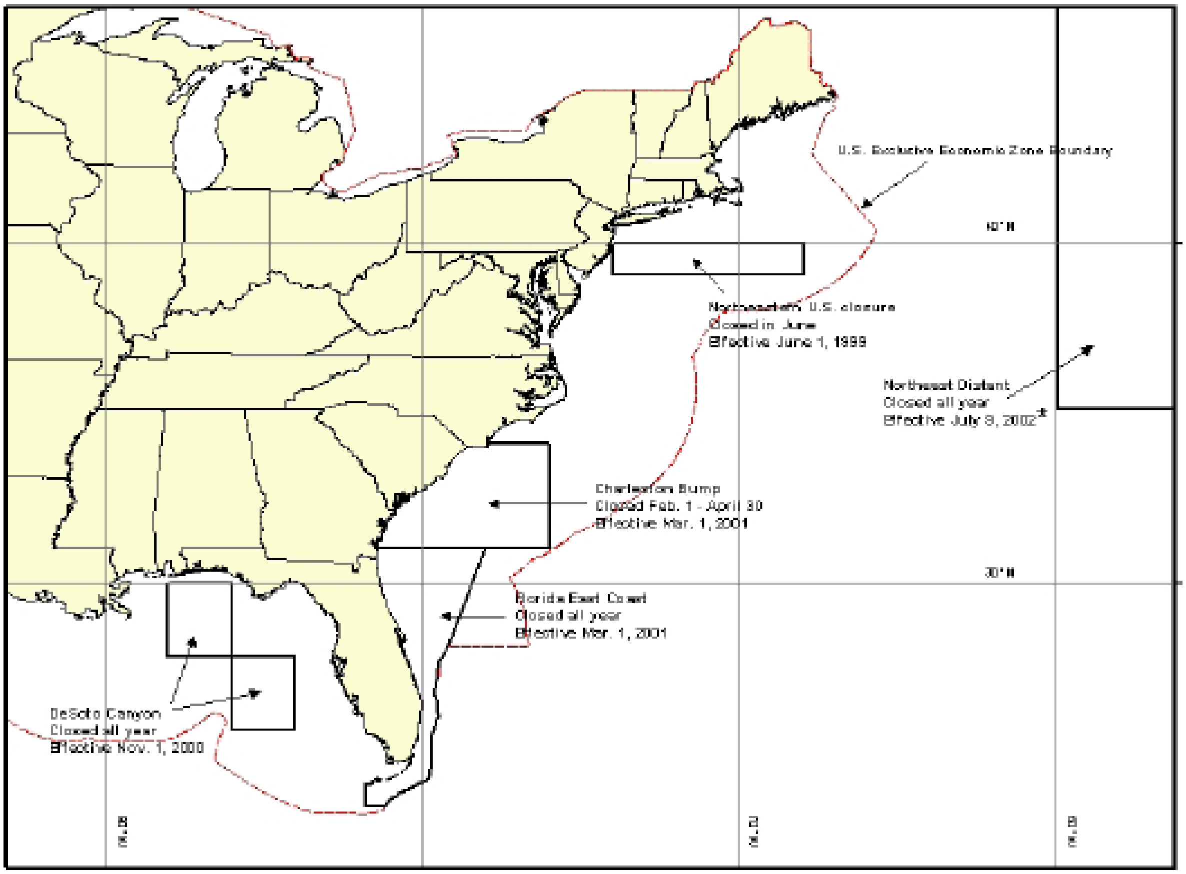

Figure 5.3.9-4. Areas Closed to Pelagic Longline Fishing by U.S. Flagged Vessels

Purse Seine Fishery

NMFS has limited observer data on the bluefin tuna purse seine fishery. There are no recorded instances of non-tuna finfish, other than minimal numbers of blue sharks, caught in tuna purse seines. Anecdotal evidence indicates that if fish are discarded, they are easily released out of the net with minimal bycatch mortality.

Commercial Handgear Fishery

Vessels targeting bluefin tuna with harpoon gear have not been selected for observer coverage since the deliberate fishing nature of the gear is such that bycatch is expected to be low. Therefore, there are no recorded instances of non-target finfish caught with harpoons and NMFS cannot quantify the bycatch of undersized bluefin tuna in this fishery. Bycatch in the swordfish harpoon fishery is virtually if not totally, non-existent. Since bycatch approaches zero in this fishery, it follows that bycatch mortality is near zero. Disposition of bycatch reported in logbooks is used to estimate mortality of bycatch in the hook and line handgear fisheries.

Bottom longline fishery

Under the Marine Mammal Protection Act (MMPA) (16 U.S.C. 1361 et seq.) the Atlantic shark gillnet fishery is classified as Category II (occasional serious injuries and mortalities), and the shark bottom longline as Category III (remote likelihood or no known serious injuries or mortalities) (July 20, 2004, 69 FR 43338). On October 29, 2003, NMFS issued a biological opinion (BiOp) pursuant to the Endangered Species Act (ESA) regarding Atlantic shark fisheries. This BiOp concluded that the level of anticipated take in the Atlantic shark fishery resulting from measures implemented in Amendment 1 to the 1999 FMP (68 FR 74746), were not likely to jeopardize the continued existence of endangered green, leatherback, and Kemp's ridley sea turtles, the endangered smalltooth sawfish, or the threatened loggerhead sea turtle. Furthermore, it concluded that the actions in the rule were not likely to adversely affect marine mammals. As a result of this conclusion, NMFS (NMFS 2003) anticipates that the continued operation of the shark bottom longline fishery will result in a five year total incidental take of the following numbers of sea turtles: Leatherback – 172; loggerhead – 1,370; a total of 30 in any combination of hawksbill, green, and Kemp's ridley sea turtles. NMFS also anticipates a five year take of 261 smalltooth sawfish, of which no lethal takes are expected. If the actual calculated incidental captures or mortalities exceed the incidental take statement, a formal consultation for that gear type must be re-initiated immediately. More information is available in Amendment 1 to the 1999 FMP and the October 2003 BiOp and is not repeated here.

Loggerhead Sea Turtles

In the bottom longline fishery, a total of 65 sea turtles were observed caught from 1994 through 2006 (Table 5.3.9-25, 5.3.9-26). Seasonal variation indicates that most of the sea turtles were caught early in the year. Of the 65 observed sea turtles, 50 were loggerhead sea turtles, of which 26 were released alive. Another nine loggerheads were released in an unknown condition and eight were released dead. Based on extrapolation of observer data in Amendment 1 to the 1999 FMP, it was estimated that a total of 2,003 loggerhead sea turtles were taken in the shark bottom longline fishery from 1994 through 2002 (NMFS, 2003a). An additional 503 unidentified sea turtles were estimated to have been taken. On average, 222 loggerhead sea turtles and 56 unidentified sea turtles were estimated to have been taken annually during this time period in the shark bottom longline fishery.

Leatherback Sea Turtles

Of the 65 observed sea turtle interactions in the bottom longline fishery from 1994 – 2006, six were leatherback sea turtles of which one was dead and three were released with their condition unknown. Based on extrapolation of observer data done for Amendment 1 to the FMP, it was estimated that 269 leatherback sea turtles were taken in the shark bottom longline fishery from 1994 through 2002 (NMFS, 2003a). On average, 30 leatherback sea turtle interactions occurred each year in the shark bottom longline fishery during this period. This analysis only estimates takes without discriminating between live and dead releases. Of the observed leatherback takes, approximately 25 percent were lethal.

Applying the observed mortality rate of 25 percent to the total leatherback takes and an additional 42 percent post-release mortality estimate due to hook ingestion to the remaining, results in an estimated total number of leatherbacks killed as a result of the interaction with bottom longline gear at 17 per year. The leatherback mortality is very conservative because it is known that leatherbacks rarely ingest or bite hooks, but are usually foul hooked on their flippers or carapaces, reducing the likelihood of post-hooking release mortality. However, leatherback-specific data for this fishery is not available and therefore the most conservative estimate is used.

Smalltooth Sawfish
As of April 1, 2003, NMFS listed smalltooth sawfish as an endangered species (68 FR 15674) under the ESA. After reviewing the best scientific and commercial information, the status review team determined that the continued existence of the U.S. Distinct Population Segment of smalltooth sawfish was in danger of extinction throughout all or a significant portion of its range from a combination of the following four listing factors: the present or threatened destruction, modification, or curtailment of habitat or range; overutilization for commercial, recreational, scientific, or educational purposes; inadequacy of existing regulatory mechanisms; and other natural or manmade factors affecting its continued existence. NMFS is working on designating critical habitat for smalltooth sawfish.

Sawfish have been observed caught (12 known interactions, 11 released alive, one released in unknown condition) in shark bottom longline fisheries from 1994 through 2006 (Morgan pers. comm., Burgess and Morgan, 2004; Carlson). Based on these observations, expanded sawfish take estimates for 1994 – 2002 were developed for the shark bottom longline fishery (NMFS, 2003a). A total of 466 sawfish were estimated to have been taken in this fishery from 1994 – 2002, resulting in an average of 52 per year. All but one of the observed sawfish was released alive.

Marine Mammals
Four delphinids have been observed caught and released alive between 1994 and 2004 (G. Burgess, pers. comm.). Bycatch estimates for the shark bottom longline fishery have not been extrapolated for marine mammals.

Seabirds
Bycatch of seabirds in the shark bottom longline fishery has been virtually non-existent. A single pelican has been observed killed from 1994 through 2005. The pelican was caught in January 1995 off the Florida Gulf Coast (between 25° 18.68 N, 81° 35.47 W and 25° 19.11 N, 81° 23.83 W) (G. Burgess, University of Florida, pers. comm., 2001). No expanded estimates of seabird bycatch or catch rates are available for the bottom longline fishery.

Gillnet fishery

On September 23, 2002, NMFS implemented a restricted area to reduce bycatch of right whales from November 15 through March 31 (67 FR 59471). In this area, only gillnets used in a strikenet fashion can operate during times when right whales are present.

Operation in this area at that time requires 100 percent observer coverage. Vessels fishing in a strikenet fashion used nets 364.8 meters long, 30.4 meters deep, and with mesh size 22.9 cm. Observed catch in the strikenet fishery consisted of 6 species of sharks (96.7 percent of total number caught) and seven species of teleosts and rays (3.3 percent of total number caught). No marine mammals or sea turtles were observed caught. The blacktip shark made up 97.5 percent of the number of sharks caught, and 86 percent of the overall catch. Bycatch included crevalle jack, red drum, and great barracuda (Table 5.3.9-27).

There were 23 species of teleosts, two species of rays, and one species of marine mammal observed caught during the driftnet season (Table 5.3.9-29). Four species of teleosts and rays made up 90.8 percent by number of the overall non-shark species in observed strikenet catches. These species were little tunny (45.6 percent); king mackerel (23.3 percent); great barracuda (11.8 percent); and red drum (10.2 percent). For incidental driftnet catch species, the highest proportion discarded dead (with observed catch greater than 10 specimens) was Atlantic sailfish, (100.0 percent), king mackerel (78.3 percent), and cobia (28.7 percent). Red drum had the highest discard proportion alive (98.1 percent) (Carlson and Baremore, 2003). Observed driftnet sets caught 23 species of teleosts and rays and no sea turtles or marine mammals. Only the great barracuda were retained, with all remaining bycatch discarded alive (Carlson, 2002).

Outside of right whale calving season, observed drift gillnet catch consisted of 26 species of teleosts and rays and one species of marine mammal, which was discarded dead. Five species of teleosts and one species of ray made up 90.6 percent by number of the overall non-shark catch. Little tunny (44.1 percent), king mackerel (20.8 percent), great barracuda (12.5 percent), Atlantic moonfish (9.4 percent), and cobia (3.8 percent) dominated the bycatch (Carlson and Baremore, 2002). During drift gillnet fishing, the highest proportion of species discarded dead (for species with greater than 10 individuals) was for tarpon, crevalle jack, king mackerel, and red drum. Cownose rays and red drum had the highest proportion of discarded alive with 78.1 percent and 50.0 percent, respectively (Carlson and Baremore, 2002).

On January 22, 2006, a dead right whale was spotted offshore of Jacksonville Beach, Florida. The survey team identified the whale as a right whale calf, and photos indicated the calf as having one large wound along the midline and smaller lesions around the base of its tail. The right whale calf was located at 30°14.4’ N. Lat., 81° 4.2’’ W. Long., which was approximately 1nautical mile outside of the designated right whale critical habitat, but within the Southeast U.S. Restricted Area. NMFS determined that both the entanglement and death of the whale occurred within the Southeast U.S. Restricted Area, and all available evidence suggested the entanglement and injury of the whale by gillnet gear ultimately led to the death of the animal.

On February 16, 2006, NMFS published a temporary rule (71 FR 8223) to prohibit, through March 31, 2006, any vessel from fishing with any gillnet gear in the Atlantic Ocean waters between 32°00’ N. Lat. (near Savannah, GA) and 27°51’ N. Lat. (near Sebastian Inlet, FL) and extending from the shore eastward out to 80°00’ W. long under the authority of the Atlantic Large Whale Take Reduction Plan (ALWTRP) (50 CFR 229.32 (g)) and the Endangered Species Act. NMFS took this action based on its determination that a right whale mortality was the result of an entanglement by gillnet gear within the Southeast U.S. Restricted Area.

The regulations at 50 CFR 229.32(g)(1) also require NMFS to close the Southeast U.S. Restricted Area for the rest of the time period, and for the time period November 15 through March 31 in each subsequent year, unless NMFS revises the restricted period or unless other measures are implemented. NMFS plans to seek assistance and recommendations from the ALWTRT at their next meeting in order to evaluate whether permanent closures within the Southeast U.S. Restricted Area are necessary.

Loggerhead Sea Turtles
Loggerhead sea turtles are rarely caught in the shark gillnet fishery. During the 1999 right whale calving season, no loggerhead sea turtles were observed caught in this fishery (Carlson and Lee 1999), and no loggerheads were observed caught with strikenets during the 2000 – 2002 right whale calving seasons (Carlson 2000; Carlson and Baremore 2001; Carlson and Baremore 2002a). However, three loggerhead sea turtles were observed caught with drift gillnets during right whale calving season, one each year from 2000 to 2002 (Carlson 2000; Carlson and Baremore 2001; Carlson and Baremore 2002a; Garrison 2003). In 2004 there were no observed sea turtle interactions in either the strikenet or drift gillnet fisheries.

No loggerhead sea turtles were caught outside of the right whale calving season in 2002 (Carlson and Baremore 2002b), and no loggerhead turtles were observed caught during or after the right whale calving season in 2003 or 2004 in the directed shark gillnet fishery (Carlson and Baremore 2003; Carlson pers. comm). In 2005 five loggerheads were observed caught, and in 2006 three loggerheads were observed caught (Table 5.3.9-30). All but two were released alive. One loggerhead sea turtle mortality was reported in abandoned fishing gear in January 2004, and was not considered part of normal fishing operations.

Leatherback Sea Turtles
In the shark gillnet fishery, leatherback sea turtles are sporadically caught. During the 1999 right whale calving season, two leatherback sea turtles were caught in this fishery, and both were released alive (Carlson and Lee 1999). No leatherback sea turtles were observed caught with strikenets during the 2000 – 2002 right whale calving seasons (Carlson 2000; Carlson and Baremore 2001; Carlson and Baremore 2002a). Leatherback sea turtles have been observed caught in shark drift gillnets including 14 in 2001 and two in 2002 (Carlson 2000; Carlson and Baremore 2001; Carlson and Baremore 2002a; Garrison 2003). NMFS temporarily closed the shark gillnet fishery (strikenetting was allowed) from March 9 to April 9, 2001, due to the increased number of leatherback interactions that year (66 FR 15045, March 15, 2001). From 2003 – 2004, no leatherback sea turtles were observed caught in gillnets fished in strikenet or driftnet methods (Carlson and Baremore 2003; Carlson pers. comm.).

Smalltooth Sawfish

To date there has been only one observed catch of a smalltooth sawfish in shark gillnet fisheries. The sawfish was taken on June 25, 2003, in a gillnet off southeast Florida and was released alive (Carlson and Baremore, 2003). The set was characteristic of a typical drift gillnet set, with gear extending 30 to 40 feet deep in 50 to 60 feet of water. Prior to this event it was speculated that the depth at which drift gillnets are set above the sea floor may preclude smalltooth sawfish from being caught. Although sometimes described as a lethargic demersal species, smalltooth sawfish feed mostly on schooling fish, thus they would occur higher in the water column during feeding activity. In fact, smalltooth sawfish and Atlantic sharks may be attracted to the same schools of fish, potentially making smalltooth sawfish quite vulnerable if present in the area fished. The previous absence of smalltooth sawfish incidental capture records is more likely attributed to the relatively low effort in this fishery and the rarity of smalltooth sawfish, especially in Federal waters. These factors may result in little overlap of the species with the gear. The sawfish was cut from the net and released alive with no visible injuries. This indicates that smalltooth sawfish can be removed safely if entangled gear is sacrificed.

Given the high rate of observer coverage in the shark gillnet fishery, NMFS believes that smalltooth sawfish takes in this fishery are very rare. The fact that there were no smalltooth sawfish caught during 2001 when 100 percent of the fishing effort was observed indicates that smalltooth sawfish takes (observed or total) most likely do not occur on an annual basis. Based on this information, the 2003 BiOp estimated that one incidental capture of a sawfish (released alive) over the next five years, will occur as a result of the use of gillnets in this fishery (NMFS, 2003a).

Marine Mammals

Observed takes of marine mammals in the Southeast Atlantic shark gillnet fishery during 1999 – 2004, totaled 12 bottlenose dolphins and four spotted dolphins. Extrapolated observations from these data suggest serious injury and mortality of 25 bottlenose dolphin and one Atlantic spotted dolphin in the shark gillnet fishery from 1999 through 2002 (Garrison, 2003).

Recreational fishery

Bycatch in the recreational rod and reel fishery is difficult to quantify because many fishermen value the experience of fishing and may not be targeting a particular pelagic species. Recreational "marlin" or "tuna" trips may yield dolphin, tunas, wahoo, and other species, both undersized and legal sized. Bluefin tuna trips may yield undersized bluefin, or a seasonal closure may prevent landing of a bluefin tuna above a minimum or maximum size. In some cases, therefore, rod and reel catch may be discarded. The Magnuson-Stevens Act (16 USC 1802 (2)) stipulates that bycatch does not include fish under recreational catch-and-release.

The 1999 Billfish Amendment established a catch-and-release fishery management program for the recreational Atlantic billfish fishery. As a result of this program, all Atlantic billfish that are released alive, regardless of size, are not considered bycatch. NMFS believes that establishing a catch-and-release fishery in this situation will further solidify the existing catch-and-release ethic of recreational billfish fishermen, and thereby increase release rates of billfish caught in this fishery. Current billfish release rates range from 89 to 99 percent. The recreational white shark fishery is by regulation a catch-and-release fishery only and white sharks are not considered bycatch.

Bycatch can result in death or injury to discarded fish. Therefore, bycatch mortality should be incorporated into fish stock assessments, and into the evaluation of management measures. Rod and reel discard estimates from Virginia to Maine during June – October could be monitored through the expansion of survey data derived from the LPS (dockside and telephone surveys). However, the actual numbers of fish discarded for many species are so low that presenting the data by area could be misleading, particularly if the estimates are expanded for unreported effort in the future.

Discard mortality

Post-release mortality studies have been conducted on few HMS at this time. Immediate mortality in recreational hook and line-caught juvenile bluefin tuna can be high (29.2 percent) due to injuries or predation (Belle, 1997). This is thought to be a conservative estimate because scientific personnel in the study were professionally trained and had extensive experience in fish handling techniques designed to reduce mortality. Mortality often occurs ten minutes or longer after the fish is released under normal circumstances. Injuries may not be readily apparent to the angler and seemingly minor capture injuries may be related to substantial internal injuries. Forty percent of sampled tuna that died during that study did not have injuries that would be apparent to the angler in the boat. Skomal and Chase (1996) provided evidence that the stress of rod and reel angling did not cause immediate post-release mortality in larger bluefin tuna (50 to 150 kg). However, they did document metabolic and pH disturbances in bluefin tuna sampled off Cape Hatteras, NC. The physiological consequences of angling stress are poorly understood for several species of large pelagic fishes (Skomal and Chase, 1996).

A study by Graves et al. (2002), investigated short-term (five days) post-release mortality of Atlantic blue marlin using pop-up satellite tag technology. A total of nine recreationally caught blue marlin were tagged and released during July and August of 1999. All hooks employed in the study were “J” hooks. The attached tags were programmed to detach from the fish after five days and to record direct temperature and inclination of the buoyant tag to determine if the fish were actively swimming after being released. After detachment, the tags floated to the surface and began transmitting recorded position, temperature and inclination data to satellites of the ArgosTM system. Three different lines of evidence provided by the tags (movement, water temperature, and tag inclination) suggested that at least eight of the nine blue marlin survived for five days after being tagged and released. One of the tags did not transmit any data which precluded the derivation of a conclusion regarding the tagged marlin’s survival.

The study was continued in 2003 to evaluate post release survival and habitat use of white marlin using pop-up satellite archival tags (PSATs) caught and released from four locations in the western North Atlantic recreational fishery (Horodysky and Graves 2005). Forty-one tags were attached to white marlin caught using dead baits rigged on straight shank (“J”) hooks (n = 21) or circle hooks (n = 20) offshore of the U.S. Mid-Atlantic, the Dominican Republic, Mexico, and Venezuela. Survival was significantly higher ($p<0.01$) for white marlin caught on circle hooks (100 percent) relative to those caught on straight-shank (“J”) hooks (65 percent). These results, along with previous studies on circle hook performance, suggest that a change in hook type can significantly increase the survival of white marlin released from recreational fishing gear. Data from these short term deployments also suggest that white marlin strongly associate with warm, near surface waters. However, based on the frequency, persistence, and patterns of vertical movements, white marlin appear to direct a considerable proportion of foraging effort well below surface waters, a behavior that may account for relatively high catch rates of white marlin on some pelagic longline sets. NMFS continues to support studies on recreational post-release mortality and intends to account for this source of mortality when additional information becomes available.

Outreach programs to address bycatch were included in the 1999 FMP and the Billfish Amendment. These programs have not yet been implemented, but the preparation of program designs is currently in progress. One of the key elements in the outreach program will be to provide information that leads to an improvement in post-release survival from both commercial and recreational gear. Additionally, an outreach program to encourage the use of circle hooks to increase post-release survival within HMS fisheries was introduced in a proposed rule published in 2001 (66 FR 66386, December 26, 2001). The final rule to promote the voluntary use of circle hooks published in 2003 (68 FR 711, January 7, 2003). Initial implementation of the outreach program began in 2004 with workshops conducted on the proper handling and release of sea turtles.

5.4 Spatial Presentation of Commercial Landings for South Atlantic Species 1990-2006 (ACCSP)

Maps of catch by area for the following species presented in Appendix B.

Common Name	**Species Name**
Almaco Jack	Seriola rivoliana
Atlantic Spadefish	Chaetodipterus faber
Banded Rudderfish	Seriola zonata
Bank Sea Bass	Centropristis ocyurus
Bar Jack	Caranx ruber
Bigeye Tuna	Thunnus obesus
Blackfin Snappper	Lutjanus buccanella
Black Grouper	Mycteroperca bonaci
Black Margate	Anisotremus surinamensis
Black Sea Bass	Centropristis striata
Black Snapper	Apsilus dentatus
Bluefin Tuna	Thunnus thynnus
Bluefish	Pomatomus saltatrix
Blueline Tilefish	Caulolatilus microps
Bluetripe Grunt	Haemulon sciurus
Blue Runner	Caranx crysos
Blue Marlin	Makaira nigricans
Blue Stripe Grunt	Haemulon sciurus
Brown Shrimp	Farfantepenaeus aztecus
Cero	Scomberomorus regalis
Cobia	Rachycentron canadum
Coney	Epinephelus fulvus
Cottonwick	Haemulon melanurum
Crevale Jack	Caranx hippos
Croaker	Micropogonias undulatus
Cubera Snapper	Lutjanus cyanopterus
Dog Snapper	Lutjanus jocu
Common Dolphin	Coryphaena hippurus
Pompano Dolphin	
French Grunt	Haemulon flavolineatum
Gag Grouper	Mycteroperca microlepis
Golden Crab	Chaceon fenneri
Golden Tilefish	Lopholatilus chamaeleonticeps
Goliath Grouper	Epinephelus itajara
Grass Porgy	Calamus arctifrons
Graysby	Epinephelus cruentatus
Gray Snapper	Lutjanus griseus

Gray Triggerfish	Balistes capriscus
Greater Amberjack	Seriola dumerili
Hogfish	Lachnolaimus maximus
Jolthead Porgy	Calamus bajonado
King Mackerel	Scomberomorus cavalla
Knobbed Porgy	Calamus nodosus
Lane Snapper	Lutjanus synagris
Lesser Amberjack	Seriola fasciata
Little Tunny	Euthynnus alletteratus
Longspine Porgy	Stenotomus caprinus
Mahogany Snapper	Lutjanus mahogoni
Margate	Haemulon album
Menhaden	Brevoortia tyrannus
Misty Grouper	Epinephelus mystacinus
Mutton Snapper	Lutjanus analis
Nassau Grouper	Epinephelus striatus
Ocean Triggerfish	Canthidermis sufflamen
Pink Shrimp	Farfantepenaeus duorarum
Porkfish	Anisotremus virginicus
Puddingwife	Halichoeres radiatus
Queen Snapper	Etelis oculatus
Queen Triggerfish	Balistes vetula
Red Drum	Sciaenops ocellatus
Red Grouper	Epinephelus morio
Red Hind	Epinephelus guttatus
Red Porgy	Pagrus pagrus
Red Snapper	Lutjanus campechanus
Rock Hind	Epinephelus adscensionis
Rock Sea Bass	Centropristis philadelphica
Rock Shrimp	Sicyonia brevirostris
Royal Red Shrimp	Pleoticus robustus
Sailfish	Istiophorus platypterus
Sailors choice	Haemulon parrai
Sand Tilefish	Malacanthus plumieri
Saucereye Porgy	Calamus calamus
Scamp	Mycteroperca phenax
Schoolmaster	Lutjanus apodus
Scup	Stenotomus chrysops
Sharks (Several species)	
Sheepshead	Archosargus probatocephalus
Silk Snapper	Lutjanus vivanus
Smallmouth Grunt	Haemulon chrysargyreum
Snowy Grouper	Epinephelus niveatus
Spadefish	Chaetodipterus faber
Spanish Grunt	Haemulon macrostomum
Spanish Mackerel	Scomberomorus maculatus

Speckled Hind	Epinephelus drummondhayi
Spiny Lobster	Panulirus argus
Spot	Leiostomus xanthurus
Swordfish	Xiphias gladius
Tiger Grouper	Mycteroperca tigris
Tomtate	Haemulon aurolineatum
Vermilion Snapper	Rhomboplites aurorubens
Wahoo	Acanthocybium solanderi
Warsaw Grouper	Epinephelus nigritus
Weakfish	Cynoscion regalis
Whiteboned Porgy	Calamus leucosteus
White Grunt	Haemulon plumieri
White Shrimp	Litopenaeus setiferus
White Marlin	Tetrapturus albidus
Wreckfish	Polyprion americanus
Yellow Jack	Caranx bartholomaei
Yellowfin Tuna	Thunnus albacares
Yellowedge Grouper	Epinephelus flavolimbatus
Yellowfin Grouper	Mycteroperca venenosa
Yellowmouth Grouper	Mycteroperca interstilitialis
Yellowtail Snapper	Ocyrus chrysurus

Name of Action

Amendment 4 to the Spiny Lobster Fishery Management Plan of Puerto Rico and the U.S. Virgin Islands and Amendment 8 to the Spiny Lobster Fishery Management Plan of the Gulf of Mexico and South Atlantic.

Type of Action

(X) Administrative	( ) Legislative
() Draft	(X) Final

Abstract

The United States is a major importer of spiny lobster, importing over 88,000 tons (over 194 million lbs) over the past 10 years, worth an estimated $2.27 billion dollars. The United States imports over 90% of the spiny lobster harvested in South and Central America and the Caribbean countries. The major exporters to the United States are the Bahamas, Brazil, Honduras and Nicaragua. All of these exporting countries have some form of minimum size requirement, but they are not standardized and enforcement is severely lacking. Therefore, NOAA Fisheries Service in coordination with the Caribbean, South Atlantic, and Gulf of Mexico Fishery Management Councils is considering minimum conservation standards on imports to curtail the flow of undersized lobster harvested in foreign countries. Eliminating the primary market for undersized lobster is expected reduce the harvest of undersized animals and increase the spawning stock biomass and long-term potential yield within the pan-Caribbean spiny lobster fishery.

FISHERY IMPACT STATEMENT

This integrated document contains all elements of the Plan Amendment, Final Environmental Impact Statement (FEIS), Initial Regulatory Flexibility Analysis (IRFA), Regulatory Impact Review (RIR), and Social Impact Assessment (SIA)/Fishery Impact Statement (FIS).

Actions within this Amendment/EIS will improve the status of the spiny lobster stock pan-Caribbean by providing an incentive for foreign nations to implement conservation standards designed to protect the spawning stock and therefore the reproductive ability of the spiny lobster population. Additionally, further protections will be provided to undersized lobsters, and berried (egg-bearing) females.

The combined economic benefits of this Amendment would be larger minimum-sized imported lobsters with greater market value and enhanced long-run domestic and foreign revenues, profits and incomes that derive from a biologically and economically improved resource. Further, economic benefits of this Amendment would be improved domestic and foreign revenues, profits and incomes that derive from a biologically and economically improved resource.

This Amendment is expected to adversely affect cultural traditions and social networks of organized groups and communities that engage in the illegal importation of Caribbean spiny lobster. Furthermore, the same combination of actions is expected to beneficially affect cultural traditions and social networks of groups and communities that engage in the legal importation of Caribbean spiny lobsters.

1.0 EXECUTIVE SUMMARY

Fisheries for spiny lobster (*Panulirus argus*) exist throughout its range in the Caribbean and tropical western Atlantic. Foreign and U.S. scientists and fisheries managers all concur the Caribbean spiny lobster is fully exploited or over-exploited in much of its range (Cochrane and Chakalall 2001). Spiny lobsters are being harvested below the respective Continental and Caribbean U.S. minimum size limits; this is adversely impacting recruitment throughout Florida and the Caribbean because of the distribution and dispersal of larvae during their long larval phase. A reduction of effort on undersized lobster and a more comprehensive enforcement tool would increase spawning stock biomass and increase potential yield. The lobster seafood industry has even recognized this fact and has asked respective governments to address the illegal harvest and exportation of undersized lobster tails to the United States.

This Amendment/EIS will examine two actions with various alternatives to restrict imports of spiny lobster into the United States to minimum conservation standards to achieve an increase in the spawning biomass of the spiny lobster stock and increase long-term yields from the fishery. Limiting Caribbean spiny lobster imports to a uniform minimum size that protects juvenile spiny lobsters would help stabilize the reproductive potential of the Caribbean spiny lobster by reducing the amount of juvenile spiny lobster mortality in foreign fisheries. Such action would result in the harvest of larger lobsters in exporting countries and approximately 50 percent of these larger lobsters will be capable of spawning, thus increasing the probability of dispersal of Caribbean spiny lobster larvae throughout the species' range. Scientists state that the harvest of juvenile tails in other Caribbean countries impacts the sustainability of U.S. lobster stocks because these harvesting countries produce the parental stocks and larvae for the U.S. stocks. In other words, if you destroy brood stock off the coast of Latin America, you effectively destroy the fisheries of other countries, regardless of the management schemes in those countries. This animal is an example of a shared resource in that it has no national boundaries because of its dependency on the ocean currents for its larval distribution.

Action 1 is intended to improve the status of the spiny lobster stock pan-Caribbean by providing an incentive for foreign nations to implement conservation standards designed to protect the spawning stock and therefore the reproductive ability of the spiny lobster population. The most effective means for creating this incentive is to improve NOAA law enforcement's (LE) capabilities in preventing undersized lobster from being imported to the United States and eliminating the market for undersized lobster tails. By implementing an import restriction on size, LE will be more capable of tracking undersized lobster shipments and developing criminal cases against suspected importers of undersized lobster, thus eliminating the market for undersize lobster tails.

Action 2 is designed to: 1) provide further protections to undersized lobsters, and 2) protect berried (egg-bearing) females. If any importation conservation standards are to have the desired effect, then the trade in "lobster meat" must be stopped to close the potential loophole of harvesting undersize lobster, processing it into meat, and then making it available in the market. Unshelled lobster tail meat shipped in its bulk raw form cannot be accurately measured and this practice has been performed by unscrupulous lobster exporters / importers to thwart law enforcement's efforts to regulate a minimum size. The protection of berried females (or those that were, prior to being stripped) is imperative if the minimum conservation sizes are implemented in order to protect the spawning stock biomass; if no protections are afforded to the females as they are actively reproducing, then all benefits from increasing the spawning stock biomass have been lost. Both of these actions will aid in increasing the spawning stock biomass and protecting the spiny lobster resource.

2.0 INTRODUCTION

This FEIS/Amendment 4 to the Spiny Lobster Fishery Management Plan (FMP) of Puerto Rico and the U.S. Virgin Islands, and Amendment 8 to the Spiny Lobster Fishery Management Plan of the Gulf of Mexico and South Atlantic will modify all three Councils' FMPs to restrict spiny lobster imports into the United States to minimum conservation standards to achieve an increase in spawning stock biomass and increase long-term yield from the fishery.

2.1 Background

The Caribbean spiny lobster (*Panulirus argus*) has a relatively long planktonic larval phase, which is referred to as the puerulus stage. Planktonic larvae are widely dispersed by ocean currents before they settle and recruit to a specific habitat. The long larval duration for spiny lobsters accounts for connectivity from their source areas to their settlement areas. Recruitment is dependent on environmental conditions, such as temperature and salinity, and on the availability of spawning adults, which is influenced by fishery factors, such as fishing pressure and minimum size limit compliance. These fishery factors can be affected by having an adequate regulatory program to protect spiny lobster (e.g., size limits and protections for berried females) and having adequate enforcement of the program. Studies also have shown local gyres or loop currents in certain locations could influence the retention of locally spawned larvae. In addition, benthic structures such as coral reefs may disturb the flow of water and lead to the settlement of larvae in a particular location (Lee et. al. 1994).

Most of the Caribbean spiny lobster research has been conducted on the Florida population, but the interconnectivity issue also has been studied in the Caribbean region and is recognized and discussed in the Caribbean Council's Spiny Lobster Fishery Management Plan. Caribbean spiny lobster ranges throughout the western Atlantic Ocean from North Carolina to Brazil, including Bermuda, the Bahamas, and all of the Caribbean and Central American areas in between (Herrnkind 1980). DNA analysis indicates a single stock structure for the Caribbean spiny lobster (Lipcius and Cobb, 1994; Silberman and Walsh 1994) throughout its range.

Some Caribbean spiny lobster fisheries managed by other countries (i.e., Brazil, Nicaragua, and Ecuador) are reportedly heavily exploited. These countries export millions of pounds of lobsters to the United States that are at or below their mean size at reproduction. Overexploiting spiny lobster stocks in foreign fisheries could jeopardize the abundance and structure of U.S. stocks because the larval recruitment of U.S. stocks is dependent on the reproductive potential of stocks managed by other countries. The potential for overfishing the Caribbean spiny lobster is relatively high because a lucrative market exists for all sizes of this species. Approximately 90 percent of the Caribbean spiny lobster marketed in the United States is harvested by foreign fisheries managed by Central and South America countries.

Limiting Caribbean spiny lobster imports to a uniform minimum size that protects juvenile spiny lobsters would help stabilize the reproductive potential of the Caribbean spiny lobster by reducing the amount of juvenile spiny lobster mortality in foreign fisheries. Such action is expected to result in the harvest of larger lobsters in exporting countries and approximately 50 percent of these larger lobsters will be capable of spawning, thus increasing the probability of dispersal of Caribbean spiny lobster larvae throughout the species' range. Scientists state that the harvest of juvenile tails in other Caribbean countries impacts the sustainability of U.S. lobster stocks because these harvesting countries produce the parental stocks and larvae for the U.S. stocks. In other words, if you destroy brood stock off the coast of Latin America, you effectively destroy the fisheries of other countries, regardless of the management schemes in those countries. This animal is an example of a shared resource in that it has no national boundaries because of its dependency on the ocean currents for its larval distribution.

There are two main issues associated with addressing the importation of undersize lobsters. First is the importation of lobsters which are below the domestic size limits, and concurrently the mean size at sexual maturity, which were legally harvested in another nation's waters. Second is the importation of lobsters below the domestic size limit, which were illegally harvested in violation of harvest restrictions in other nations. This second activity is already illegal, as the Lacey Act prohibits the importation of lobster harvested in violation of the laws of another nation.

Establishing a minimum size for imports would address both of these issues. By restructuring the importation of lobsters smaller than the domestic size limit, it will severely limit, if not eliminate, the market for legally and illegally harvested undersized lobster. This is expected to serve as an incentive for countries that do not currently have such measures to implement consistent size limits in order to protect juvenile lobster.

Establishment of a uniform minimum size for spiny lobsters imported to the U.S. would assist law enforcement officers in restricting illegal product in the market. The "big four" exporters to the United States are the Bahamas, Brazil, Honduras, and Nicaragua. All these countries have some form of minimal size limit for the Caribbean spiny lobster, but unfortunately this size limit is not standardized. Furthermore, exporting countries do not have the law enforcement resources to effectively monitor shipments to the United States.

The United States imports millions of dollars of undersized lobster each year. Most of these imports go undetected because of the enforcement loopholes that exist for international poachers. These loopholes include: (a) the lack of a U.S. minimal size limit that is applicable for all imports; (b) the use of secretive codes to disguise the undersized lobster tail shipments; (c) the increased use of "trans-shipments through countries of convenience" (i.e. shipping illegal product thru countries that have weaker lobster laws and changing the country of origin to avoid investigators); and (d) shipping the illegal tails to U.S. ports, where inspectors are not as savvy to the lobster smuggling issues.

Minimum size limits are typically used to protect the breeding stock in a fishery, and are often defined at a size that will allow individuals in a population the opportunity to breed at least once before being subject to harvest. The 3 inch (7.6 cm) carapace length (CL) minimum size limit restriction on imports that is currently being considered by the three regional Fishery Management Councils and NOAA Fisheries Service would provide about 50 percent of spiny lobsters the opportunity to spawn at least once before they can be landed by a fishery (Lyons et al. 1981). As an indication of the importance of establishing a minimum import size close to the size at maturity for spiny lobster, each Caribbean spiny lobster measuring 3" CL typically produces about 300,000 eggs per clutch. However, a more recent study demonstrates the potential difficulty in determining the size at maturity for spiny lobster. Bertelsen and Matthews (2001) compared spiny lobster fecundity between adjoining populations of spiny lobster in Florida. The authors found those lobsters in the heavily fished Florida Keys fishery reproduced at a smaller size than those in the sanctuary of the Dry Tortugas National Park. Lobsters from the fishery less than 70 mm (2.75 inches) were found to produce eggs, whereas very few lobsters less than 80 mm (3.15 inches) CL and none less than 70 mm CL produce eggs in the sanctuary population.

Current U.S. regulations for the Caribbean, established in 1983, prohibit the possession of egg-bearing females, and established a minimum size limit (3.5 inches) in terms of carapace length. The Caribbean Fishery Management Council rejected a minimum weight limit because of difficulty of weighing spiny lobsters at sea.

NOAA's Office of Law Enforcement strongly recommends an import restriction include a minimum size limit that utilizes a tail weight measured in ounces (using carapace and tail length conversions). All spiny lobsters will be required to be landed with the shell attached. The landing limit will be converted to a minimum weight limit range (in ounces and grams), noting that Florida Fish and Wildlife Commission scientists have published conversion tables that could be used to determine the most applicable length and weight requirements. The implementation of a minimum weight in ounces is critical for NOAA law enforcement as the seafood industry, processes, packs, ships, exports, imports, and sells lobster tails by weight. In addition, U.S. Customs' entry documents and the seafood industry's sales, storage and bills of lading documents typically include the tail weights (in ounces), making this measurement an effective enforcement tool to track undersized lobster, even after it enters the U.S. port.

Preliminary discussions with all three regional Fishery Management Councils and the state of Florida indicate broad support for a minimum size landing limit restriction on Caribbean spiny lobster imports. The intent is to maintain an open line of dialogue with all parties throughout the fishery management plan amendment process to ensure any problems or issues that surface as the proposed action is developed are satisfactorily addressed.

Since 2003, an effort has been underway to establish a U.S. minimal size limit that would be applicable to spiny lobster imports. This effort has been supported by the U.S. Department of Justice, NOAA's Office of Law Enforcement, Southeast Region, three regional Fishery Management Councils and, recently, by some leading seafood industry corporations, which realize the spiny lobster fishery is being decimated throughout the Caribbean basin. The United States has other existing restrictions on seafood imports involving American lobster, imported swordfish and imported tuna.

There are about 45 species of spiny lobsters species (commonly called rock lobster) in the family Palinuridae throughout the world with several occurring in the Caribbean basin. The Caribbean spiny lobster (*P. argus*; aka red lobster tail and Florida spiny lobster) is the predominant species making up approximately 95 percent of the lobster harvested and marketed in the Caribbean basin countries (i.e., Florida, Central America (Atlantic side), Bahamas, and Brazil). Symmetrical spots on the tail segments and unique markings on the tail fins of this species make it morphologically distinguishable from other species.

Spiny lobsters that originate from the Caribbean basin are tailed, sorted by weight, packed in 10-pound boxes, and shipped to the United States for consumption. Based on law enforcement officer's experiences in inspecting these boxes, the contents are exclusively one species (Caribbean spiny lobster). This is true for the Central American countries (Atlantic side), the Caribbean Island countries and Florida. Brazil poses a slight problem because it mixes Caribbean spiny lobster with *P. lauvicauda* in some shipments that are exported to the United States. However, Brazilian authorities have identified the problem and are attempting to implement a rule that would change this practice and would require species to be isolated before packing.

NOAA's Office of Law Enforcement, Southeast Region, has made several significant Lacey Act cases involving undersized lobster (w/ Honduras, Nicaragua, Bahamas, and an ongoing one with Brazil). These cases typically are criminal and are rather complex in nature due to the need for cooperation with foreign governments, poorly written foreign laws, and the millions of dollars of illegal proceeds. A U.S. minimum restriction applicable to spiny lobster imports would greatly assist law enforcement and federal prosecutors to stem the illegal and profitable flow of undersized imports into the U.S. markets.

<u>International</u>
In an international fishery like that of spiny lobster, "consensus" on addressing concerns is important, as are U.S. efforts to engage other countries in negotiations/agreements. FAO/WECAFC has organized five workshops on spiny lobster in cooperation with most regional agencies and institutions, dealing with various projects: Belize City, Belize (1997); Merida, Mexico (1998, 2000, and 2006); and Havana, Cuba (2002). A representative from the Caribbean Council attended all the workshops. A staff member of NOAA Fisheries Service's Southeast Region attended the 2006 workshop in Merida.

The 2006 Merida workshop was divided into two parts. The first part occurred September 19- 27, and was attended by senior scientists from lobster producing nations. The second part occurred September 28-29, and was attended by senior fishery managers, senior scientists, representatives from the fishing and processing industry, and selected lobster importers. The objectives of the workshop were: (1) to review and update the assessments of the status of Caribbean spiny lobster at national and regional levels and to consider the current levels of exploitation and recent trends in the fishery; and (2) to evaluate the nature and severity of current problems in the fishery, including the number of undersized lobster being caught and exported.

The workshop sought regional agreement by senior fishery managers on strategies to address problems and to ensure optimal and sustainable use of the resource. Senior scientists and senior decision makers of the following lobster producing nations participated in the workshop: Antigua and Barbuda, Bahamas, Belize, Brazil, Colombia, Costa Rica, Cuba, Dominican Republic, France on behalf of Guadeloupe and Martinique, Haiti, Honduras, Jamaica, Mexico, Nicaragua, Turks and Caicos, United States, and Venezuela. The senior fishery managers carefully considered and adopted the report of the senior scientists. In keeping with the recommendation to allow about 50 percent of the stock to reach maturity, the national representatives agreed to a minimum harvest size of 74 mm (2.91 inches) cephalothorax length. Nations with minimum size limits greater than 76 mm were encouraged to retain the larger minimum size limits because of the additional conservation and economic benefits they provide. In addition to the minimum size limit, it was agreed that managing fishing mortality also is necessary to achieve sustainable use of the resource. It was further agreed that countries that already have minimum size limits in place should take action to implement and enforce them effectively to reduce the currently high catches of juveniles in order to protect and allow the species to rebuild throughout its range.

More recently, at a Regional workshop on the lobster fisheries in Central America held in Managua, Nicaragua, December 10-11, 2007, sponsored by OSPESCA, the delegates representing Central American fishery management agencies, artisanal fishers, industry, and other institutions developed an 18 point workshop accord, which addressed, among other things, a minimum harvest size for lobster tails of 140 mm (5.5 inches). The accord also recognized industry practices and determined for commercial purposes, each box must have an average tail weight of five ounces with a range of 4.5 to 5.5 ounces. A 5.5 inch tail length and 4.5 oz weight equate to a 3.0 inch carapace length.

2.2 Management History

Gulf of Mexico and South Atlantic

The original Fishery Management Plan (FMP) from the Gulf of Mexico and South Atlantic Fishery Management Councils was written in 1982. It states “The Fishery Conservation and Management Act (FCMA) requires that stocks be managed throughout their range to the extent practicable” and “There may be a relationship between spiny lobster stocks in the Caribbean, South Atlantic and Gulf of Mexico regions" (pg. 7-1). A definition of the fishery is also provided:

> "The spiny lobster fishery consists of the spiny lobster, *Panulirus argus*, and other incidental species of spiny lobster (spotted spiny lobster, *P. guttatus*; smooth tail lobster *P. laevicauda*; Spanish lobster, *Scyllarides aeguinoctialis* and *S. nodifer*), which inhabit or migrate through the coastal waters of and the Fishery Conservation Zone (now known as the exclusive economic zone (EEZ)) of the Gulf of Mexico and South Atlantic Fishery Management Council areas and which are pursued by commercial and recreational fishermen" (pg. 12-1).

The original FMP analyzed several different potential minimum sizes, ranging from 2.75 to greater than 3 inches CL. Ultimately, the smaller minimum sizes were not used for biological reasons as they would not protect the spawning stock. The larger sizes were deemed to cost the fishery too much economically and socially, therefore, the 3 inch CL was chosen.

In multiple places within the FMP, the importation of undersized lobster was noted as a concern. Under the description of alternative optimum yields it was noted:

> "The characteristics of demand for lobster indicate preferences for the smaller-sized animals; in fact, market forces would endanger spiny lobster stocks because the greatest preference in the New York wholesale market (Exhibit 9-3) is for animals less than 3.0 inches CL, sizes at which reproduction has not yet occurred. (All of these smaller-sized lobsters are imported)" (pg. 12-4).

Further, under the possible alternatives that were not preferred, a prohibition on the import of undersized spiny lobster is listed. The rationale for not proposing the ban was two-fold. First, there was concern that changes in the import market, which supplies approximately 90% of the lobsters consumed in the United States, could have significant affects on the price-size relationship, though the magnitude of the change on the retail market could not be estimated. Second, the nations harvesting Caribbean spiny lobster were uncomfortable about the impact of import restrictions on international relationships (pg. 12-35).

Since the 1980's the FMP has been amended consistent with new requirements of the Magnuson-Stevens Act, but those amendments have not affected the Caribbean nations regarding the minimum import size for spiny lobster.

Caribbean
The original FMP for the Caribbean was written in 1981. It acknowledges the need to manage spiny lobster throughout its range and interrelated stocks could be managed as a unit or in close coordination. The plan further acknowledges that "conclusive data regarding genetics between various geographic areas…not available…establishment of an international coalition will eventually be necessary to effectively manage this migratory species throughout its range" (pg. 5). The plan addresses only the species *P.*

argus where it is limited to the geological platforms of Puerto Rico and the Virgin Islands essentially inside the 100-fathom isobath. It continues "these shelf areas include not only the Commonwealth of Puerto Rico and the territory of the Virgin Islands, but also the entire chain of the British Virgin Islands. The lobster population recognizes none of these political entities nor the limits of territorial seas" (pg. 6).

The stock unit is defined as:

> "The question of whether or not biologically distinct stocks of *P. argus* may be identified is not resolved. For purposes of this plan three biological assessment areas (distinguished by their user groups and geography) were assumed; (1) Puerto Rico, (2) St. Thomas and St. John, and (3) St. Croix. A single optimum yield is established. There is nominally one species and the source(s) of recruitment are not verified" (Section 4.2)".

The original FMP analyzed several different potential minimum sizes, ranging from 2.75 to greater than 3.5 inches CL. As in the Gulf of Mexico and S. Atlantic FMP, the smaller minimum sizes were eliminated because they would not protect the spawning stock. The larger sizes were deemed to cost the fishery too much economically and socially, therefore, the 3.5 inch CL was chosen (see below for rationale for differences in minimum size between the 2 FMPs).

Similar to the Gulf of Mexico and S. Atlantic FMP, the Caribbean FMP mentions the use of an import ban of undersized lobster as a method to improve the stocks status. Under "Recommendations to the Secretary of Commerce" the FMP states:

> "It is recommended that the Secretary of Commerce undertake whatever action may be necessary and appropriate to immediately prohibit the importation into the U.S. Virgin Islands and Puerto Rico of undersized (less than 3.5 inches CL) or berried spiny lobsters and of spiny lobster tails of less than 6 oz. total weight" (Section 5.1).

In addition, under this section, the Secretary of Commerce is asked to adopt an action plan to work with other Caribbean nations to enact conservation and management measures consistent with those adopted by the Caribbean FMC with regard to spiny lobster and other species.

As with the S. Atlantic and Gulf of Mexico FMP, since the 1980's the Caribbean FMP has been amended consistent with new requirements of the Magnuson-Stevens Act, but those amendments have not affected the above definitions or the minimum size regulations of the spiny lobster fishery.

3.0 PURPOSE AND NEED

Foreign and U.S. scientists and fisheries managers all concur the Caribbean spiny lobster is fully exploited or over-exploited[1] in much of its range (Cochrane and Chakalall 2001). Spiny lobsters are being harvested below the respective Continental and Caribbean U.S. minimum size limits and below the size at first maturity; this is adversely impacting recruitment throughout Florida and the Caribbean because of the distribution and dispersal of larvae during their long larval phase. A reduction of effort on undersized lobster and more comprehensive enforcement would increase spawning stock biomass and increase potential yield. The lobster seafood industry has even recognized this fact and has asked respective governments to address the harvest and exportation of undersized lobster tails to the United States.

This Amendment/EIS will examine various alternatives to restrict imports[2] of spiny lobster into the United States to minimum conservation standards to achieve an increase in the spawning biomass of the spiny lobster stock and increase long-term yields from the fishery.

4.0 MANAGEMENT ALTERNATIVES

The management alternatives section is divided into two actions. The first action will examine various morphometric values that imported spiny lobster would be required to meet. The morphometric values in Action 1 provide an easily measurable requirement that can be used by fishermen, importers, and law enforcement to ensure compliance. The second action examines other import restrictions, which will further protect the spiny lobster stock and close any potential loopholes that may be exploited in an effort to circumvent minimum size restrictions.

4.1 Action 1: Minimum Size Limits for Spiny Lobster (*Panulirus argus)* Imported into the United States

A. <u>Alternative 1 (No Action Alternative) – Do not establish minimum size limit restrictions on spiny lobster imported into the U.S.</u>

Under the no action alternative, imports would be subject to the management and regulations of the exporting country and violations of those regulations would be pursued through the Lacey Act.

---

[1] Fully exploited means the act of employing to the greatest possible advantage; over-exploited means exploited to the point of diminishing returns

[2] For the purpose of this amendment/EIS the term “import” (A) means to land on, bring into, or introduce into, or attempt to land on, bring into, or introduce into, any place subject to the jurisdiction of the United States, whether or not such landing, bringing, or introduction constitutes an importation within the meaning of the customs laws of the United States; but
(B) does not include any activity described in subparagraph (A) with respect to fish caught in the U.S. exclusive economic zone by a vessel of the United States" (16 U.S.C. 1802 (22)).

B. **Preferred Alternative 2** – No person in the U.S. would be allowed to import a spiny lobster (*Panulirus argus*), as follows:

1. Any spiny lobster of less than 5 ounces tail weight (5 ounces is defined as a tail that weighs 4.2 – 5.4 ounces). If the imported product does not meet this minimum weight requirement, the person importing the lobster can demonstrate compliance by showing that the product imported satisfies the tail length requirement, or that it was harvested from an animal that satisfied the minimum carapace length requirement of:
   a. Greater than 3.0 inches (7.62 cm) carapace length if the animal is whole.
   b. Greater than or equal to 5.5 inches (13.97 cm) tail length if only the tail is present.

2. *In Puerto Rico and the U.S. Virgin Islands:* Any spiny lobster of less than 6.0 ounces tail weight (6 ounces is defined as a tail that weighs 5.9 – 6.4 ounces). If the imported product does not meet this minimum weight requirement, the person importing the lobster can demonstrate compliance by showing that the product imported satisfies the tail length requirement, or that it was harvested from an animal that satisfied the minimum carapace length requirement of:
   a. Greater than or equal to 3.5 inches (8.89 cm) carapace length if the animal is whole.
   b. Greater than or equal to 6.2 inches (15.75 cm) tail length if only the tail is present.

C. Alternative 3 – No person would be allowed to import into the U.S., including Puerto Rico and the U.S. Virgin Islands, any spiny lobster (*Panulirus argus*) of less than 5 ounces tail weight (5 ounces is defined as a tail that weighs 4.2 – 5.4 ounces).
If the imported product does not meet this minimum weight requirement, the person importing the lobster can demonstrate compliance by showing that the product imported satisfies the tail length requirement, or that it was harvested from an animal that satisfied the minimum carapace length requirement of:
   a. Greater than 3.0 inches (7.62 cm) carapace length if the animal is whole.
   b. Greater than or equal to 5.5 inches (13.97 cm) tail length if only the tail is present.

Comparison of Action 1 Alternatives

Fisheries for spiny lobster (*Panulirus argus*) exist throughout its range in the Caribbean and tropical western Atlantic. The Western Central Atlantic Fishery Commission (WECAFC) held workshops in 2000 and 2002 regarding the management of the spiny lobster fisheries in the WECAFC region and the scientific committee from that workshop concluded that spiny lobster are fully exploited to over-exploited throughout its entire range. [NOTE: WECAFC is part of the Food and Agriculture Organization (FAO) and was established pursuant to FAO's Constitution. It is advisory only and has no regulatory powers, unlike other Regional Fisheries Management Organizations such as the International Commission for the Conservation of Atlantic Tunas (ICCAT).]

Several genetic studies have been conducted on spiny lobster in the Caribbean since the 1990's. The consensus from these experiments is that the spiny lobster population appears to be interconnected throughout the Caribbean with the possibility of a semi-isolated subpopulation in part of Brazil. Despite the somewhat limited information regarding the Caribbean as a whole, based on scientific studies, the U.S. population is very likely dependent on recruitment from other areas (Lyons et al. 1981, Acosta et. al. 1997).

The alternatives in Action 1, other than the status quo, are intended to eliminate the largest market for undersize spiny lobster (the U.S.) and provide an incentive for foreign nations that do not have minimum conservation standards to implement conservation standards which will improve the status of the spiny lobster stock in the U.S. and throughout the Caribbean. The most effective means for creating this incentive is to improve law enforcement (LE) capabilities for preventing undersized lobster from being imported to the United States. By implementing an import restriction on size, LE will be more capable of tracking undersized lobster shipments and developing cases against suspected importers of undersized lobster. Under existing laws (most notably the Lacey Act), LE must develop an extensive record and work in coordination with foreign nations when attempting to develop a case against an importer. This is often a very complicated and difficult process to coordinate. By changing the domestic laws to place conservation standards on imported lobster, this amendment/EIS will help protect lobster stocks, as well as provide a better tool for LE officials to deter the importation of undersized lobster.

Due to the complexity of the spiny lobster industry and the high volume of international trade, the alternatives provide a number of means for determining whether an individual lobster is indeed undersized. **Preferred Alternative 2** and **Alternative 3** are structured the same, but alter the minimum size depending on the location of importation (i.e., into the U.S. or the U.S. Caribbean). Table 4.1.1 lists each alternative and the associated minimum possession limits for the alternative. The multiple minimum size morphometrics (i.e., carapace length, tail length, and tail weight) provided in each alternative are intended to provide an understandable and practical size restriction for each component of the industry. For example, the use of carapace length (CL) is currently what fishermen, while at sea, use to verify if an individual lobster is indeed legal (Figure 4.1.1). Tail length (TL) is used by some fishermen while at sea; for example, Gulf of Mexico and South Atlantic fishermen in the EEZ who possess a tailing permit. The tail weight (TW) is used by processors, importers, and exporters. Law enforcement agents would use CL and TL for inspections at sea and dockside as is the current practice, while TW would be used in examining imports if either **Preferred Alternative 2** or **Alternative 3** were chosen.

Importers would be required to meet the minimum weight conservation standard identified in the alternatives. However, if the imported product does not meet the minimum weight requirement, the person importing the lobster can demonstrate compliance by showing that the product imported satisfies the equivalent tail length requirement, or that it was harvested from an animal that satisfied the equivalent minimum carapace length requirement.

Figure 4.1.1. A measurement of the carapace length on a spiny lobster.

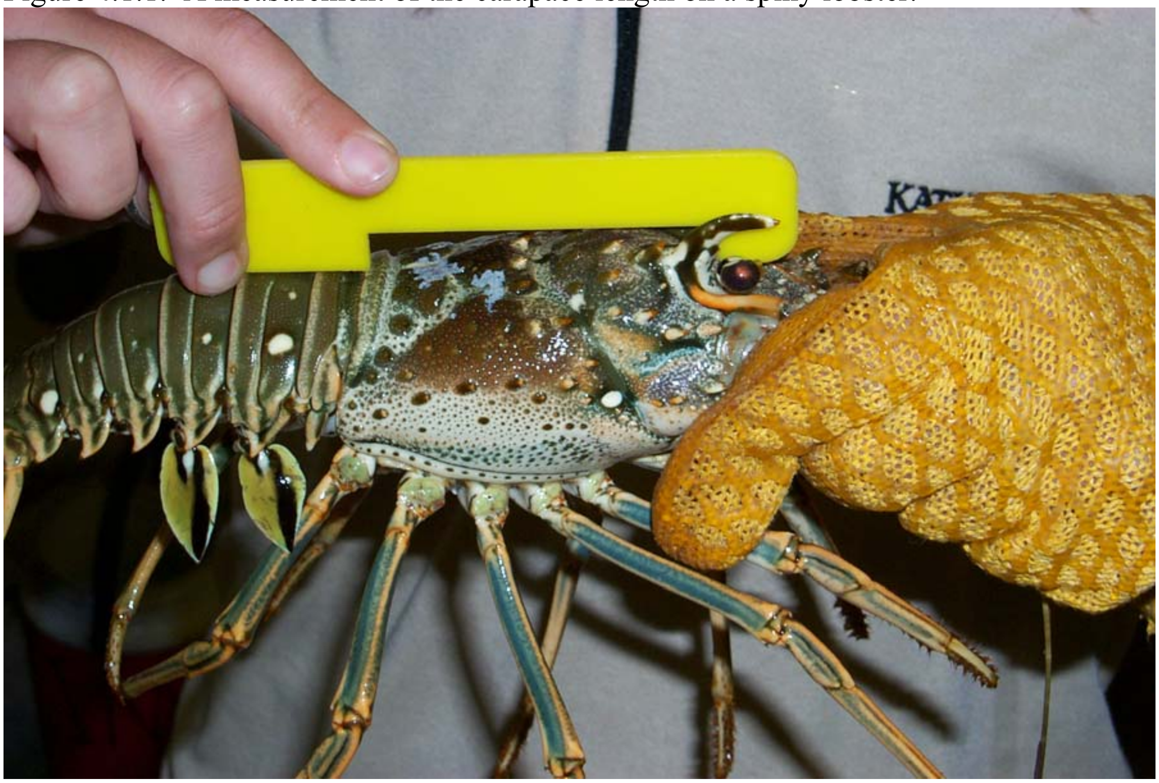

Table 4.1.1. Alternatives with respective morphometric requirements for spiny lobster importation.

Alternative	Carapace Length	Tail Length	Tail Weight/ Industry Allowances
1	N/A	N/A	N/A
2	> 3.0 inches U.S.; ≥ 3.5 inches in the Caribbean	≥ 5.5 inches U.S.; ≥ 6.2 inches Caribbean	≥ 4.2 oz U.S.; ≥ 5.9 oz Caribbean/ U.S - 5 oz weights = 4.2 - 5.4 oz; Caribbean - 6 oz weights = 5.9 - 6.4 oz.
3	> 3.0 inches	≥ 5.5 inches	≥ 4.2 oz/ 5 oz weights = 4.2 - 5.4 oz

The intent of this amendment is to utilize the tail weight in deterring under-sized lobster imports as that is the unit of measure the industry utilizes as it markets, imports, stores, transports, and sells this product. Spiny lobster is rarely, if ever, imported or marketed in the U.S. as a whole animal, but instead as frozen tails. Standard industry practice for overseas spiny lobster processing is to separate, sort, and box the tails by their tail weight prior to shipping. In addition, U.S. Customs' entry documents and the seafood industry's sales, storage and bills of lading documents typically include the tail weights (in ounces), making this measurement an effective enforcement tool to track undersized lobster, even after it enters the U.S. port. It is estimated over 99% of spiny lobster product enters the U.S. in this fashion (P. Raymond, NOAA OLE, pers. comm.).

Additionally, there was a December 2007 workshop with delegates from Central American fishery management agencies, artisanal fishers, and industry held in Managua, Nicaragua (OSPESCA). The delegates developed an 18 point workshop accord which contained recommendations for minimum conservation standards including a minimum harvest size for tails of 140 mm and a minimum tail weight of 4.5 ounces. For the commercial industry, this translates into each shipping box having an average tail weight of 5 ounces with a range from 4.5 to 5.5 ounces.

However, the 4.5 ounce tail weight recommendation was not based on scientific conversions from the recommended 140 mm tail length, but was instead based on industry practice of sorting and shipping. Tables 4.1.2 and 4.1.3 provide conversions from carapace length to tail length and tail weight based on Matthews et al. (2003). If we examine the 140 mm (5.5 inch) tail length recommendation, we see it is derived from one standard deviation of the mean for a 3.0 inch (76.2 cm) carapace length animal (table 4.1.3, in green). Therefore, if a tail length recommendation is based on one set of scientific standards, all conversions from the carapace length should be based on that same standard. Therefore, the appropriate tail weight to be used for a 3.0 inch carapace length animal would be a 4.15 ounce tail weight (Table 4.1.3, in yellow). This, like the tail length recommendation is based on one standard deviation from the mean for the measurements of a 3.0 inch carapace length animal. For the purpose of simplifying this requirement, the weight has been rounded to one decimal place to make the requirement a 4.2 ounce tail weight. For imports to the U.S. Caribbean, similar conversions from a 3.5 inch CL animal yield a minimum TW of 5.9 ounces and a TL of 6.2 inches (Table 4.1.3, in turquoise).

Therefore, in an effort to accommodate industry practices this amendment defines the 5 ounce tail as ranging from 4.2 to 5.4 ounces and a 6 ounce tail as ranging from 5.9 to 6.4 ounces. This allows industry to maintain their sorting and packaging practices while instituting the minimum tail weight conservation standard based on scientific conversions.

The use of this scientific standard has already been applied in the current regulations for the Gulf and South Atlantic joint FMP for spiny lobster. The Gulf and South Atlantic FMP allows lobsters to be tailed while at sea if the vessel has the appropriate tailing permit. The minimum size for tails to be legal is 5.5 inches, which is derived from one standard deviation of tail length for a 3.0 inch carapace length animal (Table 4.1.3 in yellow). Using the one standard deviation approach, it is expected that 84.13% of all 3.0 inch carapace length animals would be legal based on their tail length and tail weight measurements at 5.5 inches and 4.2 ounces, respectively.

Table 4.1.2. CL and average TL and TW conversions (metric and English conversions; Matthews, pers. Comm.)

Carapace length (mm)	Tail weight (g)	Tail length (mm)		Carapace length (in)	Tail weight (oz)	Tail length (in)
76.2	122.8	142.5		3.00	4.34	5.61
82.6	153.5	153.4		3.25	5.42	6.04
88.9	188.0	164.2		3.50	6.64	6.46

Table 4.1.3. CL measurements with converted TL and TW for animals minus 1 SD (metric and English conversions; Matthews, pers. Comm.)

Carapace length (mm)	Tail weight (g)	Tail length (mm)		Carapace length (in)	Tail weight (oz)	Tail length (in)
76.2	117.6	139.9		3.00	4.15	5.51
82.6	143.2	149.6		3.25	5.06	5.89
88.9	168.3	158.4		3.50	5.94	6.24

Alternative 1 would not establish restrictions on spiny lobster imports. **Preferred Alternative 2** would require all imported lobster to have a TW of 4.2 ounces or greater if imported to the U.S.; for those lobsters imported to the U.S. Caribbean, a lobster must have a TW of 5.9 ounces or greater. Because weighing tails at sea is difficult, fishermen would continue to use the CL and TL measurements as appropriate for their region or country to ensure compliance with the legal requirements. Law enforcement officials would have the ability to use those same measurements for at sea and dockside enforcement while utilizing the appropriate TW measurement for enforcement of imported lobster tails. Due to the scientific variation of lobster tail weight, an importer may demonstrate compliance with the minimum conservation standards by providing documentation that an animal that does not meet the TW requirement meets the TL or CL measurement.

Alternative 3 would require all imported lobster to have a TW of 4.2 ounces or greater regardless of the port of entry into the U.S. This alternative would function similarly to **Preferred Alternative 2** with fishermen using the CL and TL measurements and LE utilizing those measurements plus the TW. However, there is some concern in the U.S. Caribbean that there may be a loss of the conservation standards with the use of this single size approach. The U.S. Caribbean has a more restrictive conservation standard on spiny lobster (i.e., a minimum landing size of 3.5 inches) than does the continental U.S. The loss in conservation would be seen through the creation of a loophole where products may be claimed as imports even if they are not in an effort to circumvent local laws. Similarly, law enforcement may lose some of its ability in enforcing local laws because of the allowance of smaller lobster through the import market. In weighing these differences between **Preferred Alternative 2** and **Alternative 3**, it appears that requiring imports to meet the minimum conservation standards of the domestic port of entry would provide more benefits than one standard set of standards. Therefore, **Preferred Alternative 2** would be more beneficial than **Alternative 1** or **Alternative 3**.

4.2 Action 2: Implement Other Import Restrictions on Spiny Lobster

A. Alternative 1 (No Action Alternative) – Do not have other restrictions on the importation of spiny lobster.

   Under the no action alternative for Action 2, imports would be subject to the management and regulations of the exporting country and violations of those regulations would be pursued through the Lacey Act.

B. **Preferred Alternative 2** - Do not allow the importation of spiny lobster tail meat which is not in whole tail form with the exoskeleton attached; and do not allow the importation of spiny lobster with eggs attached or importation of spiny lobster where the eggs, swimmerets, or pleopods have been removed or stripped.

C. Alternative 3 - Do not allow the importation of spiny lobster tail meat which is not in whole tail form with the exoskeleton attached

D. Alternative 4 - Do not allow the importation of spiny lobster with eggs attached or importation of spiny lobster where the eggs, swimmerets, or pleopods have been removed or stripped.

Comparison of Action 2 Alternatives

If no protections are afforded to the females as they are actively reproducing, then all benefits from increasing the spawning stock biomass have been lost. The alternatives considered in Action 2, other than the no action alternative, are designed to: 1) provide further protections to undersized lobsters, and 2) protect berried (egg-bearing) females. Both of these actions will aid in accomplishing the purpose of this amendment/EIS, to increase the spawning stock biomass of the spiny lobster population.

Appendix A of this document provides copies of documents obtained from LE officials used in their investigations of undersize spiny lobster imports. Of particular interest to this action is the document on page 2 of the appendix dated 8/16/2000. In this document the seller inquires whether a buyer is interested in “approx 800-900 lbs of lobster meat.” This inquiry is made one day after the seller informs the buyer of a “lot of pressure on tails under 5 oz.” (page 1 Appendix A). Likely, there was intent to circumvent the laws regarding minimum sizes for any country and to continue bringing in illegal product regardless of how that was achieved. If any importation conservation standards are to have the desired effect, then the trade in “lobster meat” must be stopped to close the potential loophole of harvesting undersize lobster, processing it into meat, and then making it available in the market. Figure 4.2.1 illustrates what is meant by “lobster meat.”

Figure 4.2.1. An example of lobster tail meat without the exoskeleton attached.

The protection of berried females (or those that were, prior to being stripped) is also imperative if the minimum conservation sizes are implemented in order to protect the spawning stock biomass (Figure 4.2.2 and 4.2.3). Action 1 will help achieve an increase in the spawning stock biomass of spiny lobsters; if no protections are afforded to the females as they are actively reproducing, then all benefits from increasing the spawning stock biomass have been lost. Therefore, the alternatives in Action 2 are supportive of those in Action 1 and will further the conservation of the spiny lobster population.

Figure 4.2.2. A berried (egg-bearing) female.

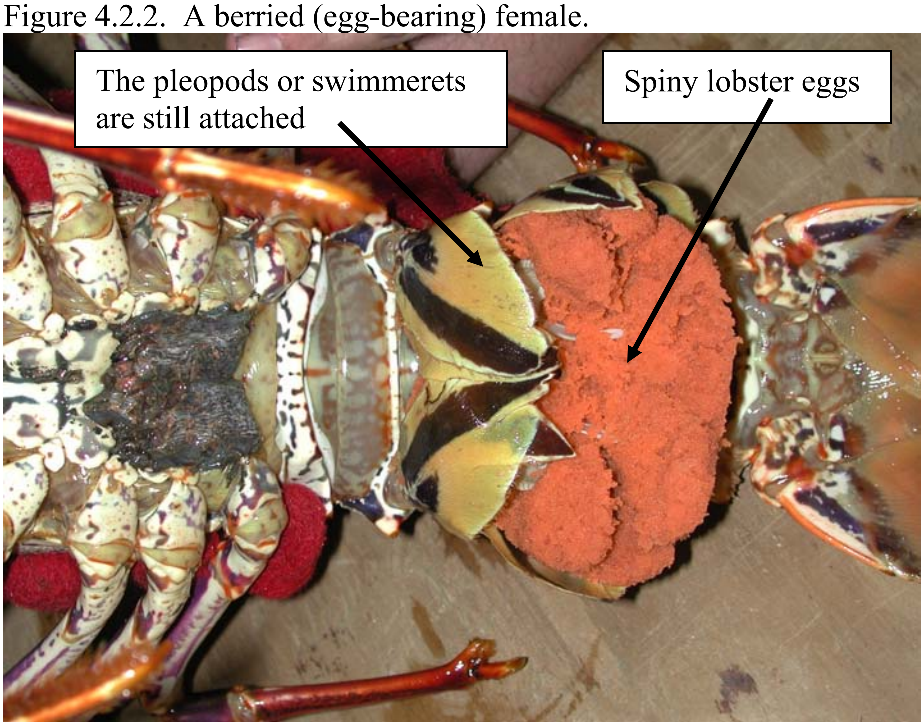

Figure 4.2.3. Examples of lobster tails that have been clipped to remove the pleopods or swimmerets and a stripped tail.

Alternative 1, No Action, would not implement any further conservation standards for imported lobster. **Preferred Alternative 2** would prohibit the importation of lobster tail meat. For the purposes of this action, lobster tail meat means that meat which is not in whole tail form with the exoskeleton attached or still part of a whole lobster. If this alternative is selected, significant loopholes with the minimum size limit would be eliminated. **Preferred Alternative 2** also prohibits importation of berried females or those females who have been obviously stripped of their eggs by removing the eggs, clipping the swimmerets, or removing the pleopods. Individual animals that have been stripped of their eggs or who have had their swimmerets or pleopods removed are easily identified by law enforcement officials once the tail is thawed and the underbelly inspected (P. Raymond, NOAA OLE, pers. comm.). Thus, a restriction on their importation would further the goal of this amendment/EIS in increasing the spawning stock biomass of the spiny lobster population.

Alternatives 3 and **4** would achieve similar goals as **Preferred Alternative 2**, but not to the same extent. These two alternatives are obviously derivatives of **Preferred Alternative 2** and would implement only one or the other restriction of prohibiting lobster tail meat or berried females. While both are viable alternatives for achieving an increase in the spawning stock biomass of spiny lobster, **Alternative 3** and **4** are not as comprehensive as **Preferred Alternative 2**.

Alternative 1 would maintain the regulations that exist under the Caribbean FMP and the South Atlantic/Gulf of Mexico FMP. **Preferred Alternative 2** would require all imported lobster to comply with domestically equivalent regulations such that no berried lobsters, or stripped (clipped) lobsters or lobster meat would be allowed for importation into the U.S. **Alternative 3** and **4** are some derivation of **Preferred Alternative 2**, but not as comprehensive. Therefore, **Preferred Alternative 2** would be more beneficial than **Alternatives 3** and **4**, and all would be more beneficial than **Alternative 1** in increasing the spawning stock biomass and protecting the spiny lobster resource.

4.3 Alternatives Considered but Rejected

During the development of this Amendment /EIS no alternatives were considered and then rejected. However, there were modifications to the alternatives as various iterations of the Amendment/EIS were developed.

Action 1 Modifications

Action 1 has maintained various morphometric size limit restrictions for imports throughout the development of the document. There were changes in the exact measurements of these limits based on insight provided by spiny lobster biologists and the peer-reviewed literature of spiny lobster. Specifically, the changes occurred to the minimum weight limit required for lobsters and the language used to delineate the 2 different sets of morphometrics used in the alternatives.

The minimum weight limit has been identified in various iterations as 4.15, 4.5, and the current 4.2 ounces. Using the Matthews et al. (2003) paper, the direct derivative for tail weight from a 3 inch carapace length animal rounded to 2 decimal places is 4.15 ounces, hence that measurements use in the original document. However, industry practice is to sort tails based on whole ounce categories plus or minus 0.5 ounces. Therefore, it was deemed most appropriate to use a minimum tail weight of 4.5 ounces based on the 4.15 ounce conversion for industry’s ease. It was later determined that it would be more appropriate to use the direct conversion based on best available science, while rounding to a single decimal place, hence the current 4.2 ounce minimum weight.

The other change in Action 1 was in regards to the language used to identify the 2 differing sets of morphometrics to be used for spiny lobster imports. The Caribbean FMC has a different minimum carapace length requirement for the spiny lobster fishery of Puerto Rico and the USVI (3.5”). There was very strong opinion in the US Caribbean that any import should meet those same requirements in the U.S. Caribbean. Therefore, a different set of morphometric minimum size limits were developed based on the 3.5 inch carapace length.

In an effort to delineate what size limit an imported lobster would be required to meet, language was developed to include the U.S. Caribbean (Puerto Rico and the USVI) and the continental U.S. A number of issues were identified in using the wording of “Continental U.S.” as this created a loophole for importers to trans-ship spiny lobster products through Hawaii, Alaska, and other U.S. territories, thereby bypassing the minimum import requirements. Therefore, the language now used in the alternatives includes **all of the U.S. except Puerto Rico and the USVI** where the minimum import sizes are based on the 3.5 inch carapace length.

5.0 AFFECTED ENVIRONMENT

5.1 Physical Environment

The Caribbean Sea is an interior sea formed by a series of basins lying to the east of Central America and separated from the North American Basin of the Atlantic by an island arc 2,500 nautical miles long which joins the Florida Peninsula to the north coast of Venezuela. This arc is demarcated by the Greater Antilles (Cuba, Jamaica, Hispaniola, and Puerto Rico) and the Lesser Antilles (the Virgin Islands, Guadeloupe, Martinique, St. Lucia, Barbados, and Trinidad).

Contained between the 10^{th} and 30^{th} degrees of north latitude, this interior sea has an elliptical form. The long northwest-southeast axis is 2,200 nautical miles and the short axis is 900 nautical miles. The total area of the Caribbean Basin is 4,320,000 km^2, divided into two unequal parts: 1) the Gulf of Mexico (1,700,000 km^2) and 2) the Caribbean Sea (2,600,000 km^2); separated by the Yucatan Peninsula and Cuba between which flows the Yucatan Channel (60 nautical miles wide and 2000 m deep).

The Gulf of Mexico is a simple depression including an extended peripheral continental shelf representing more than one-third of the surface area of the Gulf, and a central basin whose maximum depth is 3800 m. The continental shelf is rich in oil-bearing strata. The Gulf of Mexico opens on the North American Basin by the single opening of the Straits of Florida, between the tip of Florida, the north coast of Cuba, and the Bahamas Archipelago. The width of the channel is 30-50 nautical miles and its greatest depth is 800 m.

As a seismic and volcanic region, the Caribbean has a much more complex topography and has numerous openings into the North American Basin. The Jamaican Ridge, running from Cape Gracias a Dios to Jamaica and Hispaniola, divides the Caribbean into two sections-one in the northwest, the other southeast, communicating across a 1500 m sill which is 20 nautical miles wide at 100m. The northwest basin is itself divided in two by the Cayman Ridge, which from the southwest point of Cuba runs toward, without reaching it, the Gulf of Honduras. Between the Gulf of Mexico and the Cayman Ridge lies the Yucatan Basin, of which the central part is 4700 m deep. At its western extremity it communicates freely at depth of more than 5000 m with the second basin, the Cayman Basin. In the eastern part of the Cayman Basin, between the southwest point of Cuba and against the Cayman Ridge lies a narrow trench 7680 m deep.

The southeast basin, more extensive than the northwest, is in turn subdivided into three by two ridges (Beata and the Aves), having a mostly north-south orientation, parallel to the general direction of the Lesser Antilles. Between the Jamaica and Beata Ridges lies the Colombian Basin, more than 4000 m deep. Between the Beata and Aves Ridges is the Venezuelan Basin which has depths between 4000 and 5000 m; and the Grenada Basin, with a depth of more than 3000 m, is held between the Aves Ridge and the chain of the Lesser Antilles. Because the Beata Ridge does not reach the north coast of Colombia, the Colombian and Venezuelan Basins exchange freely at depths of 1600 m. The main exchanges between the Caribbean and the North American Basin are: 1) the

Windward Passage between the southeast of Cuba and the northwest part of Haiti, with a depth of 1650 m and a width of 12 nautical miles; and 2) the Anegada Passage, prolonged by the Virgin Islands Passage, with a depth of 1800 m and a length of 8 nautical miles, enabling the Atlantic to communicate with the Venezuelan Basin.

The channels between the islands of the Lesser Antilles are all of the order of a depth of 1000 m. Outside of the Greater Antilles chain, to the north of Puerto Rico and Hispaniola, lies the Puerto Rico trough, which has a maximum depth of 8648 m. This maximum depth is found no more than 200 km from a peak in Hispaniola, which reaches 3175 m for a relief of about 11,823 m in less than 200 km.

The Caribbean Basin is entirely in the tropical Atlantic. The mean annual temperature is near 25° C and seasonal variations are small. The winds, the eastern sector predominating, are tied to the trade wind system of the Northern Hemisphere. In the Gulf of Mexico in winter there is a rather marked northern component. Precipitation is 500 mm annually in the east and southeast Caribbean, 500-1000 mm annually over the Gulf of Mexico, and 2000 mm annually in the southwest part of the Caribbean (Tchernia 1980).

5.2 Biological Environment

5.2.1 Spiny Lobster (*Panulirus* argus)

The Caribbean spiny lobster (*P. argus*) populates the western Atlantic Ocean, Caribbean Sea, and Gulf of Mexico ranging from Bermuda down to Brazil (Herrnkind 1980; Figure 5.2.1). Distribution and dispersal of *P. argus* is determined by the long planktonic larval phase, called the puerulus, during which time the infant lobsters are carried by the currents until they become large enough to settle to the bottom (Davis and Dodrill 1989). As the lobsters begin metamorphosis from puerulus to the juvenile form, the ability to swim increases and they move into shallow, near shore environments to grow and develop.

Figure 5.2.1. Distribution of spiny lobster (*P. argus*)

Young benthic stages of *P. argus* will typically inhabit branched clumps of red algae (*Laurencia sp.*), mangrove roots, seagrass banks, or sponges where they feed on invertebrates found within the microhabitat. In contrast to the social behavior of their older counterparts, the juvenile lobsters are solitary and exhibit aggressive behavior to ensure they remain solitary. The inhabitation of macroalgae by the juvenile lobsters provides protection to the vulnerable individuals from predators while providing easy access to food sources (Marx and Herrnkind 1985).

Individuals two to four years old exhibit nomadic behavior emigrating out of the shallows and moving to deeper, offshore reef environments. Once in the adult phase, Caribbean spiny lobsters are thigmotactic and tend to enter social living arrangements aggregating in enclosed dens. Shelter environments may include natural holes in a reef, rocky outcrops, or artificially created environments (Lipcius and Cobb 1994).

As adults in the offshore environment, Caribbean spiny lobsters support commercial, recreational, and artisanal fisheries throughout their geographic range (Davis and Dodrill 1989). Given the wide distribution of *Panulirus argus* from Bermuda down to Brazil, it is hard to determine a definitive stock structure for this species. There are a multitude of currents and other factors that influence the movement of water throughout the range of *P. argus*. The long duration that lobsters spend in the larval stage, traveling by the currents severely impairs the ability of scientists to determine a stock structure. More recent work with DNA may be useful in determining some sort of stock structure for the Caribbean spiny lobster (Lipcius and Cobb, 1994), however the extensive larval phase may also limit this tool as it takes few successful migrants to homogenize the gene pool (Silberman and Walsh 1994). Studies have also shown that the presence of local gyres or loop currents in certain locations could influence the retention of locally spawned larvae. In addition, benthic structures such as coral reef may disturb the flow of water and lead to the settlement of larvae in a particular location (Lee, et al. 1994).

The general anatomy of *Panulirus argus* conforms to the typical decapod body plan consisting of five cephalic and eight thoracic segments fused together to form the cephalothorax. The carapace, a hard shield- like structure, protects this portion of the body and is often the part of the lobster measured and used as a standard to determine organism length. All the segments bear paired appendages that serve in locomotion, sensory, or both (Phillips, Cobb and George, 1980). From the head of the lobster, the appendages are ordered starting with the first antennae, second antennae, mandibles, first maxillae, and second maxillae. There are five pairs of walking legs called pereiopods and a six-segmented tail. The antennae function primarily to obtain sensory information by chemoreception, as do the dactyls of the walking legs and the mouthparts involved in handling food. Lobsters have great visual ability, achieved through the use of their paired, lateral compound eyes. In addition, highly distributed superficial hairs detect water movements (Ache and Macmillan, 1980).

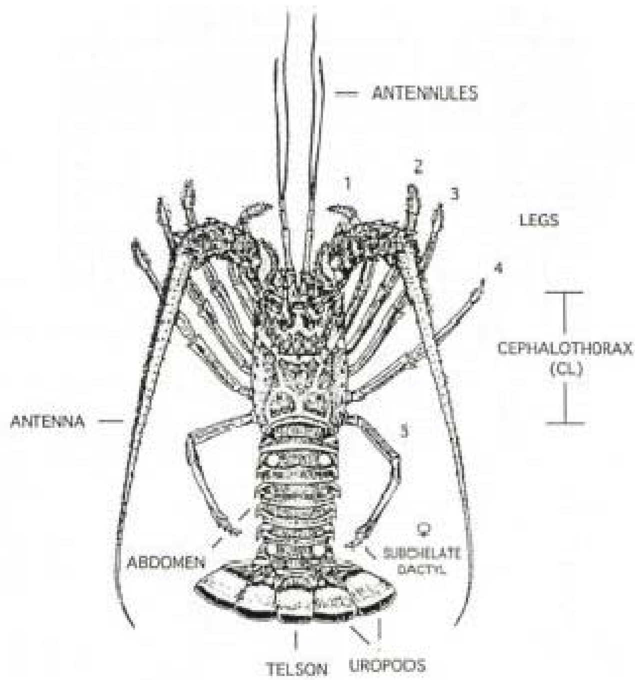

Figure 5.2.2: Morphology of *Panulirus argus* (Lipcius and Cobb, 1994).

Gills are the main organs used by lobsters for respiration. The rate of oxygen consumption in *P. argus* is dependent upon the temperature, the degree of crowding within the den, feeding and size of the lobster; oxygen consumption is not determined by the concentration of the oxygen in the water as some studies show that oxygen uptake remained the same in both hypoxic and aerated water (Phillips, Cobb and George, 1980).

Food Habits

Once *P. argus* settles out from the planktonic phase and enters the seagrass and macroalgae nursery habitat, their diet consists of small gastropod mollusks, isopods, amphipods and ostracods, most of which can be found in or within close proximity to the lobster's algal shelter. Studies suggest that as the abundance of food declines in and around their algae habitat, lobsters forage more frequently and thus have more frequent contact with conspecifics. Aggressive behavior in the juvenile lobsters, which at this time live solitarily, has been observed as a means of enforcing territoriality. The consequence of increased aggressive interactions as well as a declining food source is thought to induce the nomadic emigration from the algal nursery environment to off shore reef environments (Marx and Herrnkind, 1985).

During the adult and juvenile phases, the Caribbean spiny lobster will rest in shelters during daylight hours and emerge in the evening to forage for food. Adult lobsters are key predators in many benthic habitats with their diets consisting of slow-moving or stationary bottom-dwelling invertebrates including sea urchins, mussels, gastropods, clams and snails (Lipcius and Cobb, 1994). Juvenile lobsters also forage at night and will eat a similar diet of invertebrates, only smaller individual prey. During feeding, prey organisms are seized and maneuvered using the anterior periopods or maxillipeds, while the mandibles carry out mechanical digestion and are capable of crushing hard mollusk shell (Herrnkind, et. al. 1975). Little is known about the dietary requirements of the larval phase, plankton sized lobsters.

Larger animals such as sharks and finfish frequently prey upon adult Caribbean spiny lobsters. Studies indicate that Caribbean spiny lobsters are highly selective of the dens they choose to live in and the location of these crevices. Their evening movements away from and subsequent return to their dens illustrates the spatial orientation they have to their immediate habitats (Herrnkind, 1980).

Reproduction

Reproduction in the Caribbean spiny lobster occurs almost exclusively in the deep reef environment once mature individuals have made the permanent transition from the shallow seagrass nursery to the ocean coral reef system. Spawning season is in the spring and summer, however autumnal reproduction has been known to occur in some situations (Kanciruk and Herrnkind, 1976). The gestation period for eggs is about a month. Eggs are orange when they are fresh and brown when they are close to hatching. Studies have found that the initiation of spawning is related to water temperature with an optimal water temperature for mating of 24 degrees centigrade (Lyons, et. al., 1981).

Reproductive fecundity is dependent upon the size of the individual as well as the geographic area in which the lobster lives. Reproductive efficiency for a given size in a given area can be determined using the relationship between fecundity and carapace length. A study conducted in South Florida found that differences exist between the fecundity/carapace length relationships of individuals living in the Dry Tortugas from individuals living in the Upper and Middle Florida Keys. Based on data provided from each location, an Index of Reproductive Potential was calculated using the model developed by Kanciruk and Herrnkind (1976):

$$\text{Index} = (A \times B \times C)/D$$

Where:
A = number of females in size class/total females
B = propensity of size class to carry eggs
C = egg carrying capacity of size class female
D = constant (31.27) – present to set the 76-80 mm size class index to 100 as the standard.

Choice of mate is determined by the female as well as inter-male aggression, where larger males will prevent a smaller male from courting a female (Lipcius and Cobb, 1994).

Females mate only once during a season, while males can fertilize multiple females. During mating, the male will flick his antennules over the anterior of the female and scrape at her with the third walking legs. The male follows the female around continually trying to lift the female up and embrace her. This pattern continues until the female acquiesces and they each stand on their walking legs while the male deposits the spermatophore mass on the female sternum (Atema and Cobb, 1980). Females bearing eggs will usually live in solitary dens and infrequently forage for food (Lyons, et. al., 1981). Large adult females will produce more broods, as well as spawn eggs earlier in the reproductive period than younger females since younger individuals molt earlier in the reproductive period.

Growth and Molting

The life cycle of the Caribbean spiny lobster provides larvae with the potential to travel long distances for periods ranging from a few months to almost two years. During this time, the larval lobsters remain near the surface of the water. Maximum potential dispersal distances differ from one region to another and are primarily dependent on the currents in the area. A gyre in an area where lobster eggs have hatched may keep the larva in the same geographic area, however most of the time the larva are transported out of the area, sometimes hundreds of miles (Lee, et. al., 1994). Once the planktonic lobsters reach about 35 mm they are large enough to settle down as post larval pueruli in shallow benthic environments to grow. Growth in juveniles is rapid with most reaching a carapace length of 60-70 mm within about two years (Herrnkind, 1980). Once the lobsters reach about 70 mm and begin to sexually mature, the young *P. argus* emigrate from the nursery to deeper offshore reef environments.

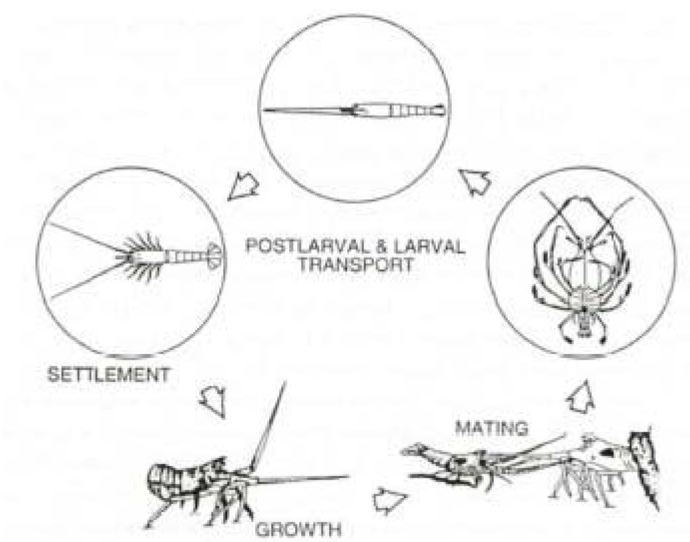

Figure 5.2.3: The Life Cycle of *Panulirus argus* (Lipcius and Cobb, 1994).

Physical growth of lobsters is achieved through molting. A thorough understanding of the molt cycle of the Caribbean spiny lobster is an important component to the management of this fishery because the catchability and captive behavior of crustaceans is directly related to the animal's proximity to molting. The molt cycle begins with the intermolt period, the time when a new cuticle is being created, tissue growth is rapid and the lobster actively forages. This period of time culminates in ecdysis, which is shedding the old cuticle or molting (Lipcius and Herrnkind, 1982).

Molting occurs primarily at night. Possible reasons for nocturnal ecdysis include decreasing the risk of cannibalism by other members of this gregarious species, and decreasing diurnal predation risks. The first action to occur during molting is the rupture of the thoracoabdominal membrane followed by a rising of the dorsal part of the cephalothorax; this action frees the eyes, bases of antennae and antennules. A series of peristaltic contractions causes the removal of the abdomen from the old cuticle, while writhing motions free the cephalothorax and attached structures. A few final wriggles and contractions terminating in a tail flip completely segregates the lobster from its old cuticle. Once molted, the lobster seeks immediate shelter, as they are especially vulnerable until their new cuticle becomes hardened (Lipcius and Herrnkind, 1982). For adult lobsters, molts average about two and a half times each year. The entire molting event takes approximately ten minutes. The new exoskeleton will take about 12 days from the start of the molt to harden such that it cannot be dented; however the shell is not completely formed until the 28^{th} day (Williams, 1984).

Studies found that feeding rates significantly increase in the time preceding a molt to accommodate the increasing metabolic needs associated with new cuticle formation. About a week before ecdysis, daily food intake for the Caribbean spiny lobster decreases rapidly, in correlation with a reduction in demanding activities such as locomotion and foraging. In the few days before and the time during ecdysis, feeding ceases altogether and the lobster becomes socially reclusive. Within a week of the molting event, *P. argus* will display maximal feeding, foraging and locomotor activity rates to accommodate for the active tissue growth that occurs (Lipcius and Herrnkind, 1982). The dramatic swings in feeding and foraging behavior associated with the molting cycle influences the success of fishermen when capturing this species. The highest catchability of spiny lobster is expected immediately following molting because lobsters are actively foraging at this time and are therefore more likely to accept bait. Conversely, the lowest catachability of spiny lobster is expected before molting when foraging decreases and the lobster becomes less mobile (Lipcius and Herrnkind, 1982).

Growth and Mortality Rates

Despite the wide body of literature on this species, limited information is available on the growth and aging of the Caribbean spiny lobster due in part to the molting habits of lobsters interfering with tagging efforts. Consequently, length data, which is substantially easier and less costly to collect, has been the dominant source of information used to estimate growth in *P. argus.* The limited quantitative information that exists on growth for this species at various locations has been compiled in a doctoral thesis by Jaime Manuel Gonzalez-Cano (1991) and was graphed below using the von Bertalanffy growth model.

$$L = Linf\,[1-e(-k(t-to))]$$

Where:
L = length of the organism at time t
Linf = asymptotic average length achieved
K = growth rate with units 1/time

T_0 = time when the length of the organism would be zero

As with any fished population, especially one with poor aging information, natural mortality rates for Caribbean spiny lobster populations have been difficult to isolate from fished rates of mortality.

Locomotion and Migration

The Caribbean spiny lobster achieves locomotion by using the five pairs of walking legs attached to the cephalothorax and can swim (backward) for brief periods using its tail for propulsion (Lipcius and Cobb, 1994). Patterns of movement in *Panulirus argus* fall into the following categories: homing, nomadism and migration. Throughout most of their life, *P. argus* is a shelter dweller during the day and forages at night. Evening movements within the home range are directed; lobsters are apparently aware of their location at all times and can find the way back to the den of origin even if detours are caused by predators or divers. Nomadism is the movement that occurs in juvenile lobsters away from the nursery habitat and to the offshore reefs. Migration is the direct movement of an entire population or sub-population over a long distance for a given period of time (Herrnkind, 1980).

Mass movements (2-60 individuals) of Caribbean spiny lobsters occur annually throughout the geographic range of the species and are dependent on latitude and climactic factors. Observed locations for the migration include Bermuda in October, the Bahamas and Florida in late October and early November, and the Yucatan and Belize in December (Herrnkind, 1985). This mass migratory behavior is thought to have evolved in response to deteriorating conditions that resulted from the periods of glaciations that occurred over the past several 100,000 years. Thus, the migration and queuing behavior became specialized by the natural selection on individuals of the harsh winters during periods of glaciations. Gonads during the migration in the fall are inactive, as they don’t begin to mature until the late winter (Herrnkind, 1985).

The first autumn storm in the tropics usually brings a severe drop in water temperature of about five degrees centigrade, as well as high northerly winds of up to 40 km/h and large sea swells. The shallow regions that the lobsters exploit during the summer months become turbid and cold, initiating the diurnal migration of thousands of lobsters to evade these conditions. The Caribbean spiny lobster is highly susceptible to severe winter cooling and will exhibit reduced feeding and locomotion at temperatures 12-14 degrees centigrade; molting individuals usually perish under these conditions. According to Herrnkind (1985), the behavioral changes observed in *P. argus* as well as the known biological information about the species lends credence to the idea that individuals migrate to evade the stresses of the cold and turbidity in the winter.

Caribbean spiny lobster initiate the migratory behavior by queuing, the single file formation of migrating individuals initiated by visual or tactile stimuli. Queuing is maintained by establishing contact between the antennules of one individual and anterior walking legs of another. Biologically, the queuing behavior is an important hydrodynamic drag reduction technique for the migration of individuals over long distances (Bill and Herrnkind, 1976). Studies done by tagging individuals found that during the migration, individuals tended to move distances of 30-50 km (Herrnkind, 1985).

Migratory movement lasts for variable periods of time and is believed to be dependent on the total number of migratory lobsters. One study in the Bahamas in 1971 found the migration to take six hours while another study in the same location in 1969 found the migration to take five days. It is thought that the more lobsters present, the longer the migration will last in order to avoid over crowding of shelters at their final destination (Kanciruk and Herrnkind, 1978). Once individuals reach sheltered habitats located in deeper water, such as a deep reef site, the migratory queuing behavior ends and the lobsters disperse.

5.2.2 Protected Species

There are 32 different species of marine mammals that may occur in the EEZ of the Gulf of Mexico, South Atlantic, and Caribbean. All 32 species are protected under the MMPA and six are also listed as endangered under the ESA (i.e., sperm, sei, fin, blue, humpback and North Atlantic right whales). There are no known interactions between spiny lobster fisheries and marine mammals. Other species protected under the ESA occurring in the Gulf of Mexico, South Atlantic, and Caribbean include five species of sea turtle (green, hawksbill, Kemp's ridley, leatherback, and loggerhead); the smalltooth sawfish, and two *Acropora* coral species (elkhorn [*Acropora palmata*] and staghorn [*A. cervicornis*]). A discussion of these species is below. Designated critical habitat for the North Atlantic right whale also occurs within the South Atlantic region. Critical habitat has been designated for green, hawksbill, and leatherback sea turtles in the Caribbean region, however, 99% or more of these areas are contained within state waters.

5.2.2.1 ESA-Listed Sea Turtles

Green, hawksbill, Kemp's ridley, leatherback, and loggerhead sea turtles are all highly migratory and travel widely throughout the South Atlantic. The following sections are a brief overview of the general life history characteristics of the sea turtles found in the South Atlantic region. Several volumes exist that cover more thoroughly the biology and ecology of these species (i.e., Lutz and Musick (eds.) 1997, Lutz et al. (eds.) 2002).

Green sea turtle hatchlings are thought to occupy pelagic areas of the open ocean and are often associated with *Sargassum* rafts (Carr 1987, Walker 1994). Pelagic stage green sea turtles are thought to be carnivorous. Stomach samples of these animals found ctenophores and pelagic snails (Frick 1976, Hughes 1974). At approximately 20 to 25 cm carapace length, juveniles migrate from pelagic habitats to benthic foraging areas (Bjorndal 1997). As juveniles move into benthic foraging areas a diet shift towards herbivory occurs. They consume primarily seagrasses and algae, but are also know to consume jellyfish, salps, and sponges (Bjornal 1980, 1997; Paredes 1969; Mortimer

1981, 1982). The diving abilities of all sea turtles species vary by their life stages. The maximum diving range of green sea turtles is estimated at 110 m (360 ft) (Frick 1976), but they are most frequently making dives of less than 20 m (65 ft.) (Walker 1994). The time of these dives also varies by life stage. The maximum dive length is estimated at 66 minutes with most dives lasting from 9 to 23 minutes (Walker 1994).

The **hawksbill's** pelagic stage lasts from the time they leave the nesting beach as hatchlings until they are approximately 22-25 cm in straight carapace length (Meylan 1988, Meylan and Donnelly 1999). The pelagic stage is followed by residency in developmental habitats (foraging areas where juveniles reside and grow) in coastal waters. Little is known about the diet of pelagic stage hawksbills. Adult foraging typically occurs over coral reefs, although other hard-bottom communities and mangrove-fringed areas are occupied occasionally. Hawksbills show fidelity to their foraging areas over several years (van Dam and Diéz 1998). The hawksbill's diet is highly specialized and consists primarily of sponges (Meylan 1988). Gravid females have been noted ingesting coralline substrate (Meylan 1984) and calcerous algae (Anderes Alvarez and Uchida 1994), which are believed to be possible sources of calcium to aid in eggshell production. The maximum diving depths of these animals are not known, but the maximum length of dives is estimated at 73.5 minutes. More routinely dives last about 56 minutes (Hughes 1974).

Kemp's ridley hatchlings are also pelagic during the early stages of life and feed in surface waters (Carr 1987, Ogren 1989). Once the juveniles reach approximately 20 cm carapace length they move to relatively shallow (less than 50m) benthic foraging habitat over unconsolidated substrates (Márquez-M. 1994). They have also been observed transiting long distances between foraging habitats (Ogren 1989). Kemp's ridleys feeding in these nearshore areas primarily prey on crabs, though they are also known to ingest mollusks, fish, marine vegetation, and shrimp (Shaver 1991). The fish and shrimp Kemp's ridleys ingest are not thought to be a primary prey item but instead may be scavenged opportunistically from bycatch discards or from discarded bait (Shaver 1991). Given their predilection for shallower water, Kemp's ridleys most routinely make dives of 50 m or less (Soma 1985, Byles 1988). Their maximum diving range is unknown. Depending on the life stage a Kemp's ridleys may be able to stay submerged anywhere from 167 minutes to 300 minutes, though dives of 12.7 minutes to 16.7 minutes are much more common (Soma 1985, Mendonca and Pritchard 1986, Byles 1988). Kemp's ridleys may also spend as much as 96% of their time underwater (Soma 1985, Byles 1988).

Leatherbacks are the most pelagic of all ESA-listed sea turtles and spend most of their time in the open ocean. However, they will enter coastal waters and are seen over the continental shelf on a seasonal basis to feed in areas where jellyfish are concentrated. Leatherbacks feed primarily on cnidarians (medusae, siphonophores) and tunicates. Unlike other sea turtles, leatherbacks' diets do not shift during their life cycles. Because leatherbacks' ability to capture and eat jellyfish is not constrained by size or age, they continue to feed on these species regardless of life stage (Bjorndal 1997). Leatherbacks are the deepest diving of all sea turtles. It is estimated that these species can dive in excess of 1000 m (Eckert et al. 1989) but more frequently dive to depths of 50 m to 84 m

(Eckert et al. 1986). Dive times range from a maximum of 37 minutes to more routine dives of 4 to 14.5 minutes (Standora et al. 1984, Eckert et al. 1986, Eckert et al. 1989, Keinath and Musick 1993). Leatherbacks may spend 74% to 91% of their time submerged (Standora et al. 1984).

Loggerhead hatchlings forage in the open ocean and are often associated with Sargassum rafts (Hughes 1974, Carr 1987, Walker 1994, Bolten and Balazs 1995). The pelagic stage of these sea turtles are known to eat a wide range of things including salps, jellyfish, amphipods, crabs, syngnathid fish, squid, and pelagic snails (Brongersma 1972). Stranding records indicate that when pelagic immature loggerheads reach 40-60 cm straight-line carapace length they begin to live in coastal inshore and nearshore waters of the continental shelf throughout the U.S. Atlantic (Witzell 2002). Here they forage over hard- and soft-bottom habitats (Carr 1986). Benthic foraging loggerheads eat a variety of invertebrates with crabs and mollusks being an important prey source (Burke et al. 1993). Estimates of the maximum diving depths of loggerheads ranges from 211 m to 233 m (692-764ft.) (Thayer et al. 1984, Limpus and Nichols 1988). The lengths of loggerhead dives are frequently between 17 and 30 minutes (Thayer et al. 1984, Limpus and Nichols 1988, Limpus and Nichols 1994, Lanyan et al. 1989) and they may spend anywhere from 80 to 94% of their time submerged (Limpus and Nichols 1994, Lanyan et al. 1989).

5.2.2.2 ESA-Listed Marine Fish

The historical range of the **smalltooth sawfish** in the U.S. ranged from New York to the Mexico border. Their current range is poorly understood but believed to have contracted from these historical areas. In the South Atlantic region, they are most commonly found in Florida, primarily off the Florida Keys (Simpfendorfer and Wiley 2004). Only two smalltooth sawfish have been recorded north of Florida since 1963 (the first was captured off of North Carolina in 1999 (Schwartz 2003) and the other off Georgia 2002 [Burgess unpublished data]). Historical accounts and recent encounter data suggest that immature individuals are most common in shallow coastal waters less than 25 m (Bigelow and Schroeder 1953, Adams and Wilson 1995), while mature animals occur in waters in excess of 100 meters (Simpfendorfer pers comm. 2006). Smalltooth sawfish feed primarily on fish. Mullet, jacks, and ladyfish are believed to be their primary food resources (Simpfendorfer 2001). Smalltooth sawfish also prey on crustaceans (mostly shrimp and crabs) by disturbing bottom sediment with their saw (Norman and Fraser 1937, Bigelow and Schroeder 1953).

5.2.2.3 ESA-Listed Marine Invertebrates

Elkhorn (*Acropora palmata)* and staghorn (*A. cervicornis*) coral were listed as threatened under the ESA on May 9, 2006. The Atlantic *Acropora* Status Review (*Acropora* Biological Review Team 2005) presents a summary of published literature and other currently available scientific information regarding the biology and status of both these species.

Elkhorn and **staghorn** corals are two of the major reef-building corals in the wider Caribbean. In the Gulf of Mexico, South Atlantic, and Caribbean they are found most commonly in the Florida Keys and U.S. Virgin Islands, though colonies exist in Puerto Rico and Flower Gardens National Marine Sanctuary in the Gulf of Mexico. The depth range for these species ranges from <1 m to 60 m. The optimal depth range for elkhorn is considered to be 1 to 5 m depth (Goreau and Wells 1967), while staghorn corals are found slightly deeper, 5 to 15 m (Goreau and Goreau 1973).

All Atlantic *Acropora* species (including elkhorn and staghorn coral) are considered to be environmentally sensitive, requiring relatively clear, well-circulated water (Jaap et al. 1989). Optimal water temperatures for elkhorn and staghorn coral range from 25° to 29°C (Ghiold and Smith 1990, Williams and Bunkley-Williams 1990). Both species are almost entirely dependent upon sunlight for nourishment, contrasting the massive, boulder-shaped species in the region (Porter 1976, Lewis 1977) that are more dependent on zooplankton. Thus, Atlantic *Acropora* species are much more susceptible to increases in water turbidity than some other coral species.

Fertilization and development of elkhorn and staghorn corals is exclusively external. Embryonic development culminates with the development of planktonic larvae called planulae (Bak et al. 1977, Sammarco 1980, Rylaarsdam 1983). Unlike most other coral larvae, elkhorn and staghorn planulae appear to prefer to settle on upper, exposed surfaces, rather than in dark or cryptic ones (Szmant and Miller 2006), at least in a laboratory setting. Studies of elkhorn and staghorn corals indicated that larger colonies of both species[3] had higher fertility rates than smaller colonies (Soong and Lang 1992).

5.3 Description of the Economic and Social Environment

5.3.1 Introduction

In September 2006, the Working Group on Caribbean spiny lobster of the Western Central Atlantic Fishery Commission (WECAFC) met in Merida, Mexico, to attend the Regional Workshop on the Assessment and Management of Caribbean Spiny Lobster. The primary objective of the workshop was to "review and update the status of Caribbean spiny lobster resource at national and regional levels to seek regional agreement on strategies to address management problems" (WECAFC 2007, p. 2). At the workshop were representatives from The Bahamas, Belize, Brazil, Colombia, Costa Rica, Cuba, Dominican Republic, France (Martinique and Guadeloupe), Haiti, Honduras, Jamaica, Mexico, Nicaragua, the Turks and Caicos Islands, United States of America (also representing Puerto Rico and the U.S. Virgin Islands), and Venezuela, as well as the Caribbean Fishery Management Council (CFMC) and Caribbean Regional Fishery Mechanism (CRFM). The estimated status of the national populations of Caribbean spiny lobster of the participating countries is presented in the Table 5.3.1.

In keeping with the recommendation to allow about 50 percent of the stock to reach maturity, the national representatives at the workshop agreed to a minimum harvest size of 74 mm (2.91 inches) cephalothorax length. Nations with minimum size limits greater than 76 mm were encouraged to retain the larger minimum size limits because of the additional conservation and economic benefits they provide.

Table 5.3.1. Estimated status of national populations of Caribbean spiny lobster of participating countries. *Source*: WECAFC 2007).

Status of Stock	Countries
Under-exploited	Venezuela (some areas)
Fully-exploited or stable	Antigua & Barbuda, Belize, Costa Rica, Cuba, Mexico, Puerto Rico & U.S. Virgin Islands, Turks & Caicos, USA (Florida), Venezuela (some areas)
Over-exploited	Nicaragua, Jamaica, Dominican Republic, Brazil, Colombia, Honduras
Unknown	Bahamas, Guadeloupe, Haiti, Martinique, other Less Antilles countries

5.3.2. Global Commercial Production of Lobster & Caribbean Spiny Lobster

Since 1962, average annual global harvest of Caribbean spiny lobster has been less than such harvest for American and rock lobster (*Jasus* spp.). See Table 5.3.2. Annual global production of Caribbean spiny lobster averages about 54 percent of all spiny lobster production (*Panulirus* spp. and *Palinurus* spp.) and about 17 percent of global production of all lobster.

Table 5.3.2. Global Production of Lobster, including Caribbean Spiny Lobster (CSL), 1962 through 2003. *Source*: FAO Fishstats, reported landings.

According to the Food and Agriculture Organization of the United Nations (FAO), world capture of Caribbean spiny lobster has greatly increased from 1950 through 2005, starting at a low of 2,957 metric tons in 1950 to 35,540 metric tons in 2005 (http://www.fao.org/fishery/species/3445). Twice annual global production has exceeded 40,000 metric tons; and since 1984, annual global production has varied between 30,000 and 41,000 metric tons. See Figure 5.3.2.

Among the countries that harvested Caribbean spiny lobster from 1996 through 2005 and reported those landings to the FAO, the Bahamas had the largest average annual landings, followed by Cuba, Brazil, Nicaragua, and the United States. See Figure 5.3.3 and Table 5.3.3. U.S. imports of frozen spiny lobster represented an average of 87 percent of reported annual Caribbean spiny lobster landings from countries other than the U.S. and Cuba. See Figure 5.3.4.

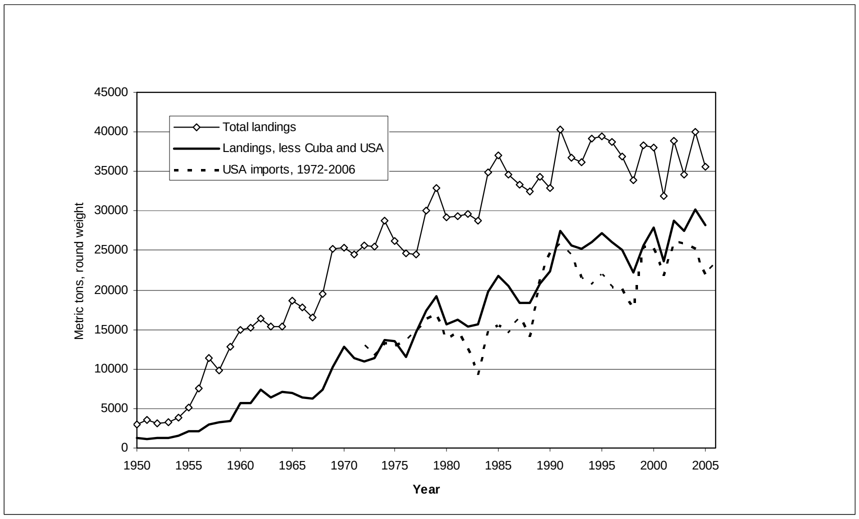

Figure 5.3.4. Global Landings of Caribbean Spiny Lobster and U.S. Imports of Frozen Spiny Lobster. Source: FAO Fishstats.

In 2003, the top five countries with landings of *Panulirus*, *Palinurus*, and *Janus* species were Australia (21.83 percent), The Bahamas (13.78 percent), which combined to produce approximately 35 percent of the world metric ton capture, Indonesia (8.80 percent), Brazil (8.27 percent), and Cuba (8.16 percent) (FAO Fishstats).

Five species of lobster are both commercially and recreationally harvested in U.S. waters. These species are: American lobster (*Homarus americanus*), California spiny lobster (*Panulirus interruptus*), Caribbean spiny lobster (*Panulirus argus*), banded or Hawaiian spiny lobster (*Panulirus marginatus*), and Spanish slipper lobster (*Scyllarides aequinoctialis*). The American lobster is a "true" lobster, whereas the others are members of the spiny/rock lobster group. In the southeast, spotted lobster[5] (*Panulirus guttatus*), ridged slipper lobster (*Scyllarides nodifer*), and smooth tail lobster (*Panulirus laevicauda*) are taken by recreational fishermen only. Since 2000, commercial landings of Hawaiian spiny lobster, which is also known as banded spiny lobster (*Panulirus marginatus*), have declined from 10,394 pounds in 2000 to 4,870 pounds in 2004.

All of the domestic catch of California spiny lobster is taken in California; however, most of the catch has been marketed in Asia and France because dealers from foreign markets have paid lobster fishers prices ranging from $6.75 to $8.00 per pound (California Department of Fish & Game, 2003; Cascorbi, 2004).[6] However, since 2000, California lobster fishers have attempted to reestablish domestic markets for California spiny lobster because of depressed overseas markets.

From 1962 through 2003, continental U.S. commercial landings of Caribbean spiny lobster have ranged from a low of 1,424 metric tons in 1962 to a high of 5,358 metric tons in 1972. See Table 4. Since 1992, an average of 2,626 metric tons has been landed in the continental U.S. annually. Puerto Rico had no reported commercial landings of Caribbean spiny lobster from 1962 through 1998 and the U.S. Virgin Islands had no such landings from 1962 through 1974. Prior to 1999, over 95 percent of commercial landings occurred in the contiguous U.S.; however, since 1999 landings in Puerto Rico have increased resulting in its productive share rising from zero up to a high of over 10 percent in 2001. See Table 5.3.4.

Commercial landings of Caribbean spiny lobster in the contiguous United States have been reported in Alabama, Georgia, Florida, Mississippi, South Carolina, and Texas since 1962; however, Florida dominates. In 35 of the 45 years from 1962 through 2006, Florida landings accounted for all of the annual commercial landings; and in each of the other 10 years, annual landings in Florida represented at least 94 percent of the total pounds commercially landed that year. This explains why the species is also called the Florida spiny lobster. See Table 5.3.5.

Table 5.3.4. U.S., U.S. Virgin Islands and P.R. Commercial Production of Caribbean Spiny Lobster, 1962 – 2003. *Source*: FAO Fishstats.

[5] *Panulirus guttatus* is also called a spotted spiny lobster, Guinea lobster, rock lobster, and spotted crawfish.
[6] The species is also harvested along Mexico's west coast; however, most of the catch occurs in California.

The commercial value of a Caribbean spiny lobster is found entirely in its tail. As such, most international trade of the species has been in frozen lobster tails. However, whole cooked frozen lobsters, live lobsters, and meat are traded as well. Although there is a small live market in the U.S., most is sold as frozen tails. Spiny lobsters imported into the U.S. that originate from the Caribbean basin are typically tailed, sorted by weight, packed in 10-pound boxes, and shipped frozen to the U.S. for consumption. Size is the critical element in the pricing of lobster tails. Caribbean lobster tails are sorted by the industry into the following sizes: 4 oz, 5 oz, 6 oz, 7 oz, 8 oz, 9 oz, 10 oz, 11 oz, 12 – 14 oz, 14 – 16 oz, 16 – 20 oz, and 20 – 24 oz. A 5-oz tail weighs from 4.5 to 5.4 oz, while a 6-oz tail weighs from 5.5 to 6.4 oz.

The Harmonized Commodity Description and Code System (HS) defines rock lobster as lobster within the family *Palinuridae*, which includes *Jasus* species (spp.), *Justitia* spp., *Linuparus* spp., *Palinurus* spp., *Palinustus* spp., *Panulirus* spp., *Projasus* spp., and *Puerulus* spp. The experiences of NOAA law enforcement officers suggest that boxes of frozen lobster that originate from the Caribbean basin are almost exclusively Caribbean spiny lobster (*Panulirus argus*) tails, with the exception being boxes from shipped from Brazil. Brazil also exports Brazilian spiny lobster (*Panulirus lauvicauda*), and some shipments have contained both Caribbean and Brazilian spiny lobsters. The Government of Brazil is acting to implement a rule that would not allow the two species to be exported in the same box.

Caribbean spiny lobster, Cape rock lobster (*Jasus lalandii*) and Australian spiny lobster (*Panulirus cygnus*) make up most, but not all, of the spiny and rock lobster found on the U.S. mainland market. California spiny lobster makes up about 2 percent of U.S. landings of spiny lobster. From 1997 through 2006 imports of spiny lobster have comprised more than 90 percent of U.S. supply. See Table 5.3.6.

Table 5.3.6. U.S. Supply of Spiny Lobsters, 1997 – 2006. *Source*: Fisheries of the United States 2006.

2004	5,938,000	94,720,000	100,658,000	7,506,000	93,152,000	94.10%	87,214,000
2005	4,144,000	86,987,000	91,131,000	7,766,000	83,365,000	95.45%	79,221,000
2006	5,605,000	85,752,000	91,357,000	14,670,000	76,687,000	93.86%	71,082,000

From 2002 through 2007, total U.S. imports of frozen rock lobster and other sea crawfish (*Palinurus* spp., *Panulirus* spp. and *Jasus* spp.) averaged 12,374.2 metric tons with a value of about $355.5 million, annually.[7] The top 5 countries of origin of those imports by volume (metric tons) are Brazil, The Bahamas, Australia, Honduras and Nicaragua,

[7] Harmonized import code HS 03 includes fish, crustaceans, mollusks, and aquatic invertebrates. HS 0306 includes crustaceans only. HS 030611000 includes rock lobster and other sea crawfish, frozen. HS 0306210000 includes rock lobster and other sea crawfish, not frozen.

who collectively represent about 68 percent of the total volume of those imports. See Table 5.3.7. Those same countries account for about 78 percent of the total dollar value of those imports. Of the top 10 countries of origin by volume of frozen rock lobster and other sea crawfish imports, 6 of those countries (Brazil, The Bahamas, Honduras, Nicaragua, Colombia and Belize) export Caribbean spiny lobster to the U.S.

Rock lobster and other sea crawfish are also imported not frozen; however, frozen imports dominate. From 2002 through 2007, U.S. imports of not frozen rock lobster (HS 0036210000) averaged 164 metric tons with a value of $2.9 million annually, as compared with about 12,372 metric tons with a value of $355.5 million for frozen. The top five countries of origin during those years by volume were Mexico (122 metric tons), Australia (10 metric tons), Peoples Republic of China (5.5 metric tons), Taiwan (4.6 metric tons), and the United Kingdom (3.3 metric tons). Mexico is exporting increasing numbers of live Caribbean spiny lobster, and it is assumed that the bulk of its exports of not frozen rock lobster are these live specimens.

Table 5.3.7. Top 20 Countries of Origin for Imports of Frozen Rock Lobster and Other Sea Crawfish (HS 0036110000), 6-Year Average, 2002 – 2007. Source: U.S. Customs Data.

5.3.3 Federal Management of Caribbean Spiny Lobster under the MSA

The Caribbean spiny lobster in the U.S. Exclusive Economic Zone (EEZ) of the Atlantic Ocean and Gulf of Mexico is jointly managed by the South Atlantic and Gulf of Mexico Fishery Management Councils through the Fishery Management Plan for Spiny Lobster (Spiny Lobster FMP) in the Gulf of Mexico and South Atlantic. In the U.S. EEZ of the Caribbean Sea surrounding Puerto Rico and the U.S. Virgin Islands, the resource is managed by the Caribbean Fishery Management Council (Caribbean FMC) through its Spiny Lobster FMP. In the Gulf and South Atlantic, the commercial fishery and, to a large extent, the recreational fishery occurs off South Florida, primarily in the Florida Keys. In order to streamline a management process that involves both state and federal jurisdictions, the Gulf and South Atlantic Spiny Lobster FMP basically extends the Florida Fish and Wildlife Commission's rules regulating the state fishery to the southeastern U.S. EEZ from North Carolina to Texas.

The Gulf and South Atlantic Spiny Lobster FMP was implemented on July 26, 1982 (47 *Federal Register (FR)* 29203). The FMP, for the most part, extended Florida's rules of regulating the fishery to the EEZ throughout the range of the fishery; and since 1982, it has been amended seven times.

The Gulf and South Atlantic Spiny Lobster FMP was first amended on July 15, 1987 (52 *FR* 22659) with certain rules deferred and implemented on May 11, 1998 (53 *FR* 17196) and on July 30, 1990 (55 *FR* 26448). This amendment (Amendment 1) updated the rules to be more compatible with Florida law. Amendment 1 required a commercial permit, limited possession of undersized lobsters as attractants, required a live well, modified recreational possession and seasonal regulations, modified closed season regulations, required the immediate release of egg-bearing lobsters, modified the minimum size limit, required a permit to separate the tail at sea and prohibited possession or stripping of egg-bearing slipper lobsters.

Amendment 2 was approved on October 27, 1989 (54 *FR* 48059) and provided a regulatory amendment procedure for instituting future compatible state and federal rules without amending the Spiny Lobster FMP to ensure federal-state compatibility. Amendment 2 modified the problems/issues and objectives of the FMP, modified the statement of optimum yield, established a protocol and procedure for an enhanced cooperative management system, and added to the vessel safety and habitat sections of the FMP.

Amendment 3 was implemented on March 25, 1991 (56 *FR* 12357) and contained provisions for adding a scientifically measurable definition of overfishing; an action plan to prevent overfishing, should it occur, as required by the National Standards of the Magnuson-Stevens Fisheries Conservation and Management Act (50 *CFR* Part 600); and the requirement for collection of fees for the administrative cost of issuing permits.

The first Regulatory Amendment to the Spiny Lobster FMP was implemented on December 30, 1992 (Regulatory Amendment 1). Regulatory Amendment 1 addressed: 1) the extension of the Florida spiny lobster trap certificate system for reducing the number of traps in federal waters off Florida, 2) the revision of the FMP's commercial permitting requirements, 3) the limitation of the number of live undersize lobster used as attractants for baiting traps, 4) the specification of gear allowed for commercial fishing in the U.S. EEZ off Florida, 5) the specification of the possession limit of spiny lobsters by persons diving at night, 6) the requirement of lobsters harvested by divers to be measured without removing from the water, and 7) the specification of uniform trap and buoy numbers for federal waters off Florida. All of these changes were implemented through the framework procedure of the FMP as established by Amendment 2.

The second Regulatory Amendment (Regulatory Amendment 2) was approved in March 1993 and implemented in August 1993 (58 *FR* 38978). Regulatory Amendment 2 addressed: 1) a change in the days for the special recreational season in federal waters off Florida, 2) a prohibition on night-time harvest off Monroe County, Florida, during that season, 3) specifies allowable gear during that season, and 4) provides for different bag limits during that season off the Florida Keys and federal waters off other areas of Florida.

Amendment 4 was implemented on September 13, 1995 (60 *FR* 41828). It provided a bag limit of 2 lobsters per day for all fishers in federal waters off North Carolina, South Carolina, and Georgia (50 *CFR* §640.23).

Amendment 5 of the Spiny Lobster FMP was part of the Comprehensive Amendment Addressing Essential Fish Habitat in Fishery Management Plans of the South Atlantic Region, which the National Marine Fisheries Service (NMFS) approved on June 3, 1999. Amendment 6 was part of the Comprehensive Amendment Addressing Sustainable Fishery Act Definitions and Other Required Provisions in FMPs of the South Atlantic Region. NMFS approved the Comprehensive Amendment in October 1998 and it was implemented on December 2, 1999 (64 *FR* 59126). Similarly, the Gulf of Mexico Fishery Management Council developed Generic Amendments to address Essential Fish Habitat and Sustainable Fishery Act. The former described the distribution and relative abundance of juvenile and adult spiny lobster for offshore, near-shore, and estuarine habitats of the Gulf; and the latter updated the description of the spiny lobster fisheries and provided fishing community assessment information for Monroe County, Florida.

Amendment 7 was implemented under a Generic Amendment that created the two Tortugas Marine Reserves: Tortugas North (120 square nautical miles) and Tortugas South (60 square nautical miles). This amendment prohibits fishing for or possession of spiny lobster in either of the two reserves. It was implemented on July 19, 2002 (67 *FR* 47467).

Currently, harvest or possession of spiny lobsters in the U.S. South Atlantic EEZ is regulated in 50 CFR 640. According to 50 CFR 640.4, anyone who sells, trades, or barters or attempts to sell, trade, or barter spiny lobster that was harvested or possessed in the EEZ off Florida, or harvested in the EEZ other than off Florida and landed in Florida must have licenses and certificates specified to be a commercial harvester, as defined in

Rule 46-24.002(a), Florida Administrative Code. Similarly, any person who sells, trades, or barters or attempts to sell, trade, or barter a Caribbean spiny lobster harvest in the U.S. EEZ other than off Florida, a Federal vessel permit must be issued and on board the harvesting vessel (50 CFR §640.4(a)(1)(ii)).

The commercial and recreational fishing season for spiny lobster in the EEZ off Florida and the EEZ off the Gulf States, other than Florida, begins on August 6 and ends on March 31 (50 CFR §640.20(b)). No person may possess a Caribbean spiny lobster in or from the Gulf and South Atlantic EEZ with a carapace length of 3.0 inches (7.62 cm) or less or a separated tail with a length less than 5.5 inches (13.97 cm) (50 CFR §640.21(b)). Current regulation prohibits the possession of a spiny lobster or parts thereof in or from the Gulf and South Atlantic EEZ from which the eggs, swimmerettes or pleopods have been removed (50 CFR §640.21(a)); and requires any berried spiny lobster to be returned immediately to the water (50 CFR §640.7(g)).

The Caribbean Fishery Management Council manages the Caribbean spiny lobster fishery in the U.S. Caribbean EEZ and territorial seas of Puerto Rico and the U.S. Virgin Islands through the FMP for the Spiny Lobster Fishery of Puerto Rico and the U.S. Virgin Islands. The Caribbean Spiny Lobster FMP was implemented in 1985. The associated regulations include that no person may possess a Caribbean spiny lobster in or from the Caribbean EEZ with a carapace length less than 3.5 inches (8.9 cm) (50 CFR §622.37(b)).

On July 26, 2007, a Notice of Intent was published in the *Federal Register* (72 *FR* 41063) announcing the Caribbean Fishery Management Council's intent to prepare a draft environmental impact statement to describe and analyze management alternatives to be included in an amendment to its Spiny Lobster FMP and the Gulf and South Atlantic Spiny Lobster FMP. The Caribbean, Gulf and South Atlantic Fishery Management Councils have expressed concern about the effects of imports of spiny lobster that are smaller than the size limits in the U.S. spiny lobster FMPs. In many instances, imports are also undersized based on size limits established in the country of origin. The Caribbean FMC has expressed intent to amend its Spiny Lobster FMP of a minimum size limit on imported spiny lobster. NOAA Fisheries believes amendment of the Gulf and South Atlantic Spiny Lobster FMP should be addressed concurrently.

5.3.4 Other Federal Laws and Regulations that Protect Spiny Lobster

Lacey Act

The Lacey Act, as amended in 1981 (16 USC §§ 3372 et seq.) prohibits any person from importing, exporting, transporting, selling, receiving, acquiring, or purchasing in interstate or foreign commerce any fish or wildlife taken, possessed, transported, or sold in violation of any law or regulation of any state or in violation of any foreign law. For example, it is a violation of the Lacey Act to import Caribbean spiny lobster that is in violation of the exporting country's minimum harvest-size standard. Many of the countries that harvest Caribbean spiny lobster have minimum harvest size standards. See Table 5.3.8.

NOAA's Office of Law Enforcement, Southeast Region, has made several significant Lacey Act cases against individuals involved in importing undersized lobsters from Honduras, Nicaragua, The Bahamas, and Brazil.

In July 2003, a Miami man pleaded guilty to importing more than $2.8 million worth of undersized spiny lobster from Nicaragua. The man and others illegally shipped into the U.S. about 190,000 pounds of frozen spiny lobsters below Nicaragua's minimum legal size of 5 ounces (Associated Press July 3, 2003).

*: At the September 2006 Regional Workshop on the Assessment and Management of Caribbean Spiny Lobster of the Working Group on Caribbean spiny lobster of the WECAFC.

In December 2003, a Norfolk, Virginia-based seafood company and its vice president pleaded guilty in federal court in Miami to conspiracy to import more than $2 million worth of undersized spiny lobster from Nicaragua to the United States. The company purposely mislabeled boxes of frozen undersized lobster to conceal that the boxes held 2-, 3-, and 4-ounce tails, all of which were below Nicaragua's legal 5-ounce limit for lobster processing and trade (South Florida Business Journal, December 15, 2003).

In May 2006, Winn-Dixie, Inc. pleaded guilty to illegal possession, transportation, and sale of undersized Caribbean spiny lobster contrary to Florida laws and regulations and the Lacey Act. On October 29, 2002, Winn-Dixie received a shipment at one of its Florida facilities of about 6,000 pounds of Caribbean spiny lobster imported from Brazil that it purchased through a broker in Illinois. It was determined that about 4,600 pounds of lobster tail failed to meet Florida and Brazil size standards (States News Service; May 22, 2006).

Florida Keys National Marine Sanctuary and Protection Act

In November 1990, Congress passed the Florida Keys National Marine Sanctuary and Protection Act that established the Florida Keys National Marine Sanctuary (FKNMS) (Pub.L 101-605).[8] The FKNMS is comprised of 9,660 square kilometers (about 2,900 square nautical miles) of coastal waters off the Florida Keys. It extends approximately 220 miles southwest of the southern tip of the Florida peninsula and includes the world's third largest coral barrier reef. Within the Sanctuary are 24 no-take zones. Fifty-eight percent of the Sanctuary resides in Florida waters and 42 percent is in federal waters. Both NOAA and the State of Florida manage the Sanctuary. The waters of the FKNMS are within the jurisdiction of both the South Atlantic and Gulf of Mexico fishery management councils.

[8] The National Marine Sanctuary System was created in 1972. Two areas in the Florida Keys were designated as sanctuaries, the first in 1975 and the second in 1981. These areas were included in the Florida Keys National Marine Sanctuary in November 1990.

Biscayne Bay National Park

Originally established as a national monument by Congress in 1968, Biscayne Bay National Park was re-designated as a national park in 1980. The Park's purpose is to preserve and protect its rare combination of terrestrial and aquatic natural resources. The Park includes approximately 173,000 acres in Miami-Dade County, and is about 22 miles long. The park extends from shore about 14 miles to the 60-foot contour and contains about 72,000 acres of coral reefs. Under existing Supervisor's rules for the Park, several areas are closed year-round to public entry to protect sensitive resources and wildlife. This also means not taking Caribbean spiny lobster in those areas.

Buck Island Reef National Monument

Buck Island Reef National Monument (Buck Island NM) in St. Croix was established in 1961 and expanded more than twenty times in size in 2001, from 880 acres to over 19,000 acres. Its area is mostly underwater and it encompasses 7 percent of the shelf around St. Croix. Federal regulation prohibits the harvest or collection of Caribbean spiny lobster within the boundaries of the national monument (36 CFR § 7.73(a)). Virgin Islands Coral Reef National Monument (Virgin Islands NM) in St. John was established in 2001 and its area encompasses 3 percent of the St. John/St. Thomas shelf. Harvest or collection of Caribbean spiny lobster is prohibited (36 CFR § 7.46(a)). The National Park Service manages both of these national monuments.

Virgin Islands National Park

Virgin Islands National Park on St. John was established by Congress in 1956 and today is managed by the National Park Service. It comprises more than half of the island of St. John and almost 9 square miles of water surrounding the island. Virgin Islands National Park attracts almost one million visitors a year, most of them arriving on cruise ships or smaller boats. Caribbean spiny lobster may be taken by hand or hand held hook within the park (36 CFR § 7.74(e)(3)).

Dry Tortugas National Park

The Dry Tortugas National Park was established by Congress in 1992 (Public Law 102-525). Possession of Caribbean spiny lobster is prohibited within boundaries of the park unless the individual took the lobster outside the park waters and the person in possession has proper State/Federal licenses and permits (36 CFR § 7.27(b)(4)(i)). The presence of lobster aboard a vessel in park waters, while one or more persons from such vessel are overboard constitutes prima facie evidence that the lobsters were harvested from park waters in violation of the above regulation.

Past Federal Actions

Indirect, but related, past federal actions that greatly affected the Caribbean spiny lobster fishery were the Migration and Refugee Assistance Act of 1962 and Cuban Refugee

Adjustment Act of 1966. The Migration and Refugee Assistance Act authorized assistance to or in behalf of refugees in the United States, which included business loans. The Cuban Refugee Adjustment Act adjusted the status of Cuban refugees to that of lawful permanent residents, which enabled them to acquire commercial fishing vessels.[9] According to Moe (1991), many of the 300,000 Cubans who fled Cuba used those government loans to obtain boats to fish lobster in Bahamian waters.[10] When Bahamian waters were closed to U.S. fishermen, those lobster fishermen moved their operations into U.S. waters.

5.3.5 State & Territory Spiny Lobster Laws and Fisheries Histories

5.3.5.1 Florida

Up until the twentieth century, landings of spiny lobster were low because the fishery was largely a bait fishery that supported Florida's finfish industry (Labisky et al., 1980).[11] However, at the turn of the century a spiny lobster commercial fishery began to develop due to the construction of the Overseas Railroad in 1912, which allowed dealers to ship spiny lobsters to northern hotels and restaurants (ibid., p. 30). The first legislation enacted by the State of Florida (State) to conserve the supply of spiny lobster in response to the growing commercial retail trade was in 1919 when it implemented a seasonal closure from March 1 to June 1, but which allowed the taking of lobster for research, fish bait, or propagation throughout the year. Two years later the closed season was changed to March 21 to June 21.

In the nineteenth century and up until the early twentieth century, spiny lobsters were typically harvested in shallow waters of Key West with cast nets, gill nets, haul seines, and grains (Labisky et al., 1980). Continuous increases in commercial demand in the early 1900s, however, stimulated expansion of the fishery so that by 1922 the primary fishing grounds extended from the shallow waters surrounding Key West to a "25-mile linear zone that encompassed the southern shores of the lower Florida Keys and the shallow Atlantic reef area both east and west of Key West" (Labisky et al., 1980). The expansion of the fishery into deeper waters necessitated gear changes from cast nets, gill nets, haul seines and grains to increasing use of bully nets and wire traps.
