From 1925-26 to 1927-28 total landings increased from 88,000 pounds to 873,000 pounds, an almost 900 percent increase. The State amended its lobster regulations in 1929 to increase the length of the closed season from three to four months (March 21 to July 21) and set, for the first time, a minimum legal size limit, which was one pound (Labisky *et* al., 1980; Prochaska and Baarda, 1975).

---

[9] As of August 1, 1966, there were 165,000 refugees from Cuba in the U.S. without legal permanent resident status (Immigration Information, vol. 19, Interim Decision #3069).

[10] The Bartlett Act of 1964 excluded foreign fishing vessels from fishing within the United States's territorial sea, which was defined as all ocean waters within 3 miles from the coast of the United States, its territories and possessions and the Commonwealth of Puerto Rico" (Public Law 88-308). Two years later Congress passed the Contiguous Fisheries Zone Act (Public Law 89-658), which created a 9-mile contiguous zone extending out from the 3-mile limit from which foreign fishing vessels would be excluded.

[11] According to Moe (1991, p. 39), spiny lobsters are "excellent bait for large snapper and grouper".

Despite declines in landings and prices per pound during the 1930s, the development of deep-freeze processing techniques enabled further expansion of the commercial retail market for spiny lobster in the 1940s. From 1940 to 1949 total commercial landings increased from 0.4 million pounds to 3.58 million pounds and price per pound increased from $0.07 to $0.22. By the 1940s, the most popular commercial fishing gears were wooden slat-traps, bully nets, and ice-can traps in that order. Slat-traps were used primarily in deeper waters "associated with the offshore reef on the Atlantic side of the Keys; bully nets were used in the shallow waters of Florida Bay; and … ice cans were used in shallow inshore waters" (Labisky *et* al., 1980, p. 33). Traps were still pulled by hand, however, which limited their numbers and use in deep waters (Moe, 1991). Also in the 1940s, there was an increase in imports of spiny lobster tails from the Caribbean, South Africa, and Australia (Labisky *et* al., 1980).

The south Florida spiny lobster fishery continued to grow in the 1950s. From 1952 to 1959 the number of boats/vessels in the fishery expanded from 102 to 254; the price per pound increased from $0.18 per pound in 1950 to $0.30 per pound in 1959; the number of traps increased from 17,000 in 1951 to approximately 52,000 in 1959; and commercial landings increased from 1.56 million pounds in 1950 to 3.18 million pounds in 1959.[12] With that growth came more State action to protect the supply of spiny lobster. In 1953, the Florida Legislature changed the timing of the closed season from the period of March 21 to July 21 to the period of April 15 to August 15, and redefined the legal size limit from one pound to a minimum tail size of 6 inches; however, in 1955, it reestablished the closed season from March 31 to August 1 (Labisky et al., 1980). In 1954, the State began to require lobster permits and fishers to report the number of traps fished (Florida Marine Fisheries Commission, December 5, 1991).

Moe (1991) notes three developments in the 1950s that had a significant impact on the spiny lobster fishery. First, the development of skin and SCUBA diving, especially around the Florida Keys, provided easy opportunities to hunt lobster with spear guns, which was legal at that time. Second, the development of hydraulic systems to haul traps eventually eliminated pulling traps in by hand. Third, lobster fishers began to keep 2 or 3 undersized lobsters, known as "shorts", in traps as attractants because the use of shorts increased catches significantly.[13] In a short period of time, "every fisherman used shorts whenever possible as well as the standard cowhide bait" (Moe, 1991, p. 385.).

According to Labisky *et al.*, the south Florida spiny lobster fishery radically changed in the1960s with the influx of thousands of Cubans into the country. Many of the approximately 300,000 Cuban immigrants obtained U.S. government loans and bought boats to fish for lobster in Bahamian waters (Moe, 1991; Labisky *et al.*, 1980). Most of

---

[12] According to Labisky et al., there were 376 boats/vessels in 1950 and 319 boats/vessels in 1951 that were engaged in spiny lobster fishing. It is unclear why the number of boats/vessels fell to 102 in 1952, or if the 1950 and 1951 figures are questionable estimates. A boat is a watercraft with carrying capacity less than 5 tons, whereas a vessel is a watercraft with a carrying capacity of 5 tons or greater.

[13] Experiments have shown that traps baited with short lobsters catch approximately three times more lobster than traps baited with any other method (Moe, 1991; Heatwole *et al.*, 1988).

these immigrants' boats were Miami based. In 1975 when Bahamian waters were closed to foreign fishing, these Miami-based boats began to fish locally.

The first gear restriction occurred in 1965, which specified the types of gear that could be used to harvest lobster (Prochaska and Baarda, 1975; Williams, 1976). Wood traps could be used, provided that they were not greater than 3 x 2 x 2 feet or the equivalent in cubic feet.[14] Permit numbers had to be placed permanently on each trap or other device used to catch lobsters, as well as on the buoy that was used to mark the traps (Prochaska and Baarda, 1975). Also, traps and buoys had to be color-coded; and up to 20 traps could be attached to a trot-line. That same year the State set the minimum carapace size to 3 inches and minimum tail measurement to 5.5 inches.

In 1968 the minimum carapace length was reduced to 3 inches. About the same time, the fishery in the Florida Keys had expanded from the Key West area to the middle keys (FWRI 2007). A 1969 act allowed a 6-inch minimum on tails separated under special permit.

In 1971, the State changed its regulations to establish a $50 permit fee and allow landings of spiny lobsters harvested from international waters during the State's closed season (Labisky *et al*., 1980). By this time there were increasing conflicts between commercial fishers and recreational divers who harvested spiny lobster, so in 1975 the State enacted legislation that created the special 2-day sport season that is scheduled the last consecutive Wednesday and Thursday of July each year, one week before the start of the commercial season. During the special 2-day sport season, recreational lobster fishers are allowed up to 6 lobsters per person per day in the Monroe County and Biscayne Bay National Park and up to 12 lobsters per person per day in other areas of the state. The bag limit during the regular lobster-fishing season is 6 lobsters per person per day, or 24 per boat per day, whichever is greater.[15]

The Florida Marine Fisheries Commission (FMFC) adopted its first fisheries management plan (FMP) for spiny lobster on July 2, 1987. For the most part, the management plan continued existing practices; however, among the new requirements was the provision of having on board live wells with re-circulating water when transporting short lobsters (Florida Marine Fisheries Commission (FMFC), December 5, 1991). In 1988, a three-year moratorium on the issue of new permits was established in an effort to limit total commercial effort. In July 1990, the FMP was amended, and among its changes was the designation of spiny lobster as a restricted species (RSE) after July 1993. The following year the Florida legislature enacted laws, which prohibited the

---

[14] As stated by Prochaska and Baarda (p. 26): The 1965 law "requires that the constructed traps be of wood slats so that when a trap is lost it will be broken up with time and thus will not continue to catch lobsters which would then be lost for both breeding stock or human consumption. The wood slat traps can be protected on the sides by reinforcement with 16 gauge, one inch poultry wire, though the bottom and top cannot be so reinforced. Partial wire reinforcing is allowed to protect the trap from the 'ravages of turtles'. Ice cans, drums and other similar devices are permitted provided that they are not equipped with grains, spears, grabs, hooks or similar devices."

[15] Recreational fishers are not allowed to use traps to capture lobster. Bully nets and diving (breath-hold, SCUBA, or hookah) are the only legal recreational fishing methods.

FMFC from adopting rules that would prohibit the possession of undersized lobsters or require traps to have escape gaps before April 1998.

In 1991, Florida instituted a recreational spiny lobster license (also known as a crawfish permit), which was purchased as an additional endorsement to the state's recreational saltwater fishing license. Also that year the State began to use two annual mail surveys of persons with a lobster license/permit to estimate the number and landings of lobsters harvested by recreational fishers who take lobsters during the special 2-day sport season and from opening day to the first Monday in September of the regular fishing season.[16]

The number of traps increased greatly from the mid 1970s through the 1980s, rising from 219,100 in 1970 to 979,766 in 1991. This rapid growth resulted in increased user conflicts on the water, excessive mortality of shorts, declining yield per trap, and concerns about trap debris (FFWCC 2007). See Figure 5.3.5.

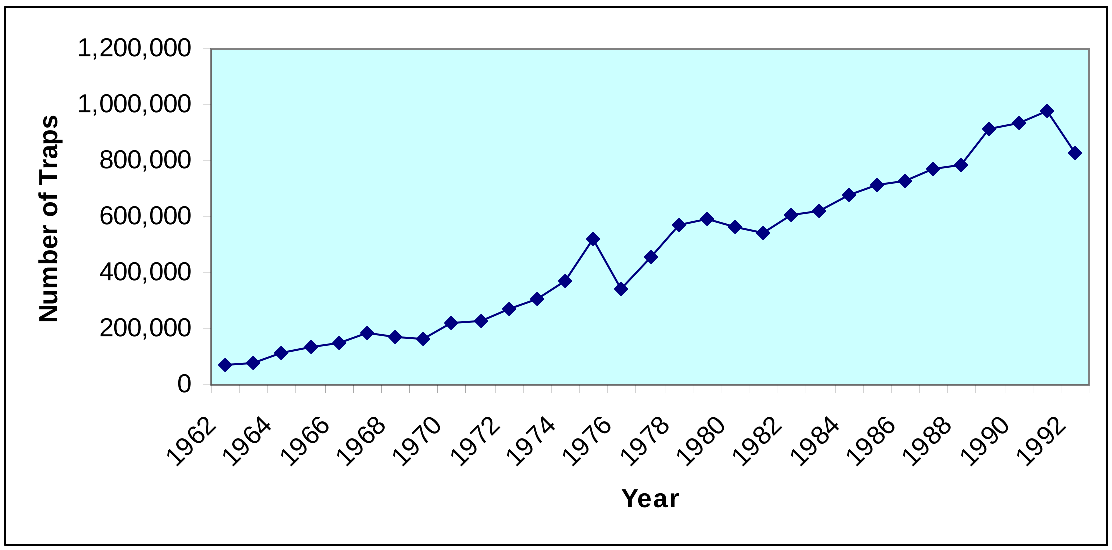

Figure 5.3.5. Annual Numbers of Traps, 1962 – 1993.

In 1992, Florida implemented the spiny lobster Trap Certificate Program (TCP), which regulated the total number of traps by requiring a certificate for each trap and setting a limit on the number of certificates. When first implemented, the initial certificate allocation was based on the trap use that had been reported for the three preceding years (Larkin and Milon).

The FFMFC is authorized to reduce the total number of certificates by decreasing the number of each individual's traps by no more than 10 percent annually. In 1993, Caribbean spiny lobster fishermen set 704,234 traps. That same year, the Florida Fish and Wildlife Commission (FFWCC) implemented the Lobster Trap Certificate Program to reduce the number of lobster traps allowed in the fishery. Since the initial allocation of

[16] The survey of recreational fishers who harvest during the regular fishing season focuses on the first month of the season because the majority of fishing effort occurs during the first month of the season (Sharp *et al.*, 2005).

certificates, the Florida Fish and Wildlife Conservation Commission (FFWCC or FWC) has decreased the number of certificates four times at 10 percent reductions: 1994, 1995, 1996, and 1999. In 2001, the FFWCC set the target number of spiny lobster traps at 400,000 and implemented a 4 percent annual reduction in traps. The FFWCC suspended the annual trap reduction in 2003; nonetheless, the program has resulted in a significant reduction in the annual numbers of traps set. During the 2005 - 2006 season, 497,042 trap tag certificates were issued; followed by 473,943 for the 2006 - 2007 season and as of December 21, 2007, there were a total of 475,320 trap tag certificates for the 2007 - 2008 season.

No one who owns one or more lobster trap certificates can be issued a commercial dive permit (68B-24.0055(2)(b)). As of January 1, 2005, and until January 1, 2010, no new commercial dive permits will be issued and no commercial dive permit will be renewed or replaced except those that were active during the 2004 – 2006 fishing season. Existing permits may only be issued to a single saltwater products license with a valid crawfish endorsement and a valid restricted species endorsement (68B-24.005(2)(c)). Failure to renew the commercial dive permit by September 30 of each year results in forfeiture of the permit.

A crawfish endorsement or crawfish license, also known as a trap number, is required for any person to use traps to harvest spiny lobster or take spiny lobster in commercial quantities (68B-24.0055(1)). The number of Crawfish Endorsements issued has declined since the 1998 -1999 season. See Figure 5.3.6. The number of individuals holding Crawfish Endorsements has also declined. During the 2005 – 2006 season, there were 1,402 endorsement holders, followed by 1,303 for 2006 – 2007, and as of December 1, 2007, there were 1,241 endorsement holders for the 2007 – 2008 season.

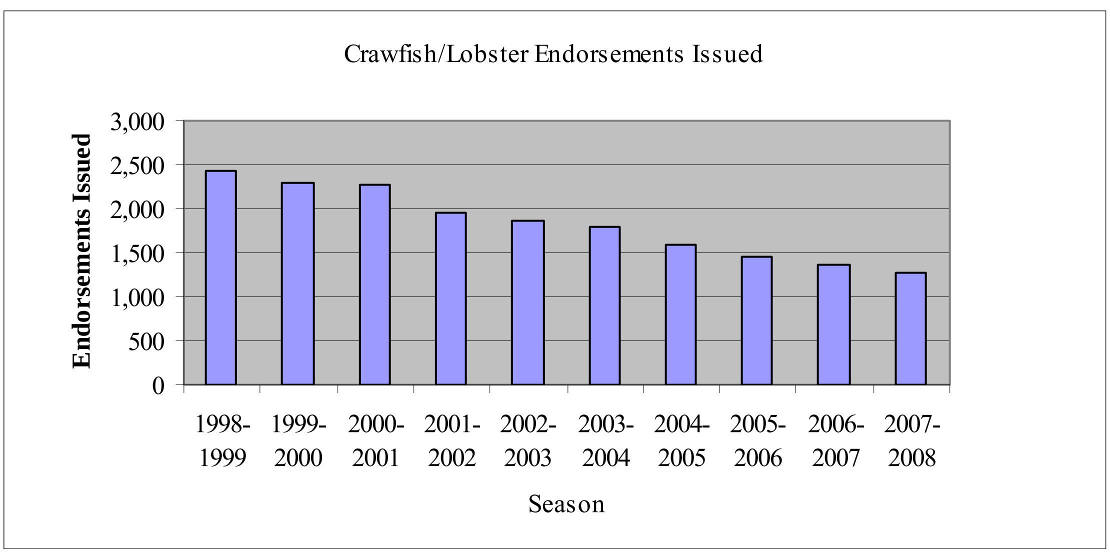

Figure 5.3.6. Number of Crawfish/Lobster Endorsements Issued. Source: Florida Fish and Wildlife Conservation Commission, Marine Fisheries Information System.

On August 5, 1994, the Special Recreational Crawfish License (SRCL) was issued after the implementation of the commercial spiny lobster trap certificate program (68B-

24.0035, Florida Administrative Code). The SRCL was intended to reduce the adverse impact on recreational fishers who were commercially licensed and using traps, but were prohibited from using lobster traps because they did not meet the qualifications that were established from the commercial lobster trap certificate program.[17] SRCLs are not issued to persons who did not possess a crawfish trap number (Crawfish Endorsement) and a Saltwater Products License during the 1993 – 1994 license year (68B-24.0035(2)(b), F.A.C.). No person issued a SRCL may also possess a Crawfish Endorsement. An SRCL is not valid unless the holder also possesses a valid Recreational Crawfish Permit required by Section 372.57(8)(d), Florida Statutes. Moreover, if the SRCL is not renewed every year, the holder loses the license. The SRCL applies to recreational fishers in state, not federal, waters, and does not permit harvesting lobsters during the 2-day sport season. License holders are required to file quarterly reports with the Florida Fish and Wildlife Conservation Commission detailing the amount of spiny lobster harvested in the previous quarter together with the amount harvested by other recreational harvesters aboard the license holder's vessel (68B-24.0035(2)(e), F.A.C.).

The number of SRCLs has declined since the 1998 – 1999 season. See Figure 5.3.7. Beginning with the 2012 – 2013 license year and every year thereafter, no SRCL will be issued or renewed (68B-24.0035(2)(g), F.A.C.).

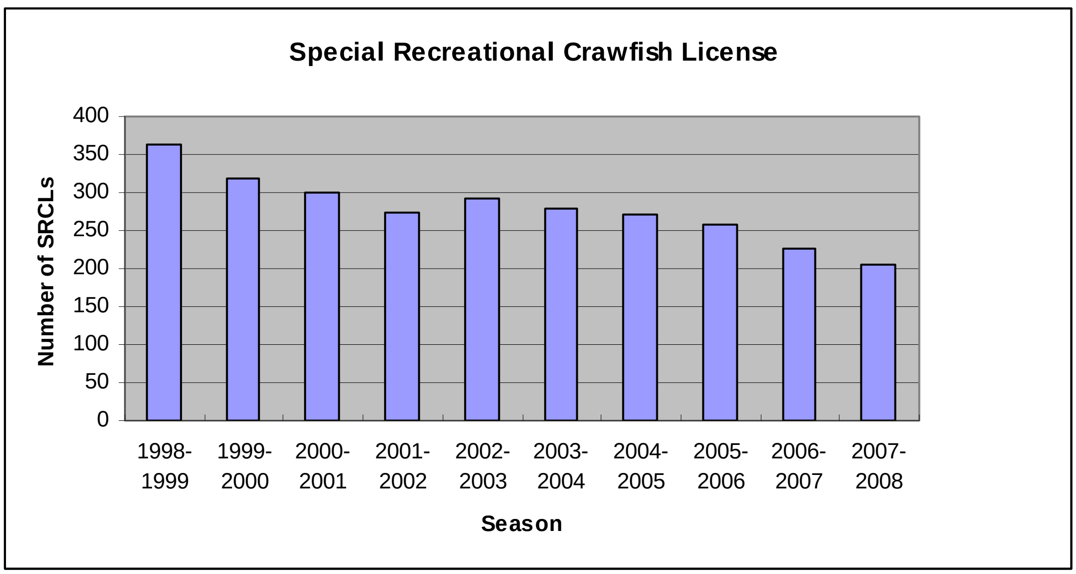

Figure 5.3.7. Number of Special Recreational Crawfish Licenses, 1998 – 1999 to 2007 – 2008 season. Source: Florida Fish and Wildlife Conservation Commission, Marine Fisheries Information System.

Currently, Florida law requires anyone who commercially harvests or sells spiny lobster to have a Saltwater Products License (SPL).[18] An SPL may be issued in the name of an individual or a valid vessel registration number issued in the name of the licensed

---

[17] A commercial license was/is required because traps were/are not legally acceptable gear in the recreational spiny lobster fishery.

[18] A Saltwater Products License (SPL) is required to harvest saltwater species in excess of the recreational bag limits, with the intent to sell, or with certain gears. For species that have no established bag limit, the bag limit is 100 pounds or 2 fish per person per day or whichever is greater.

applicant. The State also requires anyone who sells spiny lobster to have a Restricted Species Endorsement (RS) and Crawfish Endorsement.[19]

Spiny lobster harvested in Florida waters must remain in a whole condition while on or below state waters and the practice of separating the tail from the body is prohibited (68B-24.003(4)). Possession of spiny lobster tails that have been separated lobster tails on or below state waters is prohibited unless the spiny lobster is being imported pursuant to 68B-24.0045, F.A.C., or were harvested outside state waters and the separation was pursuant to a federal permit allowing such separation. If tails are separated from the body, tails must be at least 5.5 inches in length,[20] otherwise, if whole, the carapace must be greater than 3 inches long (68B-24.003(1), F.A.C.).

In Florida, the harvest or possession of egg-bearing spiny lobster is prohibited and any egg-bearing lobster found in traps must be immediately returned to the water free, alive and unharmed (68B-24.007 *F.A.C.*). The practice of stripping or otherwise molesting egg-bearing spiny lobster in order to remove the eggs is prohibited and the possession of spiny lobster or spiny lobster tails from which the eggs, swimmerets or pleopods have been removed or stripped is prohibited (68B-24.007 *F.A.C.*).

Possession of undersized lobster is prohibited, except in the spiny lobster trap fishery, where fishermen use undersized lobsters to attract legally sized ones.[21] Allowable gears are traps, hand-held net, hoop net (diameter no larger than 10 feet), bully net (diameter no larger than 3 feet), and by diving. The vessel limit for harvest with a bully net is 250 lobsters per vessel per day, for the trap fishery there is no bag or trip limit, and limits for the dive fishery are regional. Additional restrictions and requirements depend on the method of harvest.

For those in the spiny lobster trap fishery, trap certificates and tags are required for all traps. A tag must be securely attached to each trap; spiny lobster trap specifications and trap, buoy, and vessel marking requirements apply; and traps, buoys, and vessels must display the Crawfish endorsement.[22] Florida law authorizes FWC to retrieve traps left in the water after the close of the season and fines the traps' owners to cover the costs of retrieving the traps.

---

[19] Species designated as Restricted include African pompano, amberjack, black drum, black (striped) mullet, bluefish, blue crab, clams (Brevard County only), crawfish/lobster, cobia, Florida pompano, flounder, grouper, hogfish, king mackerel, permit, red porgy, cobia, sea bass, sheepshead, shrimp, snapper, Spanish mackerel, spotted sea trout, stone crab, triggerfish, tripletail, and tropical marine fish and plants including ornamental sponges.

[20] No less than 5.5 inches not including any protruding muscle tissue.

[21] A person aboard a vessel with a Crawfish endorsement and trap certificates may harvest and possess while on the water 50 undersized spiny lobster (shorts) and one short per trap aboard the boat. Shorts must be released alive and unharmed upon leaving trap lines.

[22] Traps must be constructed of wood or plastic and be no larger than 3 feet by 2 feet or the volumetric equivalent (12 cubic feet) with the entrance located on top of the trap. Each plastic trap must have a degradable panel. Traps must be baited and placed in the water beginning August 1. Traps may be worked during daylight hours only. Traps may not be placed within 100 feet of the intercoastal waterway or any bridge or seawall. Traps must be removed from the water by April 5 each year. Harvest is prohibited in designated areas of John Pennekamp Coral Reef State Park.

All vessels used by persons commercially harvesting lobster by diving, scuba, or snorkel must display the Commercial Dive Permit on the vessel SPL. A person with a Commercial Dive Permit cannot have a trap certificate. After January 1, 2005, no diver permits were issued, renewed or replaced except those that were active in 2004-05. Dive permits that are not renewed by September 30 of each year are forfeited. A 250-lobster daily vessel limit applies in Broward, Dade, Monroe, Collier, and Lee counties and adjoining federal waters.[23]

The commercial CSL and regular recreational CSL season starts on August 6 and ends on March 31 (68B-24.005(1). No person can harvest, attempt to harvest, or have in his possession, regardless or where taken, any spiny lobster during the closed season of April 1 through August 5 of each year, except during the 2-day sport season, for storage and distribution of lawfully possessed inventory stocks or by special permit issued by the Florida Fish and Wildlife Conservation Commission (68B-24.005(1)). During the 2-day sport season no person can harvest spiny lobster by any means other than by diving or with the use of a bully net or hoop net.

A Wholesale Dealer License is required for any person, firm or corporation that sells spiny lobster to any person, firm, or corporation except to the consumer and who may buy spiny lobster from any person pursuant to section 370.06(2) of the Florida Statutes or any licensed wholesale dealer.

Each spiny lobster imported into Florida must comply with the minimum size requirements and the prohibitions relating to eggbearing spiny lobster (68B-24.0045(3) F.A.C.). During the open season (August 6 through March 31), a person may possess wrung spiny lobster tails or possess spiny lobster in excess of the bag limit while on state waters if such person also possesses appropriate receipt(s), bill(s) of sale, or bill(s) of lading to show that the spiny lobster were purchased in a foreign country and are entering the state in international commerce (68B-24.0045(1)).

5.3.5.1.2 Florida County Ordinances

Zoning laws have indirectly affected the spiny lobster fishery in south Florida. In August 1986, Monroe County changed its zoning laws by implementing the Monroe County Land Use Plan (Plan). Under the Plan, commercial fishers must store, build, repair, and dip traps in industrial or commercially zoned areas, within areas designated as commercial fishing villages or in areas termed specific fishing districts (Johnson & Orbach, 1990).[24] Prior to the zoning change, fishers could store and work on traps on

[23] Divers must permanently and conspicuously display a 'divers down flag' placard on the vessel and affix the Commercial Dive Permit to the diagonal stripe with 10-inch numbers visible from the air and 4-inch numbers visible from the water. Harvest from artificial habitat is prohibited. Divers must possess a carapace measuring device and measure lobster in the water. The use of bleach or chemical solutions or simultaneous possession of spiny lobster and any plastic container capable of ejecting liquid is prohibited.

[24] Traps used to be dipped in recycled oil to protect them from the marine environment. However, that practice was prohibited beginning in 1995. Now fishermen soak traps in a brine solution to extend the life of their traps.

residential property. Under Article V, Section 9.5 – 143(f) of the Monroe County Ordinances, where a nonconforming use of land or structure is discontinued or abandoned for 6 months or 1 year in the case of stored lobster traps, then such use may not be reestablished or resumed, and subsequent use must conform to provisions detailed in the chapter of the ordinances.

5.3.5.2 Puerto Rico

Puerto Rico law requires commercial lobster fishermen to have a Common Lobster Fishing Permit (12 L.P.R.A § 25e(b)(2)). Regulation 6768, Article 8(o) states no person can fish, possess, sell or offer for sale the common lobster (P. argus) with a carapace length less than 3.5 inches."

Most spiny lobster are taken by scuba diving and fish pots. See Table 5.3.9.

Table 5.3.9. Puerto Rico Commercial Lobster Fishery Gear Types. *Source*: SEDAR 2005.

Gear Type	Landings (1000s lbs)	Percent
Scuba Diving	2,110.40	43.3
Fish Pot	1,859.00	38.1
Lobster Pot	442.7	9.1
Trammel Net	162.2	3.3
Bottom Line	78.7	1.6
Spear Fishing	77.4	1.6
Skin Diving	58.3	1.2
Gill Net	52.6	1.1
Other	34	0.7

5.3.5.3 U.S. Virgin Islands

Title 12, Chapter 9A, §319(b) of the Virgin Islands Code (V.I.C.) states "No person, firm, or corporation shall take or have in his possession at any time, regardless of where taken, any spiny lobster (crawfish or crayfish) of the species Panulirus Argus unless such spiny lobster … shall have a carapace length of more than three and one-half (3 ½) inches." According to 12 V.I.C. §319(c), lobsters must remain in a whole condition at all times while being transferred on, above or below the waters of the territory and the practice of wringing or separating the tail from the body is prohibited on the waters of the territory. Egg-bearing lobsters of any species shall not be taken, possessed or sold at any time, except that egg-bearing lobsters may be returned to pots and traps in which they have been captured, provided such egg-bearing lobsters are returned to such pots or traps in a live or unharmed condition, are provided with adequate food, and are immediately returned into the water (12 V.I.C. §319(c)). Such egg-bearing lobsters as are returned to pots or traps as aforementioned, shall not be taken or possessed or sold until the eggs have been naturally released into the water; provided they are of at least the minimum size forth in §319(b). The practice of stripping, shaving, scraping, clipping, or otherwise molesting egg-bearing lobsters in order to remove the eggs is prohibited (12 V.I.C. §319(e)).

It is unlawful for any person to spear, hook or otherwise impale any lobster in the process of capture. Lobsters may only be captured by hand, snare, pot or trap, so that short or egg-bearing lobsters may be released unharmed or returned to the pot or trap as permitted (12 V.I.C. §319(f)). The great majority of spiny lobster landings are taken by scuba gear and traps and lines. See Table 5.3.10.

Table 5.3.10. U.S. Virgin Islands Spiny Lobster Percent Landings by Gear Category, 1994 – 2003. *Source*: SEDAR 2005.

Gear Type	Percent Reported Landings
Scuba	61.51
Traps/Lines	33.23
Free Diving	2.24
Gillnets	1.16
Seine Nets	0.46
Scuba/Free Diving	0.31
Unknown	0.29
Line Fishing	0.24

Title 12, Chapter 9A, §324 of the V.I.C. states that no person shall sell, or represent for the purpose of sale, in any form, any seafood as local or native seafood unless the same shall have been originally caught or taken in this territory; nor shall any person so sell, or represent for the purpose of sale, in any form, any crustacean as local or native lobster unless the same is the species known as *Panulirus argus*; nor shall any person so sell, or represent for the purpose of sale, in any form, any meat as local or native lobster meat unless such meat is wholly from crustaceans of *Panulirus argus*.

5.3.6 Foreign Laws and International Agreements

On August 1, 1975, the Commonwealth of The Bahamas enacted a law that declared spiny lobster a creature of its Continental Shelf, which is similar to the U.S. law (16 U.S.C. 1857(2)(B)) that considers American lobster a part of our Continental Shelf (Vanderbilt Television News Archive, September 11, 1975). Consequently, Bahamian territorial waters were closed to U.S. spiny lobster fishers on and after that date. The closure had a dramatic impact on landings of spiny lobster in the southeast: pounds landed in 1975 were 32 percent less than the previous year's landings, and pounds landed in 1976 were 28 percent less than 1975 landings.[25] In Florida, pounds landed on the east

[25] According to Labisky et al. (1980), less than half of the spiny lobster landed was harvested in domestic waters and most of the foreign catch was taken from Bahamian waters. Noetzel & Wojnowski report that in 1973, about one-fifth of landings on Florida's west coast came from spiny lobsters that were harvested in

coast in 1975 were 44 percent less than pounds landed in 1974, and pounds landed in 1976 were about 57 percent less than pounds landed in 1975.[26] Pounds of spiny lobster landed on the west coast declined from approximately 6.7 million in 1974 to about 4.4 million in 1976. East coast Florida fishers have landed less spiny lobster annually since the closure of Bahamian waters in 1975; however, landings on the west coast of the state have exceeded those landed in 1974, before the closure, for four years. To mitigate the losses caused by the closure of Bahamian waters, domestic fishers began to increase the number of traps after 1975 (Shivlani & Milon, 2000).

In 1972, the Treaty between the Government of the United States of America and the Government of the Republic of Colombia Concerning the Status of Quita Sueño, Roncador and Serrana was signed, which allowed U.S. fishing vessels to operate in Colombian waters. As a result of that treaty, U.S. vessels fishing in Colombian Treaty Waters are prohibited from possessing Caribbean spiny lobster smaller than 5.5 inches (19.97 cm) tail length (50 CFR 300.126(m)). Also, a berried (egg-bearing) spiny lobster caught in treaty waters cannot be retained on board, and a berried lobster may not be stripped, scraped, shaved, clipped or in any manner molested to remove the eggs (50 *CFR* §300.132).

In an international fishery like that of spiny lobster, "consensus" on addressing concerns is important, as are U.S. efforts to engage other countries in negotiations/agreements. FAO/WECAFC has organized five workshops on spiny lobster in cooperation with most regional agencies and institutions, dealing with various projects: Belize City, Belize (1997); Merida, Mexico (1998, 2000, and 2006); and Havana, Cuba (2002). A representative from the Caribbean Council attended all the workshops. A staff member of NOAA Fisheries Service's Southeast Region attended the 2006 workshop in Merida.

The participating countries of the September 2006 workshop of the Working Group on Caribbean spiny lobster of the WECAFC agreed that there were management problems across the region, which included growth of fishing effort; weak enforcement and compliance; illegal, unreported and unregulated fishing; increasing use of artificial habitats (casitas); conflicts between trap fishers and dive fishers; open access fisheries; and reports that in some Central American countries of leaving lobster traps in the water during the countries' closed seasons. The countries also agreed that countries that did not have a minimum harvest-size in their regulations that is equal to or greater than 74 millimeters carapace-length should make efforts to do so (WECAFC 2007, p. 3).

The WECAFC member countries who attended the Merida Workshop in 2007 agreed. According to the United Nations' Food and Agricultural Organization (FAO), Belize, Bermuda, Colombia, Guyana, and Jamaica did not have minimum size-regulations as of December 31, 2007.

Caribbean waters off the coasts of Nicaragua and Honduras (1975, p. 25). According to Williams (1975), the closing of Bahamian waters to U.S. spiny lobster fishers represented a loss of approximately 90 percent of foreign water landings.

[26] On the east coast of Florida, 4,147,200 pounds were landed in 1974; 2,319,300 pounds were landed in 1975; and 987,300 pounds were landed in 1976.

5.3.7 Florida Commercial and Recreational Harvest

Caribbean spiny lobsters are harvested by both commercial and recreational fishermen. Florida law allows commercial fishermen to harvest spiny lobster by diving or using wooden, plastic or metal traps, or bully or hoop nets (68B-24.006(1)); however, wooden traps are the most popular gear type.[27] These traps are weighted with cement and include a self-deteriorating escape panel that degrades over time. Fishermen commonly string traps along a trap line, with each end of the trap line marked by a buoy. All traps must be removed by April 5 of each year (68B-24.005(4) F.A.C.). Strong coastal storms can damage and destroy the traps.

The predominant gear type used to catch spiny lobster in Florida is a pot or trap. From 1997 through 2006, about 90 percent of annual total state landings have been caught in pots and traps. See Figure 5.3.8. Diving is the second most popular gear type and takes about 9 percent of the total pounds landed annually.

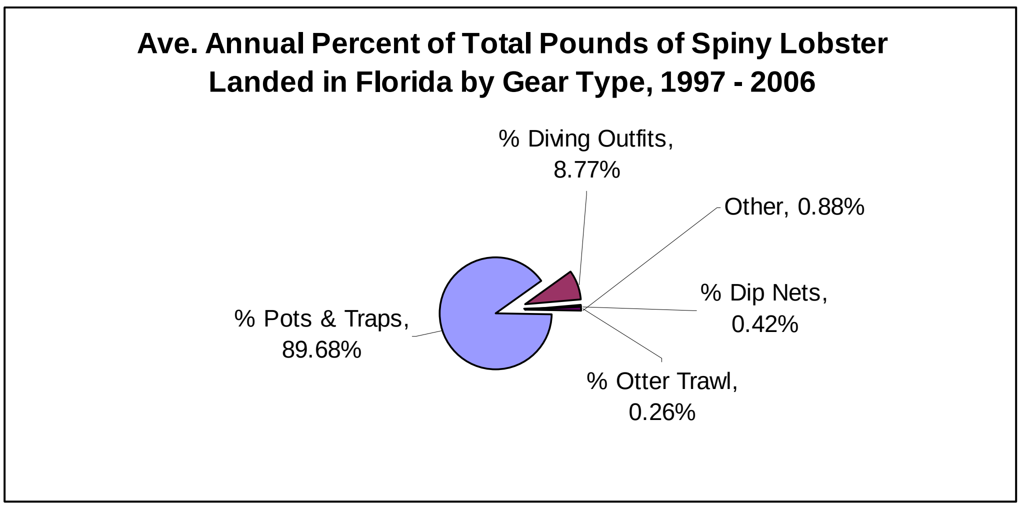

Figure 5.3.8. Average Annual Percent of Total Pounds of Spiny Lobster Landed in Florida by Gear Type, 1997 – 2006. *Source*: National Marine Fisheries Service, Accumulated Landings System.

Commercial fishermen use live undersized CSL, commonly known as "shorts", instead of cowhide or fish heads as bait to attract CSL into their traps. Florida law allows the holder of a valid Crawfish Endorsement, lobster trap certificates, and valid saltwater products license to harvest and possess, while on the water, undersized spiny lobster not exceeding 50 per boat and 1 per trap aboard each boat is used exclusively for luring, decoying, or otherwise attracting noncaptive spiny lobster into traps. Such undersized spiny lobster must be kept alive while in possession, in a shaded continuously circulating live well

---

[27] A bully net used to directly harvest spiny lobster can not have a diameter greater than 3 feet and similarly, a hoop net can not have a diameter larger than 10 feet (68B-24.007(5)). Spiny lobster taken by the use of any non-hand-held net or trawl as incidental bycatch of legally harvested targeted species is allowed if the combined whole weight of all spiny lobster does not exceed 5 percent of the total whole weight of all species legally possessed at the time.

with a pump capacity to totally replace the water at least every 8 minutes and large enough to provide at least 0.75 gallon of seawater per lobster (68B-24.003(3) F.A.C.).

Usually each season's landings peak in August then sharply decrease thereafter. See Figure 5.3.9. Effort and landings also decrease after the opening of the stone crab claw fishery on October 5 (FWRI 2007).[28] See Figure 5.3.10.

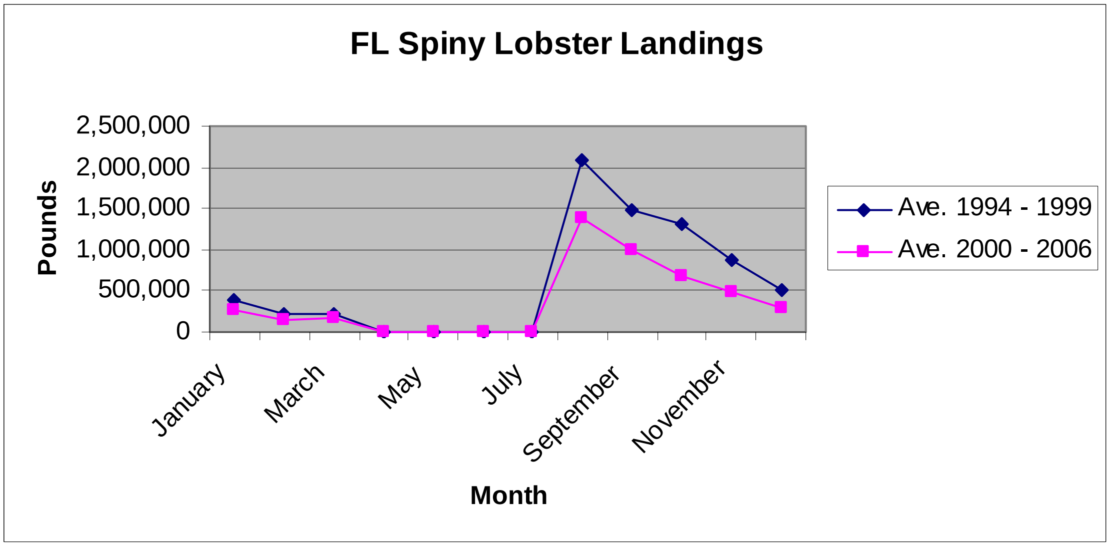

Figure 5.3.9. Florida Landings of Spiny Lobster, 1994 – 2006. *Source*: Florida Fish and Wildlife Conservation Commission, Marine Fisheries Information System.

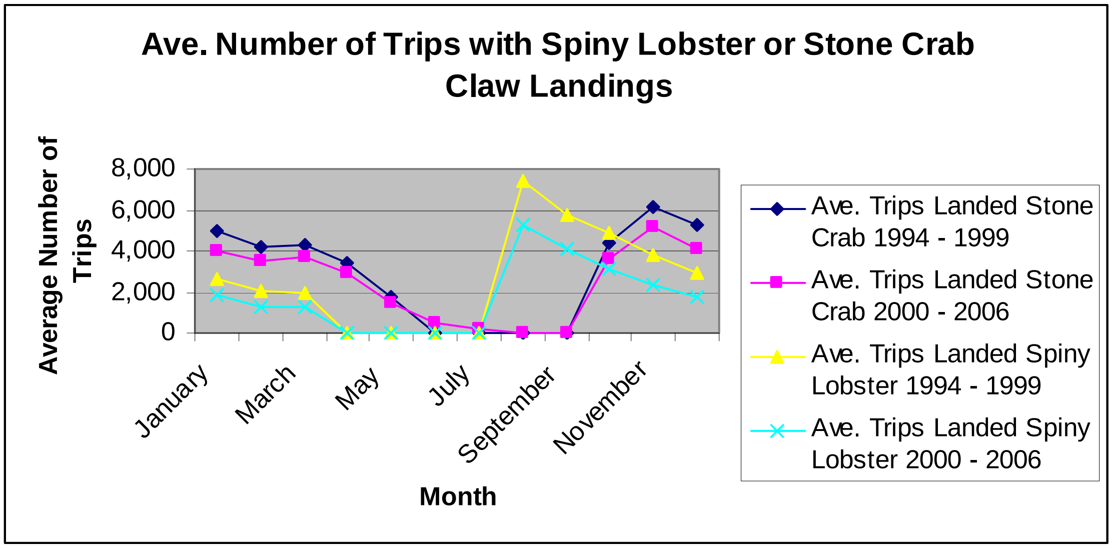

Figure 5.3.10. Average Number of Monthly Trips that Landed Either Spiny Lobster or Stone Crab Claws, 1994 – 1999 and 2000 – 2006. *Source*: Florida Fish and Wildlife Conservation Commission, Marine Fisheries Information System.

[28] Stone crab was originally a bycatch caught in spiny lobster traps; however, in the 1970s, it became a fishery. Today, many spiny lobster fishermen are also stone crab fishermen as well.

During the 2-day sport season, no person can harvest spiny lobster by any means other than by diving or using a bully net or hoop net (68B-24.005 F.A.C.)).
Bully and hoop nets and diving (breath-hold, scuba, or hookah) are the only legal recreational fishing methods (Recreational fishermen primarily dive to harvest the species; however, they also use bully nets and hoop nets). A bully net is a circular frame attached at right angles to the end of a pole and that supports a conical bag of webbing. The webbing is usually held up by means of a cord, which is released when the net is dropped over a lobster. A hoop net is a frame, circular or otherwise, that supports a shallow bag of webbing and is suspended by a line and bridles. The net is baited and lowered to the ocean bottom, to be raised rapidly at a later time to prevent the escape of the lobster.

It is estimated that the numbers of lobsters landed by recreational fishers represent an average of 23 percent of the total annual recreational and commercial numbers landed from the 1978-79 through 2003-04 fishing seasons. See Table 5.3.11.

The Florida Department of Environmental Protection (FDEP) has conducted annual mail surveys of recreational lobster fishers for the two-day sport season and the first month of the regular season since 1991 in order to estimate recreational lobster harvest and fisher participation (FDEP, 1996). Since 1985, recreational fishers have taken an average of approximately 1.5 million spiny lobsters annually through Labor Day. Statewide recreational landings for the most recent available survey that was conducted in 2006 were estimated to be 947,353 pounds (FWRI 2007). That estimate was 36 percent lower than the average landings in the previous available five years, from 2000 through 2004, and was 37 percent lower than the available historic average landings from 1992 through 2006.

5.3.8 Florida Counties with Commercial Landings of Spiny Lobster

5.3.8.1 Introduction

Seven counties account for about 99.5 percent of Florida's annual commercial landings of Caribbean spiny lobster, with Monroe County dominating by taking about 90 percent of the landings year after year. See Table 5.3.12. Both Monroe and Dade (Miami-Dade) Counties combined account for about 96 percent of the state's annual commercial landings. According to the FWRI (2007), most of the lobsters landed outside Monroe and Dade Counties from 1992 though 2006 were caught in the Keys and sold to wholesale dealers operating in Palm Beach County.

Table 5.3.12. Top 7 Counties in Commercial Landings of Caribbean Spiny Lobster, 1994 – 2006. Source: FL Fish and Wildlife Conservation Commission, Marine Fisheries Information System.

County	Ave. Annual CSL Landings	Portion of Ave. Annual FL CSL Landings	Combined Portions of FL Landings
Monroe	5,070,122	89.658%	89.6584%
Dade	366,385	6.479%	96.1375%
Palm Beach	69,507	1.229%	97.3666%
Broward	46,460	0.822%	98.1882%
Collier	34,981	0.619%	98.8068%
Brevard	20,837	0.368%	99.1753%
Duval	17,067	0.302%	99.4771%

The number of lobster/crawfish licenses has been in decline in Florida since fiscal year 1998-1999.[29] See Figure 5.3.11.

[29] The fiscal year is from July 30 to June 1.

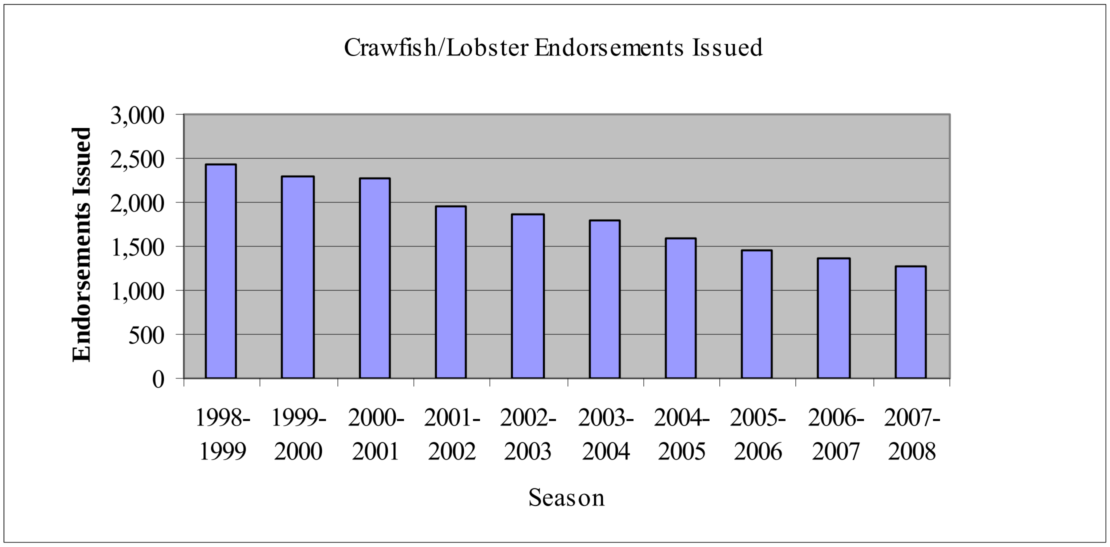

Figure 5.3.11. Florida Lobster/Crawfish License Endorsements Issued. Source: Florida Fish & Wildlife Commission.

5.3.8.2 Monroe County

Monroe County leads the state in landings of Caribbean spiny lobster year after year. From 1994 through 2006 Monroe County led the state in commercial landings of Caribbean spiny lobster, averaging about 90 percent of the state's commercial landings each year. See Table 5.3.13.

Table 5.3.13. Monroe County Commercial Landings of Caribbean Spiny Lobster. *Source*: FL Fish and Wildlife Conservation Commission, Marine Fisheries Information System.

Year	County CSL Landings (lbs)	FL CSL Landings (lbs)	Portion of FL Landings
1994	6,239,090	7,087,357	88.03%
1995	6,245,472	7,001,661	89.20%

The number of crawfish/lobster license holders has declined steadily since the 1998-99 season, and the 651 license holders for the 2006-07 season represents a 43 percent decline since the 1998-99 season. See Table 5.3.15.

Table 5.3.15. Monroe County Crawfish/Lobster License Holders. *Source*: FL Fish and Wildlife Commission.

Monroe County	
Season	License Holders
1998 - 1999	1,137
1999 - 2000	1,091
2000 - 2001	1,056

2006 - 2007	105
2007 - 2008	106

The recreational spiny lobster fishery is very important to the County as well. In 2003, recreational landings of Caribbean spiny lobster were about 1.1 million pounds, and sales of recreational lobster fishing permits exceed 100,000 annually. Sharp *et al*. (2005) estimate approximately $24 million was spent on recreational lobster fishing in the Florida Keys from the opening of the recreational season through the first Monday in September in 2001. Recreational fishers who resided outside the Keys accounted for about $22 million (92 percent) of that $24 million spent on recreational lobster fishing in the Keys. In addition to the regular recreational season there is the Special Two-Day Sport Season, which occurs on the last consecutive Wednesday and Thursday in July. Those two days are the busiest boating days of the year in the County. From the 1993 through 2001 Special Two-Day Sport Seasons, the average annual number of spiny lobsters caught in Monroe County represented about 66 percent of the annual statewide total. The number of special recreational crawfish (spiny lobster) permits has increased since the 1998 – 1999 season.

Monroe County is the southernmost county in Florida and the United States. See Figure 5.3.11. It has a total area of 9,679 km^2 (3,737 square miles), with 2,582 km^2 being land and the remaining 7,097 km^2 (about 73 percent) being water (U.S. Census Bureau). See Figure 2-6. The County is made up of the Florida Keys and portions of Big Cypress National Preserve and Everglades National Park. The Florida Keys are a series of islands that extend over 220 miles in length and make up the third largest barrier reef ecosystem in the world and the only one of its kind in the country. The State of Florida has designated the Florida Keys as an Area of Critical State Concern to protect the area's ecologically richness, culturally significance, and environmentally sensitive nature (Florida Statute 1986; Florida Administrative Code §28-29, 1975). Over 60 percent of the Keys land mass is owned by the government and the vast majority of public land has been set aside for conservation. The County has only one highway, U.S. Highway 1, which is also called the Overseas Highway. Commercial activities and residential development are mostly concentrated along that route (National Research Council, 2002). Among the County's cities are Key West, Key Largo, Big Pine Key, Marathon and Plantation Key.

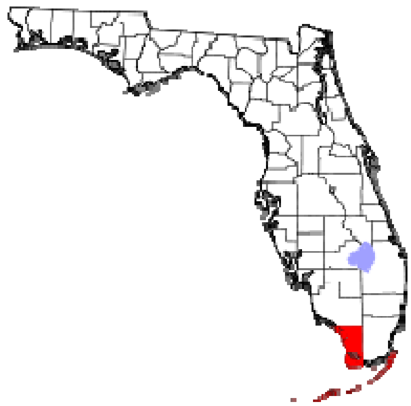

Figure 5.3.12. Monroe County. *Image Source*: Wikipedia.

More than 99.9 percent of the County's population lives on the Florida Keys. According to U.S. Census Bureau estimates, the population of the County fell 6.1 percent from April 1, 2000 to July 1, 2006, with approximately 74,737 people in 2006. During that period, there was a natural increase in population of 195 (4,642 births less 4,447 deaths) coupled with a net out-migration of 4,668 persons leaving the county (2,612 net international migration less 7,280 net internal out-migration). The number of housing units increased from 51,617 in 2000 to 52,911 in 2005, an increase of 2.5 percent. Median household income in 2004 was $42,195 and 9.2 percent of the persons in the county lived below poverty, in comparison to the statewide median household income of $40,900 and poverty rate of 11.9 percent.

Tourism is the largest sector in the county. There are more establishments in the Retail Trade (NAICS 44) and Accommodation & Food Services (NAICS 72) sectors than any other sectors, and these two sectors employ the most persons. In 2005, 35 percent of the county's employees were in Accommodation & Food Services and 21 percent in Retail Trade. See Table 5.3.17. Of the employer establishments in the Accommodation (NAICS 721) subsector, 164 (or 91) percent were in Traveler Accommodation (NAICS 7211) and 14 (or 8 percent) were in RV Parks & Recreational Camps (NAICS 7212). Similarly, of the nonemployer firms in the Accommodation subsector, 83 (or 87 percent) were in Traveler Accommodation and 4 (or 4 percent) were in RV Parks & Recreational Camps.

The Monroe County Tourist Development Council estimates more than 3.49 million people visited the County in 2003 and 3.2 million visited the Florida Keys in 2006. Of visitors surveyed from March 2005 through February 2006, 80 percent were in the Florida Keys for recreation or vacation purposes. Of those surveyed, about 84 percent reported beach activities, 75 percent viewing wildlife, 57 percent diving and snorkeling, and 30 percent fishing as activities they participated in during their visit (Monroe County Tourist Development Council, Visitor Profile Survey). See Table 5.3.17.

Table 5.3.17. Recreational Activities of Florida Keys Visitors, March 2005 – February 2006. *Source*: Monroe County Tourist Development Council, Visitor Profile Survey.

Recreational Activity	Frequency	Percent of Responses	Percent of Cases
Diving	548	3.2	18
Snorkeling	1,171	6.8	38.6
Fishing	913	5.3	30.1
Viewing Wildlife	2,260	13.1	74.5
Boating	1,390	8.1	45.8
Beach Activities	2,547	14.8	83.9
Dine Out/Night Life	2,879	16.7	94.9
Museums/Historic Areas	1,659	9.6	54.7
Sightseeing & Attractions	2,727	15.8	89.9
Cultural Events	1,170	6.8	38.5
Total	17,264	100	

In 2002, there were 42 business establishments in the Charter-Fishing and Party-Fishing-Boats subsector (NAICS 4872102) with total annual revenue of about $5.5 million and 73 employees (U.S. Census, 2002 Transportation and Warehousing Subject Series). That same year there were 23 establishments in the Excursion-and Sightseeing-Boats subsector (NAICS 4872101) with total annual revenue of $17.3 million and 224 employees.

Leeworthy and Wiley (2002) estimate for the time period of June 2000 through May 2001, the general visitor population spent over 12.1 million person days in Monroe County.
Over 80 percent of those who visit the Keys arrive by automobile. From March 2005 to February 2006, 82 percent of those who visited the Keys arrived by automobile, 16 percent by air, and 2 percent by other means (Monroe County Tourist Development Council, Visitor Profile Survey). The Port of Key West is a small port; however, it serves cruise ships with itineraries in the Eastern and Western Caribbean and the Bahamas. The Key West Chamber of Commerce estimates 881,183 cruise passenger arrivals in the Port of Key West in 2006, up from 656,866 in 2000 (**www.keywestchamber.org/cominfo/trends.pdf**). In 2006, imports with a value of $36,283 and exports with a value of $11.7 million transited through the Port of Key West. There are two commercial airports in the Florida Keys: Key West International Airport and Florida Keys Marathon Airport. Key West International Airport had 276,154 arrivals in 2006, up from 275,386 in 2000 and remains the Keys primary airport for commercial activity. At present, only one commercial carrier, Delta Airlines, serves the Marathon Airport, and on July 13, 2007, the airline announced that it was suspending flights to the airport.

Fishing is another sector that is important to the Monroe County economy. In 2005, there were 971 nonemployer firms with annual receipts of $34.5 million in the fishing sector (NAICS 1141), which represent 9.1 percent of all nonemployer firms and 5.4 percent of annual receipts for all nonemployer firms in the County that year.

5.3.8.3 Dade (Miami-Dade) County

Dade County ranks second in the state in commercial landings of Caribbean spiny lobster, averaging over 6 percent of Florida's annual landings, and the two counties combined produce 96 percent of the state's commercial landings. See Table 5.3.18. Over 15 percent of FL trap-tag certificates are held by individuals in Dade County. See Table 5.3.19.

Dade County has a total area of 6,297 km^2 (2,431 square miles), with 5,040 km^2 being land and the remaining 1,257 km^2 (about 20 percent) being water (U.S. Census Bureau). Most of the area of water is Biscayne Bay, and another significant portion is adjacent waters of the Atlantic Ocean. Among its cities are Miami, Miami Beach, Coral Gables, and Key Biscayne. See Figure 5.3.11.

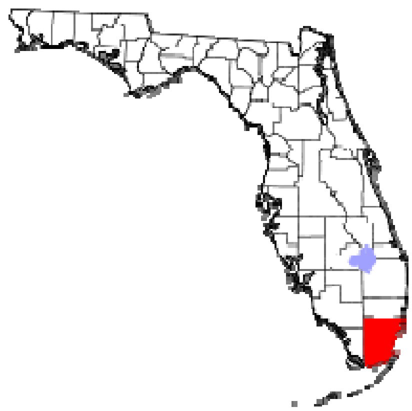

Figure 5.3.11. Dade County. *Image Source*: Wikipedia.

Dade County is the most populous county in Florida and the 8th most populous county in the nation. According to U.S. Census Bureau estimates, the population of the County grew 6.6 percent from April 1, 2000 to July 1, 2006, with approximately 2.4 million people in 2006. During that same period, the natural increase in population was 87,668 (204,079 births less 116,411 deaths) and net migration was 66,896 (257,492 net international migration less the 190,596 net internal out-migration). The number of housing units also increased from 852,414 in 2000 to 928,715 in 2005, an increase of about 9 percent. Median household income in 2004 was $34,682 and 17.1 percent of the persons in the county lived below poverty, in comparison to the statewide median household income of $40,900 and poverty rate of 11.9 percent.

Tourism is an important sector to the County economy and is the largest sector of Miami's economy. According to the Greater Miami Convention and Visitors Bureau, in 2007, 12 million overnight visitors spent $17.1 billion, an increase of $1.7 billion since 2005. Overnight visitors generated an economic impact of $13.9 billion. The Dante B. Fascell Port of Miami-Dade ranks as the world's busiest cruise/passenger port in the world. In 2006, over 3.7 million cruise passengers passed through and over 9 million tons of cargo transited through the port (Port of Miami). The combination of cruise and cargo activity supports about 98,000 jobs and generates an economic impact of $12 billion. Miami International Airport (MIA) handled 32.5 million passengers in 2006

(MIA website). Among U.S. airports, MIA ranks first in international freight, third in international passengers, and fourth in total freight.

In 2005, the County had 381 employer establishments in the industry subsector Traveler Accommodation (NAICS 7211) with 25,226 employees; 12 employer establishments in RV (Recreational Vehicle) Parks and Recreational Camps with 39 employees (U.S. Census Bureau, 2005 County Business Patterns). That same year there were 290 non-employer firms in Traveler Accommodation with annual sales of about $27.7 million and 14 non-employer firms in RV Parks & Recreational Parks with annual sales of $284,000 in the County (U.S. Census, 2005 Nonemployer Statistics). See Table 18. The largest sector by number of employees is Retail Trade (NAICS 44), which is followed by Health Care & Social Assistance (NAICS 62), Administrative and Support and Waste Management and Remediative Services (NAICS 56), Professional, Scientific & Technical Services (NAICS 54), and so on. See Table 5.3.20. Among nonemployers, the largest sector is Real Estate and Rental and Leasing (NAICS 53), which is followed by Professional, Scientific & Technical Services, Other Services (Except Public Administration), Construction, and so forth. See Table 5.3.21.

Palm Beach County is the largest county in the state by size with a total area of 6,181 km^2 (2,386 squared miles), with 5,113 km^2 being land and the remaining 1,068 km^2 (about 17.3 percent) being water, much of which is in the Atlantic Ocean and Lake Okeechobee (U.S. Census Bureau). It has 47 miles of coastline. See Figure 5.3.12.

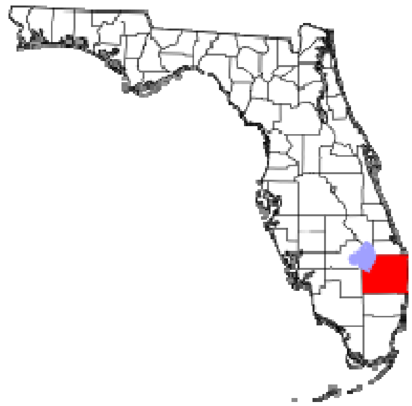

Figure 5.3.12. Palm Beach County, Florida. *Image Source*: Wikipedia.

The U.S. Census Bureau estimates the population of Palm Beach County grew over 12 percent from 2000 to 2005, with approximately 1.27 million people in 2005. The County's population growth has been dominated by in-migration from other parts of the country. From April 1, 2000 to July 1, 2006, it is estimated that there was a natural increase in the population of 6,431 (91,093 births less 88,806 deaths) and net migration of 139,754 (50,948 from net international migration plus 88,806 from net internal migration). Much of the population growth is attributable to the County being a popular destination for retirees. About 21 percent of the County's population was 65 years and over in 2005, as compared to that age group representing about 12 percent of the U.S. population and approximately 17 percent of Florida's population that year. Accompanying the increase in population has been an increase in employment. From 2000 to 2004, there was an increase of 77,553 full- and part-time jobs (U.S. Bureau of Economic Analysis). The increases in population and employment have generated increases in demand for homes, commercial and institutional buildings, and infrastructure. Median household income in the county in 2004 was $44,186 and 10.1 percent lived below poverty, as compared to the statewide median household income of $40,900 and poverty rate of 11.9 percent.

The three major multi-billion dollar industries in the county are tourism, construction, and agriculture, with tourism being number one (Palm Beach County government website, www.pbc.com/publicaffairs/facts1.htm). In 2004, over 7.2 million people visited the county, which supported $1.51 billion in wages and 7 percent of the jobs and generated an economic impact of $2.83 billion (Palm Beach County Tourist Development Council).[30]

In 2005, the top three industrial sectors by number of employees were Retail Trade (NAICS 44), Health Care & Social Assistance (NAICS 62), and Accommodation & Food Services (NAICS 72), the latter being a principal component of tourism. See Table 5.3.23. In 2005, the County had 154 employer establishments in the industry subsector Traveler Accommodation (NAICS 7211) with 5,000 to 9,999 employees; 14 employer

[30] A hotel visitor survey has found that the climate/weather, beaches/ocean, and beautiful area are what visitors like best about Palm Beach County (Palm Beach County Tourist Development Council).

establishments in RV (Recreational Vehicle) Parks and Recreational Camps with 63 employees (U.S. Census Bureau, 2005 County Business Patterns). See Table 21. That same year there were 229 non-employer firms in Traveler Accommodation with annual sales of about $27.3 million and 10 non-employer firms in RV Parks & Recreational Parks with annual sales of over $1 million in the County (U.S. Census, 2005 Nonemployer Statistics). Other important industrial sectors of the County economy include Professional, Scientific & Technical Services (NAICS 54), Retail Trade (NAICS 44), and Health Care and Social Assistance (NAICS 62).

5.3.8.5. Broward County

Broward County ranks fourth in annual landings of Caribbean spiny lobster. From 1994 through 2006 its landings represented 0.81 percent of the average annual landings during those years. County landings have dropped since reaching a peak of over 57,000 pounds in 2000. See Table 5.3.24.

Broward County has a total area of 3,418 km^2 (1,320 square miles), with 3,122 km^2 being land and the remaining 296 km^2 (about 9 percent) being water (U.S. Census Bureau). Approximately 64 percent of the county's total area lies within the Everglades conservation area, and development is restricted to 410 square miles (Broward County Planning Services Division). Major Cities include Coral Springs, Fort Lauderdale, Hollywood and Pembroke Pines. See Figure 5.3.13.

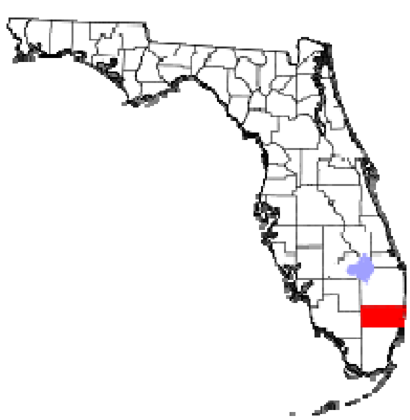

Figure 5.3.13. Broward County. *Image Source*: Wikipedia.

Broward County is the second most populated county in Florida and is the 15th most populous county in the nation. According to U.S. Census Bureau estimates, the population of Broward County grew 10.1 percent from April 1, 2000 to July 1, 2006, with approximately 1.79 million people in 2006. During that same period, the natural increase in population was 43,623 (142,787 births less 99,164 deaths) and net migration was 120,768 (100,986 net international migration plus 19,782 net internal migration), for a total increase of 164,391 people. The increase in population has resulted in increased demand for homes, retail and commercial buildings and infrastructure. Housing units increased from 741,043 in 2000 to 790,308 in 2005, an increase of less than 7 percent (U.S. Census). Median household income in the county in 2004 was $43,136 in 2004 and 11.6 percent of the persons in the county lived below poverty, as compared to the statewide median household income of $40,900 and the poverty rate of 11.9 percent. Service industries and retail trade dominate the county's economic environment. In 2005, there were more establishments in the Professional, Scientific & Technical Services sector (NAICS 54) than any other sector, and there were more paid employees in Retail Trade than any other sector. See Table 5.3.25.

Tourism's contribution is significant. In 2005, the county had a record of over 10 million visitors, a 6.3 percent increase from 2004 (Broward County Department of Urban Planning and Redevelopment, 2006). Tourism generates more than $8.4 billion and employs more than 112,000 people in the county. In 2005, Fort Lauderdale-Hollywood International Airport's over 22 million passengers broke the previous year's record of travelers passing through the facility.

In 2005, the County had 344 employer establishments in the industry subsector Traveler Accommodation (NAICS 7211) with 10,000 to 24,999 employees; 15 employer establishments in RV Parks and Recreational Camps (NAICS 7212) with 20 to 99 employees (U.S. Census Bureau, 2005 County Business Patterns). That same year there were 318 non-employer firms in Traveler Accommodation with annual sales of about $23.8 million and 17 non-employer firms in RV Parks & Recreational Parks with annual sales of $486,000 in the County (U.S. Census, 2005 Nonemployer Statistics).

*:	Zero in 2005 County Business Patterns					

Port Everglades infuses more than $2.4 billion annually to the county's economy (ibid). It handles about 4 million cruise passengers and over 26 million tons of cargo annually, and nearly 6,400 cargo and cruise ships call at the port each year (ibid). According to Broward County Department of Urban Planning and Redevelopment, Port Everglades has been ranked as one of the five fastest growing container ports among the nation's 20 largest seaports. It handles more than 22.1 percent of the entire state of Florida's waterborne imports and exports.

Fishing is another sector that is important to the Broward County economy, and coral reefs are important habitat for species targeted by commercial and recreational fishermen. In 2002, there were 26 business establishments in the charter-fishing-&-party-fishing-

boat subsector (NAICS 4872102) in the County (2002 Economic Census, Transportation and Warehousing Subject Series).

5.3.9 Puerto Rico

Puerto Rico is an archipelago comprised of the main island (Puerto Rico) and several smaller oceanic islands: Mona, Monito, Desecheo, Caja de Muertos, Vieques, and Culebra, and still smaller islands known as the "Cordillera de Fajardo." Its waters extend 9 nautical miles (10.36 statute miles) off its shore. See Figure 5.3.14. About one-third of the population lives around the capitol city of San Juan, and over 11 percent of the population in San Juan. Other major municipalities are Bayamón, Ponce, Carolina, Arecibo, Guaynabo, and Mayaguez.

Figure 5.3.14. Puerto Rico. *Image Source*: Central Intelligence Agency.

According to the U.S. Census Bureau, the population of Puerto Rico increased about 3 percent from April 1, 2000 to July 1, 2006, with approximately 3.93 million people in 2006. The increase in population has been accompanied by a larger percentage increase in housing units. Housing units increased from about 1.26 million in 2000 to approximately 1.44 million in 2005, an increase of about 14.2 percent. In 2005, median household income in Puerto Rico was $17,184, as compared to $46,242, which was the median household income for the U.S. as a whole.

Manufacturing dominates Puerto Rico's industrial sector. In fiscal year 2002, the Manufacturing sector accounted for approximately 42 percent of Puerto Rico's Gross Domestic Product. The value of sales, receipts or shipments from manufacturing was approximately $58.6 billion. See Table 5.3.25. The chemical industry is the largest component of the manufacturing sector, with about a 64 percent share (Government

Development Bank for Puerto Rico 2003), and that in turn is dominated by the pharmaceutical and medicine-manufacturing sector. Food, electronics, and apparel manufacturing are other major manufacturing industries in the Territory.
Retail Trade and Wholesale Trade follow Manufacturing as key sectors. In 2002, Retail and Wholesale Trade combined accounted for sales, receipts or shipments totaling $46.5 billion. The top three sectors by number of employees are Retail Trade, Health Care & Social Assistance, and Construction.

San Juan Port is one of the world's busiest cruise ship ports and is a central hub for Caribbean cruises. Port of Ponce is the second largest port and Mayaqúez Port, the third. Smaller ports and harbors include Guánica, Guayanilla, Guayana, Fajardo, Culebra, and Vieques.

Puerto Rico's coastline attracts tourists, and tourism, including eco-tourism, is a very important industry; it represents about 6 percent of the Territory's Gross National Product (Message of the Executive Director of Puerto Rico Tourism Company, February 9-13, 2006). An estimated 5 million tourists visited Puerto Rico in 2004 (Central Intelligence Agency). It is anticipated that recent changes in passport law, which restrict the places where one may travel without a passport, may cause an increase in the number of U.S. citizens who visit the Territory because no U.S. passport is required to travel there.[31] The eastern coast of Puerto Rico, from Fajardo to Humacao and the offshore nature islands of Vieques and Culebra, have been popular destinations for tourists who snorkel and dive. Another popular snorkeling and diving location is off La Parguera on the southwestern coast, where one can find elkhorn and staghorn corals. Rincón, a municipality on the west coast, is a popular site for coastal tourism, where tourists engage in surfing, tanning, fishing, snorkeling, and SCUBA diving (Pendleton, 2002).

Fishing is another sector that is important to the Puerto Rican economy, and coral reefs are important habitat for species targeted by commercial, recreational and subsistence fishermen. During the period from 1995 through 2002, commercial fishermen caught an average of 1.6 million tons of fish annually, with 87 percent of the fishermen targeting reef fish and invertebrates, including conch and lobster (NOAA Coral Reef Ecosystem Research Plan). In 2005, domestic landings of shallow water reef fish totaled 771,656 pounds (350,022 kilograms) with a value of $1,766,337. These landings represent approximately 66 percent of total pounds of fish landed in Puerto Rico that year. In 2005, 173,445 pounds of spiny lobster were landed with a dockside value of $997,005 and 195,701 pounds of conch were landed with a dockside value of $498,094 (Fisheries of the United States 2005).

5.3.10 U.S. Virgin Islands

The U.S. Virgin Islands consists of the main islands of St. Croix, St. John, and St. Thomas, and 54 smaller islands and keys. Combined it has a land mass of about 134 square miles (346 square kilometers) and territorial waters that encompass approximately 972 square miles (1,564 square kilometers). The U.S. Virgin Islands' waters extend 3 nautical miles (3.45 statute miles) off its shore. See Figure 5.3.15.

[31] As stated in the final rule for Documents Required for Travelers Departing From or Arriving in the United States at Air-Ports-of-Entry from Within the Western Hemisphere (71 FR 68411, November 24, 2006), "Beginning January 23, 2007, all United States citizens and nonimmigrant aliens from Canada, Bermuda and Mexico departing from or entering the United States from within the Western Hemisphere at air-ports-of-entry will be required to present a valid passport."

Figure 5.3.15. U.S. Virgin Islands. *Image Source:* Central Intelligence Agency.

According to the U.S. Census Bureau, the population of the U.S. Virgin Islands increased from 101,809 in 1990 to 108,612 in 2000, about a seven percent increase. From 1990 to 2000, the population of St. Croix increased from 50,139 to 53,234, the population of St. John increased from 3,504 to 4,197 and the population of St. Thomas expanded from 48,166 to 51,181. The population increase was accompanied by an increase in the number of housing units, which rose from 39,290 in 1990 to 50,202 in 2000, an increase of over 27 percent in ten years. Median household income of the U.S. Virgin Islands as a whole was $24,704 in 2000, compared to the U.S. median of $41,994 at that time. *The World Factbook* estimates the July 2007 population to be 108,448 (www.cia.gov/library/publications/the-world-factbook/geos/rq.html).

Tourism is the largest contributor to the U.S. Virgin Islands' economy; it accounts for 80 percent of the Territory's Gross Domestic Product and employment (Central Intelligence Agency). In 1994, the total number of visitor arrivals was approximately 1.9 million and that number increased to over 2.6 million by 2004. It is anticipated that recent changes in U.S. passport laws, which restrict the places a U.S. citizen can travel to without a passport, may cause an increase in the number of U.S. citizens who visit the Territory because no U.S. passport is required to travel there. A survey conducted for the Virgin Islands Department of Planning and Natural Resources found that 100 percent of hotel industry participants answered that there would be a significant impact on tourist visits to the U.S. Virgin Islands if the coast/beaches were degraded or fisheries and/or coral reefs declined (U.S. Virgin Islands 2003).

Retail Trade is the largest sector by number of establishments, number of employees, annual payroll, and value of sales, receipts or shipments. See Table 5.3.26. Accommodation & Food Services is the second largest sector, followed by Construction. In 2002, the value of construction work was about $286 million, an increase of about 55 percent from 1997, and an increase of about 70 percent from 1992 (U.S. Census Bureau, Economic Census). Among this construction are new, remodeled, and expanded hotels and resorts. Important industries within manufacturing include petroleum refining, watch assembly, rum distilling, pharmaceuticals, textiles, and electronics.

5.3.11 Hurricanes

Hurricanes can have both positive and negative economic impacts on spiny lobster fishermen, especially those that use traps. The beneficial impact is that a hurricane can cause lobsters to move and go into traps and nets, which increases landings. However, the negative impacts include damages to and losses of traps, other gear, and vessels and associated losses of landings and revenues.[32]

On September 25, 1998, Hurricane Georges struck Florida with reported maximum sustained winds of approximately 95 miles per hour with gusts up to 115 miles per hour and an approximate storm surge of up to seven (7) feet. Several counties had widespread damage, including Monroe County (Wetherell). One of the worst hurricane seasons on record was the 2005 season. Of those that hit the coast of Florida, the four of Dennis (July), Katrina (August), Rita (September), and Wilma (October) had a significant adverse impact on spiny lobster trap fishers. According to a May 1, 2006, article at *keysnews.com*, Florida Keys lobster trap fishermen "reported losing up to 70 percent of their traps in the four hurricanes that skirted the Keys in 2005. Officials have estimated that the hurricanes cost lobster fishermen $35 million in lost traps and catch" (O'Hara, May 1, 2006). In April 2006, the Florida Hurricane Relief Fund, which was established in 2004, gave $0.5 million to the Florida Keys Commercial Fishermen's Association (Association) to help lobster and stone crab fishers in Monroe and Miami-Dade counties replace traps lost to the 2005 hurricane season. According to the Association's executive director, the money will be equally distributed among the fishermen who apply for aid (ibid).[33]

5.4 Administrative Environment

5.4.1 Federal Fishery Management

Federal fishery management is conducted under the authority of the Magnuson-Stevens Act (16 U.S.C. 1801 et seq.), originally enacted in 1976 as the Fishery Conservation and Management Act. The Magnuson-Stevens Act claims sovereign rights and exclusive fishery management authority over most fishery resources within the EEZ, an area extending 200 nautical miles from the seaward boundary of each of the coastal states, and authority over US anadromous species and continental shelf resources that occur beyond the EEZ.

Responsibility for federal fishery management decision-making is divided between the Secretary and eight regional fishery management councils that represent the expertise and interests of constituent states. Regional councils are responsible for preparing, monitoring, and revising management plans for fisheries needing management within their jurisdiction. The Secretary is responsible for promulgating regulations to implement proposed plans and amendments after ensuring management measures are consistent with the Magnuson-Stevens Act and with other applicable laws summarized in Section 10. In most cases, the Secretary has delegated this authority to NMFS.

---

[32] Traps are not insurable.

[33] To prove eligibility, a commercial lobster and stone crab fishermen "must show tax receipts for the past several years and documents showing their landings" (O'Hara, May 1, 2006).

The Councils are responsible for fishery resources in federal waters of their respective regions. These waters extend to 200 nautical miles offshore from the nine-mile seaward boundary of the states of Florida Texas and the territory of Puerto Rico, and the three-mile seaward boundary of the Atlantic side of Florida and the states of Alabama, Georgia, Louisiana, Mississippi, North Carolina, South Carolina, and the territory of the USVI.

The Councils consist of voting members: public members appointed by the Secretary; one each from the fishery agencies of the state or territory, and one from NMFS. The public is also involved in the fishery management process through participation on advisory panels and through council meetings that, with few exceptions for discussing personnel matters and litigation, are open to the public. The regulatory process is also in accordance with the Administrative Procedures Act, in the form of "notice and comment" rulemaking, which provides extensive opportunity for public scrutiny and comment, and requires consideration of and response to those comments.

Regulations contained within FMPs are enforced through actions of the NOAA's Office of Law Enforcement, the USCG, and various state authorities. To better coordinate enforcement activities, federal and state enforcement agencies have developed cooperative agreements to enforce the Magnuson-Stevens Act.

5.4.2 State Fishery Management

The purpose of state/territory representation at the council level is to ensure state/territory participation in federal fishery management decision-making and to promote the development of compatible regulations in state/territory and federal waters. The state and territorial governments have the authority to manage their respective state/territorial fisheries. Each of the states and territories exercises legislative and regulatory authority over their states'/territories' natural resources through discrete administrative units. Although each agency is the primary administrative body with respect to the states'/territories' natural resources, all states/territories cooperate with numerous state/territory and federal regulatory agencies when managing marine resources.

6.0 ENVIRONMENTAL CONSEQUENCES

6.1 Action 1: Minimum Size Limits for Spiny Lobster (*Panulirus argus)* Imported into the United States

6.1.1 Direct and Indirect Effects on the Physical, Biological, and Ecological Environment

Many regional populations of spiny lobsters are fully capitalized or overfished as indicated by declining catch-per-unit effort in local fisheries (Ehrhardt 1994; Fonteles-Filho 1994). The distribution and dispersal of *P. argus* is determined by the long planktonic larval phase, called the puerulus, during which time the infant lobsters are carried by the currents until they become large enough to settle to the bottom (Davis and Dodrill 1989). Individuals two to four years old exhibit nomadic behavior emigrating out of the shallows and moving to deeper, offshore environments. Given the wide distribution and nomadic behavior, it is hard to determine a definitive stock structure for this species. Additionally, there are a multitude of currents and other factors that influence the movement of water throughout the range of *P. argus* making it more difficult to predict, with any certainty, the distribution and settlement patterns of larvae.

The strong flow of the Caribbean Current as well as localized gyres in the south of Cuba, Central America, Puerto Rico, and around the Florida Keys increases the probability of the mixing of larval populations from different regions. Because of this mixing, regional cooperation is extremely important in managing the spiny lobster population. During a number of meetings (e.g., Merida, 2000 and OSPESCA, 2007), representatives from the various Caribbean, Central, and South American Nations have begun building a cooperative management strategy. This strategy includes the acknowledgement that spawning biomass and potential yield would benefit from an increase in the minimum size of lobster being caught. However, numerous issues still exist with implementation of this strategy in a number of participating countries.

As a means to facilitate this strategy, a number of countries and industry representatives have sought a law in the U.S. that would implement minimum conservation standards on lobster being imported into the U.S. As the top importer of spiny lobster products, the U.S. has considerable influence in the market of those products. If an import law were implemented to require spiny lobster products to meet minimum conservation standards, exporting countries and the fisheries within those countries would have incentive to meet those minimum conservation standards. These minimum conservation standards would achieve an increase in the spawning biomass and increase potential yield by limiting imports to a size at which approximately 50 % of the population has had a chance to spawn prior to harvest.

The measures presented for restricting imports are nearly identical to those put forth in the various meetings throughout the history of cooperative management meetings. As an example, the OSPESCA workshop accords of 2007 recommended a minimum harvest size for lobster tails of 140 mm (5.5 inches) and an average tail weight of 5 ounces, ranging from 4.5 to 5.5. The conservation standards presented in Action 1 **Alternative 3** are consistent with these recommendations. The difference in tail weight between the workshop accords and those in the document are a matter of an industry practice versus scientific conversions.

As discussed in Section 4.1, the 4.5 ounce tail weight recommendation was not based on scientific conversions from the recommended 140 mm tail length, but was instead based on industry practice of sorting and shipping. Tables 4.1.2 and 4.1.3 provide conversions from carapace length to tail length and tail weight based on Matthews et al. (2003). If we examine the 140 mm (5.5 inch) tail length recommendation, we see it is derived from one standard deviation of the mean for a 3.0 inch (76.2 cm) carapace length animal (table 4.1.3, in green). Therefore, if a tail length recommendation is based on one set of scientific standards, all conversions from the carapace length should be based on that same standard. Therefore, the appropriate tail weight to be used for a 3.0 inch carapace length animal would be a 4.15 ounce tail weight (Table 4.1.3, in yellow). This, like the tail length recommendation is based on one standard deviation from the mean for the measurements of a 3.0 inch carapace length animal. For the purpose of simplifying this requirement, the weight has been rounded to one decimal place to make the requirement a 4.2 ounce tail weight. For imports to the U.S. Caribbean, similar conversions from a 3.5 inch CL animal yield a minimum TW of 5.9 ounces and a TL of 6.2 inches (Table 4.1.3, in turquoise).

Preferred Alternative 2 would require imports to meet one of two sets of standards, dependent on port of entry for the product. For those products entering the U.S., the requirements would be the same as those for **Alternative 3** (4.2 oz TW, > 3" CL, 5.5" TL); for those products entering the U.S. Caribbean the minimum conservation standards would be slightly more restrictive. Currently, the U.S. Caribbean has a domestic law requiring spiny lobster to have a CL of at least 3.5 inches. Therefore, in an effort to be fair and equitable to U.S. Caribbean fishermen, the measures for importing spiny lobster to the U.S. Caribbean would require lobster to have at least a 5.9 oz TW, 3.5 inch CL, or 6.2 inch TL

The differences between the continental U.S. and U.S. Caribbean minimum size limits stems from the scientific uncertainty of the size at 50% maturity for spiny lobster and the fecundity of a typical female at a given size. As an illustration of fecundity at size, from the Florida Fish and Wildlife Conservation Commission's Ad Hoc Advisory Board synopsis:

"For spiny lobster, the typical number of eggs produced per clutch of a 3 inch carapace length female is 300 thousand eggs. A 3.5 inch carapace length female produces 500 thousand eggs; a 4 inch carapace length female produces 700 thousand eggs. A 3 inch carapace length lobster may produce two clutches, but by the time female lobsters attain a 4 inch carapace length, the typical number of clutches per breeding season is three, perhaps four."

By increasing the size limit from 3 to 3.5 inches, an increase of 250% to 350% in egg releases would be seen in a breeding season per lobster. Obviously this is an enormous increase in egg production and would have a significant impact on future lobster population size and structure.

To further understand the fecundity dynamics of female lobster and the uncertainty around size at maturity Bertelsen and Matthews (2001) examined two populations of spiny lobster in the Florida Keys. The authors compared the size structure, fecundity, and reproductive season of spiny lobsters in the Dry Tortugas National Park sanctuary with those of spiny lobsters in the south Florida fishery. The number of lobsters of both sexes larger than the legal size limit declined sharply in the fishery but not in the sanctuary. Clutch sizes were larger in the sanctuary (avg. 0.8 million) than in the fishery (avg. 0.3 million), and the reproductive season was shorter and more intense in the sanctuary than in the fishery. In addition, lobsters in the sanctuary begin egg production at a larger size and produce more eggs per gram of body mass than lobsters in the fishery.

Lobsters less than 70 mm CL were found to produce eggs in the fishery but very few lobsters less than 80 mm CL and none less than 70 mm CL produce eggs in the sanctuary.

Because of the obvious benefits of having a 3.5 inch CL minimum size, the Caribbean Council adopted this measure in their FMP and feel it would be more beneficial to the pan-Caribbean spiny lobster population to implement this size limit throughout the species range. Therefore, the Caribbean Council feels it is prudent and justifiable to require imports to meet the same minimum conservation standards as those applied to the local lobster population and which must be met by fishermen that harvest those lobsters.

Based on the discussion of the relationship between size and fecundity, **Preferred Alternative 2** would be more beneficial to the spiny lobster population than either **Alternative 1** or **Alternative 3**. **Preferred Alternative 2** would require at least some portion of lobster to meet the more conservative morphometric requirements (those imported to the U.S. Caribbean) and therefore benefit the population more. However, **Alternative 3** is more conservative than **Alternative 1** and would be more beneficial to the population than not having any import conservation standards in place. If **Alternative 1** were to be the preferred alternative, there would continue to be importation of lobsters below any size at maturity (i.e., juvenile lobsters), which would continue to contribute to the over-exploitation problems seen in much of the range of spiny lobsters. Therefore, **Preferred Alternative 2** would be the most beneficial to the pan-Caribbean spiny lobster population followed by **Alternative 3** and **Alternative 1** in decreasing order of benefits.

Aside from an increase in the spawning biomass and increase in potential yield, requiring lobsters to meet minimum conservation standards is expected to have effects on the communities these animals inhabit. The spiny lobster is an important predator and prey organism in the reef and seagrass community. After the larvae settle out of the planktonic phase, they enter the seagrass and macroalgae habitat where they feed on small gastropods, mollusks, amphipods, and ostracods. As adults, the lobsters feed on slow-moving or stationary invertebrates such as sea urchins, mussels, gastropods, clams, and snails (Lipcius and Cobb 1994). At both the juvenile and adult stage, spiny lobsters are an important food item for larger finfish and sharks.

By increasing the spawning biomass, it would be expected for more lobsters to settle out of the planktonic phase and into the juvenile habitat. More lobsters in the juvenile habitat would in turn have an effect on the food web dynamics of the seagrass macroalgae community and those inhabitants. Likewise, more lobsters would reach adult size and migrate out to the reef community where they would forage on slow moving or sessile invertebrates of that community. There would also be an expected increase of finfish and sharks preying on the increased biomass of lobsters. This series of events from increasing the spawning biomass would be expected to have overall benefits on the seagrass and reef communities inhabited by spiny lobster. Therefore, **Preferred Alternative 2** would indirectly have the most beneficial effect on the environment of the spiny lobster with **Alternative 3** providing somewhat reduced benefits and **Alternative 1** providing no additional benefits above what is witnessed in the seagrass and reef environments now.

The impacts of **Alternatives 1-3** will have no adverse affect on protected species occurring in U.S. waters, as this action is primarily administrative in nature. In the event these alternatives reduce spiny lobster fishing effort in exporting countries, the likelihood of adverse impacts from the fishery occurring to ESA-listed species located there may be reduced. However, any such benefit is anticipated to be very minor.

6.1.2 Direct and Indirect Effects on the Economic Environment

The greatest economic impact of the alternatives under consideration for Action 1, other than Alternative 1, should be on those who illegally import undersized Caribbean spiny lobster. Some currently legally imported spiny lobster are expected not to meet the proposed import-size standards and will be affected; however, the majority of legal spiny lobster imports are not expected to be affected by the proposed size standards. See Section 7.5.1. The greatest direct economic effect will be the significant reduction in illegal imports of undersized lobsters and the greatest indirect effects will be the associated reductions in illegal revenues, profits and revenues generated by those imports. The other direct economic effect will be fewer legal imports from countries whose size standards do not meet or exceed those proposed in each of the two alternatives, which will have associated reductions in legal revenues, profits and revenues generated by those imports. However, in the long run, the status of the domestic and foreign stocks should improve and with those improvements there should be associated economic benefits. See Section 7.5.1.4 for a comparison of the direct and indirect economic costs and benefits of the various alternatives for this particular action. The direct and indirect effects of this action are dependent upon the second action because without additional harvest restrictions, illegal importers may increase their use of methods to avoid detection of undersized lobsters, such as removing the meat from the shell and packaging it into chunks.

Action 1, other than Alternative 1, will also indirectly affect people who are presently damaged economically by the illegal importation of Caribbean spiny lobster, particularly Florida, Puerto Rico, and U.S. Virgin Islands spiny lobster fishermen who compete economically with those who add to the national supply of spiny lobster by importing and selling undersized lobsters. Domestic spiny lobster fishermen should benefit economically from an increase in market price that is associated with a reduction of market supply of spiny lobster that is caused by the improved detection and prevention of black market imports.

6.1.3 Direct and Indirect Effects on the Social Environment

Action 1, Alternatives 2 and 3 is expected to directly affect how people in the U.S. trade for non-domestically harvested Caribbean spiny lobster, especially those who presently knowingly or unknowingly import spiny lobsters that do not meet size standards of the country of origin. It should make those people who purposively import undersized spiny lobster less confident in black market activity, which should cause them to abandon or at least greatly reduce such illegal trade. At the same time, those who legally import spiny lobsters should become more confident that their import activities support sustainable spiny lobster fisheries, which may alter their domestic marketing of imported Caribbean spiny lobster by promoting it as a product of sustainable trade and fishing practices. However, the amount of confidence lost by black market traders or gained by legal importers would also depend upon the second action because Action 1 alone would not prevent illegal importers from removing the meat from the shell and packaging it into chunks to avoid detection of undersized lobsters. It should be noted, the proposed actions would also directly and indirectly affect those individuals, groups or communities that legally harvest and trade spiny lobster from countries that do not have size or other harvest restrictions that meet or exceed those proposed in the alternatives; however, most countries have size and harvest restrictions that satisfy the proposed import standards. In combination, both Action 1, Alternatives 2 and 3 and Action 2, Alternatives 2, 3, and 4 are expected to adversely affect cultural traditions and social networks of organized crime groups and communities that engage in the illegal importation of undersized spiny lobsters. Furthermore, the same combination of actions is expected to beneficially affect cultural traditions and social networks of groups and communities that engage in the legal importation of Caribbean spiny lobsters.

Action 1, other than Alternative 1, should indirectly affect people who buy, handle, transport, process, sell, and/or consume Caribbean spiny lobster after it has been imported by reducing the quantity of spiny lobster imported annually into the United States. The greatest indirect effect should be on those who knowingly or unknowingly buy, handle, transport, process, sell and/or consume imported undersized lobsters. In combination with Action 2, Alternatives 2, 3, and 4, Action 1, Alternatives 2 and 3 should adversely affect cultural traditions and social networks of organized crime groups and communities that purposively engage in the buying, handling, transports, processing, selling, and/or consumption of illegally imported spiny lobster by decreasing both the confidence and abilities of people within those groups and/or communities to engage in such activities. At the same time, Action 1, other than Alternative 1, in combination with Action 2, other than Alternative 1, should benefit cultural traditions and social networks of groups and communities that purposively support legal and sustainable trade practices by increasing the confidence and abilities of people within those groups and/or communities to buy, handle, transport, process, sell and/or consume imported spiny lobsters that are consistent with legal and sustainable trade and fishing practices.

Action 1, other than Alternative 1, should also indirectly affect domestic Caribbean spiny lobster fishermen by increasing their confidence in Federal efforts to protect and sustain their fishing livelihoods. In turn, the increased confidence should support existing cultural traditions and social networks of domestic spiny lobster fishermen and communities.

6.1.4 Direct and Indirect Effects on the Administrative Environment

Implementation and enforcement of size limits and other conservation standards is an administrative action designed to benefit the biological environment of the target species.

Therefore, the actions in this amendment will affect the administrative environment. Sections 5.3 and 5.4 discuss the affected administrative environments and the valued environmental components (VEC) of the administrative environment within the lobster fishery. This amendment will affect three VECs within the administrative environment: management, law enforcement, and industry.

Promulgating regulations is a management action that requires development, implementation, and monitoring of the regulations and their effects. This action is designed to improve the stock status of the Caribbean spiny lobster throughout its range, therefore it will be incumbent upon management to monitor the spiny lobster stock and ensure the regulations are having the desired effect on the stock. If the desired effects are not seen within the spiny lobster population, management will need to evaluate the regulations and adjust accordingly to achieve the purpose identified in the purpose and need section: improve stock status.

The other necessary component of regulations is the enforcement of those regulations. Without the efforts of law enforcement officials, no change in the lobster stock would be expected regardless of the regulations developed and implemented. Currently, the law enforcement environment is over-burdened in its attempts to stem the flow of undersized lobster entering the U.S. This burden is two-phased; one being the volume of lobster imports that enters the country (see Section 5.3) and the second is the lack of a strong regulation to enforce minimum conservation standards on imported lobsters. The volume of lobster imports is not likely to see a decrease as food resources throughout the world are constantly stretched to support a growing population. Therefore, a stronger regulatory framework to work under will provide the only relief to law enforcement officials.

Currently, any cases developed by law enforcement agents must be done under the Lacey Act. This law requires the cooperation of foreign nations, which has proven difficult in the past for a number of reasons, including resources, political will power, and foreign cooperation. With the implementation of either **Preferred Alternative 2** or **Alternative 3** law enforcement will have a more appropriate tool to stop or greatly reduce undersize imports from entering the country. Imports that do not meet the minimum conservation standards set forth in this amendment will be illegal and agents will be able to develop cases against those responsible for the imports without the need for foreign cooperation. Further, **Preferred Alternative 2** would be of greater value to law enforcement than **Alternative 3**.

Preferred Alternative 2 would require imports to meet the minimum conservation standards of the domestic law for the port of entry into which the imports are arriving. For example, imports into the USVI and Puerto Rico would need to have a TW measurement of 5.9 oz or greater. By requiring imports to meet the conservation standards of the port of entry, potential loopholes for harvesting domestic product and labeling it as imported product in an effort to circumvent domestic laws will be eliminated. This will eliminate the potential burden for law enforcement agents of disseminating local product from imported product as it all has to meet one set of standards. Therefore, **Preferred Alternative 2** would directly benefit law enforcement agents the most.

The third administrative environment effected by requiring imports to meet minimum conservation standards is that of the industry itself. Current industry practice sorts, packs, and sells lobster tails by weight category. These categories are generally whole ounce categories such as 4 ounce or 7 ounce tails, which includes a range of weights. For example a 7 ounce would have tails ranging in weight from 6.5 to 7.5 ounces. Under either **Preferred Alternative 2** or **Alternative 3** industry practice would have to change slightly to accommodate the minimum weight requirements into the appropriate whole weight category. **Preferred Alternative 2** would require industry to change the weight range for a 5 ounce tail to include tails weighing 4.2 ounces as opposed to the current 4.5 ounces for those imports into the U.S.; for those lobsters imported to the U.S. Caribbean, the 6 ounce category would need to be changed to include lobsters that weighed 5.9 ounces as opposed to the current 5.5 ounces. **Alternative 3** would require industry to change the weight range for a 5 ounce tail to include tails weighing 4.2 ounces as opposed to the current 4.5 ounces for all imports. And obviously, the 2, 3, and 4 ounce weight categories would need to be eliminated completely.

The implementation of minimum conservation standards is expected to indirectly benefit the administrative environment. Industry is expected to indirectly benefit through the increased production of the lobster stock, thus meeting an ever growing demand globally for protein sources. Law enforcement will be able to focus on a wider range of enforcement issue without having to devote such an inordinate amount of time to developing cases against importers of illegal size lobster as they now have to do through the Lacey Act.

6.2 Action 2: Other Import Restrictions

6.2.1 Direct and Indirect Effects on the Physical, Biological, and Ecological Environment

These other conservation standards applied to the spiny lobster products (i.e., prohibitions on the possession/importation of lobster tail meat, berried lobsters, lobsters that have been stripped or clipped) are expected to benefit the biological and ecological environment by providing additional protection to the spawning stock in the wider Caribbean. The degree to which these restrictions benefit the spiny lobster resource will depend largely on the effectiveness of enforcement at the country of exportation and the ability of LE officials to curtail the flow of such product. Establishing additional restrictions on the imports of spiny lobster such as prohibiting lobster meat and berried lobster, in combination with the size limits proposed in Action 1, would compliment efforts in improving the status of the spiny lobster stock. Prohibiting imports of berried lobster would allow for females to release those clutches and produce additional clutches, which will eventually recruit to the adult population and the fishery. While eliminating the allowance of lobster meat will protect smaller individuals that would otherwise be harvested and processed into lobster meat product.

As discussed in section 4.2, lobster importers/exporters developed methods for circumventing minimum size standards when there was “a lot of pressure on under 5 oz” by creating a “lobster meat” product. This “lobster meat” product would have the effect of undermining any conservation standard minimum size limits developed to increase the spawning stock biomass of the spiny lobster population. Therefore, **Preferred Alternative 2** and **Alternative 3** would eliminate this loophole that was developed when importers/exporters realized LE officials were cracking down on illegal size imports. By doing so, **Preferred Alternative 2** and **Alternative 3** are expected to have positive direct effects on the biological and ecological environment of spiny lobster.

Any measure designed to protect individuals in an active reproductive mode would obviously directly benefit the stock and help to achieve an increase in spawning stock biomass and long-term yield. The second part of **Preferred Alternative 2** and **Alternative 4** would achieve such a protection (prohibiting the importation of spiny lobster with eggs attached or importation of spiny lobster where the eggs, swimmerets, or pleopods have been removed or stripped). In order to achieve the maximum benefits of the minimum conservation standards in Action 1, females in the process of reproducing must be allowed to complete that biological process without disruption. Therefore, in order to afford females with the most protection, even those animals that have been physically mutilated (removal of eggs, swimmerets, etc) to “hide” the condition of the animal must be considered illegal.

Aside from an increase in the spawning biomass and increase in potential yield, requiring lobsters to meet minimum conservation standards is expected to have effects on the communities these animals inhabit. The spiny lobster is an important predator and prey organism in the reef and seagrass community. After the larvae settle out of the planktonic phase, they enter the seagrass and macroalgae habitat where they feed on small gastropods, mollusks, amphipods, and ostracods. As adults, the lobsters feed on slow-moving or stationary invertebrates such as sea urchins, mussels, gastropods, clams, and snails (Lipcius and Cobb 1994). At both the juvenile and adult stage, spiny lobsters are an important food item for larger finfish and sharks.

By increasing the spawning biomass, it would be expected for more lobsters to settle out of the planktonic phase and into the juvenile habitat. More lobsters in the juvenile habitat would in turn have an effect on the food web dynamics of the seagrass macroalgae community and those inhabitants. Likewise, more lobsters would reach adult size and migrate out to the reef community where they would forage on slow moving or sessile invertebrates of that community. There would also be an expected increase of finfish and sharks preying on the increased biomass of lobsters. This series of events from increasing the spawning biomass would be expected to have overall benefits on the seagrass and reef communities inhabited by spiny lobster. Therefore, **Preferred Alternative 2** would indirectly have the most beneficial effect on the environment of the spiny lobster with **Alternative 3** providing somewhat reduced benefits and **Alternative 1** providing no additional benefits above what is witnessed in the seagrass and reef environments now.

The impacts of **Alternatives 1-3** will have no adverse affect on protected species occurring in U.S. waters, as this action is primarily administrative in nature. In the event these alternatives reduce spiny lobster fishing effort in exporting countries, the likelihood of adverse impacts from the fishery occurring to ESA-listed species located there may be reduced. However, any such benefit is anticipated to be very minor.

.

6.2.2 Direct and Indirect Effects on the Economic Environment

The greatest economic impact of the alternatives under consideration for Action 2 should be on those who illegally import Caribbean spiny lobster with eggs or with their eggs or pleopods removed. Some currently legally imported spiny lobster is expected not to meet the proposed harvest restrictions and will be affected; however, the majority of legal spiny lobster imports are not expected to be affected by these proposed alternatives. See Section 7.5.2. The greatest direct economic effect will be significantly less illegal imports and the greatest indirect effects will be associated reductions in illegal revenues, profits and revenues generated by those imports. The other direct economic effect will be fewer legal imports from countries whose size and other harvest standards do not meet or exceed those proposed in the two actions, which will have associated reductions in legal revenues, profits and revenues generated by those imports. However, in the long run, the status of the domestic and foreign stocks should improve and with that improvements there should be associated economic benefits. See Sections 7.5.1.4 and 7.5.2.5 for a comparison of the direct and indirect economic costs and benefits of the various alternatives for this action. The direct and indirect effects of the first action are dependent upon this action because without additional harvest restrictions, illegal importers may increase their use of methods to avoid detection of undersized lobsters, such as removing the meat from the shell and packaging it into chunks.

Action 2 should also indirectly affect people who are presently damaged economically by the illegal importation of Caribbean spiny lobster, particularly Florida, Puerto Rico, and U.S. Virgin Islands spiny lobster fishermen who compete economically with those who add to the national supply of spiny lobster by importing and selling lobsters with eggs or with their eggs or pleopods removed. Domestic spiny lobster fishermen should benefit economically from an increase in market price that is associated with a reduction of market supply of spiny lobster due to improved detection and prevention of black market imports.

6.2.3 Direct and Indirect Effects on the Social Environment

The United States is the largest importer of Caribbean spiny lobster, and the illegal international trade of the species is a serious problem. Action 2 is designed to reduce the problem by improving the detection and prevention of the illegal importation of female lobsters with eggs or those that have had their eggs removed and lobster meat taken from undersized lobsters.

Action 2, other than Alternative 1, is expected to directly affect how people in the U.S. trade for non-domestically harvested Caribbean spiny lobster, especially those who presently knowingly or unknowingly import female spiny lobsters with their eggs attached or removed and/or lobster meat taken from undersized lobsters. It should make those people who illegally import spiny lobster less confident in black market activity, which should cause them to abandon or at least greatly reduce such illegal trade. At the same time, those who legally import spiny lobsters should become more confident that their import activities support sustainable spiny lobster fisheries, which may alter their domestic marketing of imported Caribbean spiny lobster by promoting it as a product of sustainable trade and fishing practices. However, the amount of confidence lost by black market traders or gained by legal importers would also depend upon the first action because Action 2 alone would not discourage and reduce the importation of undersized lobsters. It should be noted, the proposed actions would also directly and indirectly affect those individuals, groups or communities that legally harvest and trade spiny lobster from countries that do not have these other harvest restrictions that meet those proposed in the alternatives; however, most countries have harvest restrictions that satisfy the proposed import standards. In combination, both Action 1 and Action 2 are expected to adversely affect cultural traditions and social networks of organized crime groups and communities that engage in the illegal importation of Caribbean spiny lobster. Furthermore, the same combination of actions is expected to beneficially affect cultural traditions and social networks of groups and communities that engage in the legal importation of Caribbean spiny lobsters.

Action 2 should indirectly affect people who buy, handle, transport, process, sell, and/or consume Caribbean spiny lobster after it has been imported by reducing the quantity of spiny lobster imported annually into the United States. The greatest indirect effect should be on those who knowingly or unknowingly buy, handle, transport, process, sell and/or consume illegally imported lobsters. In combination with Action 1, Action 2 should adversely affect cultural traditions and social networks of organized crime groups and communities that support, engage in, and benefit from the buying, handling, transports, processing, selling, and/or consumption of illegally imported spiny lobster. Also, in combination with the first action, this second action should increase the confidence of people, who receive Caribbean spiny lobster after importation, that the spiny lobsters that they are buying, handling, transporting, processing, selling and/or consuming are products of legal and sustainable trade and fishing practices.

Action 2 would also indirectly affect domestic Caribbean spiny lobster fishermen by increasing their confidence in Federal efforts to protect and sustain their fishing livelihoods. In turn, the increased confidence will support existing cultural traditions and social networks of domestic spiny lobster fishermen and communities.

6.2.4 Direct and Indirect Effects on the Administrative Environment

Implementation and enforcement of size limits and other conservation standards is an administrative action designed to benefit the biological environment of the target species. Therefore, the actions in this amendment will affect the administrative environment. Sections 5.3 and 5.4 discuss the affected administrative environments and the valued environmental components (VEC) of the administrative environment within the lobster fishery. This amendment will affect three VECs within the administrative environment: management, law enforcement, and industry.

Promulgating regulations is a management action that requires development, implementation, and monitoring of the regulations and their effects. This action is designed to improve the stock status of the Caribbean spiny lobster throughout its range, therefore it will be incumbent upon management to monitor the spiny lobster stock and ensure the regulations are having the desired effect on the stock. If the desired effects are not seen within the spiny lobster population, management will need to evaluate the regulations and adjust accordingly to achieve the purpose identified in the purpose and need section: improve stock status.

The other necessary component of regulations is the enforcement of those regulations. Without the efforts of law enforcement officials, no change in the lobster stock would be expected regardless of the regulations developed and implemented. Currently, the law enforcement environment is over-burdened in its attempts to stem the flow of undersized lobster entering the U.S. This burden is two-phased; one being the volume of lobster imports that enters the country (see Section 5.3) and the second is the lack of a strong regulation to enforce minimum conservation standards on imported lobsters. The volume of lobster imports is not likely to see a decrease as food resources throughout the world are constantly stretched to support a growing population. Therefore, a stronger regulatory framework to work under will provide the only relief to law enforcement officials.

Currently, any cases developed by law enforcement agents must be done under the Lacey Act. This law requires the cooperation of foreign nations, which has proven difficult in the past for a number of reasons, including resources, political will power, and cooperation. NOAA’s Office of Law Enforcement, Southeast Region, has made several significant Lacey Act cases involving undersized spiny lobster (w/ Honduras, Nicaragua, Bahamas, and an ongoing one with Brazil). These cases typically are criminal and are rather complex in nature due to the need for cooperation with foreign governments, poorly written foreign laws, and the millions of dollars of illegal proceeds. When investigating these significant lobster import cases, NOAA’s Special Agents and Department of Justice prosecutors have frequently encountered defense attorneys and defendants that have attempted to undermine the foreign lobster laws of the harvesting countries in order to invalidate the Lacey Act and the U.S. efforts to apprehend those responsible. A U.S. minimum restriction applicable to spiny lobster imports would greatly assist law enforcement and federal prosecutors to stem the illegal and profitable flow of undersized imports into the U.S. markets. With the implementation of **Preferred Alternative 2**, **Alternative 3**, or **Alternative 4** law enforcement will have a more appropriate tool to stop or greatly reduce illegal import products from entering the country. Imports that do not meet the minimum conservation standards set forth in this amendment will be illegal and agents will be able to develop cases against those responsible for the imports without the need for foreign cooperation. Further, **Preferred Alternative 2** would be of greater value to law enforcement than **Alternative 3** or **Alternative 4**.

Preferred Alternative 2 would require imports to meet the minimum conservation standards of the existing domestic laws. For example, the possession/harvest of berried females is illegal in both domestic FMP's. By requiring imports to meet the conservation standards of the domestic rules, potential loopholes for harvesting domestic product and labeling it as imported product in an effort to circumvent domestic laws will be eliminated. This will eliminate the potential burden for law enforcement agents of disseminating local product from imported product as it all has to meet one set of standards. Therefore, **Preferred Alternative 2** would directly benefit law enforcement agents the most.

The third administrative environment effected by requiring imports to meet minimum conservation standards is that of the industry itself. Current industry practice sorts, packs, and sells lobster tails by weight category. These categories are generally whole ounce categories such as 4 ounce or 7 ounce tails, which includes a range of weights. For example a 7 ounce would have tails ranging in weight from 6.5 to 7.5 ounces. Under either **Preferred Alternative 2, Alternative 3,** or **Alternative 4** no industry practice would have to change, other than the illegal activity seen in the documents identified in an earlier discussion and seen in Appendix A. Any mention of "lobster meat" would immediately be cause for concern by LE officials and thus, would not be expected to be seen in the industry practices.

The implementation of minimum conservation standards is expected to indirectly benefit the administrative environment. Industry is expected to indirectly benefit through the increased production of the lobster stock, thus meeting an ever growing demand globally for protein sources. Law enforcement will be able to focus on a wider range of enforcement issue without having to devote such an inordinate amount of time to developing cases against importers of illegal size lobster as they now have to do through the Lacey Act.

6.3 Comparison of Alternatives to Magnuson-Stevens Act National Standards

National Standard 1

This national standard states conservation and management measures shall prevent overfishing while achieving, on a continuing basis, the optimum yield from each fishery. The intent of this amendment is to provide foreign countries a market incentive to enhance the sustainability of the Pan-Caribbean spiny lobster population by restricting imports and the possession of imported products. This restriction is designed to realize the long-term benefits of a properly managed resource, which will increase yield (and thereby achieve optimum yield) by allowing those individuals that would otherwise perish in the status quo fishery to reach a sexually mature size and contribute to the reproductive capability of the stock.

National Standard 2

This national standard requires conservation and management measures be based on the best scientific information available. The rationale in developing the amendment is based on numerous peer-reviewed scientific studies from the U.S., the U.S. Caribbean and other similar tropical reef fisheries. These resources were analyzed and discussed in Sections 4 and 6, and provide the basis for the decision and selection of preferred alternatives.

National Standard 3

This national standard requires to the extent practicable, an individual stock of fish shall be managed as a unit throughout its range, and interrelated stocks of fish shall be managed as a unit or in close coordination. Spiny lobsters are found from North Carolina to Brazil throughout the Caribbean. This amendment will implement a minimum import size in an attempt to protect juvenile lobsters throughout the Caribbean.

National Standard 4

This national standard requires conservation and management measures not discriminate between residents of different states. This amendment will apply only to imports and in no way assigns domestic harvest privileges among U.S. fishermen.

National Standard 5

This national standard requires conservation and management measures shall, where, practicable, consider efficiency in the utilization of fishery resources; except that no such measure shall have economic allocation as its sole purpose. This amendment will only apply to imports and does not address the efficiency of the domestic fishery.

National Standard 6

This national standard requires conservation and management measures take into account and allow for variations among, and contingencies in, fisheries, fishery resources, and catches. This amendment will only apply to imports and does not address the management flexibility of the domestic fishery.

National Standard 7

This national standard requires conservation and management measures, where practicable, minimize costs and avoid unnecessary duplication. Currently there are no duplicative efforts for restricting imported spiny lobster products. Costs should be very minimal, as the requirements being implemented aim to remove undersized product from the marketplace, which can be quickly made up for by using only legal-sized lobsters.

National Standard 8

This national standard requires management and conservation measures take into account the importance of fishery resources to fishing communities by utilizing economic and social data in order to provide for the sustained participation of such communities and to the extent practicable, minimize adverse economic impacts on such communities. Social and economic analyses were performed for this document and are discussed in the appropriate sections. The intent of this amendment is to reduce importation of under-sized lobsters, thereby creating a sustainable fishery resource for these communities to continue utilizing; and any adverse domestic impacts are only expected for importers, not fishermen and communities.

National Standard 9

This national standard requires management and conservation measures minimize bycatch, to the extent practicable, and to the extent bycatch cannot be avoided, minimize mortality. The intent of this amendment is to eliminate undersize lobster from entering the marketplace. These undersize individuals would be considered bycatch in the continental fishery, thus an incentive for avoiding the capture of these individuals is an additional effect of the amendment.

National Standard 10

This national standard requires management and conservation measures promote, to the extent practicable, the safety of human life at sea. A minimum import size has no effect on safety at sea.

6.4 Mitigation Measures

Environmental impacts identified in sections 6.1, 6.2, and the following section, 6.5, did not identify any adverse environmental impacts. Therefore, there are no mitigation measures to be carried out.

6.5 Cumulative Effects Analysis

As directed by NEPA, federal agencies are mandated to assess not only the indirect and direct impacts, but the cumulative impacts as well. NEPA defines a cumulative impact as "the impact on the environment which results from the incremental impact of the action when added to other past, present, and reasonably foreseeable future actions regardless of what agency (Federal or non-Federal) or person undertakes such other actions. Cumulative impacts can result from individually minor but collectively significant actions taking place over a period of time" (40 C.F.R. 1508.7). Cumulative effects can either be additive or synergistic. A synergistic effect is when the combined effects are greater than the sum of the individual effects.

This section uses an approach for assessing cumulative effects that is based upon guidance offered by the CEQ publication "Considering Cumulative Effects" (1997). The report outlines 11 items for consideration in drafting a CEA for a proposed action.

1. Identify the significant cumulative effects issues associated with the proposed action and define the assessment goals.
2. Establish the geographic scope of the analysis.
3. Establish the timeframe for the analysis.
4. Identify the other actions affecting the resources, ecosystems, and human communities of concern.
5. Characterize the resources, ecosystems, and human communities identified in scoping in terms of their response to change and capacity to withstand stress.

6. Characterize the stresses affecting these resources, ecosystems, and human communities and their relation to regulatory thresholds.
7. Define a baseline condition for the resources, ecosystems, and human communities.
8. Identify the important cause-and-effect relationships between human activities and resources, ecosystems, and human communities.
9. Determine the magnitude and significance of cumulative effects.
10. Modify or add alternatives to avoid, minimize, or mitigate significant cumulative effects.
11. Monitor the cumulative effects of the selected alternative and adapt management.

The CEA for the biophysical environment will follow these 11 steps. Cumulative effects on the biophysical environment and the socio-economic environment will be analyzed separately.

1. Identify the significant cumulative effects issues associated with the proposed action and define the assessment goals.

In Section 5.0 (Description of the Affected Environment) the valued environmental components (VECs) that exist within the spiny lobster fishery environment are identified and the basis for their selection is established. This is associated with the completion of Step 1 in the CEQ's 11-step process. The VECs are as follows:

1. Managed Resource – Spiny Lobster (*P. argus*)
2. Non-target species
3. Habitat including EFH for *P. argus* and non-target species
4. Endangered and other protected resources
5. Human Communities

2. Establish the geographic scope of the analysis.

The analysis of impacts focuses on two different geographic areas. The first geographic area is related to the distribution and habitat of spiny lobster (Figure 5.2.1). Other affected VECs including non-target species, habitat, and endangered species are also within this geographic scope. The human community has a different geographic scope, which includes the range of the other VECs as well as the U.S. This community includes the fishing community which coincides with the managed species' geographic range, as well as the area where processing, importing, and shipping of frozen lobster tails takes place. Spiny lobster imports are known to arrive in the U.S. at ports from Los Angeles to Miami to New York. Additionally, with nationwide seafood restaurants that rely on these products, potentially all of the U.S. could be affected by any measures implementing minimum conservation standards for spiny lobster products.

3. Establish the timeframe for the analysis

The temporal scope of impacts of past and present actions for *managed resources*, *non-target species*, *habitat*, and *human communities* is primarily focused on actions that have occurred after FMP implementation (1982 for South Atlantic/Gulf; 1981 Caribbean). However, the primary temporal focus of this document coincides with the regionalization acknowledgement of the management of spiny lobster. Starting in 1999, Caribbean nations began to coordinate and cooperate on the management of spiny lobster while acknowledging that doing so was the only way to ensure successful management of the species. This amendment, in part, is a product of this region-wide effort to manage the spiny lobster stock throughout its range in the Caribbean and western Atlantic.

4. Identify other actions affecting the resources, ecosystems, and human communities of concern

As stated numerous times throughout the document, there is a Caribbean-wide initiative to manage the spiny lobster stock throughout its range through multi-national agreements, accords, and cooperation. Currently, a number of Caribbean nations are in the process or have already implemented minimum conservation standards in their fisheries regulations for spiny lobster. The actions in this amendment/EIS are consistent with the actions of these other nations; therefore, the other actions affecting the resources, ecosystems, and human communities identified in this amendment/EIS add no cumulative impact to what is being encountered already.

5. Characterize the resources, ecosystems, and human communities identified in scoping in terms of their response to change and capacity to withstand stresses.

All resources, ecosystems, and human communities identified in scoping and public input of this amendment/EIS are able to withstand the changes proposed in this document. The actions in this document are designed to increase the spawning stock biomass of the spiny lobster population and increase the long-term potential yield in the fishery. As discussed in sections 6.1 and 6.2, these changes are expected to benefit all affected environments.

6. Characterize the stresses affecting these resources, ecosystems, and human communities and their relation to regulatory thresholds

The stresses identified in this amendment/EIS are full or over-exploitation of the spiny lobster stock. In order to achieve the regulatory threshold of achieving OY, as defined in the MSA, the spawning stock biomass of the species must be increased. This action is designed to achieve that increase in spawning stock biomass and therefore increase long-term potential yield which will allow the fishery to achieve OY.

7. Define a baseline condition for the resources, ecosystems, and human communities

Because of its economic significance to both commercial and artisanal fisheries, it is difficult to determine a baseline or "naturally occurring condition" because the species has always been exploited. However, a modified but ecologically sustainable condition would be one in which the population increases the spawning stock biomass to a point where the population reaches a condition near to one in which only natural mortality is seen. Though achieving a condition approaching only natural mortality is nearly impossible to do with a species fished and exploited as heavily as spiny lobster, an attempt to increase the spawning stock biomass will ensure the species continues to be ecologically sustainable. This in turn will allow communities dependent on the spiny lobster fishery to maintain that dependence.

8. Identify the important cause-and-effect relationship between human activities and resources, ecosystems, and human communities

The full- or over-exploitation of the spiny lobster stock is a direct effect of human efforts. Spiny lobster is important economically to both commercial and artisanal fisheries, which has led to this exploitation. The effect of the human action being undertaken in this amendment/EIS will be the recovery of the spawning stock and an increase in long-term yield in the fishery.

9. Determine the magnitude and significance of cumulative effects

Cumulative effects of this action have no more magnitude or significance beyond that of the actions in this amendment/EIS themselves. Those effects are intended to increase the spawning stock biomass and thereby increase the long-term potential yield in the fishery. Both of these effects are expected to be beneficial for the affected environments.

10. Modify and add alternatives to avoid, minimize, or mitigate significant cumulative effects

No significant cumulative effects were identified, so no changes are necessary to the alternatives. However, if significant effects are identified, after this document is completed, an additional amendment will be undertaken to develop framework procedures for management of spiny lobster including procedures for addressing imports. This framework will allow managers to quickly adapt management to achieve the goals in the purpose and need if they are not achieved through this amendment or as new information becomes available.

11. Monitor the cumulative effects of the selected alternative(s) and adapt management

The effects of the selected alternatives will be monitored by two separate methods. The first is the monitoring conducted by law enforcement officials in their inspection and review of imports. If the selected alternatives are successful in achieving the secondary goal of reducing undersized lobster into the U.S., law enforcement officials should no longer see lobster tails that weigh below the 5 oz weight category.

The other way the effectiveness of this action will be monitored is through the productivity of the fishery. If this action is successful in achieving the stated purpose of increasing spawning stock biomass, increases in catch and catch per unit effort should be noticeable throughout the Caribbean. After this document is completed, an additional amendment will be undertaken to develop framework procedures for management of spiny lobster including procedures for addressing imports. This framework will allow managers to quickly adapt management to achieve the goals in the purpose and need if they are not achieved through this amendment or as new information becomes available.

6.6 Unavoidable Adverse Effects

Environmental impacts identified in sections 6.1, 6.2, and 6.5 did not identify any adverse effects.

6.7 Relationship Between Short-Term Uses and Long-Term Productivity

The intent of implementing minimum conservation standards is to increase long-term potential yield and increase the spawning stock biomass. The loss of short-term uses is negligible in comparison to the long-term benefits expected from the implementation of actions in this amendment/EIS. In fact, the short-term uses lost through the actions in this amendment/EIS will only be on the scale of a few days to a few weeks (Matthews, pers. Comm.). However, long-term productivity is expected to increase dramatically (see discussion in section 6.1.1 on reproduction at size).

6.8 Irreversible and Irretrievable Commitments of Resources

There are no irreversible or irretrievable commitments of agency resources proposed herein. The actions to impose minimum conservation standards are readily changeable by the Councils in the future. There may be some loss of immediate income (irretrievable in the context of an individual not being able to benefit from compounded value over time) to some sectors from the implementation of minimum conservation standards.

6.9 Any Other Disclosures

There are no additional disclosures regarding the proposed actions.

6.10 Evaluation of Significance Factors

The Council on Environmental Quality regulations implementing the National Environmental Policy Act and NOAA's Administrative Order (NAO) 216-6 require that decision-makers take into account both context and intensity when evaluating the significance of impacts resulting from a major federal action (40 CFR §1508.27; NAO 216-6, Section 6.01(b)). Evaluating significance with respect to context requires consideration of the local, regional, national, and/or global impacts of the action. Intensity refers to the severity of the impact, and is to be evaluated using specific criteria outlined at 40 CFR § 1508.27(b) and at NAO 216-6, Section 6.01(b). The key findings of the implementation of minimum conservation standards related to the significance of the impacts associated with the enhancement of the pan-Caribbean spiny lobster population follow. The findings are organized under the intensity criteria and include a consideration of the context in which the impacts occur.

1. Impacts may be both beneficial and adverse. A significant effect may exist even if the Federal agency believes that on balance the effect will be beneficial (40 CFR § 1508.27(b)(1); NAO 216-6, Section 6.01(b)(1)).

Implementing these minimum conservation standards will create an incentive for foreign nations harvesting spiny lobster to adhere to meet these standards in order to continue importing lobsters into their largest market, the U.S. In meeting these minimum conservation standards, nations throughout the Caribbean will be fostering the recovery and growth of the spiny lobster population (see Section 6.1.1 for a discussion of fecundity at size). This in turn will lead to a long-term increase in potential yield and the continued existence and possible expansion of the spiny lobster fishery throughout the Caribbean. Therefore, the impacts are beneficial to both the biological environment of spiny lobster and from producers (fishermen) to consumers in the human environment.

2. The degree to which the proposed action affects public health or safety (40 CFR § 1508.27(b)(2); NAO 216-6, Section 6.01(b)(2)).

The proposed actions are not likely to affect public health and safety. The implementation of minimum conservation standards will not affect harvest methods related to the safety of fishermen at sea, nor will it change the quality or safety of food.

3. Unique characteristics of the geographic area, such as proximity to historic or cultural resources, park lands, prime farmlands, wetlands, wild and scenic rivers, or ecologically critical areas (40 CFR § 1508.27(b)(3); NAO 216-6, Section 6.01(b)(3)).

This action effects the fisheries for spiny lobster throughout its range in the Caribbean and western Atlantic. Although there are a number of unique characteristics to the Caribbean basin, no effects on these areas is expected from the implementation of minimum conservation standards.

4. The degree to which the effects on the quality of the human environment are likely to be highly controversial (40 CFR § 1508.27(b)(4); NAO 216-6, Section 6.01(b)(4)).

The implementation of minimum conservation standards for spiny lobster products is not expected to be highly controversial. The potential impacts from the action are well known, and are not a source of uncertainty or related controversy.

5. The degree to which the possible effects on the human environment are highly uncertain or involve unique or unknown risks (40 CFR § 1508.2 7(b)(5); NAO 216-6, Section 6.01(b)(5)).

Minimum conservation standards such as size limits and animal condition restrictions have been used throughout the world in fisheries management. Therefore, their effect on the human environment is well known, and does involve any unique or unknown risks.

6. The degree to which the action may establish a precedent for future actions with significant effects or represents a decision in principle about a future consideration (40 CFR § 508.27(b)(6); NAO 216-6, Section 6.01(b)(6)).

The use of minimum conservation standards have been used for many years in a variety of fisheries throughout the world. Restrictions on imported products have also been in existence for many years. Therefore, this action does not present any new or unusual issues for future consideration.

7. Whether the action is related to other actions with individually insignificant but cumulatively significant impacts. Significance exists if it is reasonable to anticipate a cumulatively significant impact on the environment. Significance cannot be avoided by terming an action temporary or by breaking it down into small component parts (40 CFR § 1508.27(b)(7); NAO 216-6, Section 6.01(b)(7)).

This action is not expected to have a cumulative impact on the environment as discussed in section 6.5.

8. The degree to which the action may adversely affect districts, sites, highways, structures, or objects listed in or eligible for listing in the National Register of Historic Places or may cause loss or destruction of significant scientific, cultural, or historical resources (40 CFR § 1508.27(b)(8); NAO 216-6, Section 6.01(b)(8)).

The implementation of minimum conservation standards is not expected to have any effect on districts, sites, highways, structures, or objects in or eligible for listing in the National Register of Historic Places, or cause loss or destruction of significant scientific, cultural, or historical resources.

9. The degree to which the action may adversely affect an endangered or threatened species or its habitat that has been determined to be critical under the Endangered Species Act of 1973 (40 CFR § 1508.27(b)(9); NAO 216-6, Section 6.01(b)(9)).

The effects on endangered or threatened species or their habitat has been explored throughout the document (sections 5.2, 6.1.1, 6.2.1, 9.4, 9.13.5, and 9.14). No adverse effect was found for endangered or threatened species in the analysis performed for these sections.

10. Whether the action threatens a violation of Federal, State, or local law or requirements imposed for the protection of the environment (40 CFR § 1508.27(b)(10); NAO 216-6, Section 6.01(b)(10)).

All actions proposed under the Magnuson Stevens Fishery Conservation and Management Act must abide by federal, state, and local regulations imposed to protect the environment. This action does not threaten any violations of federal, state, or local law.

11. Whether the action may result in the introduction or spread of a non-indigenous species (NAO 216-6, Section 6.01(b)(11)).

The implementation of minimum conservation standards on an indigenous species will neither introduce nor spread non-indigenous species. Even if “market replacements” are brought in to supplement any reduction in spiny lobster imports, those replacements will be frozen, processed animals.

7.0 REGULATORY IMPACT REVIEW

7.1 Introduction

The NMFS requires a Regulatory Impact Review (RIR) for all regulatory actions that are of public interest. The RIR does three things: (1) it provides a comprehensive review of the level and incidence of impacts associated with a regulatory action; (2) it provides a review of the problems and policy objectives prompting the regulatory proposals and an evaluation of the major alternatives which could be used to solve the problem; and (3) it ensures that the regulatory agency systematically and comprehensively considers all available alternatives so that the public welfare can be enhanced in the most efficient and cost effective way.

The RIR also serves as the basis for determining whether any proposed regulations are a "significant regulatory action" under certain criteria provided in Executive Order 12866 (E.O. 12866) and whether the approved regulations will have a "significant economic impact on a substantial number of small business entities" in compliance with the Regulatory Flexibility Act of 1980 (RFA).

7.2 Problems and Objectives in the Fishery

The purpose and need, issues, problems, and objectives of the proposed Amendment are presented in Section 1.2 and are incorporated herein by reference. According to the Western Central Atlantic Fishery Commission, international trade of illegally harvested Caribbean spiny lobster is a serious problem, and especially problematic is the trade of lobsters whose sizes are below the legal minimum size standards of the country of origin. The U.S. is the largest importer of Caribbean spiny lobster, and existing regulations are insufficient to prevent the illegal importation of spiny lobster that is illegally harvested in its country of origin. U.S. law enforcement's ability to screen imports for compliance with the Lacey Act is compromised by vague foreign minimum harvest-size and other laws that are intended to protect Caribbean spiny lobster. By implementing uniform importation standards, law enforcement's ability to effectively prevent the importation of undersized and berried lobsters will be improved. This in turn may help protect the species both in the U.S. and in the Caribbean as a whole.

7.3 Methodology

This RIR assesses management measures from the standpoint of determining the resulting changes in costs and benefits to society. These proposed actions would impose import restrictions to eliminate illegal trade of Caribbean spiny lobster, and as such, its largest cost would be the losses of revenues and profits incurred by individuals who illegally import Caribbean spiny lobsters by bringing into the U.S. lobsters that violate the harvest and trade laws of the countries of origin. Similarly, the largest secondary cost would be the losses of revenues and profits by individuals who buy illegal lobsters from black-market importers and losses of incomes by employees of such importers.

These proposed actions may also reduce some legal imports of Caribbean spiny lobster. Hence, these actions may reduce the revenues and profits earned by some who legally import Caribbean spiny lobster and reduce the incomes of those employed by those legal importers. However, the bulk of the costs should be the losses of illegal revenues, profits and incomes that derive from black-market transactions.

To the extent practicable, the net effects of the proposed measures should be stated in terms of producer and consumer surplus, changes in profits, and employment in the direct and support industries. However, most of the costs are expected to be incurred by black-market importers and there is insufficient information to quantify possible changes to legal imports and associated economic variables. Therefore, the impacts of the proposed action are described in terms of qualitative changes in costs and benefits that derive from possible decreases in legal, not illegal, imports.

7.4 Description of the Fisheries

The Caribbean spiny lobster fishery is described in Section 5.3, and is incorporated herein by reference.

7.5 Impacts of the Management Alternatives

7.5.1 Action 1: Minimum Conservation Sizes of Spiny Lobster (Panulirus argus) Import Products into the United States

Three alternatives are considered for this action: a status-quo alternative and two alternatives that impose import-size standards.

7.5.1.1 Alternative 1

This is the status quo alternative, and, as such, would not impose minimum import-size standards for Caribbean spiny lobster. Current regulations are insufficient to prevent the illegal importation of Caribbean spiny lobster that is illegally harvested in its country of origin because U.S. law enforcement's ability to screen imports for compliance with the Lacey Act is compromised by those who intentionally falsify the country of origin and vague harvest standards of the country of origin.. Without improved methods of detection, illegal importation of undersized lobsters will continue and remain a serious threat to the long-run biological and economic success of this species.

The U.S. is the largest importer of Caribbean spiny lobster and illegal international trade of Caribbean spiny lobster has been and remains to be a serious problem. From 2002 through 2007, total U.S. imports of frozen rock lobster and other sea crawfish (HS 0306110000: *Palinurus* spp., *Panulirus* spp. and *Jasus* spp.) averaged 12,374.2 metric tons with a value of about $355.5 million, annually. The top 5 countries of origin of those imports by volume (metric tons) are Brazil, The Bahamas, Australia, Honduras and Nicaragua, who collectively represent about 68 percent of the total volume of those imports. Those same countries account for about 78 percent of the total dollar value of those imports. Of the top 10 countries of origin by volume of frozen rock lobster and other sea crawfish imports, 6 of those countries (Brazil, The Bahamas, Honduras, Nicaragua, Colombia and Belize) export Caribbean spiny lobster to the United States. See Table 7.5.1.1.

The Western Central Atlantic Fishery Commission (WECAFC) has reported that harvesting and trading of Caribbean spiny lobster below the minimum legal size is a serious problem, especially in Brazil. According to a 2002 report for the Second Workshop on the Management of Caribbean Spiny Lobster Fisheries in the WECAFC Area, during the 2001 lobster season in Brazil, 8.2 tons of lobsters from a 10-ton sample were under the minimum legal size. If that sample is indicative of lobsters imported into the U.S. from Brazil, then 82 percent ($62.1 million) of the $75.7 million of rock lobster imported annually from Brazil is illegal. See Table 7.5.1.1.

The top 5 countries of origin of non-frozen rock lobster and other sea crawfish (HS 0306210000) by volume are Mexico, Australia, China, Taiwan and United Kingdom. See Table 7.5.1.2 next page. Mexico is the only one among the top 10 countries of origin that harvests Caribbean spiny lobster. Among all countries of origin of non-frozen rock lobster the following harvest Caribbean spiny lobster: Mexico, Nicaragua, Turks and Caicos Islands, Honduras, Costa Rica, Venezuela, Guatemala, and Jamaica.

Table 7.5.1.1. Countries of Origin of U.S. Imports of Frozen Rock Lobster and Other Sea Crawfish (HS 030611000).[1] *Source*: USDA, Foreign Agricultural Service.

The lucrative legal and illegal markets for this species make overfishing a reality in Brazil, Colombia, Dominican Republic, Honduras, Jamaica, and Nicaragua. See Table 7.5.1.3.

Overexploiting Caribbean spiny lobster stocks in foreign fisheries could jeopardize the abundance and structure of U.S. stocks because the larval recruitment of U.S. stocks is dependent on the reproductive potential of stocks managed by other countries. The potential long-term adverse impact of the status-quo alternative is smaller domestic stocks of Caribbean spiny lobster and smaller commercial and recreational harvests because larval recruitment of U.S. stocks are dependent upon the reproductive potential of stocks managed by other countries. Florida commercial and recreational lobster fishers, as well as lobster dealers and others who derive economic benefits from Caribbean spiny lobster fishing in Florida, would experience the greatest long-term cost.

Table 7.5.1.3. Estimated status of national populations of Caribbean spiny lobster of WECAFC countries. *Source*: WECAFC 2007.

Status of Stock	Countries and Territories
Under-exploited	Venezuela (some areas)
Fully-exploited or stable	Antigua & Barbuda, Belize, Costa Rica, Cuba, Mexico, Puerto Rico & U.S. Virgin Islands, Turks & Caicos, USA (Florida), Venezuela (some areas)
Over-exploited	Nicaragua, Jamaica, Dominican Republic, Brazil, Colombia, Honduras
Unknown	Bahamas, Guadeloupe, Haiti, Martinique, other Less Antilles countries

In 2006, Florida landings of Caribbean spiny lobster valued about $27 million, and from 1997 through 2006 averaged about $23.5 million annually. See Table 7.5.1.4. Florida commercial fishermen catch Caribbean spiny lobster to be landed and used as bait.

Fishermen use the live undersized lobsters, known as "shorts", to attract Caribbean spiny lobster into traps. See Table 7.5.1.5.

In 2003, recreational landings of Caribbean spiny lobster were about 1.1 million pounds, and sales of recreational lobster fishing permits exceed 100,000 annually. Sharp et al. (2005) estimate approximately $24 million was spent on recreational lobster fishing in the Florida Keys from the opening of the recreational season through the first Monday in September in 2001. Fishers who resided outside the Keys accounted for about $22 million (92 percent) of the total monies spent on recreational lobster fishing in the Keys. In addition to the regular recreational season there is the Special Two-Day Sport Season, which occurs on the last consecutive Wednesday and Thursday in July. Those two days are the busiest boating days of the year in the County. From the 1993 through 2001 Special Two-Day Sport Seasons, the average annual number of spiny lobsters caught in Monroe County represents about 66 percent of the annual statewide total.

7.5.1.2 Alternative 2 of Action 1

Part A: No person in the U.S. would be allowed to import a spiny lobster (*Panulirus argus*), as follows:

Any spiny lobster of less than 5 ounces tail weight (5 ounces is defined as a tail that weighs 4.2 – 5.4 ounces). If the imported product does not meet this minimum weight requirement, the person importing the lobster can demonstrate compliance by showing that the product imported satisfies the tail length requirement, or that it was harvested from an animal that satisfied the minimum carapace length requirement of:

a. Greater than 3.0 inches (7.62 cm) carapace length if the animal is whole.
b. Greater than or equal to 5.5 inches (13.97 cm) tail length if only the tail is present.

Part B: No one in Puerto Rico or the U.S. Virgin Islands would be allowed to import a Caribbean spiny lobster (*Panulirus* argus) Any spiny lobster of less than 6.0 ounces tail weight (6 ounces is defined as a tail that weighs 5.9 – 6.4 ounces). If the imported product does not meet this minimum weight requirement, the person importing the lobster can demonstrate compliance by showing that the product imported satisfies the tail length requirement, or that it was harvested from an animal that satisfied the minimum carapace length requirement of:

a. Greater than or equal to 3.5 inches (8.89 cm) carapace length if the animal is whole.
b. Greater than or equal to 6.2 inches (15.75 cm) tail length if only the tail is present.

Under this alternative, tail weight would not be the only measurement used by law enforcement inspectors to determine if an individual tail or whole lobster is legal or not. Individual tails or lobsters that are inspected and do not meet the tail weight requirement, but have the appropriate carapace length or tail length measurement would be considered legal. In other words, any whole lobster or separated tail that meets or exceeds the carapace-length standard or the tail-weight standard would be a legally imported Caribbean spiny lobster, whether it satisfies the tail-weight standard or not. Consequently, to be judged as illegal, a whole lobster would not meet or exceed the tail-weight standard, tail-length standard or carapace-length standard, and a tail would not meet or exceed the tail-weight standard or tail-length standard.

7.5.1.2.1 Part A of Alternative 2 of Action 1

Many countries that harvest Caribbean spiny lobster have minimum harvest-size standards. See Table 7.5.1.6.

The following countries and territories have reported harvesting Caribbean spiny lobster during the period from 1962 through 2003, according to the FAO: Anguilla, Antigua and Barbuda, The Bahamas, Belize, Bermuda, Brazil, British Virgin Islands, Colombia, Costa Rica, Cuba, Dominican Republic, Grenada, Haiti, Honduras, Martinique, Mexico, Grenada, St. Kitts and Nevis, St. Lucia, Saint Vincent and Grenadines, Turks and Caicos, Nicaragua, Puerto Rico, Saint Kitts and Nevis, Trinidad and Tobago, Turks and Caicos Island, U.S., U.S. Virgin Islands, and Venezuela (Bolivarian Republic of). From 2002 through 2007 the following 17 countries that harvest Caribbean spiny lobster were the countries of origin of rock lobster imported into the U.S.: Bahamas, Belize, Brazil, Colombia, Costa Rica, Dominican Republic, Guatemala, Guyana, Haiti, Honduras, Jamaica, Mexico, Nicaragua, Panama, Trinidad and Tobago, Turks and Caicos Islands, and Venezuela. See Tables 7.5.1.1 and 7.5.1.2. This analysis initially presumes any imported spiny lobster that could be affected by this alternative would originate from one of the above 17 countries.

However, if any past shipments of spiny lobster remained within U.S. Customs jurisdiction until shipped out of a Florida port and did not come into possession in Florida, they were not required to be in compliance with Florida size standards. Therefore, the NMFS encourages importers of spiny lobster and others to provide comment on the assumption that past Caribbean spiny lobster imports that entered the country at a Florida port came to be possessed in Florida.

1. Countries listed in bold and italicized are countries of origin of U.S. imports of rock lobster from 2002 through 2007.
2. Has a whole weight standard of 5 ounces.

The following countries of origin have a carapace size standard that exceeds 3 inches (7.62 cm): Bahamas (8.2 cm), Colombia-San Andres (8.01 cm), Dominican Republic (8.05 cm), Honduras (8.01 cm), Turks and Caicos Islands (8.3 cm), and Venezuela (12.0 cm) have a carapace size standard that exceeds 3 inches. It is expected that spiny lobsters with a carapace size greater than 3 inches correspond to tail lengths and weights that comply with Part A, and, consequently, Part A is not expected to affect legal imports from the Bahamas, Dominican Republic, Honduras, Turks and Caicos Islands and Venezuela, or those lobsters legally harvested in Colombia's San Andres region.

Of the countries of origin with a tail-length size standard, the following three have a standard that equals or exceeds the 5.5-inch (14.0 cm) standard of Part A: Bahamas (14.0 cm), Colombia-San Andres (14.0 cm), Colombia-Guajira (21.0 cm), and Honduras (14.5 cm). It is expected that legal imports from countries with a tail-length size standard equal or greater than 5.5 inches comply with the tail weight and carapace length standards imposed by Part A. Therefore, legal imports of spiny lobster from the Bahamas, Colombia and Honduras are not expected to be affected by Part A of this alternative.

Five of the countries of origin have a tail-weight size standard and of those five, the following three have a standard that meets or exceeds 4.2 ounces (119.1 grams): Honduras (5 oz.), Nicaragua (5 oz.), and Turks and Caicos Islands (7 oz.). See Table 7.5.1.6. Legal imports from these 3 countries should not be affected by Part A of this alternative.

It follows from the previous three paragraphs that legal imports from the following 7 countries of origin should not be affected by Part A because of their size standards: Bahamas, Colombia, Dominican Republic, Honduras, Turks and Caicos Islands, Nicaragua, and Venezuela. It also follows that some legal imports from Belize, Brazil, Costa Rica, Guatemala, Guyana, Haiti, Jamaica, Mexico, Panama, and Trinidad and Tobago could be affected by Part A of this alternative. In the past 6 years, Guyana and Trinidad and Tobago have been the country of origin only once and there have been no imports of rock lobster from these countries since 2004. See Table 7.5.1.1.

As stated previously, the harvest and international trade of Caribbean spiny lobsters less than the legal minimum size is a serious problem. As the U.S. is the largest importer of spiny lobster, this alternative would significantly reduce black-market trade of this species.

Brazil (7.5 cm) and Mexico (7.46 cm) have a carapace size standard that is less than 3 inches (7.62 cm). Panama is reported to have a size limit; however, a preliminary review of Panama fishing laws did not find such a standard. Costa Rica, Guatemala, Guyana, Haiti, and Trinidad and Tobago have no carapace-size standard. In September 2006, the Working Group on Caribbean spiny lobster of the Western Central Atlantic Fishery Commission (WECAFC) met in Merida, Mexico, to attend the Regional Workshop on the Assessment and Management of Caribbean Spiny Lobster. The primary objective of the workshop was to review and update the status of Caribbean spiny lobster at national and international levels to seek international agreement on strategies to address management problems. Among the workshop's participants were representatives from Costa Rica, Haiti, and the Caribbean Regional Fishery Mechanism (CRFM) who agreed to a minimum carapace-length standard of 7.4 cm (2.91 inches). Guyana and Trinidad and Tobago are members of the Caribbean Regional Fishery Mechanism, and it is expected that those two countries will establish a carapace-size standard equal to or greater than 7.4 cm.

Belize (11.3 cm), Brazil (13.0 cm) and Mexico (13.5 cm) have tail-length standards less than required by Part A (14.0 cm), and the following countries of origin have no tail-length standard: Costa Rica, Guatemala, Guyana, Haiti, Jamaica, and Trinidad and Tobago. Belize has a tail-weight standard (4.0 oz.) less than the 4.2 oz. minimum established by Part A and Brazil, Costa Rica, Guatemala, Guyana, Haiti, Jamaica, Mexico, and Trinidad and Tobago have no tail-weight standards.

Florida law (*Florida Administrative Code* 68B-24.003(1)) states no person shall harvest or possess any spiny lobster with a carapace measurement of 3 inches or less or, if the tail is separated from the body, a tail measurement less than 5.5 inches. This analysis presumes that any spiny lobster that enters the country at a Florida port comes to be possessed in Florida. Consequently, that assumption means any spiny lobster that enters the country at a Florida port must already comply with the 3-inch carapace length and 5.5-inch tail length standards that would be imposed by Part A. It is anticipated that any lobster that meets the 3-inch carapace and 5.5-tail length standards would satisfy the tail weight standard, and comply with Part A as a whole. Therefore, this analysis presumes any spiny lobster that has entered and continues to enter the country at a Florida port becomes a possession in Florida and is not affected by Part A.

All rock lobster imports from Haiti and Guatemala historically have entered at a Florida port, and thus, this analysis presumes no legal imports of spiny lobster from Haiti or Guatemala would be affected by this alternative. Imports of rock lobster from Belize, Brazil, Costa Rica, Jamaica, Mexico and Panama enter the U.S. at both Florida and non-Florida ports. About 98 percent of the pounds and total dollar value of rock lobster annually imported from Jamaica enter at a Florida port. See Table 7.5.1.7. These rock lobster imports include all *Palinurus* species, *Panulirus* species and *Jasus* species.

Table 7.5.1.7. Percent of Imports of Frozen and Non-frozen Rock Lobster (HS 030611000 and 0306210000) from Belize, Brazil, Costa Rica, Jamaica, Mexico and Panama, 2006 – 2007, into Florida and Other State Ports.[1, 2]

	% FL Ports		% Non-FL Ports		Annual Ave 1000s $	
Country	Pounds	Dollars	Pounds	Dollars	Total All Ports	Non-FL Ports
Belize	31%	29%	69%	71%	7,488	5,316
Brazil[3]	4%	6%	96%	94%	75,739	71,952
Costa Rica	67%	75%	33%	25%	420	105
Jamaica	98%	98%	2%	2%	3,503	70
Mexico	46%	37%	54%	63%	8,125	5,119
Panama	1%	1%	99%	99%	2,615	2,589
Total					97,890	85,150

1. These imports include *Palinurus* species, *Panulirus* species and *Jasus* species.
2. These imports include both legal and undetected illegal imports.
3. If a 2001 sample of Brazilian lobster operations is representative of imports of rock lobster from that country, then 82 percent of the imports from Brazil are illegal.

The above countries harvest multiple species of rock lobster. For example, Mexico harvests and trades four species and Brazil and Jamaica two species each. Hence, imports of Caribbean spiny lobster from the above countries represent part, not the entirety, of the rock lobster imported from these countries.

It is illegal to harvest spiny lobsters with a carapace length less than 7.62 cm (76.2 mm) in Jamaica and Belize. As stated in section 4.1, it is estimated that 84 percent of those spiny lobsters with a 3-inch (7.62-cm) tail length would meet the tail length or tail weight requirement of Part A. Consequently, if all of the historical legal spiny lobster imports from these countries were no larger than their countries' minimum legal size, 84 percent of the spiny lobsters legally imported from Jamaica and Belize would not be affected by Part A. It is more likely, however, that many of the spiny lobsters legally imported from these countries exceed the minimum legal size. Therefore, it is more likely that less than 16 percent of the spiny lobsters legally imported from Jamaica and Belize would be affected by Part A. Those spiny lobsters currently imported legally but under the size required by Part A would have to remain in the water and grow at least another tenth of a millimeter before being harvested in either of the above two countries. It is similarly expected that spiny lobsters which are presently and legally exported whole or in part to the U.S. from Belize, Brazil, Costa Rica, Jamaica, Mexico and Panama and do not satisfy Part A requirements would have to remain in the water for no more than one additional molt.

Physical growth of lobsters is achieved through molting. An adult lobster molts an average of two and a half times each year. The entire molting event takes approximately ten minutes. The new exoskeleton will take about 12 days from the start of the molt to harden such that it cannot be dented; however the shell is not completely formed until the 28th day (Williams, 1984). In most countries harvesting molting or soft shelled lobsters is prohibited. This analysis presumes the average spiny lobster completes a molting cycle (from molt to hardened shell) every 4.8 months (12 months/2.5 molts) and at least once every lobster season.
This analysis assumes any spiny lobster that is currently legally imported into the U.S., but does not meet Part A size standards, would have to remain in the water an additional 4.8 months. Therefore, this alternative may be better understood as eliminating the illegal importation of spiny lobster and delaying, not prohibiting, some of the legal importation of a spiny lobster. The delay has advantages to both lobster fishermen and U.S. importers because larger lobsters have greater market value, and in the long run, the economic benefits of a sustainable resource should exceed the economic costs.

The bulk of the economic costs of this alternative would be the losses of revenues and profits associated with the illegal importation of Caribbean spiny lobster and the losses of income derived from that illegal activity. Decreases in revenues and profits earned from presently legal importation of spiny lobster would also occur; however, it is anticipated that most legal imports would not be affected by this alternative. The economic benefits of this alternative would be larger minimum-sized imported lobsters with greater market value and domestic and foreign revenues, profits and incomes that derive from a biologically and economically improved resource.

7.5.1.2.2 Part B of Alternative 2 of Action 1

Title 12, Chapter 9A, Section 319(b) of the *Virgin Island Code* (V.I.C.) states, "No person, firm or corporation shall take or have in his possession at any time, regardless of where taken, any spiny lobster (crawfish or crayfish) of the species *Panulirus argus* unless such spiny lobster … shall have a carapace length of more than three and one-half (3 ½) inches". This existing law is more stringent than with the minimum carapace length restriction imposed by Part B. Thus, the proposed carapace restriction of Part B has no effect on imports into the U.S. Virgin Islands. A spiny lobster with a carapace length greater than 3.5 inches is expected to have a tail length and tail weight that meets the tail length and weight restrictions that would be imposed by Part B. Consequently, this analysis expects this alternative would have no effect on imports of spiny lobster into the U.S. Virgin Islands. U.S. Customs data shows there were no imports of rock lobster (frozen or not) into the U.S. Virgin Islands from 2001 through 2007, which further supports the conclusion that this alternative would not affect imports into the U.S. Virgin Islands.

Puerto Rico regulation currently prohibits the possession of spiny lobster (*P. argus*) with a carapace less than 3.5 inches. This existing law is consistent with the minimum carapace length restriction imposed by Part B. Therefore, the proposed carapace restriction of Part B should have no effect on spiny lobster imports into Puerto Rico.

Part B is expected to have no economic impact on imports into Puerto Rico or the U.S. Virgin Islands.

7.5.1.2.3 Total Economic Impact of Alternative 2 of Action 1

The bulk of the economic costs of this alternative would be the losses of revenues and profits associated with the illegal importation of Caribbean spiny lobster and the losses of income derived from that illegal activity. Decreases in revenues and profits earned from presently legal importation of spiny lobster would also occur; however, it is anticipated that most legal imports would not be affected by this alternative. The economic benefits of this alternative would be larger minimum-sized imported lobsters with greater market value and enhanced long-run domestic and foreign revenues, profits and incomes that derive from a biologically and economically improved resource.

7.5.1.3 Alternative 3 of Action 1

No person shall import into the U.S. a Caribbean spiny lobster that is smaller than the existing Continental U.S. minimum size limit. Specifically, no one in the U.S. would be allowed to import a Caribbean spiny lobster (*Panulirus* argus):

1. 3.0 inches (7.62 cm) or less carapace length if the animal is whole.
2. Less than 5.5 inches (13.97 cm) tail length if only the tail is present.
3. Less than 5 ounces (5 ounces is defined as a tail that weighs 4.5 to 5.4 ounces).

This alternative extends the import restrictions established by Part A of Alternative 2 from the Continental U.S. to include the Continental U.S, Puerto Rico and U.S. Virgin Islands. The economic impact of this alternative in the Continental U.S. is equivalent to the economic impact of Part A of Alternative 2. See section 7.5.1.2.1.

Both Puerto Rico and the U.S. Virgin Islands have laws that prohibit the possession of spiny lobster with a carapace less than 3.5 inches long. This alternative would allow the importation of Caribbean spiny lobsters with a carapace less than 3.5 inches, which would be in contradiction with Puerto Rico and U.S. Virgin Islands law. This alternative would encourage illegal fishing operations in these territories. Domestic fishing operations in either of these two territories could illegally take undersized lobsters in territorial waters and claim them to be imports that meet the smaller size standard.

7.5.1.4 Comparison of Alternatives of Action 1

A comparison of the economic costs and benefits of the three alternatives is presented in Table 7.5.1.8.

Table 7.5.1.8. Summary of Economic Costs and Benefits of Action 1 Alternatives.

Action 1: Establish Import-Size Standards				
Alternative		**Description**	**Economic Cost**	**Economic Benefit**
1		Don't impose import-size standards	Continues illegal importation of undersized lobster Supports illegal fishing and overfishing Leads to long-run biological and economic damages	Maintains status quo revenues, profits and incomes from imports of Caribbean spiny lobster
2	Part A: U.S.	No imports with carapace length 3.0 inches or less No imports with tail length 5.5 inches less No imports with tail weight less than 5 ounces	Reduces some revenues, profits and incomes from legal trade	Reduces illegal importation of undersized lobster and associated illegal revenues, profits and incomes Discourages illegal fishing and overfishing Increases revenues, profits and incomes in long-run from legal use of resource
	Part B: Puerto Rico and U.S. Virgin Islands	No imports with carapace less than 3.5 inches No imports with tail length 6.2 inches less No imports with tail weight less than 5.9 ounces	None	None
3	U.S.	No imports with carapace length 3.0 inches or less No imports with tail length 5.5 inches less No imports with tail weight less than 5 ounces	Reduces some revenues, profits and incomes from legal trade	Reduces illegal importation of undersized lobster and associated illegal revenues, profits and incomes Discourages illegal fishing and overfishing Increased revenues, profits and incomes in long-run from legal use of resource
	Puerto Rico & U.S. Virgin Islands	No imports with carapace length 3.0 inches or less No imports with tail length 5.5 inches less	Encourages illegal operations in these territories Encourages overfishing in these territories	Increases revenues, profits and incomes from legal trade

		No imports with tail weight less than 5 ounces	Increases revenues, profits and incomes from illegal use of territorial resource Leads to long-run biological and economic damages to territorial resource	

7.5.2 Action 2: Establish other restrictions on importation of Caribbean spiny lobster

Four alternatives are considered for this action: a no action alternative and three alternatives. The second alternative is a combination of restrictions that are separated in the third and fourth alternatives.

7.5.2.1 Alternative 1 of Action 2

This is the no action alternative, and, as such, would not prohibit the importation of Caribbean spiny lobster meat that is removed from the exoskeleton nor importation of berried lobsters or those whose eggs, swimmerets or pleopods have been removed or stripped.

One method that illegal importers of spiny lobster use to reduce detection is by removing the meat from the exoskeleton of the lobsters and processing it into chunks. This alternative would maintain that loophole, and if Alternative 2 or 3 of Action 1 were implemented, it is likely that there would be increased imports of processed spiny lobster meat in order to avoid detection of undersized lobsters. Thus, this alternative in conjunction with Alternative 2 or 3 of Action 1 would likely increase the adverse biological and economic impacts caused by the importation of illegal spiny lobster.

In Florida, the harvest or possession of eggbearing spiny lobster is prohibited and any egg-bearing lobster found in traps must be immediately returned to the water free, alive and unharmed (68B-24.007 *F.A.C.*). The practice of stripping or otherwise molesting eggbearing spiny lobster in order to remove the eggs is prohibited and the possession of spiny lobster or spiny lobster tails from which the eggs, swimmerets or pleopods have been removed or stripped is prohibited (68B-24.007 *F.A.C.*). The U.S. Virgin Islands prohibits the take, possession or sale of egg-bearing spiny lobsters (Title 12 Chapter 9A §319(b) *V.I.C.*). Any egg-bearing lobsters captured in traps or pots must be returned into the water in a live and unharmed condition; and the practice of stripping, shaving, scraping, clipping or otherwise molesting egg-bearing lobsters in order to remove the eggs is prohibited (Title 12 Chapter 9A §319(d,e) V.I.C.). In Puerto Rico, there is a similar prohibition on the possession of egg-bearing spiny lobsters and molestation of egg-bearing lobsters.

According to the Western Central Atlantic Fishery Commission, most countries have laws forbidding the harvest of egg-bearing females, and the greatest offenses of those laws tend to be in foreign artisanal fisheries. See Table 7.5.2.1. One method that illegal harvesters of berried females use to remove the eggs is by removing the pleopods (also known as swimmerettes). Under the tail of a Caribbean spiny lobster are four pairs of small leaf-like structures which are the pleopods. Each pleopod on a female has two lobes: one lobe is paddle-like and the other resembles small pincers. The fertilized eggs attach to long hairs called "setae" on the pincer-like lobes of her pleopods. Prohibiting the removal of the pleopods would be easy to enforce because it is easy to detect if they have been removed or not. The status quo alternative would not reduce the illegal importation of female lobsters that have had their eggs removed and the associated adverse biological and economic impacts to the stock from such a practice.

Table 7.5.2.1. Other Foreign Harvest Restrictions for Caribbean Spiny Lobster. *Source*: FAO website.

Country[1]	**Prohibits Exportation Lobster Meat?**	**Prohibits Harvest of Berried Lobsters?**	**Prohibits Removal of Eggs?**	**Prohibits Removal of Pleopods?**
Anguilla		Yes	Yes	
Antigua & Barbuda		Yes	Yes	Yes
Bahamas		**Yes**	**Yes**	**Yes**

1. Countries listed in bold and italicized are countries of origin of U.S. imports of rock lobster from 2002 through 2007.

7.5.2.2 Alternative 2 of Action 2

This alternative would prohibit the importation of: 1) spiny lobster (tail) meat without the exoskeleton attached and 2) spiny lobster with eggs attached or where the eggs or pleopods (swimmerets) have been removed or stripped.

7.5.2.2.1 Prohibiting Importation of Meat Removed from the Shell

Most imports of spiny lobster are parts or wholes of the lobster with the meat attached to the exoskeleton; however, some imports are lobster meat that has been removed from the shell. One method that illegal importers have used and continue to use to avoid detection is to remove the meat from the exoskeletons of undersized and berried lobsters and then package the meat in chunks. This alternative would eliminate such illegal imports. It would also prohibit any currently legal imports of Caribbean spiny lobster meat that has been removed from the shell. Preliminary information suggests the ban on imports of lobster meat that has been extracted from the shell would have the greatest impact on illegal, not legal, trade.

The bulk of the economic costs of this ban would be the losses of illegal revenues and profits associated with the illegal importation of Caribbean spiny lobster meat and the losses of income derived from that illegal activity. Decreases in revenues and profits earned from presently legal importation of spiny lobster meat would also occur; however, the losses of legal revenues, profits and incomes are expected to be substantially lower by comparison. The economic benefits of this prohibition would be improved domestic and foreign revenues, profits and incomes that derive from a biologically and economically improved resource.

7.5.2.2.2 Prohibiting Importation of Berried Lobsters or Removal of Eggs or Pleopods

From 2002 through 2007, rock lobster imports have originated from the following 17 countries that harvest Caribbean spiny lobster: The Bahamas, Belize, Brazil, Colombia, Costa Rica, Dominican Republic, Guatemala, Guyana, Haiti, Honduras, Jamaica, Mexico, Nicaragua, Panama, Turks and Caicos Islands, Trinidad and Tobago, and Venezuela. See Tables 7.5.1.1 and 7.5.1.2. Of these 17 countries, Guatemala, Guyana, and Trinidad and Tobago do not have laws that prohibit the harvest of spiny lobsters with eggs or removal of eggs. See Table 7.5.2.1. Combined rock lobster imports from these three countries represent $183,000 (about 0.05 percent) of $356 million of frozen imports and $9,000 (about 0.3 percent) 0f the $2.9 million of non-frozen imports.

Panama has a law that prohibits the harvest of berried lobsters, but may not prohibit the removal of eggs. Imports of rock lobster from Panama represent about 0.7 percent of frozen rock lobster imports and none of the non-frozen imports.

Any imports of berried Caribbean spiny lobster or those with their eggs removed from the following countries are presently illegal under the Lacey Act: The Bahamas, Belize, Brazil, Colombia, Costa Rica, Dominican Republic, Haiti, Honduras, Jamaica, Mexico, Nicaragua, Turks and Caicos Islands, and Venezuela. Consequently, a prohibition against the importation of berried lobsters or removal of eggs would not affect any legal imports from those 13 countries.

As stated previously in section 7.5.2.1, the possession of egg-bearing spiny lobster is prohibited in Florida, Puerto Rico and the U.S. Virgin Islands. Therefore, any imports of berried spiny lobster into Florida, Puerto Rico or the U.S. Virgin Islands, regardless of country of origin, are presently illegal. In 2006 and 2007, all imports of rock lobster from Guatemala entered the U.S. in Florida and this analysis presumes those imports came into possession in Florida. Hence, it is expected that all imports from Guatemala presently must comply with Florida law and any imports of berried lobsters from that country are illegal. Guyana and Trinidad and Tobago, the only other countries that do not prohibit the harvest of berried lobsters, have not exported rock lobster to the U.S. since 2005.

Florida, Puerto Rico, and the U.S. Virgin Islands prohibit the removal of eggs from female lobsters. In Florida, it is illegal to remove pleopods (or swimmerets). The U.S. Virgin Islands prohibits the practice of stripping, shaving, scraping, clipping or otherwise molesting egg-bearing lobsters in order to remove the eggs is prohibited and Puerto Rico prohibits the molestation of egg-bearing lobsters, which includes removal of the pleopods.

The typical method that illegal importers use to remove eggs from berried lobsters is to remove the pleopods (or swimmerets). Of the 17 countries that export Caribbean spiny lobster to the U.S., only the Bahamas and Belize have laws that prohibit such removal. Hence, the illegal importation of female lobsters that have had their eggs removed by clipping away their pleopods is a problem and would likely increase if Alternative 2 or 3 of Action 1 is implemented because illegal importers would likely substitute larger female lobsters that have had their eggs removed for undersized lobsters.

The bulk of the economic costs of prohibiting the importation of berried Caribbean spiny lobsters or those with their eggs or pleopods removed would be the losses of revenues and profits associated with the illegal importation of female spiny lobsters that have had their eggs stripped off by removing the pleopods and the losses of incomes that derive from such illegal activity. The economic benefits of this prohibition would be improved domestic and foreign revenues, profits and incomes that derive from a biologically and economically improved resource.

7.5.2.2.3 Total Economic Impact of Alternative 2 of Action 2

The bulk of the economic costs of prohibiting the importation of Caribbean spiny lobster meat that is removed from the exoskeleton would be the losses of revenues and profits associated with the illegal importation of both undersized spiny lobsters and those lobsters that have had their eggs removed and the losses of incomes that derive from such illegal activity. Decreases in revenues, profits and incomes earned from presently legal importation of spiny lobster meat separated from the shell would also occur; however, they are anticipated to be substantially lower by comparison to the losses of illegal revenues, profits and incomes generated from illegal operations that remove the meat from the shell.

Similarly, the prohibition against the importation of berried Caribbean spiny lobsters or those with their eggs or pleopods removed is expected to have the greatest impact on illegal operations that would lose revenues and profits generated from the illegal importation of female spiny lobsters that have had their eggs stripped off by removing the pleopods and the losses of incomes that derive from such illegal activity.

The economic combined benefits of this alternative would be improved domestic and foreign revenues, profits and incomes that derive from a biologically and economically improved resource.

7.5.2.3 Alternative 3 of Action 2

This alternative would prohibit the importation of spiny lobster meat without the exoskeleton attached and is identical to part 1 of Alternative 2, which bans the importation of spiny lobster meat without the exoskeleton attached. Consequently, its economic impact is identical to the economic impact described in section 7.5.2.2.1.

7.5.2.4 Alternative 4 of Action 2

This alternative would prohibit the importation of spiny lobster with eggs attached or where the eggs or pleopods (swimmerets) or have been removed or stripped. This alternative is identical to part 2 of Alternative 2. Thus, its economic impact is identical to the economic impact described in section 7.5.2.2.2.

7.5.2.5 Comparison of Economic Costs and Benefits of Alternatives

A summary of the economic costs and benefits of the four alternatives of Action 2 is presented in Table 7.5.2.2.

Table 7.5.2.2 Comparison of Economic Costs and Benefits of Action 2 Alternatives

Action 2: Establish Other Import Restrictions			
Alternative	**Description**	**Economic Cost**	**Economic Benefit**
1	Don't impose other import restrictions	Continues illegal importation of lobsters Supports illegal fishing and overfishing Leads to long-run biological and economic damages	Maintains status quo revenues, profits and incomes from trade
2	No imports of lobster meat detached from shell	Reduces some revenues, profits and incomes from legal trade	Reduces illegal importation of undersized and berried lobsters and those with eggs removed and associated illegal revenues, profits and incomes Discourages illegal fishing and overfishing Increases revenues, profits and incomes in long-run from legal use of resource
	No imports berried lobster or with eggs or pleopods removed	Reduces some revenues, profits and incomes from legal trade	Reduces illegal importation of berried lobsters and those with their eggs removed Discourages illegal fishing and overfishing Increases revenues, profits and incomes in long-run from legal use of resource
3	No imports of lobster meat detached from shell	Reduces some revenues, profits and incomes from legal trade	Reduces illegal importation of undersized and berried lobsters and those with eggs removed and associated illegal revenues, profits and incomes Discourages illegal fishing and overfishing Increases revenues, profits and incomes in long-run from legal use of resource
4	No imports berried lobster or with eggs or pleopods removed	Reduces some revenues, profits and incomes from legal trade	Reduces illegal importation of berried lobsters and those with their eggs removed Discourages illegal fishing and overfishing Increases revenues, profits and incomes in long-run from legal use of resource

7.6 Public and Private Costs of Regulations

The preparation, implementation, enforcement, and monitoring of this or any Federal action involves the expenditure of public and private resources which can be expressed as costs associated with the regulations. Costs associated with this amendment include:

Council costs of document preparation, meetings,
public hearings, and information dissemination $100,000

NOAA Fisheries administrative costs of document
preparation, meetings and review $100,000

Annual law enforcement costs ....$ Less than current costs

7.7 Determination of Significant Regulatory Action

Pursuant to E.O. 12866, a regulation is considered a "significant regulatory action" if it is expected to result in: (1) an annual effect of $100 million or more or adversely affect in a material way the economy, a sector of the economy, productivity, competition, jobs, the environment, public health or safety, or State, local, or tribal governments or communities; (2) create a serious inconsistency or otherwise interfere with an action taken or planned by another agency; (3) materially alter the budgetary impact of entitlements, grants, user fees, or loan programs or the rights or obligations of recipients thereof; or (4) novel legal or policy issues, arising out of legal mandates, the President's priorities or the principles set forth in this executive order. Based on the information above, this regulatory action was determined not to be economically significant because it would not have an annual effect of $100 million or more or adversely affect in a material way the economy or a sector of the economy, productivity, competition, or jobs. However, the action has been determined to be significant for purposes of E.O. 12866 because it may raise novel legal or policy issues in regards to international trade agreements.

8.0 REGULATORY FLEXIBILITY ANALYSIS

8.1 Introduction

The purpose of the Regulatory Flexibility Act (RFA) is to establish a principle of regulatory issuance that agencies shall endeavor, consistent with the objectives of the rule and applicable statutes, to fit regulatory and informational requirements to the scale of businesses, organizations, and governmental jurisdictions subject to regulation. To achieve this principle, agencies are required to solicit and consider flexible regulatory proposals and to explain the rationale for their actions to assure that such proposals are given serious consideration. The RFA does not contain any decision criteria; instead, the purpose of the RFA is to inform the agency, as well as the public, of the expected economic impacts of the alternatives contained in the FMP or amendment (including framework management measures and other regulatory actions) and to ensure that the agency considers alternatives that minimize the expected impacts while meeting the goals and objectives of the FMP and applicable statutes.

With certain exceptions, the RFA requires agencies to conduct a regulatory flexibility analysis for each proposed rule. The regulatory flexibility analysis is designed to assess the impacts various regulatory alternatives would have on small entities, including small businesses, and to determine ways to minimize those impacts. In addition to analyses conducted for the RIR, the initial regulatory flexibility analysis provides: (1) a description of the reasons why action by the agency is being considered; (2) a succinct statement of the objectives of, and legal basis for the proposed rule; (3) an identification, to the extent practicable, of all relevant Federal rules which may duplicate, overlap, or conflict with the proposed rule; (4) a description and, where feasible, an estimate of the number of small entities to which the proposed rule will apply; (5) a description of the projected reporting, record-keeping, and other compliance requirements of the final rule, including an estimate of the classes of small entities which will be subject to the requirements of the report or record; and (6) a description of significant alternatives to the proposed rule which accomplish the stated objectives of applicable statues and which minimize any significant economic impact of the proposed rule on small entities.

8.2 Statement of need for, objectives of, and legal basis for the proposed rule

The purpose and need, issues, problems, and objectives of the proposed Amendment are presented in Section 1.2 and are incorporated herein by reference. According to the Western Central Atlantic Fishery Commission, international trade of legally undersized Caribbean spiny lobster (*Panulirus argus*) is a serious problem. The U.S. is the largest importer of Caribbean spiny lobster and existing laws are insufficient to prevent the importation of lobsters illegally caught and traded. U.S. law enforcement's ability to screen imports for compliance with the Lacey Act is compromised by vague foreign minimum harvest-size and other laws that are intended to protect Caribbean spiny lobster. By implementing uniform importation standards, law enforcement's ability to effectively prevent the importation of undersized, berried lobsters and those with their eggs removed will be improved. This in turn may help protect the species both in the U.S. and in the Caribbean as a whole. These proposed actions are being considered by the National Marine Fisheries Service under the authority of the Magnuson-Stevens Fishery Conservation and Management Act.

8.3 Identification of Federal rules which may duplicate, overlap or conflict with the proposed rule

The Lacey Act, as amended in 1981 (16 USC §§ 3372 et seq.) prohibits the trade of fish, wildlife, or plants taken in violation of any foreign, state, tribal or other U.S. law. For example, it is a violation of the Lacey Act to import Caribbean spiny lobster (CSL) that is in violation of the country of origin's minimum harvest-size standard or other harvesting laws. Many of the countries that harvest CSL have minimum harvest-size standards and other harvest restrictions, some of which are equivalent to or greater than the proposed import standard and restrictions. See Table 7.5.1.6. No federal regulations or other federal laws have been identified that may duplicate, overlap or conflict with the proposed rule. However, Alternative 3 of Action 2 would produce import standards that are inconsistent with legal harvest standards established in Puerto Rico and the U.S. Virgin Islands.

8.4 Description of the projected reporting, record-keeping and other compliance requirements of the proposed rule, including an estimate of the classes of small entities which will be subject to the requirement and the type of professional skills necessary for the preparation of the report or records

The two proposed actions would not impose reporting or record-keeping requirements on any U.S. entity. Alternatives 2 and 3 of Action 1 would establish import-size standards. See Sections 7.5.1.2 and 7.5.1.3 for descriptions. Alternatives 2 through 4 of Action 2 would establish other import restrictions. See Sections 7.5.2.2 through 7.5.2.4 for descriptions.

8.5 Description and estimate of the number of small entities to which the proposed rule will apply

The two proposed actions would affect small businesses that import CSL into the United States from countries: 1) with legal minimum size standards that are less than those proposed in Alternatives 2 or 3 of Action 1 or without such standards and 2) without prohibitions against harvesting female lobsters with eggs, detaching eggs and/or removing pleopods (or swimmerets). It is anticipated that no small governmental jurisdictions or small not-for-profit organizations would be affected by this proposed action.

The following countries and territories have reported harvesting CSL during the period from 1962 through 2003, according to the FAO: Anguilla, Antigua and Barbuda, The Bahamas, Belize, Bermuda, Brazil, British Virgin Islands, Colombia, Costa Rica, Cuba, Dominican Republic, Grenada, Haiti, Honduras, Martinique, Mexico, Grenada, St. Kitts and Nevis, St. Lucia, Saint Vincent and Grenadines, Turks and Caicos, Nicaragua, Puerto Rico, Saint Kitts and Nevis, Trinidad and Tobago, Turks and Caicos Island, U.S., U.S. Virgin Islands, and Venezuela (Bolivarian Republic of). From 2002 through 2007 the following 17 countries that harvest Caribbean spiny lobster were countries of origin of rock lobster imported into the U.S.: Bahamas, Belize, Brazil, Colombia, Costa Rica, Dominican Republic, Guatemala, Guyana, Haiti, Honduras, Jamaica, Mexico, Nicaragua, Panama, Trinidad and Tobago, Turks and Caicos Islands, and Venezuela. See Tables 7.5.1.1 and 7.5.1.2. Caribbean spiny lobster is just one species among those identified as "rock lobster." Rock lobster includes all *Panulirus*, *Palinurus* and *Jasus* species.

Businesses that import CSL into the U.S. are expected to be within the following industries: Fish and Seafood Merchant Wholesalers (NAICS 424460), Fish and Seafood Markets (NAICS 445220), Fish and Frozen Seafood Processing (NAICS 311712), Packaged Frozen Food Merchant Wholesalers (NAICS 424420), and Supermarkets and Other Grocery (Except Convenience) Stores (NAICS 445110). The small business size standards for these industries are presented in Table 8.1 and corresponding 2002 Economic Census figures for the U.S. are presented in Tables 8.2 and 8.3.

Table 8.1. Industries of Small Businesses that Could Be Affected by Proposed Actions

Industry Description	NAICS Code	SBA Size Standard
Fish and Seafood Merchant Wholesalers	424460	100 employees
Fish and Seafood Markets	445220	$6.5 million
Packaged Frozen Food Merchant Wholesalers	424420	100 employees
Fish and Frozen Seafood Processing	311712	500 employees
Supermarkets and Other Grocery (Except Convenience) Stores	445110	$25 million

Table 8.2. Employer Establishments in Industries Likely to Import Caribbean Spiny Lobster for U.S. *Source*: 2002 Economic Census.

NAICS	Paid Employees	Annual Payroll $1000s	Estab.	Sales $1000s
424460	22,476	703,564	2,515	11933,530
445220	9,902	170,428	2,042	1,501,257
424420	94,880	3,607,395	3,629	66,097,512
311712	36,268	923,963	6,06	7,564,091
445110	2,437,750	42,790,166	66,150	395,233,897

In 2005 in Puerto Rico, there was one establishment in NAICS 31171, 13 in NAICS 424420, 6 establishments in NAICS 424460, 975 in NAICS 445110, and 7 in NAICS 445220 (U.S. Census Bureau, County Business Patterns for Puerto Rico). In the U.S. Virgin Islands in 2002, there were 16 employer establishments in NAICS 4244 with annual sales of about $77 million, 43 in NAICS 44511 with combined annual sales of about $204 million, 14 in NAICS 4452 with combined annual sales, and 6 in NAICS 311 of about $0.6 million. See Table 8.3.

Table 8.3 2002 Economic Census of Puerto Rico and U.S. Virgin Islands. *Source*: U.S. Census Bureau, 2002 Economic Census of Island Areas.

44522	7	10	861			

A: Census Bureau did not disclose.

8.5.1 Small Businesses that Could Be Affected by Alternatives 2 and 3

8.5.1.1 Small Businesses that Could Be Affected by Part A of Alt. 2

No legal imports from the following 7 countries of origin should be affected by Part A of Alternative 2 of Action 1 because of their size standards: Bahamas, Colombia, Dominican Republic, Honduras, Turks and Caicos Islands, Nicaragua, and Venezuela. See Section 7.5.1.2.1.

This action should affect more illegal importers of CSL than legal importers; however, some legal imports from Belize, Brazil, Costa Rica, Guatemala, Guyana, Haiti, Jamaica, Mexico, Panama, and Trinidad and Tobago could be affected by Part A of Alternative 2 of Action 1. In the past 6 years, Guyana and Trinidad and Tobago have been the country of origin only once and there have been no imports of rock lobster from these countries since 2004.

Florida law prohibits the possession of CSL that does not meet the size standards equivalent to Part A of this alternative. It is presumed for this initial analysis that imports of CSL that have entered and continue to enter the country at a Florida port come into possession in Florida and, therefore, already comply with Florida size requirements and the requirements that would be established by Part A. However, if any historical imports of spiny lobster remained within U.S. Customs jurisdiction until shipped out of a Florida port and did not come into possession in Florida, those imported spiny lobsters were not required to be in compliance with Florida size standards. Consequently, some of those past imports of CSL may not have satisfied the requirements being proposed in Part A. Therefore, the NMFS encourages any small businesses that imported and/or presently import spiny lobster through a Florida port to comment on the assumption that Caribbean spiny lobster imports that entered and continue to enter the country at a Florida port come to be possessed in Florida. All rock lobster imports from Haiti and Guatemala historically have entered at a Florida port, and therefore, this analysis presumes no legal imports of spiny lobster from Haiti or Guatemala would be affected by this alternative. Imports of rock lobster from Belize, Brazil, Costa Rica, Jamaica, Mexico and Panama enter the U.S. at both Florida and non-Florida ports. About 98 percent of the pounds and total dollar value of rock lobster annually imported from Jamaica enter at a Florida port. See Table 7.5.1.7. These rock lobster imports include all *Palinurus* species, *Panulirus* species and *Jasus* species.

Most rock lobster imports originate from Brazil. A preliminary review of 2006 through 2007 imports of frozen rock lobster from Brazil showed 17 different businesses that imported rock lobster from that country into the United States. Of those businesses, 3 were identified as being owned by a corporation or headquartered in a foreign country and at least 7 are not small businesses. Thus, it is initially concluded that at most 7 small businesses that import rock lobster from Brazil could be affected by the proposed action. At least 89 percent of the imports of rock lobster, however, are brought into the U.S. by foreign corporations and large businesses.

Small businesses indirectly affected would be those in Florida who benefit directly and indirectly from commercial and recreational harvest of Caribbean spiny lobster and are dependent upon the sustainability of the resource. See Section 5.3.7.

U.S. Customs data shows there were no imports of rock lobster (frozen or not) into the U.S. Virgin Islands from 2001 through 2007 and it is anticipated that few to zero imports and importers of rock lobster into the U.S. Virgin Islands would be affected by the alternative actions under consideration.

8.5.1.2 Small Businesses that Could Be Affected by Part B of Alt. 2

No legal imports of Caribbean spiny lobster into Puerto Rico or the U.S. Virgin Islands are expected to be affected by this Part B. See Section 7.5.1.2.2. Hence, no small businesses are expected to be affected by Part B of this alternative.

8.5.2 Small Businesses that Could Be Affected by Alternative 3

This alternative would: (1) directly and indirectly affect the same small businesses and have the same economic impact as Part A of Alternative 2 as described in Section 8.5.1.1 and (2) directly affect small businesses that import Caribbean spiny lobster into Puerto Rico and the U.S. Virgin Islands and indirectly small businesses that harvest and benefit from the harvest of Caribbean spiny lobster in Puerto Rico and the U.S. Virgin Islands. The impact on small businesses that import CSL into the two territories could be beneficial by increasing the allowed imports into the territories; however, the import standards would contradict existing laws in Puerto Rico and the U.S. Virgin Islands and could encourage overfishing of spiny lobster in territorial waters and illegal harvest in those waters, which would have an indirect and adverse impact small lobster fishing businesses. See Section 7.5.1.3.

8.5.3 Small Businesses that Could Be Affected by Alternatives 2 - 4

8.5.3.1 Small Businesses that Could Be Affected by Alternative 2

One method that illegal importers have used and continue to use to avoid detection is to remove the meat from the exoskeletons of undersized and berried spiny lobsters and then package the meat in chunks. This alternative would eliminate such illegal imports. It would also prohibit any currently legal imports of Caribbean spiny lobster meat that has been removed from the shell. Preliminary information suggests the ban on imports of lobster meat that has been extracted from the shell would have the greatest impact on illegal, not legal, trade. Most imported spiny lobster meat has the exoskeleton attached and would not be affected by this alternative; however, small businesses that import meat of the Caribbean spiny lobster that is separated from the shell would be directly affected by this alternative. See Section 7.5.2.2. Small businesses that exploit the resource or those that do business with those that do would benefit in the long-run by the improved status of the species.

From 2002 through 2007, rock lobster imports have originated from the following 17 countries that harvest Caribbean spiny lobster: The Bahamas, Belize, Brazil, Colombia, Costa Rica, Dominican Republic, Guatemala, Guyana, Haiti, Honduras, Jamaica, Mexico, Nicaragua, Panama, Turks and Caicos Islands, Trinidad and Tobago, and Venezuela. See Tables 7.5.1.1 and 7.5.1.2. Of these 17 countries, Guatemala, Guyana, and Trinidad and Tobago do not have laws that prohibit the harvest of spiny lobsters with eggs or removal of eggs. See Table 7.5.2.1. Combined rock lobster imports from these three countries represent $183,000 (about 0.05 percent) of $356 million of frozen imports and $9,000 (about 0.3 percent) of the $2.9 million of non-frozen imports. Panama has a law that prohibits the harvest of berried lobsters, but may not prohibit the removal of eggs. Imports of rock lobster from Panama represent about 0.7 percent of frozen rock lobster imports and none of the non-frozen imports. Therefore, this alternative may directly affect small businesses that import spiny lobster from Guatemala, Guyana, Panama, and Trinidad and Tobago by causing them to import fewer lobsters. However, the long-run improvement of the status of the species would generate beneficial economic impacts to those small businesses that directly and indirectly benefit from exploitation of the resource.

8.5.3.2 Small Businesses that Could Be Affected by Alternative 3

This alternative prohibits the importation of spiny lobster meat that is not attached to the exoskeleton. As stated previously, most spiny lobster imports have been meat within the shell; however, small businesses that import meat of the Caribbean spiny lobster that is separated from the shell would be affected by this alternative. See Section 7.2.2.2.2 and first paragraph of 8.5.3.1.

8.5.3.3 Small Businesses that Could Be Affected by Alternative 4

This alternative prohibits the importation of female lobsters with eggs attached and lobsters with either eggs or pleopods (or swimmerets) removed. See second paragraph of Section 8.5.3.1.

8.6 Substantial number of small entities criterion

The two actions being considered are not expected to affect a substantial number of small businesses each year. These actions are designed to significantly reduce illegal trade of Caribbean spiny lobster and the bulk of the adverse economic impacts are expected to affect illegal, not legal, importers of the lobster.

8.7 Significant economic impact criterion

The outcome of "significant economic impact" can be ascertained by examining two issues: disproportionality and profitability.

Disproportionality: Do the regulations place a substantial number of small entities at a significant competitive disadvantage to large entities?

Profitability: Do the regulations significantly reduce profit for a substantial number of small entities?

The two proposed actions are not expected to generate a significant adverse economic impact on small businesses that legally import Caribbean spiny lobster. It is expected that a substantial majority of currently legal imported lobster would not be affected. The purposes of the actions are to: 1) improve the detection of illegally traded Caribbean spiny lobsters and prosecution of those engaged in the illegal trade and 2) reduce the costs of such detection and legal action.

The National Marine Fisheries Service encourages small businesses to comment on any of the potential economic impacts of the two actions and their alternatives under consideration in this section and other sections of this document.

8.8 Description of significant alternatives

The two proposed actions are not expected to have a significant adverse economic impact on a substantial number of small entities that import Caribbean spiny lobster, either separately or in combination. Consequently, no significant alternatives, as defined by the RFA, have been considered; however, discussion of the expected impacts of the alternatives considered for each of the two actions as required by E.O. 12866 is contained in Section 7.

9.0 OTHER APPLICABLE LAWS

The MSFCMA (16 U.S.C. 1801 et seq.) provides the authority for U.S. fishery management. But fishery management decision-making is also affected by a number of other federal statutes designed to protect the biological and human components of U.S. fisheries, as well as the ecosystems within which those fisheries are conducted. Major laws affecting federal fishery management decision making are summarized below.

9.1 Administrative Procedures Act

All federal rulemaking is governed under the provisions of the Administrative Procedure Act (APA) (5 U.S.C. Subchapter II), which establishes a "notice and comment" procedure to enable public participation in the rulemaking process. Under the APA, NOAA Fisheries is required to publish notification of proposed rules in the *Federal Register* and to solicit, consider and respond to public comment on those rules before they are finalized. The APA also establishes a 30-day wait period from the time a final rule is published until it takes effect.

9.2 Coastal Zone Management Act

The Coastal Zone Management Act (CZMA) of 1972 (16 U.S.C. 1451 et seq.) encourages state and federal cooperation in the development of plans that manage the use of natural coastal habitats, as well as the fish and wildlife those habitats support. When proposing an action determined to directly affect coastal resources managed under an approved coastal zone management program, NOAA Fisheries is required to provide the relevant state agency with a determination that the proposed action is consistent with the enforceable policies of the approved program to the maximum extent practicable at least 90 days before taking final action.

9.3 Information Quality Act

The Data Quality Act (DQA) (Public Law 106-443), which took effect October 1, 2002, requires the government for the first time to set standards for the quality of scientific information and statistics used and disseminated by federal agencies. Information includes any communication or representation of knowledge such as facts or data, in any medium or form, including textual, numerical, cartographic, narrative, or audiovisual forms (includes web dissemination, but not hyperlinks to information that others disseminate; does not include clearly stated opinions).

Specifically, the Act directs the Office of Management and Budget (OMB) to issue government wide guidelines that "provide policy and procedural guidance to federal agencies for ensuring and maximizing the quality, objectivity, utility, and integrity of information disseminated by federal agencies." Such guidelines have been issued, directing all federal agencies to create and issue agency-specific standards to 1) ensure Information Quality and develop a pre-dissemination review process; 2) establish administrative mechanisms allowing affected persons to seek and obtain correction of information; and 3) report periodically to OMB on the number and nature of complaints received.

Scientific information and data are key components of FMPs and amendments and the use of best available information is the second national standard under the MSFCMA. To be consistent with the Act, FMPs and amendments must be based on the best information available, properly reference all supporting materials and data, and should be reviewed by technically competent individuals. With respect to original data generated for FMPs and amendments, it is important to ensure that the data are collected according to documented procedures or in a manner that reflects standard practices accepted by the relevant scientific and technical communities. Data should also undergo quality control prior to being used by the agency.

9.4 Endangered Species Act

The Endangered Species Act (ESA) of 1973 (16 U.S.C. Section 1531 et seq.) requires that federal agencies use their authorities to conserve endangered and threatened species, and that they ensure actions they authorize, fund, or carry out are not likely to harm the continued existence of those species or the habitat designated to be critical to their survival and recovery. The ESA requires NOAA Fisheries, when proposing a fishery action that "may affect" critical habitat or endangered or threatened species, to consult with the appropriate administrative agency (itself for most marine species, the U.S. Fish and Wildlife Service for all remaining species) to determine the potential impacts of the proposed action. Consultations are concluded informally when proposed actions "may affect but are not likely to adversely affect" endangered or threatened species or designated critical habitat. Formal consultations, resulting in a biological opinion, are required when proposed actions may affect and are "likely to adversely affect" endangered or threatened species or designated critical habitat. If jeopardy or adverse modification is found, the consulting agency is required to suggest reasonable and prudent alternatives.

On April 28, 1989, NOAA Fisheries Southeast Region (SERO) completed a formal consultation, including a Biological Opinion (Opinion), on the effects of commercial fishing activities in the Southeast Region on threatened and endangered species. The Opinion concluded that the Gulf of Mexico and South Atlantic spiny lobster fishery was likely to adversely affect, but not jeopardize the continued existence of ESA-listed sea turtles. Subsequent, informal consultations on the continued authorization of the fishery determined it was not likely to adversely affect ESA-listed species. The impacts of the Caribbean spiny lobster fishery on ESA-listed species were last evaluated in a formal consultation, concluded on May 19, 2005. The opinion concluded that Caribbean spiny lobster fishing was likely to adversely affect, but not jeopardize the continued existence of ESA-listed sea turtles.

As provided in 50 CFR 402.16, reinitiation of formal consultation is required when discretionary involvement or control over the action has been retained (or is authorized by law) and: (1) the amount or extent of the incidental take is exceeded; (2) new information reveals effects of the agency action that may affect listed species or critical habitat in a manner or to an extent not previously considered; (3) the agency action is subsequently modified in a manner that causes an effect to the listed species or critical habitat not previously considered; or (4) if a new species is listed or critical habitat designated that may be affected by the identified action.

Since the completion of the most recent formal consultations on these fisheries, two species of *Acropora* coral have been listed under the ESA, and may be affected by spiny lobster fishing. Additionally, new information is available revealing effects of the action that may affect listed species or critical habitat in a manner or to an extent not previously considered. Accordingly, NOAA Fisheries Office of Sustainable Fisheries has requested initiation of a Section 7 consultation with the SERO's Protected Resources Division for this amendment. NOAA Fisheries anticipates completion of the consultations on the Gulf of Mexico/South Atlantic and Caribbean spiny lobster fisheries prior to Secretarial review and approval of the fishery plan amendments for the spiny lobster fisheries.

9.5 Rivers and Harbors Act of 1899

The Rivers and Harbors Act was created in 1899 to prevent navigable waters of the United States from being obstructed. Section 10 of the Act requires that anyone wishing to dredge, fill, or build a structure in any navigable water and associated wetlands obtain a permit from the ACOE. An activity affecting wetlands may require a Section 404 and Section 10 permit, thus both sections are often included together in a permit notice. When these activities are permitted, and there is direct loss of submerged habitat, such as seagrasses, then mitigation is often required to compensate for this loss.

9.6 Clean Water Act

In 1972, Congress passed the Clean Water Act (CWA) - also known as the Water Pollution Prevention and Control Act - to protect the quality of the nation's waterways including oceans, lakes, rivers and streams, aquifers, coastal areas, and aquatic resources. The law sets out broad rules for protecting the waters of the United States; Sections 404 and 401 apply directly to waters and aquatic resources protection.

Section 404 of the Clean Water Act (often referred to as "Section 404" or simply "404") forbids the unpermitted "discharge of dredge or fill material" into waters of the United States. Section 404 does not regulate every activity in aquatic resources or coastal areas, but requires anyone seeking to fill any area to first obtain a permit from the Army Corps of Engineers (ACOE). Constructing bridges, causeways, piers, port expansion, or any other construction or development activity along a waterway or in aquatic resources generally requires a 404 permit. When a fill project is permitted, there may be mitigation required to replace lost aquatic resources.

Section 401 of the Clean Water Act requires that an applicant for a Section 404 permit obtain a certificate from their state's environmental regulatory agency (if the state has delegated such authority to the agency) that the activity will not negatively impact water quality. This permit process is supposed to prevent the discharge of pollutants (pesticides, heavy metals, hydrocarbons) or sediments into waters, which may be above acceptable levels, because decreased water quality may endanger the health of the people, fish, and wildlife. However, acceptable pollutant levels have not been established for many aquatic resources, which make it difficult for state agencies to fully assess a project's impact on water quality.

9.7 National Marine Sanctuaries Act

Under the National Marine Sanctuaries Act (NMSA) (also known as Title III of the Marine Protection, Research and Sanctuaries Act of 1972), as amended, the Secretary of Commerce is authorized to designate National Marine Sanctuaries to protect distinctive natural and cultural resources whose protection and beneficial use requires comprehensive planning and management. The National Marine Sanctuaries are administered by NOAA's National Ocean Service. The Act provides authority for comprehensive and coordinated conservation and management of these marine areas. The National Marine Sanctuary System currently comprises 13 sanctuaries around the country, including sites in American Samoa and Hawaii. These sites include significant coral reef and kelp forest habitats, and breeding and feeding grounds of whales, sea lions, sharks, and sea turtles. A complete listing of the current sanctuaries and information about their location, size, characteristics, and affected fisheries can be found at http://www.sanctuaries.nos.noaa.gov/oms/oms.html.

9.8 Fish and Wildlife Coordination Act

The Fish and Wildlife Coordination Act protects the quality of the aquatic environment needed for fish and wildlife resources. The Act requires consultation with the Fish and Wildlife Service and the fish and wildlife agencies of States where the "waters of any stream or other body of water are proposed or authorized, permitted or licensed to be impounded, diverted . . . or otherwise controlled or modified" by any agency (except TVA) under a Federal permit or license. NOAA Fisheries was brought into the process later, as these responsibilities were carried over, during the reorganization process that created NOAA. Consultation is to be undertaken for the purpose of "preventing loss of and damage to wildlife resources", and to ensure that the environmental value of a body of water or wetland is taken into account in the decision-making process during permit application reviews. Consultation is most often (but not exclusively) initiated when water resource agencies send the FWS or NOAA Fisheries a public notice of a Section 404 permit. FWS or NOAA Fisheries may file comments on the permit stating concerns about the negative impact the activity will have on the environment, and suggest measures to reduce the impact.

9.9 Executive Orders

9.9.1 E.O. 12114: Environmental Assessment of Actions Abroad

The purpose of this Executive Order is to enable responsible officials of Federal agencies having ultimate responsibility for authorizing and approving actions encompassed by this Order to be informed of pertinent environmental considerations and to take such considerations into account, with other pertinent considerations of national policy, in making decisions regarding such actions. While based on independent authority, this Order furthers the purpose of the National Environmental Policy Act and the Marine Protection Research and Sanctuaries Act and the Deepwater Port Act consistent with the foreign policy and national security policy of the United States, and represents the United States government's exclusive and complete determination of the procedural and other actions to be taken by Federal agencies to further the purpose of the National Environmental Policy Act, with respect to the environment outside the United States, its territories and possessions.

Agencies in their procedures shall establish procedures by which their officers having ultimate responsibility for authority and approving actions in one of the following categories encompassed by this Order, take into consideration in making decisions concerning such actions, a document described in Section 2-4(a):
(a) major Federal actions significantly affecting the environment of the global commons outside the jurisdiction of any nation (e.g., the oceans or Antarctica);
(b) major Federal actions significantly affecting the environment of a foreign nation not participating with the United States and not otherwise involved in the action;

(c) major Federal actions significantly affecting the environment of a foreign nation which provide to that nation:

> (1) a product, or physical project producing a principal product or an emission or effluent, which is prohibited or strictly regulated by Federal law in the United States because its toxic effects on the environment create a serious public health risk; or
>
> (2) a physical project which in the United States is prohibited or strictly regulated by Federal law to protect the environment against radioactive substances.

(d) major Federal actions outside the United States, its territories and possessions which significantly affect natural or ecological resources of global importance designated for protection under this subsection by the President, or, in the case of such a resource protected by international agreement binding on the United States, by the Secretary of State. Recommendations to the President under this subsection shall be accompanied by the views of the Council on Environmental Quality and the Secretary of State.

The purpose of this amendment/EIS is to increase the spawning biomass of the spiny lobster population in the waters of the Caribbean and tropical western Atlantic (the oceans). It has been determined in section 6 there will be significant biological affects in a positive form; and as indicated numerous times throughout the document, the restrictions considered in this document were developed in accordance with a number of international agreements and accords passed by foreign nations.

9.9.2 E.O. 12866: Regulatory Planning and Review

Executive Order 12866: Regulatory Planning and Review, signed in 1993, requires federal agencies to assess the costs and benefits of their proposed regulations, including distributional impacts, and to select alternatives that maximize net benefits to society. To comply with E.O. 12866, NOAA Fisheries prepares a Regulatory Impact Review (RIR) for all fishery regulatory actions that either implement a new fishery management plan or significantly amend an existing plan. RIRs provide a comprehensive analysis of the costs and benefits to society associated with proposed regulatory actions, the problems and policy objectives prompting the regulatory proposals, and the major alternatives that could be used to solve the problems. The reviews also serve as the basis for the agency's determinations as to whether proposed regulations are a "significant regulatory action" under the criteria provided in E.O. 12866 and whether proposed regulations will have a significant economic impact on a substantial number of small entities in compliance with the RFA. A regulation is significant if it is likely to result in an annual effect on the economy of at least $100,000,000 or has other major economic effects.

9.9.3 E.O. 12630: Takings

The Executive Order on Government Actions and Interference with Constitutionally Protected Property Rights, which became effective March 18, 1988, requires that each federal agency prepare a Takings Implication Assessment for any of its administrative, regulatory, and legislative policies and actions that affect, or may affect, the use of any real or personal property. Clearance of a regulatory action must include a takings statement and, if appropriate, a Takings Implication Assessment. Management measures limiting fishing seasons, areas, quotas, fish size limits, and bag limits do not appear to have any taking implications. There is a takings implication if a fishing gear is prohibited, because fishermen who desire to leave a fishery might be unable to sell their investment, or if a fisherman is prohibited by federal action from exercising property rights granted by a state.

9.9.4 E.O. 13089: Coral Reef Protection

The Executive Order on Coral Reef Protection (June 11, 1998) requires federal agencies whose actions may affect U.S. coral reef ecosystems to identify those actions, utilize their programs and authorities to protect and enhance the conditions of such ecosystems; and, to the extent permitted by law, ensure that actions they authorize, fund or carry out not degrade the condition of that ecosystem. By definition, a U.S. coral reef ecosystem means those species, habitats, and other national resources associated with coral reefs in all maritime areas and zones subject to the jurisdiction or control of the United States (e.g., federal, state, territorial, or commonwealth waters).

9.9.5 E.O. 13112: Invasive Species

The Executive Order requires agencies to use authorities to prevent introduction of invasive species, respond to and control invasions in a cost effective and environmentally sound manner, and to provide for restoration of native species and habitat conditions in ecosystems that have been invaded. Further, agencies shall not authorize, fund, or carry out actions that are likely to cause or promote the introduction or spread of invasive species in the U.S. or elsewhere unless a determination is made that the benefits of such actions clearly outweigh the potential harm; and that all feasible and prudent measures to minimize the risk of harm will be taken in conjunction with the actions. The actions undertaken in this amendment will not introduce, authorize, fund, or carry out actions that are likely to cause or promote the introduction or spread of invasive species in the U.S. or elsewhere.

9.9.6 E.O. 13132: Federalism

The Executive Order on federalism requires agencies in formulating and implementing policies that have federalism implications, to be guided by the fundamental federalism principles. The Order serves to guarantee the division of governmental responsibilities between the national government and the states that was intended by the framers of the Constitution. Federalism is rooted in the belief that issues that are not national in scope or significance are most appropriately addressed by the level of government closest to the people. This Order is relevant to FMPs and amendment given the overlapping authorities of NOAA Fisheries, the states, and local authorities in managing coastal resources, including fisheries, an the need for a clear definition of responsibilities. It is important to recognize those components of the ecosystem over which fishery managers have no direct control and to develop strategies to address them in conjunction with appropriate state, tribes and local entities (international too). The proposed management measures in this Amendment to the Spiny Lobster FMPs of the Caribbean and the South Atlantic/Gulf of Mexico have been developed with the local, federal and international officials.

9.9.7 E.O. 13141: Environmental Review of Trade Agreements

This Executive Order requires the U.S. Trade Representative, through the interagency Trade Policy Staff to conduct environmental reviews of three of the most common agreements: comprehensive multilateral trade rounds, bilateral or multilateral free-trade agreements, and major new trade liberalization agreements in natural resource sectors. Although the procedures for environmental impact assessment in Executive Order 13141 are not subject to NEPA, they follow similar guidelines. Understanding the importance of this E.O. in relation to this Amendment/EIS, NOAA Fisheries Service has made a concerted effort to involve the USTR and other agencies involved with trade negotiations to inform them of the intention of the actions being undertaken by the Councils and NOAA Fisheries Service.

9.9.8 E.O. 13158: Marine Protected Areas

Executive Order 13158 (May 26, 2000) requires federal agencies to consider whether their proposed action(s) will affect any area of the marine environment that has been reserved by federal, state, territorial, tribal, or local laws or regulations to provide lasting protection for part or all of the natural or cultural resource within the protected area.

9.9.9 E.O. 12898: Environmental Justice

This Executive Order mandates that each Federal agency shall make achieving environmental justice part of its mission by identifying and addressing, as appropriate, disproportionately high and adverse human health or environmental effects of its programs, policies, and activities on minority populations and low-income populations in the United States and its territories and possessions. Federal agency responsibilities under this Executive Order include conducting their programs, policies, and activities that substantially affect human health or the environment, in a manner that ensures that such programs, policies, and activities do not have the effect of excluding persons from participation in, denying persons the benefit of, or subjecting persons to discrimination under, such, programs policies, and activities, because of their race, color, or national origin. Furthermore, each federal agency responsibility set forth under this Executive Order shall apply equally to Native American programs.

Specifically, federal agencies shall, to the maximum extent practicable; conduct human health and environmental research and analysis; collect human health and environmental data; collect, maintain and analyze information on the consumption patterns of those who principally rely on fish and/or wildlife for subsistence; allow for public participation and access to information relating to the incorporation of environmental justice principals in Federal agency programs or policies; and share information and eliminate unnecessary duplication of efforts through the use of existing data systems and cooperative agreements among Federal agencies and with State, local, and tribal governments. The proposed actions would be applied to all participants in the fishery, regardless of their race, color, national origin, or income level, and as a result are not considered discriminatory. Additionally, none of the proposed actions are expected to affect any existing subsistence consumption patterns. Therefore, no environmental justice issues are anticipated and no modifications to any proposed actions have been made to address environmental justice issues.

9.10 Marine Mammal Protection Act

The MMPA established a moratorium, with certain exceptions, on the taking of marine mammals in U.S. waters and by U.S. citizens on the high seas. It also prohibits the importing of marine mammals and marine mammal products into the United States. Under the MMPA, the Secretary of Commerce (authority delegated to NOAA Fisheries) is responsible for the conservation and management of cetaceans and pinnipeds (other than walruses). The Secretary of the Interior is responsible for walruses, sea otters, polar bears, manatees, and dugongs.

In 1994, Congress amended the MMPA, to govern the taking of marine mammals incidental to commercial fishing operations. This amendment required the preparation of stock assessments for all marine mammal stocks in waters under U.S. jurisdiction; development and implementation of take-reduction plans for stocks that may be reduced or are being maintained below their optimum sustainable population levels due to interactions with commercial fisheries; and studies of pinniped-fishery interactions. The MMPA requires a commercial fishery to be placed in one of three categories, based on the relative frequency of incidental serious injuries and mortalities of marine mammals. Category I designates fisheries with frequent serious injuries and mortalities incidental to commercial fishing; Category II designates fisheries with occasional serious injuries and mortalities; Category III designates fisheries with a remote likelihood or no known serious injuries or mortalities. To legally fish in a Category I and/or II fishery, a fisherman must obtain a marine mammal authorization certificate by registering with the Marine Mammal Authorization Program (50 CFR 229.4) and accommodate an observer if requested (50 CFR 229.7(c)) and they must comply with any applicable take reduction plans.

The Caribbean spiny lobster trap/pot and Florida spiny lobster trap/pot fisheries are listed as part of a Category III fishery (72 FR 66048; November 27, 2007) because there has only been one documented interaction between these gears and marine mammals.

9.11 Paperwork Reduction Act

The Paperwork Reduction Act (PRA) of 1995 (44 U.S.C. 3501 et seq.) regulates the collection of public information by federal agencies to ensure that the public is not overburdened with information requests, that the federal government's information collection procedures are efficient, and that federal agencies adhere to appropriate rules governing the confidentiality of such information. The PRA requires NOAA Fisheries to obtain approval from the Office of Management and Budget before requesting most types of fishery information from the public. This action contains no PRA requirements.

9.12 Small Business Act

The Small Business Act of 1953, as amended, Section 8(a), 15 U.S.C. 634(b)(6), 636(j), 637(a) and (d); Public Laws 95-507 and 99-661, Section 1207; and Public Laws 100-656 and 101-37 are administered by the SBA. The objectives of the act are to foster business ownership by individuals who are both socially and economically disadvantaged; and to promote the competitive viability of such firms by providing business development assistance including, but not limited to, management and technical assistance, access to capital and other forms of financial assistance, business training and counseling, and access to sole source and limited competition federal contract opportunities, to help the firms to achieve competitive viability. Because most businesses associated with fishing are considered small businesses, NMFS, in implementing regulations, must make an assessment of how those regulations will affect small businesses. Implications to small businesses are discussed in the RIR herein (Section 7).

9.13 Magnuson-Stevens Act Essential Fish Habitat Provisions

The Magnuson-Stevens Act includes EFH requirements, and as such, each existing, and any new, FMPs must describe and identify EFH for the fishery, minimize to the extent practicable adverse effects on that EFH caused by fishing, and identify other actions to encourage the conservation and enhancement of that EFH. The Council and NMFS have determined there are no adverse effects to EFH in this amendment as discussed in the Environmental Consequences section (Section 6).

9.14 Migratory Bird Treaty Act

Under the Migratory Bird Treaty Act (MBTA), it is unlawful to pursue, hunt, take, capture, kill, possess, trade, or transport any migratory bird, or any part, nest, or egg of a migratory bird, included in treaties between the United States and Great Britain, Mexico, Japan, or the former Union of Soviet Socialists Republics, except as permitted by regulations issued by the Department of the Interior (16 U.S.C. 703-712). Violations of the MBTA carry criminal penalties; any equipment and means of transportation used in activities in violation of the MBTA may be seized by the United States government and, upon conviction, must be forfeited to it. To date, the MBTA has been applied to the territory of the United States and coastal waters extending three miles from shore. Furthermore, Executive Order 13186 (see Section 9.5.9) was issued in 2001, which directs federal agencies, including NOAA Fisheries, to take certain actions to further implement the MBTA.

9.15 National Environmental Policy Act

The National Environmental Policy Act (NEPA) of 1969 (42 U.S.C. 4321 et seq.) requires federal agencies to consider the environmental and social consequences of proposed major actions, as well as alternatives to those actions, and to provide this information for public consideration and comment before selecting a final course of action. Because NOAA Fisheries Service is proposing a major fishery action that may significantly affect the quality of the human environment, NOAA Fisheries Service has prepared this EIS to comply with NEPA and its implementing regulations.

9.16 Regulatory Flexibility Act

The purpose of the Regulatory Flexibility Act (RFA 1980, 5 U.S.C. 601 et seq.) is to ensure that federal agencies consider the economic impact of their regulatory proposals on small entities, analyze effective alternatives that minimize the economic impacts on small entities, and make their analyses available for public comment. The RFA does not seek preferential treatment for small entities, require agencies to adopt regulations that impose the least burden on small entities, or mandate exemptions for small entities.

Rather, it requires agencies to examine public policy issues using an analytical process that identifies, among other things, barriers to small business competitiveness and seeks a level playing field for small entities, not an unfair advantage.

After an agency determines that the RFA applies, it must decide whether to conduct a full regulatory flexibility analysis (IRFA or Final Regulatory Flexibility Analysis) or to certify that the proposed rule will not "have a significant economic impact on a substantial number of small entities. In order to make this determination, the agency conducts a threshold analysis, which has the following 5 parts: 1) Description of small entities regulated by proposed action, which includes the SBA size standard(s), or those approved by the Office of Advocacy, for purposes of the analysis and size variations among these small entities; 2) Descriptions and estimates of the economic impacts of compliance requirements on the small entities, which include reporting and recordkeeping burdens and variations of impacts among size groupings of small entities; 3) Criteria used to determine if the economic impact is significant or not; 4) Criteria used to determine if the number of small entities that experience a significant economic impact is substantial or not; and 5) Descriptions of assumptions and uncertainties, including data used in the analysis. If the threshold analysis indicates that there will not be a significant economic impact on a substantial number of small entities, the agency can so certify.

9.17 Small Business Act

Enacted in 1953, the Small Business Act requires that agencies assist and protect small-business interests to the extent possible to preserve free competitive enterprise.

9.18 Public Law 99-659: Vessel Safety

Public Law 99-659 amended the Magnuson-Stevens Act to require that a FMP or FMP amendment must consider, and may provide for, temporary adjustments (after consultation with the U.S. Coast Guard and persons utilizing the fishery) regarding access to a fishery for vessels that would be otherwise prevented from participating in the fishery because of safety concerns related to weather or to other ocean conditions.

10.0 SOCIAL IMPACT ASSESSMENT REQUIREMENTS AND DATA ISSUES

INTRODUCTION

Mandates to conduct Social Impact Assessments come from both the National Environmental Policy Act (NEPA) and the Magnuson-Stevens Fishery Conservation and Management Act (Magnuson-Stevens Act). NEPA requires federal agencies to consider the interactions of natural and human environments by using a "...systematic, interdisciplinary approach which will ensure the integrated use of the natural and social sciences...in planning and decision-making" [NEPA section 102 (2) (a)]. Under the Council on Environmental Quality's (CEQ, 1986) Regulations for Implementing the Procedural Provisions of the National Environmental Policy Act, a clarification of the terms "human environment" expanded the interpretation to include the relationship of people with their natural and physical environment (40 CFR 1508.14). Moreover, agencies need to address the aesthetic, historic, cultural, economic, social, or health effects which may be direct, indirect or cumulative

(Interorganizational Committee on Guidelines and Principles for Social Impact Assessment, 1994).

Recent amendments to the Magnuson-Stevens Act require FMPs address the impacts of any management measures on the participants in the affected fishery and those participants in other fisheries that may be affected directly or indirectly through the inclusion of a fishery impact statement [Magnuson-Stevens Act section 303 (a) (9)]. Most recently, with the addition of National Standard 8, FMPs must now consider the impacts upon fishing communities to the extent practicable to assure their sustained participation and minimize adverse economic impacts upon those communities [Magnuson-Stevens Act section 301 (a) (8)]. Consideration of social impacts is a growing concern as fisheries experience increased participation and/or declines in stocks. With an increasing need for management action, the consequences of such changes need to be examined to minimize the negative impacts experienced by the populations concerned to the extent practicable.

DATA LIMITATIONS AND METHODS

Social impacts are generally the consequences to human populations that follow from some type of public or private action. Those consequences may include alterations to "...the ways in which people live, work or play, relate to one another, organize to meet their needs and generally cope as members of a society..." (Interorganizational Committee on Guidelines and Principles for Social Impact Assessment, 1994:1). In addition, included under this interpretation are cultural impacts that may involve changes in values and beliefs, which affect the way people identify themselves within their occupation, communities and society in general. Social impacts analyses help determine the consequences of policy action in advance by comparing the status quo with the projected impacts. Therefore, it is important that as much information as possible concerning a fishery and its participants be gathered for an assessment.

It is important to identify any foreseeable adverse effects on the human environment. With quantitative data often lacking, qualitative data can be used to provide a rough estimate of some of the impacts based on the best available science. In addition, when there is a body of empirical findings available from the social science literature, it needs to be summarized and referenced in the analyses.

SUMMARY OF SOCIAL IMPACT ASSESSMENT

Descriptions of the affected communities and expected effects of the alternatives considered in this amendment are provided in sections 5 and 6, respectively.

MACRO SEAFOODS INC.
SEAFOOD EXPERIENCE SINCE 1971.

)O N.W. 77TH AVE,
SUITE 26
HIALEAH GARDENS FL 33016

TEL: (305) 827-5001
FAX:(305)827-5003
E-MAIL: SHAINDELE@AOL.COM

AUGUST 15, 2000

The seller admits to shipping 3 oz tails, then follows that statement up with the crackdown on under 5 oz tails (which are all illegal tails), but offers a solution to continue the trade in illegal size tails

ACE,

SHIPMENT LEAVING WEDNESDAY FROM NICA WITH APPROX 2800 LBS OF 3 OZ

THEY HAVE CLOSED DOWN THE BUYING OFFICES AT THE WHARF AS THERE IS ALOT OF PRESSURE (FOR NOW) ON UNDER 5 OZ, SO I EXPECT THIS BUSINESS WILL HAVE TO COME RECTLY FROM KEYS AND NOT THRU NORMAL SELLERS, THIS SIZE WILL BECOME ARCER.

INSURANCE: RECEIVED CALL THAT PROBABLITY OF PUTTING THE PACKAGE YOU REQUESTED IS LOOKING GOOD AND I MAY HAVE CALL THIS AFTERNOON.

P.

AUGUST 16/00

ACE,

APPROX 800-900 LBS OF LOBSTER MEAT FROM NICA DUE TO ARRIVE ON SAME BOAT AS 3 OZ

PRICE $8.75/LB

CAN YOU SELL THIS ? YES

LET ME KNOW

PETER

The buyer is notified their illegal 3 oz lobster tails are on the way with an inquiry as to whether they could sell lobster "meat." This is important because it is the beginning of the "meat" sale and seems to coincide exactly with the information concerning the crackdown on tails under 5 oz., again another way to continue with illegal business as usual

MACRO SEAFOODS INC.

AUGUST 18, 2000

INVOICE # 2103

CASES	SIZE	NET WT.	LOBSTER TAILS	PRICE PER LB/UB DISCOUNTED	AMOUNT
65 CS	3 OZ	2600 LBS	FROZEN IQF MARAZUL BRAND	$10.90	$28,340.00
16 CS		640 LBS	LOBSTER MEAT NICA BRAND	$8.75	$ 5,600.00

Lobster meat shows up on the invoice along with the 3 oz tails. This invoice shows the sale of 3,240 lbs of illegal, undersized lobster

PRODUCT OF NICARAGUA

AMOUNT $ 33,940.00

NO OF CASES: 81

SENT "IN BOND" VIA BESTWAY TRANSPORT FROM MIAMI

APPENDIX B – SUMMARY OF SCOPING COMMENTS

SPINY LOBSTER SCOPING – ISLAMORADA, FL
JANUARY 24, 2008
DRAFT SUMMARY NOTES:

Mr. Eugenio Pineiro, Chairman of the Caribbean Council, read the chairman's statement on behalf of the Caribbean, Gulf, and South Atlantic Fishery Management Councils. Other members of the scoping meeting board were as follows: Tony Iarocci, chair of the South Atlantic Council's spiny lobster committee; Miguel Rolon, Executive Director of the Caribbean Council; Gregg Waugh, Deputy Executive Director of the South Atlantic council; Joe Kimmel, NMFS SERO; and Diana Martino, Caribbean council staff.

There were 9 members of the public present.

Gregg Waugh presented an overview of the scoping document and issues under consideration.

Karl Lessard – reviewed the Gulf Council's Spiny Lobster AP position: the AP supported Approach 1.

Gary Graves – Keys Fisheries, Marathon, Florida. Industry in his area support Approach 1; they also support prohibiting scrubbing tails, possession of berried lobsters, etc. They are concerned about using tail weight; fishermen can measure length on a boat but not weight. Fishermen may bring lobsters in that can't be exported because they don't meet the minimum size limit. They support 5.5" tail length for imports from the whole Caribbean. He distributed a sheet with information on production from his plant for tails that measure 5.5" and their weight; tails from shedding/molting lobsters may not weigh as much.

Bruce Irwin – member of South Atlantic Council Spiny Lobster AP. He thanked the CFMC for taking the initiative to address this issue to protect the stock of lobster. He supports Approach 1 with one point of concern about the weight as mentioned by Gary Graves.

Scot Zimmerman – FL Keys Commercial Fishermen's Association. We will be submitting written comments. Generally support the Councils' efforts to address imports. Support Approach 1. Concerned about a decline in landings in Florida and feel it is due to harvest of small lobsters in the Caribbean area. Mentioned a concern about the collection of wild juveniles for grow-out and potential impacts on the lobster stock.

Tom Hill – Key Largo Fisheries and a member of SFA. Support Approach 1. He is concerned about using weight because it changes with the size of tail due to molting, etc.

Tom Mathews – mentioned the concern of Paul Raymond (NMFS Law Enforcement) to consider the tail weight to aid enforcement. Writing the regulations as an import rule would address the concerns of industry because the tail weight requirement would only

apply to imports. A number of Caribbean countries have a voluntary (memorandum of agreement) 4.5 – 5.4 ounce tail size rule (ESPESKA) and this is what the countries want to see as an import regulation. Weight is important for tracking imports; this is very important for law enforcement and for making legal cases.
The scoping meeting ended at 7 p.m.

APPROACH 1 FROM THE SCOPING DOCUMENT

Approach 1 would be to prohibit imports smaller than the existing U.S. minimum size limits. For example, no one in the Continental U.S. would be allowed to import a Caribbean spiny lobster (Panulirus argus):

1. Less than 3.0 inches (7.62 cm) carapace length if the animal is whole.
2. Less than 5.5 inches (13.97 cm) tail length if only the tail is present.
3. Less than 5 ounces if want a tail weight (e.g., 4.2 – 5.4 ounces).

For Puerto Rico and the U.S. Virgin Islands, no one would be allowed to import a Caribbean spiny lobster (Panulirus argus):

1. Less than 3.5 inches (8.89 cm) carapace length if the animal is whole.
2. Less than 6.2 inches (15.75 cm) tail length if only the tail is present.
3. Less than 5.9 ounces if want a tail weight (need to specify what 5.9 or 6 ounces means in the industry).

CARIBBEAN FISHERY MANAGEMENT COUNCIL
268 Muñoz Rivera Ave.
Suite 1108
San Juan PR 00918-1920
Scoping Meetings
Summary
October 10, 2007

The Caribbean Fishery Management Council is requesting public comment on the following issues:
Queen Conch: Management alternatives for the queen conch fishery in the exclusive economic zone (EEZ) off St. Croix, USVI. The EEZ off Lang Bank (East of St. Croix) is seasonally open for harvesting of queen conch and regulations are in place that limit the size, establish a seasonal closure (July-September) and limits the harvest of commercial and recreational fishers. The Government of the Territory of the US Virgin Islands has extended the seasonal closure of queen conch from July 1 to December 31, in the territorial waters in St. Croix and has requested that the Council establish compatible regulations in the EEZ. The USVI have also established a quota for the fishery of 50,000 pounds per year. The alternatives considered by the Council include (1) No Action; (2) establishing compatible regulations (extended seasonal closure and 50,000 pounds per year) and (3) a complete closure of the queen conch fishery in the US Caribbean EEZ.

Escape Vents in traps: In order to reduce bycatch and fishing mortality in the stocks that are overfished, undergoing overfishing and approaching an overfishing condition, the

Council is considering the use of escape vents in fish traps and lobster pots. A number of options are being considered: ranging from one escape vent with shapes and sizes that could be rectangular (1” x 3” to 2” x 4”), circular (2.5” to 5”) or diamond shape (4.0” x 2” to 5.0” x 2.5”); 2 escape vents of each of the shapes and sizes mentioned above; 2 escape vents of different shapes and sizes (combination of one rectangular and one circular, etc.); and no action for fish traps. The same alternatives are considered for the lobster pots but the sizes of the rectangular shapes range from 2” x 20” to 21/4” x 20”.

Spiny Lobster: In this case, the management alternatives to implement a minimum size limit on imported spiny lobster may include, but are not limited to: a “no action”; alternatives to restrict the minimum import size based on carapace length; alternatives to restrict the minimum import based on tail length; and alternatives to restrict the importation of meat, which is not whole lobster or tailed lobster.

Scoping Meetings for Queen Conch, Lobster and Reef fish (traps and pots)
Summary of Comments
October 16,2007
Holiday Inn Windward Passage Hotel
St. Thomas, U.S.V.I.

1. Roberto Tapia - Enforcement DPNR
Additional enforcement staff members should be onboard by the end of next year for the U.S.V.I. Provided **no comments on the lobster**, queen conch, and reef fish issues.

2. David Berry - Commercial Fisherman
Queen Conch: Do not impose a closure (cost jobs).
Need re-stocking, hatchery production.
Spiny lobster: Juvenile lobsters being fished is the right thing to do.
Escape vents: No action.
Other comments: Support for the fishermen instead of fighting fishermen.

3. Julian Magras - Chairman, St. Thomas Fishermen's Association
Queen conch: No action.
Spiny lobster: Supports a carapace length of 3.5" for imports.
Escape vents: Regulations do not effect Puerto Rico (with a trap fishery in decline), nor the St. Croix fisherman (only 1 fishing trap) but directed to St. Thomas fishermen. The federal jurisdiction is 67% of the USVI area and this is discrimination, and 85% of trap fishers in St. Thomas. (See statement attached). No action.

4. David Olsen - Director, U.S.V.I. Division of Fish and Wildlife
Agrees with the comments made by Julian Magras

5. Louis Blanchard - Commercial Fisherman
Queen conch: No action.
Spiny lobster: No action.
Escape vents: Need to wait for results on the escape vents study currently

underway in St. Thomas. No action.
6. Michael Beny - Commercial Fisherman
Queen conch: No opinion.
Spiny lobster: Only allow lobsters as big as, or bigger than local size allowed (1 3.5" carapace length).
Escape vents: No action.

7. Jimmy Magner - Commercial Fisherman
Queen conch: Queen conch is not overfished in St. Croix (cited SEDAR 2007). Keep St. Croix open. (No action). If proven to be decreasing, then put a catch limit. Insufficient data. Studies are needed to gather more data.
Spiny lobster: Imports into the US should not be allowed if lobster size is less than 3.5" carapace length.
Escape vents: No action until survey is finished.

8. Harry Clinton - Recreational Fisherman
Agrees with the comments previously made. Local groups are already taking steps to protect the fisheries in the U.S.V.I., there is no need for the federal government to impose more regulations.
Queen conch: No comment.
Spiny lobster: Agrees with a carapace length of 3.5" for imports.
Escape vents: No comment.

9. Warren Querrard and Danny Beny - Commercial Fishermen
Queen conch: No action.
Spiny lobster: Agrees with a carapace length of 3.5" for imports.
Escape vents: No action.

10. Ricky LaPlace - Commercial Fisherman
Queen conch: No action.
Spiny lobster: Agrees with a carapace length of 3.5" for imports
Escape vents: No action.

11. Braison Bryant and father Terry Bryant - Commercial Fishermen
Queen conch: No comment.
Spiny lobster: Agrees with a carapace length of 3.5" for imports.
Escape vents: No action.

12. Ernest Quentel- Commercial Fisherman
Queen conch: Seasonal closure.
Spiny lobster: Agrees with a carapace length of 3.5" for imports.
Escape vents: No action. The escape panel suggested would make the fishermen lose 95% of their catch.

October 17,2007
Buccaneer Hotel, St. Croix, U.S.V.I.

1. Leopold Giddens - Commercial Fisherman, Fredericksted
There are 250 licensed commercial fishers in St. Croix and at least 75% of them should be present. DPNR needs to present the data.
Queen conch: No comment.
Spiny lobster: No comment.
Escape vents: No comment.

2. Edward Schuster - Chairman, Fisheries Advisory Committee (FAC) and President of St. Croix Fishermen Association
Queen conch: The FAC recommends a 5-month closure. DPNR established a 6-month closure. The FAC recommended changing the bag limit of 150 conchs per fisher to 200 conchs per boat to prevent overfishing. There is a need to self-regulate. A study needs to be conducted during the seasonal closure to assess the population for a more accurate account of the population. The FAC recommended to use 3 clean, 2 unclean conchs to the pound, instead of bringing the shell to shore. There are problems with dumping sites. It represents a risk to travel with the shells onboard. There should be no imports of queen conch during the closed season.
Spiny lobster: A study on larvae recruitment should be conducted in St. Croix. No comment on imports size.
Escape vents: Lobster traps not used in St. Croix but multi-purpose traps for fish and lobster. The Council should consider conducting a trap vents study in St. Croix, since the St. Croix fishers use hexagonal mesh instead of the square mesh used in St. Thomas.

3. Baltazar Felix IU - Commercial Fisherman
Queen conch: No Action. If not able to maintain fishery, then extend the closure.
Spiny lobster: No comment.
Escape vents: No comment.

4. Roltalia Nisbett – St Croix Resident
Queen conch: Allowance of 200 queen conchs per boat rather than 150 per fisher. No additional months of closure.
Spiny lobster: No comment.
Escape vents: No comment.

5. Frank Johnston – Conch Diver
Queen conch: Maintain the regulations as they are (three-month closure).
Hire more people during the months of closure to enforce the law.
Spiny lobster: Lobster imports should be compatible with local laws (3.5" carapace length).
Escape vents: Not needed, since the current mesh size and the escape panel already established are working good. No action.

6. Joseph Gilbert – Commercial Fisherman
Queen conch: Christmas is a very important time for conch fishers. No closure during the month of December. There was a recent incident on loitering by shells [NOTE: the regulations, both state and federal, require that conch be brought to shore intact, in the shell. These shells are dumped at various sites including areas of tourism. A judge ordered the shells to be dumped at sea.]
Spiny lobster: No comment.
Escape vents: No comment.

7. Gerson Martinez - Commercial Fisherman
Queen conch: Closed season should be from June to October 31**.** Conch is not depleted in St. Croix. Closure should be postponed until further studies are conducted.
Spiny lobster: Lobster imports should be compatible with local laws (3.5" carapace length).
Escape vents: No action. The mesh size used in St. Croix is working. Escape vents would represent a considerable economic loss.

9. Robert Thomas - St. Croix Resident
Comments on the logic of reporting 10 pounds of conch, which would be considered too little, and 100 pounds, which would be considered too much; either way the fishermen looses and there will be more regulations. Things are bad in the Island. There is no enforcement.
Queen conch: Leave the month of December open. There is a problem with the shells, they destroy the bottom of the vessels.
Spiny lobster: No comment.
Escape vents: No comment.

October 23,2007
Pierre Hotel
San Juan, Puerto Rico

1. Hector Mpez - Port Agent, Department of Natural and Environmental Resources (DNER)
Requested information from Dr. Olsen regarding the conch that remains in the freezer during the closure - how can they track what was caught before the season? How to prove it is not imported?
Queen conch: No comment.
Spiny lobster: No comment
Escape vents: No comment.

2. Aida Rosario - DNER Secretary's Designee
Queen conch: This is a matter for the U.S.V.I.
Spiny lobster: Agrees with a carapace length of 3.5" for imports, but Puerto Rico would have to revise the interstate law for imports to see how it would be applied.
Escape vents: Mesh size works; studies done at the Fisheries Research Laboratory show that the mesh size (1.5" hex and 2" square) were the most productive and still allow for

the escape of juveniles. Larger mesh sizes were not economically a good return. Need to study measures that are not protecting the resource and the impact on fishers.

October 24,2007
Ponce Hilton Hotel
Ponce, Puerto Rico

1. Maria Roman Reyes- Juana Diaz resident
Queen conch: No comment.
Spiny lobster: No comment.
Escape vents: There is no enforcement and the fishers are not marking their traps because they get stolen. They do not want to use GPS, etc., but keep the way of living. The regulations are so complicated that high school drop-outs are not entering the fishery.

2. Luis S. Rodriguez - Commercial Fisherman, Guayama Villa Pesquera Punta Pozuelo
Queen conch: No comment
Spiny lobster: No comment
Escape vents: The mesh size works. The material that is available now will not allow for cutting the mesh, it will make the trap too weak.

3. Miguel Ortiz - President, Villa Pesquera Pozuelo
Recreational fishers are fishing more and selling the catch. There is no enforcement and no license requirements for recreational fishers in place yet. Dorado and other species harvested during tournaments are sold. This happens everywhere around the Island.
Queen conch: No comment
Spiny lobster: Agrees with a carapace length of 3.5" for imports.
Escape vents: No action. It would hurt the fishermen. They would lose a lot of fishes that they are allowed to catch. Too much paper work, regulations in state waters and federal regulations do not help. The red hind seasonal closure is not working, too much fish wasted - area closures would work better, but the seasonal closure for the snapper works well. The imports are also competition because is fish for less money. No support has been given to the regulations that are in place.

4. Julio Reyes - Commercial Fisherman, Pescaderia Pastille, Juana Diaz
Queen conch: No comment
Spiny lobster: Agrees with a carapace length of 3.5" for imports
Escape vents: No action

October 25,2007
Mayaguez Holiday Inn
Mayaguez, Puerto Rico

1. Victor Padilla - Commercial Fisherman
Queen conch: No comment
Spiny lobster: Agrees with a carapace length of 3.5" for imports

Escape vents: No Action. The material available for traps today is very bad. The costs have increased. People are retiring from fishing because there are too many regulations and it is expensive to fish. The trap mesh oriented vertically, instead of horizontally allow small fish to escape (> 1.5 inch height). This might be a better solution rather than having an escape vent in the trap. Need to study the fishing with mallorquines (3 panels) being used for fishing lobsters. It does not allow the lobster to [walk] march, migrate. These nets trap everything, lobsters by the hundreds and small. The lobsters fished this way loose their legs, antennae, etc., and many other species are affected too. In contrast, the fishers know where to set the traps.

2. Andres Maldonado - Commercial Fisherman, Cab0 Rojo
Queen conch: The peak spawning season for queen conch is September (2nd week) and October. Open July and close October. Enforcement is not being done as it should, since the market is already flooded the first week of the open season. Fishing is being done during the closed season. The new regulations for St. Croix are not going to work since there is no enforcement, and the increased closure would force illegal actions. A three-month closure is not easy.
Spiny lobster: If lobster is one stock, maintain same opportunity for lobster spawning with the 3.5" carapace length size for imports.
Escape vents: No comment

3. Pedro Silva - Commercial Fisherman, Mayaguez
Queen conch: No comment
Spiny lobster: Agrees with a carapace length of 3.5" for imports
Escape vents: No action. Mallorquines and chinchorros are more damaging to fish. There is an enforcement problem. There are no regulations for recreational fishers, or no enforcement of regulations for the recreational fishers. Recreational fishers sell their catch against the law. Interventions at sea are only with commercial fishers and not with recreational. Enforcement agents need training.

November 13,2007
Curriculum Center
St. Croix, U.S.V.I.
(Second Scoping Meeting requested by the Fishermen)

1. Tom Daley - Commercial Fisherman
Mr. Daley brought a replica of the suggested escape vent and various species of fish to demonstrate how legally caught fish fall through the escape vent of more than 1" by 4".
Queen conch: Supports the six month closure for conch, as well as establishing a quota.
Spiny lobster: No comment.
Escape vent: The 1" by 4" allows the juveniles to escape. Any other size would be useless. St. Croix should be dealt with separately from St. Thomas and Puerto Rico in terms of the management measures that are put in place. The economy is in bad shape in St. Croix, and many people look at fishing as an alternative to make a living.

2. Edward Schuster - Commercial Fisherman
Queen conch: The closure should be £tom June to November, it should not run until December. Peak period for spawning runs until November. Supports the quota and the six-month closure. Studies should be conducted before having any more closures. Fishermen are more than willing to cooperate in the studies.
Spiny lobster: No comment.
Escape vents: No comment.

3. Gerson Martinez - Commercial Fisherman
Queen conch: Supports a six-month closure from June through November. December is not a peak spawning month.
Spiny lobster: No comment.
Escape vents: 2" by 4" and 2" by 6" allows all species of fishes that are caught legally to escape. No action.

4. Carlos Farchetti - Chief of Enforcement, U.S.V.I.
Queen conch: Supports the six-month closure From June through November. There are a lot of juvenile conch areas. More data should be gathered and presented to conclude if the conch is really in danger. Suggests having these juvenile areas videotaped, without identifying the location.
Spiny lobster: No comment.
Escape vents: No comment.

5. Winston Ledee - Commercial Fisherman, St. Thomas
Queen conch: Supports a six-month closure from June to November
Spiny lobster: No comment.
Escape vents: No action until studies are finished. There is no need for escape vents in lobster traps.

APPENDIX C – PUBLIC HEARING COMMENTS

CARIBBEAN FISHERY MANAGEMENT COUNCIL
268 MUNOZ RIVERA AVENUE, SUITE 1108
SAN JUAN, PUERTO RICO 00918

SPINY LOBSTER IMPORTS PUBLIC HEARINGS

SUMMARY OF COMMENTS

The Caribbean Fishery Management Council held public hearings on the Draft Environmental Impact Statement (DEIS) to establish a size limit for spiny lobster imports into the United States (see attached notice).

Following are the comments received at the public hearings:

Mayaguez, Puerto Rico
July 17, 2008

1. Fred Lentz – Fisherman/ Rincón, Puerto Rico

   In agreement with establishing a minimum size for imports of spiny lobsters into the U.S. Caribbean. He believes this would benefit the local fishers because the importers and restaurants will have to buy spiny lobster of the same size that the locals are required to fish and sell them for, resulting in a better economic return for the local fishermen.

2. Providencio Linares- Caribbean Maritime Educational Center

   In agreement with establishing a minimum size for imports of spiny lobsters into the U.S. Caribbean

San Juan, Puerto Rico
July 18, 2008

No deponents. No comments were received.

St. Thomas, U.S. Virgin Islands
July 21, 2008

1. David Olsen – Representing the St. Thomas Fishermen's Association (STFA)

   The STFA supports the establishment of a minimum size for imports of spiny lobster into the U.S. Caribbean. Dr. Olsen read for the record a letter offering the position and comments of the STFA (see letter attached.)

St. Croix, U.S. Virgin Islands
July 22, 2008

1. Michael Danse and Therese Chretien – Interested persons/St. Croix, USVI

   In agreement with establishing a minimum size for imports of spiny lobsters into the U.S. Caribbean.

MAGNUSON – STEVENS ACT/NEPA PUBLIC HEARINGS THE CARIBBEAN, GULF OF MEXICO, AND SOUTH ATLANTIC COUNCILS' AMENDMENT TO ADDRESS THE IMPORTATION OF SPINY LOBSTER PRODUCTS THAT DO NOT MEET U.S. CONSERVATION STANDARDS

SUMMARY OF PUBLIC COMMENTS

JULY 2008

Three public hearings were held, and all hearings began at 5:30 pm. The following Council members were present: Eugenio Piñeiro-Soler (Chair, CFMC), George Geiger (Chair, SAFMC), and Robert Gill (GMFMC). The following Council staff was present: Gregg Waugh (SAFMC), Assane Diagne (GMFMC), and Phyllis Miranda (GMFMC).

Gregg Waugh reviewed the issues in the import amendment; copies of the import amendment and public hearing summary were provided to all members of the public.

A summary of the comments received is shown below:

I. Public Hearing #1. July 21, 2008; Radisson Hotel; 3820 N. Roosevelt Blvd.; Key West, Florida. There were three members of the public present for the spiny lobster public hearing.

Mr. Peter Backel, Owner of Stock Island Lobster Company and member of the Florida Spiny Lobster Advisor Board. Our company has been in business since 1953 and these changes are long overdue. We support the preferred alternatives of the South Atlantic Council and believe that one import size limit (3" carapace length and 5.5" tail length) is the way to go.

Mr. Scott Zimmerman, Executive Director of the Florida Keys Commercial Fishermen's Association. Our organization supports the amendment; it has great potential to reduce mortality of shorts and this would support further recruitment to Florida from the Pan-Caribbean lobster stock. Protecting Pan-Caribbean lobsters through this import amendment is important for our stock here in Florida.

Ms. Libby Featherston, Ocean Conservancy, read portions of a draft letter that will be submitted during the written comment period. She supports a prohibition of imports that do not meet our standards in terms of size, berried, and lobster meat. She supports Alternative 2 for Action 1 and Alternative 2 for Action 2 (SAFMC preferred alternatives).

II. Public Hearing #2. July 22, 2008; Banana Bay; 4590 Overseas Highway; Marathon, Florida. There were two members of the public present (Karl Lassard and Scott Zimmerman) for the spiny lobster public hearing and one provided comments.

Mr. Scott Zimmerman, Executive Director of the Florida Keys Commercial Fishermen's Association. We support the minimum size import limitation. We would request the Councils examine one part of Alternative 2a that specifies greater than 3" carapace length – this does not reflect the 3" size limit which is Florida law. He spoke with Jason at the NMFS SERO today. We will be providing written comments. We are currently importing millions of pounds of small lobster tails and this has a negative impact on our resource in Florida given the stock linkages.

III. Public Hearing #3. July 23, 2008; Doubletree Hotel; 2649 S. Bayshore Dr.; Miami, Florida. There were no members of the public present for the spiny lobster public hearing.

APPENDIX D – RESPONSE TO COMMENTS RECEIVED ON THE DRAFT ENVIRONMENTAL IMPACT STATEMENT (DEIS)

NOAA Fisheries Service received eight comments on the DEIS. Five were in full support of the measures described in the DEIS; Response: NOAA Fisheries Service agrees.

One comment was in support, but wanted to see the larger size limits applied to all imports; Response: While applying the larger size limit to all imports may be more beneficial in the long-term, a number of international and trade issues are of concern with trying to implement the larger size restrictions. Therefore, NOAA Fisheries Service used international collaboration as well as best available scientific information to develop the two sets of size limit standards to meet international needs as well as current domestic regulations.

Another comment was concerned with the impacts of the no action alternatives as preferred alternatives had not been selected. The Councils have selected their preferred alternatives (these have been identified in the document), which were identified as having a Lack of Objection. There was also a concern about the discussion and comparison of a fished versus a non-fished population of spiny lobster. The commenter wished to see a comparison between two fished populations in different parts of the Caribbean. While this would be an ideal discussion to include in the document, NOAA Fisheries Service is unaware of any studies having been conducted in this manner and merely wanted to demonstrate the potential for differences in spiny lobster populations in regards to size at 50% maturity. Another concern dealt with the use of one standard deviation instead of only one morphometric measurement. The commenter agreed this was more user-friendly, but felt clarification was needed to verify that the lesser lengths and weights are still large enough to accomplish the goals of this action. NOAA Fisheries Service believes the commenter mistook the weight range explanation and the one standard deviation discussion. The one standard deviation discussion deals with the appropriate tail length and tail weight to be used when derived from a carapace length measurement. For example, current regulations in the Gulf of Mexico and South Atlantic require a carapace length greater than 3 inches. The regulations also allow (with the appropriate permit) a tail length of 5.5 inches. The 5.5 inch tail length requirement was derived from a 3-inch carapace length animal's average tail length minus one standard deviation, thus the appropriate tail weight requirement should be derived in the same manner (i.e., the average tail weight of a 3-inch carapace length animal minus one standard deviation). The range of tail weights given for a 5-ounce animal use this approach (hence the 4.2 ounce lower end allowed), but recognize industry packing practices and define the range of weights for a 5-ounce animal (4.2 – 5.4 ounces).

The final comment received stated the agency had no comment on the DEIS.

ABBREVIATIONS AND ACRONYMS

ABC	Acceptable Biological Catch
ACCSP	Atlantic Coastal Cooperative Statistics Program
ACE	Ashepoo-Combahee-Edisto Basin National Estuarine Research Reserve
APA	Administrative Procedures Act
AUV	Autonomous Underwater Vehicle
B	A measure of stock biomass either in weight or other appropriate unit
B_{MSY}	The stock biomass expected to exist under equilibrium conditions when fishing at F_{MSY}
B_{OY}	The stock biomass expected to exist under equilibrium conditions when fishing at F_{OY}
B_{CURR}	The current stock biomass
CEA	Cumulative Effects Analysis
CEQ	Council on Environmental Quality
CFMC	Caribbean Fishery Management Council
CPUE	Catch per unit effort
CRP	Cooperative Research Program
CZMA	Coastal Zone Management Act
DEIS	Draft Environmental Impact Statement
EA	Environmental Assessment
EBM	Ecosystem-Based Management
EEZ	Exclusive Economic Zone
EFH	Essential Fish Habitat
EFH-HAPC	Essential Fish Habitat - Habitat Area of Particular Concern
EIS	Environmental Impact Statement
EPAP	Ecosystem Principles Advisory Panel
ESA	Endangered Species Act of 1973
F	A measure of the instantaneous rate of fishing mortality
$F_{30\%SPR}$	Fishing mortality that will produce a static SPR = 30%.
$F_{45\%SPR}$	Fishing mortality that will produce a static SPR = 45%.
F_{CURR}	The current instantaneous rate of fishing mortality
FMP	Fishery Management Plan
F_{MSY}	The rate of fishing mortality expected to achieve MSY under equilibrium conditions and a corresponding biomass of B_{MSY}
F_{OY}	The rate of fishing mortality expected to achieve OY under equilibrium conditions and a corresponding biomass of B_{OY}
FEIS	Final Environmental Impact Statement
FMU	Fishery Management Unit
FONSI	Finding Of No Significant Impact
GOOS	Global Ocean Observing System
GFMC	Gulf of Mexico Fishery Management Council
IFQ	Individual fishing quota
IMS	Internet Mapping Server
IOOS	Integrated Ocean Observing System
M	Natural mortality rate

MARMAP	Marine Resources Monitoring Assessment and Prediction Program
MARFIN	Marine Fisheries Initiative
MBTA	Migratory Bird Treaty Act
MFMT	Maximum Fishing Mortality Threshold
MMPA	Marine Mammal Protection Act of 1973
MRFSS	Marine Recreational Fisheries Statistics Survey
MSA	Magnuson-Stevens Act
MSST	Minimum Stock Size Threshold
MSY	Maximum Sustainable Yield
NEPA	National Environmental Policy Act of 1969
NMFS	National Marine Fisheries Service
NMSA	National Marine Sanctuary Act
NOAA	National Oceanic and Atmospheric Administration
NRC	National Research Council
OY	Optimum Yield
POC	Pew Oceans Commission
R	Recruitment
RFA	Regulatory Flexibility Act
RIR	Regulatory Impact Review
SAFE	Stock Assessment and Fishery Evaluation Report

6.0 Threats to the South Atlantic Ecosystem

6.1 Adverse impacts of non-fishing activities

The waters and substrate that comprise essential fish habitat (EFH) as defined by the Magnuson-Stevens Fishery Conservation and Management Act (Magnuson-Stevens Act), and under jurisdiction of the South Atlantic Fishery Management Council (SAFMC), are diverse, widely distributed, and closely affiliated with other aquatic and terrestrial environments. These characteristics make them readily susceptible to a large number of human activities.

The Essential Fish Habitat (EFH) Interim Final Rule (Federal Register 62 FR 244) defines EFH as "those waters and substrate necessary to fish for spawning, breeding, feeding, or growth to maturity." The following definitions apply for interpreting the definition of the EFH rule:

- Waters include aquatic areas and their physical, chemical, and biological properties that are used by fish and invertebrates, and where appropriate may include areas historically used by fish and invertebrates;
- Substrate includes sediment, hard bottom, structures underlying the waters, and biological communities;
- Necessary means the habitat required to support a sustainable fishery and a healthy ecosystem; and
- Spawning, breeding, feeding, or growth to maturity covers species' full life cycle.

Fish habitat is the geographic area where the species occurs at any time during its life. This area can be described by ecological characteristics, location, and time. EFH includes waters and substrate that focus distribution; (e.g., coral reefs, marshes, or submerged aquatic vegetation), and other characteristics that are less distinct such as turbidity zones, water quality, and salinity gradients. Habitat use may change or shift over time due to climatic change, human activities and impacts, and/or other factors such as change with life history stage, species abundance, competition with other species, and environmental variability in time and space. The type of habitat available, its attributes, and its functions are important to species productivity, diversity, health, and survival.

Convention for Threats Identification

The ecological requirements for managed species and biotic communities, including identification of EFH, are addressed in this document. Threats to those habitats are described in terms of those that generally occur landward of the shoreline (Threats to Estuarine Processes) and those that occur oceanward of the shoreline (Threats to Offshore Processes). Threats to Estuarine Processes include but are not limited to agriculture; aquaculture; silviculture; urban/suburban development; commercial and industrial activities; navigation; recreational boating; mining; hydrologic modifications; transportation projects; and natural events and global change. Threats to Offshore

Processes include navigation; dumping; offshore sand and mineral mining; oil and gas exploration, development, and transportation; commercial and industrial activities; and natural events and global change. A more comprehensive list of individual activities that may be considered as threats is provided in Section 6.3.17.

Every reasonable effort was made to identify the principal non-fishing and fishing-related threats to EFH and to provide examples and information concerning the relationship between threat-related activities and EFH. Other information sources and examples undoubtedly exist and related studies are underway or are in various stages of publication. Accordingly, the following discussion is a starting point for the identification of threats to EFH. While it meets the strict time limitations imposed by the Magnuson-Stevens Act, regular updating is required to ensure comprehensive and current coverage of the topic addressed.

6.1.1 Freshwater/estuarine/inshore processes

Many species of the South Atlantic region are dependent during at least some life history stages on near-shore waters vulnerable to impacts from land-based sources. Especially vulnerable are species or species groups that require estuaries or freshwater tributaries as primary larval or post-larval habitat. In the southeast, these species include anadromous fish such as striped bass, blueback herring, alewife, American shad, hickory shad, and sturgeons; and brackish species including Atlantic menhaden, summer and southern flounder, red drum, spot, croaker, weakfish, penaeid shrimp, blue crab, and others (Epperly and Ross 1986).

Nearshore EFHs at risk from land-based impacts include submerged shellfish beds; subtidal and intertidal mudflats and shell hash; SAV beds, including eelgrass (*Zostera marina*), Cuban shoal grass (*Halodule wrightii*), and widgeon grass (*Ruppia maritima*); tidal freshwater forested wetlands dominated by tupelo-cypress communities (*Taxodium distichum*, *Nyssa aquatica*), and emergent tidal marshes including both saltmarshes dominated by smooth cordgrass (*Spartina alterniflora*) and brackish marshes dominated by black needlerush (*Juncus roemerianus*). These habitats may be affected both by direct destruction and by degradation of water quality or other factors such as hydrologic modification. Elimination or degradation of wetlands not immediately adjacent to EFH also may diminish the quality and productiveness of downstream estuaries.

The precise relationship between fishery production and habitats is undetermined. Accordingly, the exact degree to which habitat alteration has affected fishery production is also unknown, but is thought to be substantial. Turner and Boesch (1987) assembled and examined evidence of the relationship between the extent of wetland habitats and the yield of fishery species that depend on coastal bays and estuaries. The evidence examined show that fishery stock losses follow wetland losses and fishery stock gains follow wetland gains. While most of the studies were related to shrimp production, other fisheries are likely follow this trend.

In the southeastern U.S., the dominant sources of land-based impacts include major land-disturbing activities such as agriculture, silviculture, and residential and commercial development. The following discussions characterize major threats in the coastal zone of the southeast, summarize ways that EFH is impacted, and characterize the current extent of such impacts. Impacts can occur at three scales: immediate watersheds of EFH; broader watersheds of important estuarine nurseries; and distant or indirect impacts mediated through more widespread movement of water and its chemical and physical make-up.

6.1.1.1 Agriculture

Agriculture in the southeast has undergone dramatic changes over time. Most operations were at one time individual and small-scale enterprises, but in recent years have transformed into highly integrated, large-scale industries. Besides the extensive conversion of wetlands to crop and animal production, the most dramatic change in southern agriculture is the large scale expansion in animal production that has occurred during the last decade. The most dramatic increases have occurred in corporate hog operations in North Carolina. According to North Carolina Agricultural Statistics, the 1996/1997 hog numbers (8,969,200) for the 44 coastal counties are more than quadruple the 1986 numbers (2,117,800) for the same area. At the same time, the number of hog farms has declined precipitously, by a factor of three.

Other southeastern states have not yet experienced the same increase in swine herds. South Carolina's coastal counties, in fact, experienced a net reduction in swine herds from 374,000 head in 1986 to 194,900 head in 1996 (South Carolina Agricultural Statistics). Georgia had a similar decrease in the coastal plain counties, decreasing from 400,911 head in 1987 to 317,795 head in 1992 (Georgia Agricultural Statistics). Florida numbers experienced a decline in Atlantic watersheds from about 23,541 head in 1987 to 12,482 head in 1992 (Florida Agricultural Statistics). Part of the reason for the differences in hog production among the states is the development of industrial hog-growing technologies in North Carolina, plus differences in state regulatory programs. South Carolina, for instance, recently adopted very stringent and restrictive new laws governing hog-growing operations.

Poultry production, a second major agricultural animal product, has also increased substantially in the southeast. Again, North Carolina leads the nation in several poultry categories. In 1996, 313,735,000 birds were produced in coastal North Carolina; up from 45,588,966 birds in 1986. South Carolina coastal counties also showed a significant increase in production over this decade: 57,834,000 birds were produced in 1986 and 140,038,000 in 1996. The increases in the Georgia and Florida Atlantic coastal counties were much more moderate from 1987 to 1992, with production rates of 12,907,265 to 15,438,031 birds, and 2,780,706 to 2,886,335 birds, respectively (all data from state agricultural statistics).

Patterns in cropland use also have been in flux. In the North Carolina coastal plain, harvested cropland has remained almost static during the past decade, at about three million acres. However, fertilizer use has increased from 848,927 tons in 1986 to 2,006,251 tons in 1996 (not including swine and other animal waste land application). During the same period, South Carolina has experienced a net decrease in harvested acreage in the coastal plain, from 1,759,162 acres to 1,589,420 acres, but a net increase in fertilizer usage of about 38% to 331,597 tons. Harvested cropland along the Georgia coast is up slightly, to about 900,000 acres in 1992. Comparable data on fertilizer usage are not yet available. Harvested cropland in the Florida Atlantic coastal plain is down from about 1.1 million acres in 1992 to 675,081 acres in 1996. (All data from state agricultural statistics).

The overall pattern in crop production is one of great intensification of use on a fairly stable land base. Large increases in fertilizer usage and manure-based nitrogen fluxes (from surface and groundwater and from airborne sources) have occurred during the last decade in at least some southeastern states, including watersheds that were already artificially enriched.

Nutrient pollution can result in cascading ecological and economic impacts, including fish kills due to oxygen depletion, seagrass die-offs, excessive and sometimes toxic algal blooms, changes in marine biodiversity, increases in human illnesses, and loss of tourism (NRC 2000). For example, in southeast Florida nutrient inputs to Lake Okeechobee from central Florida agriculture activities (primarily sugar) are then discharged to important estuaries including the St. Lucie estuary. Timed releases associated with flood control activities result in large quantities of nutrient-laden water inputs to the St. Lucie estuary. Between 2004 and 2005, it is estimated that approximately 320 billion gallons of this water was diverted to the St. Lucie estuary. Many researchers have suspected that algal blooms and resulting fish kills in 2005-2006 were a result of this activity.

<u>Potential Threats to EFH from Agriculture</u>

Potential threats include: conversion of wetlands to agricultural lands, or for farm related purposes such as roads and irrigation ponds; direct and non-point source discharge of fill, nutrients, chemicals, and surface and ground waters into streams, rivers, and estuaries; hydrologic modification of ditches, dikes, farm ponds and other similar structures and water control devices; damage to wetlands and submerged bottoms by livestock grazing and/or movement; and cumulative and synergistic effects caused by association of these and other related activities.

Certain agricultural activities present a threat to EFH in the southeast. The major components of this threat include wetland conversion, nutrient over enrichment with subsequent deoxygenation of surface waters, shading by excessive algae and plant growth, and stimulation of toxic dinoflagellates; sedimentation; and delivery of toxicants into sensitive waters. Agriculture (including silviculture) accounted for 87% of all wetland losses observed nationally between the mid 1950's and mid 1970's (Tiner 1984). This loss has been estimated at more than 458,000 acres per year between the mid 1950's and mid 1970's in the coterminous U.S. (Tiner 1984). The most extensive losses observed in the southeast were in Florida and North Carolina where agricultural drainage continues to destroy large tracts of wetlands (Tiner 1984). Current agriculture conversion statistics for the southeast show that:

- During the mid-1970s to the mid-1980s "Florida showed a net wetland loss of 260,000 acres, mainly from the destruction of palustrine wetlands. Two-thirds of the loss of palustrine wetlands was attributable to agricultural development..." (Hefner et al. 1994).
- "Between the mid-1970s and mid 1980s, more than 100,000 acres of freshwater forested wetlands in Georgia were destroyed, mostly because of conversion to land uses such as agriculture" (Dahl et al. 1991).
- Between 1982 and 1989, South Carolina lost 155,500 acres, of this amount agriculture was responsible for 28% (Dahl 1997).
- In North Carolina about one-third of the wetland alteration in the coastal plain has occurred since the 1950s. Of this amount, agriculture was responsible for about 42% (Cashin et al. 1992).

Excessively enriched waters often do not support desirable species or populations of fish and invertebrates. They also may not support food chain and other ecological assemblages needed to sustain desirable species and populations. When overly abundant, nutrients such as nitrogen (ammonia) and phosphorus may degrade or eliminate EFH and its flora and fauna through several processes. Most problematic of these is the process whereby dissolved oxygen in the water is reduced by decaying plant life that prospered under nutrient rich conditions. In severe oxygen depletion situations fish and invertebrates may suffocate from oxygen deprivation.

Nutrient enrichment may also lead to direct toxicity when toxic organism populations "bloom" or become excessively large -- situations that are becoming more prevalent and which are discussed in detail in subsequent sections. Although affected by acidity, water temperature, and other factors, total ammonia concentrations in excess of about 2 mg/L normally exceed the chronic exposure level for fish (Mueller and Helsel 1996). In alkaline water at high temperature, the criteria may be exceeded by total ammonia concentrations of less than 0.1 mg/L. The natural conversion of ammonia to nitrate in streams removes oxygen from water and, therefore, may also harm fish (Mueller and Helsel 1996). While less problematic in estuarine and marine environments, phosphorus is a major factor in nutrient enrichment and eutrophication of freshwater systems. There are no minimum discharge standards for phosphorus; however, the U.S. EPA recommends that phosphates should not exceed 0.05 mg/L when discharged into streams entering lakes and reservoirs (Muller and Helsel 1996). Since freshwater systems may be used directly by anadromous fish, and they may also discharge into coastal waters, the quality of these waters has considerable bearing on many commercially and recreationally important aquatic resources and their habitats, including EFH. The nutrient inputs from central Florida agriculture (i.e., sugar) to Lake Okeechobee, the St. Lucie estuary, and Indian River Lagoon are suspected to have caused algal blooms, seagrass die-offs, and notable bivalve and fish kills in 2005-2006. In addition, the nutrient inputs are also suspected to have adversely impacted reefs located just outside the St. Lucie Inlet (e.g., Peck's reef).

In extreme situations living resources may be temporally or permanently displaced due to shifts in the aquatic food web, or by the physical presence of certain plant life. Excessive plant growth may also impede requisite functions (e.g., photosynthesis) of desirable plant life, hence EFH, as in the case of SAV where leaves may become covered with dense growths of algae, diatoms, and other biota such as bacteria and fungi.

Agriculture is believed to be the single largest contributor of nutrients into southeastern watersheds. The largest human additions of nitrogen result from an increased use of inorganic fertilizers (NRC 2000). In the Tar-Pamlico Estuary Basin in North Carolina, agriculture is responsible for approximately 45% of total nitrogen loading to the estuary, and 55% of phosphorus loading (NCDEHNR 1997a). An additional 33% of nitrogen and 17% of phosphorus comes from atmospheric sources that include, but is not limited to agriculture (NCDEHNR 1994, 1997a). In the adjacent Neuse River Basin, 54% of nitrogen is estimated to arise from agricultural sources (NCDEHNR 1993, 1997b). These two tributaries discharge into Pamlico Sound, the nation's second largest estuary, and the largest in the southeast.

Animal production is a threat to southeastern estuarine nutrient balances. The current usual management practice for manure from swine and other confined domestic mammals is storage and treatment in anaerobic lagoons followed by land application. This process relies on volatilization of nitrogen to account for roughly 80% of the total produced nitrogen, with concomitant downwind delivery in a zone of influence of roughly 100 kilometers (Rudek 1997). Airborne deposition of nitrogen into coastal waters in the region has been verified from field data to be a major source of enrichment in a number of southeastern estuaries. The most complete work at this time is focused on the Neuse River Estuary in North Carolina, where primary production was boosted two to three times by atmospheric deposition at ambient levels (Paerl et al. 1995a, 1995b). Actual plant uptake by crops on land-application fields accounts for no more than 10% of nitrogen use. Surplus nitrogen is delivered to shallow groundwater systems which, in turn, feed warm-season surface flows into adjacent streams and rivers. Thus, the vast majority of this material is redeposited on land and in surface waters.

Studies by Barker (1997) and Barker and Zublena (1995) also show that many North Carolina coastal counties are receiving swine-based nitrogen and/or phosphorus at levels in excess of total crop-plant growth needs. This analysis actually underestimates the problem, because it considers only direct land-applied nutrients and ignores swine-based atmospheric deposition in these counties. A report compiled for Senator Tom Harkin (D-IA) analyzed manure production patterns nationally by county and found zones of very high production in coastal North Carolina and in individual counties in the other three southeastern states. That document also reports excessive production above crop growth needs in many areas (Minority Staff 1997).

A recent estimate of agricultural emissions of ammonia from the North Carolina coastal plain is about 200.3 million lbs of nitrogen from animal waste, and 15 million lbs of nitrogen from fertilizers. Hogs alone contribute about 135 million lbs of nitrogen emissions in coastal North Carolina; larger than the entire National Atmospheric Deposition Program estimate of airborne deposition from all sources in the North Carolina coastal plain (Rudek 1997).

In response to nutrient enrichment problems and public concern, the North Carolina General Assembly has moved to impose a two-year moratorium on the development of new or enhanced hog farms, pending the replacement of current anaerobic lagoon technology with a more acceptable alternative.

High nutrient loadings also have been documented in other southeastern river basins and estuaries. Among seven river basins in Florida and Georgia examined recently by the U.S. Geological Survey, two in Georgia (the Altamaha and the Satilla) were found to be very high in nitrogen inputs at 5,470 $(kg/yr)/km^2$ and 5,430 $(kg/yr)/km^2$, respectively. Animal waste was the dominant source of nitrogen loading in both basins. Fertilizer was the biggest source in the St. Johns River Basin in Florida, and the Ogeechee Basin in Georgia. The most dominant sources of nutrient loading are non-point-source in origin, and predominantly agricultural (USGS 1997).

The National Water Quality Assessment Program is also examining the Santee Basin and nearby coastal drainages in South Carolina. Data from 1994 covering 24,868 square miles in South and North Carolina are being considered for this analysis. Although definitive information is not yet available, nutrient pollution of lakes and the rivers themselves has been identified as a major water quality issue for the program (USGS 1994). The first reports from this program are now available and include an annotated bibliography of water quality databases and recent publications on the water quality of the region (Abrahamsen et al. 1997).

Impacts of sediment from non-point-sources including agriculture and silviculture remain at the top of the water pollution list nationally (USEPA 1990) and in the southeastern states (NCDEHNR 1996b). While sediment-based impacts are typically considered to be most acute in freshwater systems, sediment pollution can also threaten EFH. Because sedimentation is a natural process in most aquatic systems it is generally not problematic except where deposition rates vastly exceed ambient conditions. In these situations, benthic animals and plants and demersal fishes that are unable to adjust or relocate may be buried or undergo disruption in growth and reproduction. Lethal and non-lethal effects of turbidity include ingestion of non-food particles by shellfish and polychaete worms, clogging of pores and gills, erosion of gills and other apparatuses such as fins, tentacles, and cilia that may be used for locomotion and feeding, burial of eggs and juveniles, and burial of substrates that may be needed for cover, attachment, and reproduction. In areas that support SAV, primary production levels may be reduced where light penetration is limited by increased turbidity.

While generally less important as a potential threat to EFH in the South Atlantic region, sediment deprivation may be locally troublesome since subsidence and erosion of wetlands and other habitats may result. Impounded coastal wetlands used for rice culture and other agricultural crop production in North Carolina, South Carolina, and Georgia are notable since large areas have been permanently altered even though tidal flow has been restored in many cases. In the Altamaha River Estuary in Georgia vast areas of freshwater and brackish tidal forested wetlands have been converted to emergent wetlands following construction of dikes and ditches that interrupted both deposition of alluvial materials and other processes.

Sediment pollution from agriculture is widespread in the coastal zone of the southeastern states. For example, North Carolina's "303d list," the listing of degraded water bodies required to be compiled by the Clean Water Act, contains an array of coastal streams degraded at least in part by agricultural sediment pollution. These include tributaries of the northeast Cape Fear River and Black River; Potecasi Creek (Chowan River); Trent River (Neuse Basin); Little River (Pasquotank Basin); Tranter's, Grindle, Conetoe and Town creeks (Tar-Pamlico Basin); and Newport River (NCDEHNR 1996a).

Pathogens from agricultural sources also threaten EFH, especially shellfish waters. The biggest single threat is probably poorly managed animal waste. A secondary source is land-disturbing activity related to putting new land into agricultural production. This may result in additional delivery of fecal coliform bacteria in quantities of potential concern.

The most dramatic cases of contamination of EFH from agricultural sources include spills of animal waste into coastal watersheds. North Carolina has suffered a number of recent spills, including many in the summer of 1995. A large swine lagoon rupture in 1995 spilled about 25 million gallons of waste into the New River Estuary causing severe anoxia, stimulating toxic algal blooms, and elevating fecal bacteria concentrations in both the receiving waters and sediments. Effects of this event persisted for over 61 days (Burkholder et al. 1997). Similar, but smaller, events were documented into tributaries of the Cape Fear River Estuary, North Carolina, from both swine and poultry sources. Impacts included large nutrient delivery, algal blooms, and contamination with huge loads of fecal bacteria; including pathogenic *Clostridium perfringens* (Mallin et al. 1997). This study documented 30 animal waste spills in North Carolina in 1995 and 1996. Bacteria from other agricultural sources also may contribute to contamination of shellfish waters. As wetland landscapes are developed for agriculture, offsite water delivery is enhanced (Skaggs et al. 1980). Many scientists believe that this hydrologic effect may contribute to elevated fecal coliform counts in receiving waters. This is suggested by preliminary studies in Otter Creek, Broad Creek, and the South River, North Carolina (J. Sauber, personal communication).

The variation in the scope and composition of agricultural non-point-source discharges and in the receiving waters creates an almost endless range of possible effects on aquatic resources, including EFH. Exposure of estuarine finfish and shellfish to toxic levels of insecticides, herbicides, and fungicides may occur, resulting in significant declines in populations (Scott 1997). Sublethal effects also are evident. For example, many compounds released by agricultural operations may adversely affect hormones such as estrogen and androgen that are linked to immune suppression (Scott 1997). These compounds usually do not kill the animal immediately, but reduce its life span and often its ability to reproduce.

Agricultural compounds that have been identified as having properties damaging to aquatic organisms include the commonly used herbicides aldicarb and atrazine and others such as, endosulfan, chlorpyrifos, and trace metals such as copper and mercury.
The enormous variation in the scope and composition of agricultural nonpoint source discharges and in the environmental nature of the receiving waters creates an almost endless range of possible effects on aquatic resources, including EFH. As noted in Scott (1997):

"Agricultural nonpoint source (NPS) runoff may result in significant discharges of pesticides, suspended sediments and fertilizers into estuarine habitats adjacent to agricultural areas or downstream from agricultural watersheds. Exposure of estuarine finfish and shellfish to toxic levels of insecticides, herbicides, and fungicides may occur, resulting in significant declines in field populations. Development of new management techniques such as Integrated Pest Management (IPMs), Best Management Practices (BMPs), and Retention Ponds (RP) are risk management tools which have been used to reduce contaminant risk from agricultural NPS runoff."

In association with Scott's (1997) observations, the National Ocean Service (NOS), Charleston Laboratory examined effects of NPS agricultural runoff on living marine resources in an attempt to define impacts on fishery resources and to develop risk reduction strategies to minimize/mitigate impacts. Investigations involving coastal estuarine ecosystems in South Carolina examined several sites used for vegetable farming (e.g., tomatoes, cucumbers, snap beans), where varied levels of risk reduction strategies were employed. The studies used grass shrimp (*Palaemonetes pugio*) and the mummichog (*Fundulus heteroclitus*) as well as other macropelagic populations. These two species represent more than 85% of the total macrofaunal (greater than 15mm) densities in small tidal creek nursery grounds in South Carolina and they are important due to their role in estuarine food webs. The studies demonstrated that pesticide exposure caused fish and invertebrate abundance reductions and mortality. Comparison of field results with laboratory toxicity tests clearly established that implementation of an integrated risk reduction strategy can significantly reduce NPS agricultural pesticide runoff. At intensively managed (IPM, BMPs, and RP) agricultural sites where strict NPS control techniques were administered, instream pesticide (azinphosmethyl, endosulfan, and fenvalerate) levels were reduced by 89-90% (Preceding from Scott 1997).

According to Scott (1997) the commonly used herbicides aldicarb and atrazine are potential endocrine disrupting chemicals (e.g., compounds that adversely affect hormones such as estrogen and androgen) and are linked to immune suppression. A 1992, Texas investigation found atrazine at concentrations greater than 60 ug/L in 98% of surface water samples that were taken on an annual basis. Laboratory toxicity tests of atrazine effects on estuarine phytoplankton revealed that chronic, low level atrazine exposure over multiple generations lead to enhanced sensitivity of phytoplankton and combined alachlor and atrazine exposure caused greater than simple additive toxicity in phytoplankton (Scott 1997).

The chronic effects of agriculture derived non-point source discharge have been extensively studied in Florida where impacts are occurring on a large scale basis. Essentially all of Florida Bay has undergone significant and undesirable biological, chemical, and physical change due to large scale agricultural practices, including hydrologic modification, in the Everglades. While these changes are occurring primarily in waters that lie outside of SAFMC jurisdiction, they are notable because of their size, magnitude, and complexity. Two basic lessons from the Everglades/Florida Bay situation also have application in watersheds found along the South Atlantic. They are: (1) the chronic environmental and ecological effects of regional agricultural practices may be extremely large and devastating and (2) the financial costs associated with analyzing and remedying these effects are likely to be enormous and possibly ineffective.

The factors associated with EFH degradation by agricultural related hypoxia are only poorly understood, but are of concern. Thus far, the extensive hypoxic zones and conditions observed in the Gulf of Mexico have not occurred in the South Atlantic region. Exceptions include relatively small, yet harmful, localized events in portions of North Carolina and South Carolina. In this region, North Carolina's estuarine waters are particularly vulnerable due to their shallow depths, poor flushing characteristics, and the abundance of hog farms found in the coastal zone. Although the most conspicuous effect of hypoxia is the mortality of larger fish and possibly invertebrates, even greater harm may be occurring with sensitive larval and juvenile forms since they are most vulnerable to oxygen depletion and other forms of environmental perturbation.

6.1.1.2 Aquaculture

Potential Threats to EFH from Aquaculture

Potential threats include: dredging and filling of wetlands and other coastal habitats and other modification of wetlands, submerged bottoms, and waters through introduction of pens, nets, and other containment and production devices; introduction of waste products and toxic chemicals; and introduction of exotic organisms; in addition to competition with wild stock for food sources.

Nationwide aquaculture is a vibrant industry with the annual value of product sold exceeding $866 million in 2005, although revenues have declined somewhat over the past 10 years (U.S. Department of Agriculture 2006). Within the Atlantic southeastern U.S., the annual value of product sold amounted to over $94 million in 2005, with Florida ($57.4 million) and North Carolina ($24.7 million) leading Georgia ($4.5 million) and South Carolina ($4.7 million). All aquaculture facilities in these states are located either on uplands or in coastal waters and no offshore aquaculture farms presently exist in the Atlantic southeastern U.S. The primary aquaculture operations in the Atlantic southeastern U.S. are shellfish farms (including hatcheries for production of seed stock), production of marine species in closed-recirculation systems, and production for enhancement of native fishery stocks.

The growing demand for seafood reflects both the growth of the U.S. population and the increased awareness of health benefits that result from a diet that includes seafood (Nesheim and Yaktine 2007). Currently, more than 80% of the U.S. seafood supply is imported, with over 40% of that amount coming from foreign aquaculture operations. Considering the substantial economic incentive to increase aquaculture production in the U.S. and the gradual elimination of technological barriers, expansion of the domestic aquaculture industry is expected over the next decade. Offshore areas may receive particular attention for development (Stickney et al. 2006).

Aquaculture and Fishery Habitats

Aquaculture has long been a source of human food. Within the last century, the technology of aquaculture has changed dramatically allowing application of semi-intensive and intensive farming systems. While this concentrates aquaculture activities to relatively small spatial areas and sets the stage for potential environmental conflicts, these concerns can be mitigated through appropriate management measures (Marine Aquaculture Task Force 2007). Balancing the demand for seafood and economic growth with the need to maintain coastal and marine ecosystems is a challenge that aquaculture accepts.

Nash et al. (2005) used the framework of an ecological risk assessment to examine common perceptions about the impacts of aquaculture on coastal and offshore habitats. The framework for this assessment was developed by the United Nations World Health Organization, has undergone extensive peer review, and is widely applied nationally and internationally. Ten types of potential impacts from aquaculture are noted: (1) increased organic loading from fecal material, uneaten food, and the decomposition of dead fish; (2) increased inorganic loading from fecal material and uneaten food; (3) residual heavy metals from uneaten food (primarily zinc) and from antifouling treatments (primarily copper); (4) transmission of disease to wild populations; (5) transmission of residual therapeutants to wild populations; (6) biological interactions from non-native species or genetically modified organisms with native populations from escapees, eggs, and gametes; (7) physical interactions with native populations through entanglement with nets, moorings, and other structures; (8) physical impacts on habitat from dredging, filling, nets, moorings, or other structures needed to establish a facility; (9) reductions in native populations from use of wild-caught juveniles for grow out; and (10) harvesting of industrial fisheries for use as fish feed. The assessment concludes that the level of risk from these sources is none to low when proper management measures are in place, including siting facilities to avoid areas with low water circulation or high boat traffic, judiciously managing stocking densities and managing waste, carefully selecting grow-out stock, and adhering to best management practices to control fouling, escapes, predation, diseases, and so forth. Use of geographic information systems (GIS) has led to spatial models that aid the examination of alternative sites for aquaculture operations (for an example from the southeastern U.S., see Arnold et al. 2000).

NOAA is building a broad based aquaculture program to enable expansion of all suitable forms of marine aquaculture within the context of complementing seafood production from wild catch, safeguarding environmental resources, and balancing multiple uses. An important objective of this program is to establish a comprehensive regulatory program for marine aquaculture operations. This program will complement existing regulatory programs that already apply to aquaculture operations, such as regulation the U.S. Army Corps of Engineers and U.S. Coast Guard of the placement of structures within navigable waters, regulation of water quality by the U.S. Environmental Protection Agency and individual states, regulation of therapeutants by the Food and Drug Administration, and oversight of interactions with fisheries and endangered species by NOAA's National Marine Fisheries Service.

6.1.1.3 Silviculture

Forested wetlands are the most abundant wetland type along the eastern seaboard. They include such diverse types as black spruce bogs, cedar swamps, red maple swamps, and bottomland hardwood forests (Tiner 1984). Scrub/shrub and forested wetlands account for over 59.4 million acres within coastal counties from North Carolina to Florida (Field et al. 1991). These wetlands also have been the most affected by forestry practices and, to a lesser degree, development. At a national level, from the mid 1950's to the mid 1970's, about 440,000 acres/year of palustrine wetlands (including forested wetlands) were lost (Tiner 1984). About 87% of this loss is accounted for by agricultural development; including silviculture (Tiner 1984). Trends in the southeast follow the national trend with North Carolina and Florida registering the most extensive wetland losses (Tiner 1984).

<u>Potential Threats to EFH from Silviculture</u>
Potential threats include: conversion of wetlands to silviculture production sites or for tree removal and other silviculture related purposes such as roads and irrigation ponds; direct and/or non-point-source discharge of fill, nutrients, chemicals, and surface and ground waters into streams, rivers and estuaries; hydrological modification to include ditches, dikes, irrigation ponds and other similar structures and water control devices; damage to wetlands and submerged bottoms by timber harvest activities; connected actions such as the construction of roads, and cumulative and synergistic effects caused by association of these and other silviculture and non-silviculture related activities.

The southeastern United States produces more industrial timber than any other region of the world. This timber production is from a forest base that includes almost one-half of the world's industrial forest plantations (Lee et al. 2005). Silviculture presents a significant threat to EFH largely due to the concentration of this activity in landscape positions near certain EFH, especially anadromous fish spawning and nursery areas and brackish primary and secondary nursery areas. Although silviculture typically is a less intensive land use activity than agriculture or urban development (Hughes 1996), the periodic intense disturbances associated with harvest, the installation and maintenance of dense drainage systems in wetlands and former wetlands, changes in vegetation, and the use of nutrient supplements and toxicants can significantly and adversely affect surface waters, EFH, and their associated biota.

The most important fundamental change with installation of intensive silviculture pertains to the water management system. Dense drainage systems allow the removal of significant amounts of water from hydric soil sites, intercept rain, and dewater stored groundwater. The effect on the wetlands can be serious if water tables are lowered such that hydric soils lose their water content. Organic constituents of hydric soils can then be oxidized, causing soil subsidence and liberation of previously bonded metals and nutrients. Clearing vegetation from wetland soils may also divert surface water into runoff pathways to the extent that both annual average runoff and event-related peak flows are exacerbated (Daniel 1981; McCarthy and Skaggs 1992). This runoff is a threat because it can change salinity regimes in receiving brackish water systems and it carries excess nutrients and other potential pollutants into sensitive waters and EFH (Pate and Jones 1980).

Conversion of mixed forested wetland and depressional cypress dome areas to silviculture is known to significantly reduce the water table. Studies have shown that slash pine (*Pinus elliottii*) through evapotransport can reduce the water table in an area by up to 36-inches depending on tree maturation. This reduction in subsurface water is higher than wetland canopy species that might have been originally found in a converted wetland area and contribute to soil subsidence and oxidation (value loss). Further this change in land-use (conversion of a wetland to silviculture) and the accompanying hydrological alterations change how these areas are regulated. In Florida, some silviculture areas are not regulated by state or federal agencies as wetlands even though many of the wetland characteristics are still evident (hydric soils, wetland vegetation, and hydroperiod). As a result conversion of these areas to commercial and residential development is expedited and compensatory mitigation for wetland function loss (albeit impaired or reduced) is not sought (Kruczynsky, personal communication).

The sensitivity of EFH to water balance perturbations is variable and poorly understood. Although some important species are highly sensitive to excessive salinity changes at young age classes (e.g., brown shrimp; Hunt et al. 1980), relatively little is known about the overall implications of flow modification from drained silvicultural areas. Limited studies on pumped drainage water in North Carolina showed minor impact to juvenile and adult spot and Atlantic croaker in response to pumping (Broad Creek Study Report). Effects on spring post-larval settlement periods for brown shrimp remain speculative since the effects of rainfall during pumping have not been determined.

In the Altamaha drainage in Georgia, water balance disturbance is thought to be a key factor in declining catch per unit effort of blue crab and shrimp (J. Holland, personal communication) and an in-depth hydrological investigation of that area has been proposed. Livingston et al. (1997) showed that reductions in freshwater inflow to the Apalachicola River Estuary in Florida led to initial turbidity reductions and increased primary productivity. Over time productivity reductions and major food web shifts were observed, probably in response to decreased nutrient delivery. As reported by Livingston et al. (1997) food web shifts remained minor so long as river flow did not greatly exceed natural limits. There is a concern that southeastern watersheds would respond in a similar manner.

Silviculture also has the potential to significantly affect nutrient delivery patterns into EFH, both through soil amendments with nitrogen and phosphorus and through changes in nutrient processing and delivery systems. Modification of these delivery patterns can be a threat to EFH. Typical forestry operations in the southeast add limited nitrogen and phosphorus during the growing cycle (Amatya et al. 1996). In addition, typical wetland soils are effective at removing incident nitrogen through nitrification and denitrification pathways. Wetlands are important sinks for atmospherically derived nitrogen. As such, riparian and isolated wetlands may buffer EFH from vehicle and animal waste-derived nitrogen enrichment. Drainage networks effectively short-circuit this buffering capacity by reducing retention periods and denitrification opportunities (Whigham et al. 1988; EDF and WWF 1992).

The huge areas involved and their proximity to sensitive estuaries makes forestry a major player in nutrient enrichment. For instance, in North Carolina's Neuse River Estuary, forests account for 17% of total nitrogen delivery (NCDEHNR 1993). The adjacent Pamlico Basin reflects a forestry contribution for nitrogen of about 10% (NCDEHNR 1994).

Sediment yields from silviculture in the coastal zone are not considered a substantial threat to EFH. Sedimentation is typically lower than Piedmont or mountain sites as a result of lower terrestrial slopes and enhanced opportunity for deposition in the slower moving receiving waters, including canal systems.

Information is poor on forestry contributions to fecal coliform contamination in the southeast. Initial studies have found relationships between elevated runoff rates after clear cutting and fecal coliform delivery, but other factors were also at work (J. Sauber, personal communication).

Non-nutrient pollution from silviculture is also of concern, though poorly documented. A number of studies have shown release of mercury and other metals from peat soils subjected to intensive drainage (Evans et al. 1984; Gregory et al. 1984). Elevated mercury concentrations also have been found in organic sediments in riparian coastal watersheds (Otte et al. 1987). In North Carolina, fish from the Waccamaw Basin show elevated mercury levels (NCDEHNR 1996b) and metal levels in sediments are elevated throughout the Albemarle-Pamlico Region due to a variety of sources (Riggs et al. 1991). Although not directly related to silviculture, real estate ventures by timber companies have converted large areas of forest land to residential property. This has resulted in much faster rates of surface water runoff and discharge of waters that contain higher concentrations of pesticides and fertilizers. In coastal areas and in inland locations bordering rivers and streams, property values may be greatly increased and the conversion of forest land to residential and commercial property is proceeding at a rapid rate. Further, connected actions, such as the construction of access roads to silviculture sites increase the overall area of impact.

6.1.1.4 Urban/Suburban Development

The southeastern United States has undergone one of the highest rates of landscape changes in the country, in part due to changing demographics and land use practices over the last few decades (Milesi et al. 2003). In particular this trend has been observed in the coastal regions of the southeast. Nine of our nation's ten largest cities are located in coastal watersheds (Bureau of the Census 2002). With its extensive and accessible coastline and mild winter climate the southeast coastal zone is one of the nation's fastest growing regions. The regional growth rate here is more than four times the national average (Chambers 1992) and between 1980 and 2010 the South Atlantic coastal population is expected to increase by as much as 73% (Chambers 1992). While coastal watershed counties comprise less than 25% of the land area in the United States, they are home to more than 52% of the total U.S. population. A study of coastal population trends predicts average increases of 3,600 people a day moving to coastal counties, reaching a total population of 165 million by 2015. These figures do not include the 180 million people who visit the coast every year (U.S. Commission on Ocean Policy 2004).

As the population increases so does urbanization. People require homes and related infrastructure such as roads, schools, water and sewer facilities, power transmission lines, etc. These needs often are met at the expense of EFH since residential growth has led to large scale modification of wetlands and other irreplaceable environments. Research indicates that nearby water bodies can become seriously degraded when more than 10% of the watershed is covered by roads, parking lots, roof tops, and similar surfaces (NRDC 1999). Tiner (1984) estimates that about 8% of the national rate of wetland losses that occurred from the mid 1950's to the mid 1970's resulted from urban development. Other effects of urbanization include increased sedimentation rates during and after construction, loss of surrounding upland recharge areas and wetland biofiltration and habitat functions. These effects could be ameliorated to some extent by maintaining sufficient buffers and less exploitive developmental patterns. The effect could be dampened by constructing within existing land contours and removing only the canopy necessary for project success. Currently in areas under development all existing vegetation is cleared and burned, all contours are removed and wetland soils are removed and replaced or filled over. Buffer ordinances, if they exist, are typically between 30 and 50 feet adjacent to estuarine systems; this width is not strongly supported by scientific literature.

Chemicals produced and used by people also find their way into the waters as point-source and non-point source runoff. Examples include oil from roads and parking lots, and pesticides, herbicides, and fertilizers from golf courses and residential lawns. This has reduced water quality in waters and wetlands adjacent to urban developments. As a result, the quality of EFH is often much reduced and thousands of acres of shellfish waters are closed. The South Carolina Department of Natural Resources' (SCDNR) Tidal Creek Project (TCP) provides insight into the effects of urbanization and suburban development on South Carolina tidal creeks (Holland et al. 1996, 2004; Sanger et al. 1999a,b). This study has implications for other states as well. The study examines developmental effects on salinity, dissolved oxygen (DO), and pollution in tidal creeks having trophic, shelter, and nursery functions required by commercially, recreationally, and ecologically important fish and invertebrates. The study reveals the complexity of the environmental and ecological factors involved and shows correlations between development; changes in tidal creek chemical, physical, and biological characteristics; and alteration of species distribution, composition, and abundance. In general, the physical-chemical characteristics of headwater creeks were significantly altered when the amount of impervious surface exceeded 10-20% and living resources were altered when the amount of impervious surface exceeded 20-30% cover.

The TCP identified salinity as a major factor in controlling the distribution and abundance of living marine resources (Holland et al. 1996, 2004). In watersheds having the greatest areas of roofs, roads, and parking lots it was found that recruitment and colonization by benthic fauna in these areas was less predictable than in more stable environments. TCP confirms that suitable DO concentrations are essential for maintaining balanced indigenous populations of fish, shellfish, and other aquatic biota in tidal creeks and that pollution-related decreases in DO may pose the greatest threat to the environmental quality of estuaries (Holland et al. 1996, 2004). With respect to contaminants, an examination of both metal and organic contaminants taken in connection with the TCP study indicate that metal contaminants were 2-10 times lower in forested watersheds compared to industrial/urban watersheds (Sanger et al. 1999a). Organic contaminants, such as PAHs, PCBs, and DDT were also much lower in forested creeks compared to the industrial/urban creeks.

In another study at larger watershed scales (14-digit Hydrologic Unit Code), Van Dolah et al. (in press), noted significant correlations in the concentrations of inorganic and organic contaminants and fecal coliform bacteria concentrations with the amount of urban suburban development. The correlation between contaminant concentrations and urban/suburban land cover, was stronger in tidal creek habitats within these watersheds, compared to data obtained from larger open water habitats within these watersheds. Additionally the percentage of sites within the watersheds having elevated contaminants and fecal coliform bacteria was much greater in watersheds having greater than 50% urban/suburban development compared with those watersheds having less than 30% urban/suburban cover.

As the linkage between urban and suburban development and declining fish abundance and health or quality is reinforced, the implications of anticipated population growth in coastal areas become even greater. This situation is especially critical in the southeast where recreationally and commercially important species are almost totally dependent on estuaries for their survival and for about $5.5 billion in annual commercial fishery benefits (Chambers 1990).

Potential Threats to EFH from Urban/Suburban Development

Potential threats include conversion of wetlands to sites for residential and related purposes such as roads, bridges, parking lots, commercial facilities, reservoirs, hydropower generation facilities, and utility corridors; direct and/or nonpoint-source discharge of fill, nutrients, chemicals, cooling water, and surface waters into ground water, streams, rivers and estuaries; hydrological modification to include ditches, dikes, flood control and other similar structures; damage to wetlands and submerged bottoms; and cumulative and synergistic effects caused by association of these and other developmental and non-developmental related activities.

Wetlands and other important coastal habitats continue to be adversely and irreversibly altered for urban and suburban development. (Note: certain related activities such as navigation are discussed in later sections). Of major concern is the piecemeal elimination of wetlands by filling for houses, roads, septic tank systems, etc. Wetland filling can directly eliminate or diminish the functional value of EFH and associated areas and resources. While the total area of wetlands affected by development is unknown, the rate of conversion was once estimated at 8% of the national average loss of 458,000 acres or 36,640 acres per year (Tiner 1984). Requests to alter coastal areas remain high and between 1981 and 1996, for example, in the southeast the NOAA Fisheries Service reviewed more than 23,871 proposals requesting to alter wetlands for housing, shoreline structures, docks, roadways, and other related activities. A survey of 5,622 of these proposals involved 19,729 acres of wetlands (see Tables 26, 27, 28, & 29). Between 1996 and 2006, NOAA Fisheries Service reviewed an additional 1,962 applications to fill wetlands to construct housing and 1,886 applications for shoreline modifications. Note that the acreage cited would not include wetland impacts from nationwide permits, dock footprint, loss of bottom area under pilings, or a great percent of shoreline fortification that is designated as "*di minimus*" by the COE and typically can range one to three feet from an existing seawall or bulkhead.

Another major threat posed by urban and suburban development is that of non-point-source discharges of the chemicals used in day to day activities, in operating and maintaining homes, roads, vehicles, etc. In addition to chemical input, changes that affect the volume, rate, location, frequency, and duration of surface water runoff into coastal rivers and tidal waters are likely to be determinants in the distribution, species composition, abundance, and health of southeastern fishery resources and their habitat. Results of various studies in the South Atlantic Bight indicate that chemical contaminants from industrial, urban/suburban, and agricultural sources may cause impacts in estuarine ecosystems. Highest contaminant concentrations and greatest impacts were observed in the headwaters of small tidal creeks, which are nursery grounds for fish, crustaceans and molluscs. Protection and management of nonpoint-source runoff loading into these watersheds is essential in protecting habitat quality (Scott et al. 1997). In the long-term, impacts of chemical pollution (e.g., petroleum hydrocarbons, halogenated hydrocarbons, metals, etc.) are likely to adversely impact fish (Schaaf et al. 1987). Despite current pollution control measures and stricter environmental laws, toxic organic and inorganic chemicals continue to be introduced into marine and estuarine environments.

Results of the previously mentioned TCP investigation confirm that suitable DO concentrations are essential for maintaining balanced indigenous populations of fish, shellfish, and other aquatic biota in tidal creeks and that pollution related decreases in DO may pose the greatest threat to the environmental quality of estuaries. The study found that:

- DO in tidal creeks fluctuated with phases of the moon, time of day, and tidal stage.
- DO in tidal creeks in developed and undeveloped watersheds often did not meet the state water quality standard of 4mg/L.
- The most stressful DO levels occurred during early morning and at night-time low tides.
- The DO levels in tidal creeks in developed watersheds were less predictable and had greater unexplained variance than those of undeveloped watersheds.
- Point in time DO measurements in tidal creeks do not adequately represent exposure of living resources stressful low DO levels.
- Living resources in tidal creeks in developed watersheds were more frequently exposed to stressful low DO levels than those inhabiting tidal creeks with undeveloped watersheds.
- The factors that contribute to low DO in South Carolina tidal creeks need further study and a DO budget for tidal creeks and associated saltmarshes is needed so that the major factors controlling low DO conditions can be identified and addressed from a management perspective.

With respect to contaminants, bioassays of sediments taken in connection with the TCP study indicate that potentially toxic conditions for living marine resources may occur in the upper reaches of tidal creeks in developed watersheds. Polyaromatic hydrocarbons in sediments were highest where surface runoff from roads was discharged into tidal creeks and sediment bound pesticides were more prevalent in the marsh and near houses. (Preceding is a summary taken from Holland et al. 1996).

Finally with regard to urban/suburban development, and in particular regard to nonpoint-source discharges, the South Carolina Statewide Water Quality Assessment for FY 1992-1993 (SCDHEC 1994) provides an indication of the role of non-point source discharges in one southeastern state. According to the Assessment:

- Nonpoint-source (NPS) pollution is the most responsible factor for nonsupport of classified water uses in rivers, lakes, and estuaries in the state.
- Of the 26,313 river miles assessed via water quality monitoring stations, 10,534 miles, or 40%, were determined to be partially supporting or not supporting overall use. NPS sources of pollution were identified as the contributing factor 33% of the time. These NPS sources included agriculture, pasture land, silviculture, construction, urban runoff/storm sewers, resource extraction, and hydromodification.
- South Carolina has approximately 945 square miles of estuaries, including marshes. The assessment analyzed data collected from 342 square miles of

estuaries. About 30% of the estuarine areas do not fully support overall use. NPS pollution sources were identified as the contributing factor 38% of the time.

- Of the 135 shellfish areas assessed, 63% were impacted by NPS, including marinas, 22% were impacted by point sources, and 27% were unconditionally approved (the percentages totaled exceed 100% due to multiple source impacts).
- The South Carolina NPS Task Force listed the 32 highest priority water bodies/watersheds that are targeted for implementation action. Of these water bodies/watersheds, 15 are located in the coastal zone.
- Sixty-two watershed units are located in the coastal zone. Based on information from the Statewide Assessment and from more recent Watershed Water Quality Management Strategies, 44% of these units have been impaired by NPS pollution; 39% have been impaired by unknown sources of pollution; 24% have been impaired by point sources; 16% have been impaired by natural or other sources; and 30% have no known impairment [The percentages totaled exceed 100% due to multiple source impacts. Also, based on the Statewide Assessment, 38 of the 62 watershed units (or 61%) have not been fully assessed].

Point source discharges related to urbanization derive mainly from municipal sewage treatment facilities or storm water discharges that are controlled through Environmental Protection Agency (EPA)-mandated regulations under the Clean Water Act and by state water quality regulations. Threats related to these discharges are probably less important than the other factors previously discussed because efforts are underway to improve treatment. The primary concerns with municipal point-source discharges involve treatment levels needed to attain acceptable nutrient inputs and overloading of treatment systems due to rapid development of the coastal zone. It is also important to consider that the portion of water entering estuaries from sewage treatment plants is increasing. In locations where treatment is poor, or water conditions are unsuitable for adequate dilution of discharges, EFH may be adversely affected. Of primary concern is excessive nutrification of receiving waters, but other factors such as those associated with nonpoint -source discharges also apply.

The EPA withdrew the storm water Phase II direct final rule published on April 7, 1995 (60 FR 17950) and promulgated a new final rule in its place (60 FR 17958). This action by the EPA instituted changes to the National Pollutant Discharge Elimination System (NPDES) stormwater permit application regulations under the Clean Water Act for Phase II dischargers. Phase II dischargers generally include all point-source discharges of storm water from commercial, retail, light industrial and institutional facilities and from municipal separate storm sewer systems serving populations of less than 100,000. This rule establishes a sequential application process in two tiers for all Phase II stormwater discharges. The first tier provides the NPDES permitting authority flexibility to require permits for those Phase II dischargers that are determined to be contributing to a water quality impairment or are a significant contributor of pollutants to waters of the U.S. "Permitting authority" refers to the EPA or States and Indian Tribes with approved NPDES programs. The EPA expects this group to be small because most of these types of dischargers have already been included under Phase I of the storm water program.

The second tier includes all other Phase II dischargers. This larger group will be required to apply for permits by the end of six years, but only if the Phase II regulatory program in place at that time requires permits. The EPA has stated that it is open to, and committed to, exploring a number of non-permit control strategies for the Phase II program that will allow efficient and effective targeting of real environmental problems. As part of this commitment, the EPA has initiated a process to include stakeholders in the development of a supplemental Phase II rule under the Federal Advisory Committee Act. This rule was finalized March 1, 1999 and determines the nature and extent of requirements that apply to the various types of Phase II facilities prior to the end of the six-year application period defined by the rule.

However, in practice, the EPA's NPDES for Phase II dischargers program, can be slow to implement and has limited enforcement authority. Further, stormwater requirements in the State of Florida have resulted in the loss/conversion of wetlands as required treatment ponds are commonly placed in wetlands whose capacity to assimilate contaminates far exceeds any benefit provided by the area loss for stormwater abatement. Further conversion of wetlands to stormwater ponds permanently eliminates these areas ability to contribute dissolve and particulate detrital organic carbon and their ecological habitat functions. These conversions are not seen or recorded as wetland losses although the lost ecologically contribution of these areas has an enormous impact on fisheries.

6.1.1.5 Transportation

Transportation projects such as the construction and maintenance of bridges and roadways typically involve long-term planning and permit consultation with NOAA Fisheries Service. Such projects can occur over estuarine waters, within estuarine emergent wetlands, and/or other important wetlands that are hydrologically connected to tidal waters. From 1996 to 2005 NOAA Fisheries Service reviewed 2,352 actions related to transportation.

<u>Potential threats to EFH from transportation projects</u>

Potential threats include fragmentation of the ecosystem by isolation and bifurcation of EFH, storm water discharges and runoff, shading of submerged aquatic vegetation from bridges, and blasting associated with bridge or structure demolition.

Transportation project can lead to habitat fragmentation, which results in the isolation of EFH from certain life history stages of recreationally and commercially important fisheries. This isolation limits the food chain by not allowing certain assemblages of organisms to easily traverse from one ecotype to another. This is especially true for fisheries such as the snapper grouper complex that use mangroves swamps and seagrass beds for one or more life history stages. This fragmentation could also potentially limit movements of catadromous and anadromous fishes by isolating populations from a spawning or nursery ground. Fragmentation can also result in the isolation of large tracts of freshwater wetlands. Through this isolation, the trophic functions provided by these wetlands are limited and allochthonous input is cut off to downstream estuaries and EFH.

Flushing of upstream wetlands and EFH can be impacted by fragmentation. If mitigation measures (e.g., culverts and bridges) are not taken to maintain adequate flow on both sides of a roadway, waters can become stagnant and limit the benefits to commercial and recreational fisheries.

Storm water discharges are a concern where bridges or roadways cross or are adjacent to EFH. Runoff from roadways could impact EFH if water is not collected and treated prior to discharge. The treatment of the storm water, including surface water management systems, should be located outside of EFH.

Blasting and demolition pose threats to EFH and managed fisheries. Direct and indirect impacts to EFH should be avoided and best management practices utilized when demolition occurs. This can include detonating small charges (otherwise known as test blasts or fish scares) to direct fish away from the area where the demolition will take place. Bubble curtains are also used in some cases to minimize fish kills.

Direct and indirect affects to EFH can also result from construction. Submerged aquatic vegetation can be impacted directly or indirectly from the installation of pilings and shading associated with bridges. The areas adjacent to bridges can be impacted as well from the shadow cast from the structure. These impacts must be considered when evaluating the effects of a transportation project on EFH.

6.1.1.6 Industrial/Commercial Activities

The southeastern U.S. is a prime location for industrial siting. The climate is favorable, economic incentives exist, land is readily available and relatively inexpensive, an adequate labor base exists, and the infrastructure for shipping of supplies and products is well developed. Further, the region's many rivers and streams provide an abundance of water needed for textile mills, paper mills, and heavy manufacturing (e.g., steel fabricating) and other similar facilities.

In addition to a favorable setting for industrial development, commercial growth is ever expanding. Although less conspicuous in many areas, the tourism industry also is a vital part of the coastal economy and many of the South's most popular vacation spots are located on or near the coast. With expansion of this industry, new hotels, related businesses, marinas, roads, and other facilities are being built. The increase in visitors and resource users is expected to continually grow and may diminish only when, as a result of overuse and development, the environmental quality of the area is reduced. Population growth and tourism bring many benefits to coastal communities, including new jobs and businesses and enhanced educational opportunities. Burgeoning industries associated with tourism and recreation in coastal areas (such as hotels, resorts, restaurants, fishing and dive stores, vacation housing, marinas, and other retail businesses) have created one of the nation's largest and fastest-growing economic forces (U.S. Commission on Ocean Policy 2004). In just four southeast Florida coastal counties, recreational diving, fishing, and ocean-watching activities generate $4.4 billion in local sales and almost $2 billion in local income annually (Johns 2001) and more than 2.9 million people visit the Florida Keys each year (Leeworthy and Vanasse 1999).

<u>Potential Threats to EFH from Industrial/Commercial Activities</u>

Potential threats include conversion of wetlands to industrial and appurtenant sites such as roads, parking, and administrative and distribution centers; point and nonpoint-source discharge of fill, nutrients, chemicals, cooling water, air emissions, and surface and ground waters into streams, rivers, estuaries and ocean waters; hydrological modification to include ditches, dikes, water and waste lagoons; intake and discharge systems; hydropower facilities; and cumulative and synergistic effects caused by association of these and other industrial and non-industrial related activities. In addition to ongoing activities, previous industrial and commercial activities have, in many locations, led to deposition of harmful materials that are subject to resuspension and reincorporation into aquatic food chains.

Industrial and commercial development can affect EFH in a number of ways. Most apparent is the conversion of wetlands and upland buffers to sites for buildings, plants, parking, storage and shipping or materials and products, and treatment or storage of wastes or by-products. Because of an abundance of hard impervious surfaces associated with industrial and commercial operations they are often major contributors of non-point-source contaminants into aquatic environments, including those that support EFH. Many industries, (e.g., paper mills), consume and pollute large volumes of water needed to sustain a healthy coastal environment. Industries may also produce airborne emissions that contain contaminants. These contaminants have been shown to reappear in coastal waters and EFH. A readily observable example is acidification of waters from atmospheric deposition of industrial emissions and coal fired power plants. Commercial development along the South Atlantic coast also has been extensive and relatively few coastal areas are free of commercial development. Past development practices were especially detrimental and before adequate regulation it was not uncommon to excavate and fill marshes and shallow water environments for residential, commercial and industrial uses. Such practices have been largely eliminated because most of the coast is either developed or protected from such practices. However, uplands are a decreasing commodity in the coastal zone and the demand for filling wetlands and other aquatic sites is likely to persist. Consequently, proposals aimed at altering wetlands for commercial and other purposes will continue to require local, state, and federal involvement if significant adverse impacts to EFH are to be effectively controlled.

The total amount of EFH that has been eliminated or degraded by commercial and industrial development is unknown, but it is extensive. NOAA Fisheries Service data show that between 1981 and 1996, 1,466 proposals were received for industrial and commercial development in wetlands that are subject to the regulatory provisions of the Rivers and Harbor Act and Section 404 of the Clean Water Act. In association with this, 430 proposals sought approval to alter about 3,202 acres of EFH (see Tables 26, 27, 28, & 29). Between 1996 and 2006, NOAA Fisheries Service reviewed approximately 2,126 applications for industrial and commercial activities and associated wetland impacts in the South Atlantic area.

Point-source discharges from commercial activities may be similar to those associated with urban and suburban development. Accordingly, the information and discussions contained in Section 4.1.1.3 should apply. Pollution and water use may alter the flow, pH, hardness, dissolved oxygen, and chemical composition parameters that affect individuals, populations, and communities (Carins 1980). Within aquatic systems industrial point-source discharges also may alter species and population diversity, nutrient and energy transfer, productivity, biomass, density, stability, connectivity, and species richness and evenness both at the point of discharge and downstream locations (Carins 1980). Growth, visual acuity, swimming speed, equilibrium, feeding rate, response stimuli, predation rate, photosynthetic rate, spawning seasons, migration routes, and resistance to disease and parasites of finfish, shellfish, and related organisms may be altered by chemical and thermal changes. Some industries, such as paper mills, are major water users and associated effluent can dominate and control conditions in substantial portions of rivers and other water bodies where they are located. Usually parameters such as substrate, currents, dissolved oxygen, pH, nutrients, temperature, and suspended materials are key factors affecting the distribution and abundance of EFH. The direct and synergistic effects of other discharge components such as heavy metals and various chemical compounds are not well understood, but current research shows that these constituents may be of greater importance than previously thought. For example, more subtle factors such as endocrine disruption in aquatic organisms and reduced ability to reproduce or compete for food are being uncovered (Scott et al. 1997).

The cumulative effect of many types of discharges on various aquatic systems also is not well understood, but attempts to mediate their effects are reflected in various water quality standards and programs in each state and within the various water systems. Industrial wastewater effluent is regulated by the EPA through the NPDES permitting program. This program provides for issuance of waste discharge permits as a means of identifying, defining, and controlling virtually all point-source discharges. The complexity and the magnitude of effort required to administer the NPDES permit program limit overview of the program and federal agencies. Consequently, the NOAA Fisheries Service and the FWS generally do not provide comments on NPDES application notices. For these same reasons, it is not presently possible to estimate the singular, combined, and synergistic effects of industrial (and domestic) discharges on aquatic ecosystems.

Where chronic non-point-source discharges and accidental releases of harmful or toxic substances mix, especially harmful effects on aquatic life and habitat, including EFH, is likely. An added concern with industrial operations is the release of contaminants into the atmosphere. Such materials may be transported various distances and directly and indirectly deposited into aquatic ecosystems (Baker et al. 1993). In the southeast, surface water acidification and mercury accumulation in sediments are of particular concern since sources of these material lie in other regions and are not subject to local and regional (southeastern) controls. In view of this, the regulation of surface water contamination from atmospheric pollution should be addressed from a local, regional, and international perspective.

6.1.1.7 Navigation

Support for navigation in the southeast Atlantic region has resulted in widespread modification of subtidal and intertidal areas used by commercial and recreational vessels. Significant modification to offshore habitats has also occurred and this is discussed in the Marine/offshore Processes Section. Primary threats to EFH from navigation in estuarine waters include the construction, maintenance, and expansion of thousands of miles of waterways such as the Atlantic Intracoastal Waterway and the myriad of other channels that lead to marinas, ports, turning basins, and harbors. Construction and maintenance of existing ports and recreationally-based marinas and basins have altered substantial areas of EFH. Expansion of existing channels and waterways to accommodate larger vessels, primarily mega-yachts and Post-Panamax vessels, is becoming an increasing threat to inshore EFH, namely seagrasses. Dredged material disposal and disposal of contaminated sediments is also an issue. Filling of wetlands and conversion of EFH from shallow to deep water habitats are persistent threats associated with new facilities and the maintenance and expansion of existing facilities. Where coastal inlets are stabilized and maintained for navigation purposes effects on nearshore environments and fish and invertebrate populations may be substantial in addition to blockages of littoral sediment transport.

A second major concern related to navigation is the host of environmental problems associated with vessel operations. These range from contamination of water by oil, grease, anti-fouling paints, and discharges of sewage, garbage, and debris to the direct destruction of EFH by grounding, anchor damage, propwashing, scarring, etc. Most physical damage is accidental; however, activities such as propwashing could be avoidable for example, through better signage in waterways near shallow SAV habitats and a greater of level of enforcement. However, regarding the latter, it should be recognized that many State and local enforcement programs are severely understaffed and underfunded.

<u>Potential Threats to EFH from Navigation</u>

Navigation related threats to EFH located within estuarine waters can be separated into two categories: Navigation support activities and vessel operations. Navigation support activities include, but are not limited to, excavation and maintenance of channels (includes disposal of excavated materials); construction and operation of ports, mooring and cargo handling facilities; construction and operation of ship repair facilities; and construction of channel stabilization structures such as jetties and revetments. Potentially harmful vessel operations activities include, but are not limited to: discharge or spillage of fuel, oil, grease, paints, solvents, trash, and cargo; grounding/sinking/prop scaring in ecologically/environmentally sensitive locations; exacerbation of shoreline erosion due to wakes; salt water intrusion into brackish systems; and transfer and introduction of exotic and harmful organisms through ballast water discharge.

<u>Navigation Support Activities</u>

The most conspicuous navigation-related activity in many estuarine waters is the construction and maintenance of navigation channels and the related disposal of dredged materials. The amount of subtidal and intertidal area affected by new and maintenance dredging is unknown, but undoubtedly great. Orlando et al (1988) analyzed 18 major east coast estuaries from North Carolina to Florida east coast and found over 703 miles of navigation channels and 9,844 miles of shoreline modifications related to navigation works. Between 1981 and 1986 the NOAA Fisheries Service received over 4,877 proposals for new navigation projects in the South Atlantic region. A detailed analysis showed that 1,692 of these proposals involved plans to alter 24,825 acres of EFH through dredging and filling (Tables 26, 27, 28, & 29). From 1996-2006, NOAA Fisheries Service received 1,055 applications for maintenance dredging related activities and 720 application-related to construction of marinas and navigation channels in the South Atlantic area.

However, the potential threats to EFH from widening and deepening navigation channels warrant close examination. In many South Atlantic areas, marina owners and inland navigation districts have submitted applications to the Corps of Engineers for widening and deepening activities to accommodate mega-yachts and provide navigation access for mega-yacht vessels to private interior berthing, testing, and repair facilities located in the vicinity of inlets. Mega-yachts are typically classified as private luxury recreational motor or sailing vessels that are greater than 80 feet in length and there are approximately 735 that would access South Atlantic navigation channels (FWS 2005). In Palm Beach County, Florida alone proposed impacts associated with Atlantic Intracoastal Waterway and other channel expansion projects exceed 30 acres of seagrass habitat within Lake Worth Lagoon and typically involve dredging deeper than the Water Resources Development Act Congressionally authorized depths, for example from -10 NGVD to -16 NGVD. The seagrass habitats located around inlets are typically unique and ecologically significant due to the influence of clear oceanic waters that enter through the inlet and provide water clarity that cannot be found in locations further from the inlet. For example, the seagrass habitat located in close proximity to the Lake Worth Inlet (Florida) allows seagrass to grow at depths of over 10 feet as opposed to more remote seagrass habitat, which may only reach depths of 4 feet.

According to a FWS report, the overriding factor in the decline of estuarine and marine wetlands in the U.S. between 1998 and 2004 was the loss of emergent saltmarsh to open saltwater systems due to and manmade activities such as dredging, water control, and commercial and recreational boat traffic (Dahl 2006). While channel excavation itself is usually visible only from the surface while the dredge or other equipment are in the area, the need to dispose of excavated materials has left its mark in the form of confined and unconfined disposal sites, including those that have undergone human occupation and development. Chronic and individually small discharges and disturbances routinely affect water and substrate and may be significant from a cumulative or synergistic perspective. EFH impacts include, direct removal/burial of organisms as a result of dredging and placement of dredged material; turbidity/siltation effects, including increased light attenuation from turbidity; contaminant release and uptake of nutrients, metals, and organics; release of oxygen consuming substances; noise disturbance to aquatic and terrestrial organisms; and alteration of hydrodynamic regimes and physical habitat.

The maintenance and stabilization of coastal inlets also is a prominent navigation activity. Studies and reports by the COE, the NOAA Fisheries Service, and others link jetty construction to possible changes in plankton movement (USACE 1980; USDC 1991; Miller 1988; Miller et al. 1984). This is a major concern since significant modification of inlet hydrodynamics may diminish the ability of sub-adult fish and invertebrates to reach estuarine nursery grounds. Where significant reductions in recruitment (into estuarine waters) of desirable species is realized, production declines in ecologically, recreationally and commercially important species may result. The use of jetties to stabilize navigation channels at coastal inlets also has been linked to changes in coastal geomorphology that affects nearshore environments. For example, coastal geologists have expressed concern that construction of jetties at Oregon Inlet on the North Carolina Outer Banks could cause catastrophic beach erosion and accelerate barrier island migration (Pilkey and Dixon 1996). Such change could adversely affect the extensive and highly productive submerged vegetation beds which are located behind the coastal barriers.

The relocation of freshwater/saltwater transition zones due to channel deepening may be, in some cases, responsible for significant environmental and ecological change. As an example, salinity shifts after channel deepening and water diversion in the lower Savannah River caused vegetation shifts from freshwater to brackish species in surrounding wetlands. In the lower Savannah River, increased mortality of sub-adult striped bass also has been linked to salinity increases caused by navigation-related modifications such as channel deepening and flow diversion. Modifications that increase estuarine salinities may also create more hospitable conditions for shellfish predators such as boring sponge, oyster drill, and keyhole limpet.

In southeast Florida, increased channelization by dredging and the addition of rocky structures may have favored shifts from estuarine assemblages to reef assemblages because of comparatively higher abundances and diversities of incoming ichthyoplankton, higher inshore salinities, and replacement of vegetation with hard structure that favors reef species (Lindeman 1997). Similar situations are possible in other watersheds where dredging and dredged material disposal are prominent features; however, little documentation of these changes is available. Another example includes the St. Johns River in North Florida. The St. Johns River's watershed encompasses 50% or more of the east coast of Florida flowing north and in the 1800's flowed out onto an alluvial flood plan of shallow non-navigable sand bars. Construction of the Jacksonville Port has deepened and channelized the river mouth, now -52 NGVD. As a result, the amount of salt water intrusion has completely altered the estuarine system of the lower St. Johns River.

The expansion of ports and marinas has become an almost continuous process due to economic growth, competition between ports, and significant increases in vessel numbers and vessel size. Elimination or degradation of aquatic and upland habitats are commonplace since port and marina expansion almost always require the use of open water, submerged bottoms, and riparian zones. Ancillary related activities and development often utilize even larger areas, many of which provide water quality and other functions needed to sustain living marine resources. Vessel repair facilities use highly toxic cleaners, paints, and lubricants that can contaminate waters and sediments. Modern pollution containment and abatement systems and procedures can prevent or minimize toxic substance releases; however, constant and diligent pollution control efforts must be implemented. The operation of these facilities also poses an inherent threat to EFH by adversely affecting water quality in and around these facilities. The extent of the impact usually depends on factors such as flushing characteristics, facility size, location, depth, and configuration. When facilities such as marinas are constructed it is common to restrict shellfish harvest in a set or established zone that may be affected by sewage and other hazardous materials. It is now common practice to consider safe zones with respect to public health and aquatic resources when siting marina and port facilities.

Major ports in the South Atlantic region include Morehead City and Wilmington in North Carolina; Georgetown, Charleston, and Port Royal in South Carolina; Savannah and Brunswick in Georgia; and Fernandina Beach, Jacksonville, Port Canaveral, Port Everglades, Fort Pierce, Palm Beach, and Miami in Florida. Many eastern seaboard ports are subject to proposals to widen and deepen to accommodate Post-Panamax vessels or deep-draft vessels too large to fit through the Panama Canal. Impacts resulting from these projects can be substantial and can involve alternatives to dredge through coral reef, hardbottom habitat, and seagrasses.

In 2005, the Port of Miami, located in Biscayne Bay which is a State of Florida designated Outstanding Florida Water, completed a harbor deepening project that used confined blasting to fracture rock that was too hard to be removed via conventional dredge. In 2004, the Corps of Engineers finalized an Environmental Impact Statement to widen and deepen the entrance channel and other interior areas of the Port to -50 NGVD. The Recommended Plan would impact approximately 415 acres of habitat including over 6.3 acres of seagrass habitat, 28.7 acres of low-relief hardbottom/reef habitat, 20.7 acres of high relief hardbottom/reef habitat, 123.5 acres of rock/rubble habitat, and 236.4 acres of unvegetated bottom habitat (COE 2003).

The COE recently finalized a Reef Report for Port Everglades Outer Entrance Channel Expansion Project that concluded that over 150,000 corals and 21 acres of reef could be lost through proposed expansion activities (COE 2006). This project is in the feasibility phase and the COE proposes to release the draft Environmental Impact Statement in October 2007. In addition to the reef impacts, this project could impact up to 5 acres of seagrass (including one acre of the federally listed *Halophila johnsonii*), 11.55 acres of mangroves (8.48 acres of which are currently held in a conservation easement for impacts from previous Port activities), and 20.09 acres of previously dredged hardbottom, for which no compensatory mitigation is currently proposed (FWS 2005).

Cargo arriving and departing through these ports is diverse and ranges from highly toxic and hazardous chemicals and petroleum products to relatively benign materials such as wood chips. Major spills and other discharges of hazardous materials are uncommon, but are of constant concern since large and significant areas of estuarine habitat and fishery resources are at risk. Expansion of these facilities and certain operation and maintenance activities are likely to occur at the expense of EFH.

There have been recent positive trends in the development of beneficial uses for clean dredged materials. For example, the deepening of the Wilmington Harbor navigation channel in North Carolina generated rock that is being used for creation of an offshore reef. Similar activities are being investigated in connection with planned deepening of Charleston Harbor in South Carolina. These activities will require monitoring to evaluate their success, but if beneficial other uses of dredged material could be developed. On a cautionary note, conversion of one habitat type to another may not be desirable since associated ecological trade-offs could be harmful to desirable or managed species. The classic example of this is the Winyah Bay, South Carolina dredged material disposal site, where submerged and intertidal bottoms have been converted to emergent marsh without any assessment of the ecological role of the disposal site.

Dredging and disposal of excavated materials is a major component of all southeastern ports and many marinas. Dredged materials are often contaminated and extensive testing for heavy metals and other contaminants is required. At many locations finding suitable disposal sites for dredged materials is also difficult and costly. Whenever contaminated dredged materials are placed in offshore waters, or in locations where decant is discharged into surrounding waters there is high probability that these contaminants will reenter aquatic food webs. As existing upland disposal sites are filled this problem is likely to be exacerbated. Already, direct overboard dispersal of dredged material occurs at some location such as in reaches of the Atlantic Intracoastal Waterway in North Carolina. In other locations such as the Savannah River, Georgia, a technique referred to as “agitation dredging” is used. In this case, about 200,000 cubic yards of materials are resuspended from ship berths each year by bottom dragging or by hydraulic excavation with direct disposal into the adjacent navigation channel. In addition, hydraulic bottom scour systems are presently in place in Wilmington, North Carolina, and experimental use of these devices is planned at one facility in Savannah and at the U.S. Navy’s Kings Bay, Georgia, Submarine Base. The environmental impact associated with the use of this technique is unclear, but significant use of bottom scouring devices could be problematic since planktonic and weak swimming fish and invertebrates could be impinged or entrained in intakes and plumbing, and turbidity and sedimentation could be exacerbated. Of particular concern is those aquatic environments that contain anadromous fish since planktonic and weak swimming fish could be heavily impacted.

An additional, but more limited dredging practice is the prop dredging of bottoms, mostly by recreational vessels, to obtain navigable depths. This practice is generally performed without benefit of state or federal permits and is almost always destructive.

The SAFMC is opposed to open water disposal of dredged material into aquatic systems when adverse impacts to habitat used by fisheries under its jurisdiction are likely. The SAFMC urges state and federal agencies, when reviewing permits considering open water disposal, to identify the direct and indirect impacts such projects could have on fisheries habitat. It is also their view that the conversion of one naturally functioning aquatic system at the expense of creating another (marsh creation through open water disposal) must be justified using the best available information.

Construction of piers and docks also affects EFH, but the degree of the impact is often disputed. Impacts are dependent on the size, location, and number of similar structures in a given area. Pier and dock construction often involves jetting of pilings and this causes temporary and localized affects on EFH due to increased sedimentation and habitat displacement. Sedimentation may be a problem in systems such as SAV that are already stressed and are declining or have marginal value due to low water clarity. The pilings are treated and toxic chemicals are released into the waters and sediments, but this is not perceived to be a major problem since the pilings are eventually covered with encrusting and fouling organisms. Perhaps the greatest threats from piers and docks are those associated with marsh and SAV shading and the erosion, due to wave action, of substrates in the vicinity of support piles. Substantial harm to SAV and benthic communities may also result from secondary effects associated with boat use, including constant grounding due to wave and tidal action.

The overall biological effects of piers and docks has not been well quantified. However, between 1981 and 1996, the NOAA Fisheries Service reviewed requests for almost 6,000 piers and docks along the southeast coast between North Carolina and Florida. Between 1996 and 2006, NOAA Fisheries Service reviewed an additional 7,540 applications to construct docks and pilings. In areas having marginal depths and especially where SAV is present, habitat damage in the vicinity of piers and docks may be substantial and disproportionately large in cases where such structures are abundant (Ludwig et al. 1997). These structures represent a substantial feature in southeastern watersheds and they warrant continued monitoring and regulatory review. In response to this, NOAA Fisheries Service and U.S. Army Corps of Engineers Jacksonville District jointly developed *Dock Construction Guidelines in Florida for Docks or Other Minor Structures Constructed in or over Submerged Aquatic Vegetation, Marsh or Mangrove Habitat* in addition to the *Key for Construction Conditions for Docks or Other Minor Structures Constructed in or over Johnson's seagrass (Halophila johnsonii)* (see http://www.saj.usace.army.mil/permit/hot_topics/Dock_Guidelines/dockindex.htm). In general, these guidelines provide environmentally responsible access to Florida waters.

<u>Vessel Operations</u>
In connection with watercraft operation and support the USEPA (1993) has identified several principal concerns. These include pollutants discharged from boats; pollutants generated from boat maintenance activities; exacerbation of existing poor water quality conditions; pollutants transported in storm water runoff from parking lots, roofs, and other impervious surfaces; and the physical alteration or destruction of wetlands and of shellfish and other bottom communities during the construction of marinas, ramps, and related facilities.

Marinas and other sites where vessels are moored or operate often are plagued by accumulation of anti-fouling paints in bottom sediments, by fuel spillage, and overboard disposal of trash and wastewater. In areas where vessels are dispersed and dilution factors are adequate, the water quality impacts of vessel operations are likely to be offset to some degree. In a study of marinas in North Carolina it was found that marinas may contribute to increases in fecal coliforms, sediment oxygen demand, and chlorophyll a, and decreases in dissolved oxygen (NCDEHNR 1990). In addition, boating and other activities (e.g., fish waste disposal) may contribute to increased water temperature, bioaccumulation of pollutants by organisms, water contamination, sediment contamination, resuspension of sediments, loss of SAV and estuarine vegetation, changes in sediment composition loss of benthic organisms, changes in circulation patterns, shoaling, and shoreline erosion. Pollutants associated with marinas include nutrients, metals, petroleum hydrocarbons, pathogens, and polychlorinated biphenyls (USEPA 1993).

Marina personnel and boat owners use a variety of boat cleaners, such as teak cleaners, fiberglass polish, and detergents and cleaning boats over the water, or on adjacent upland, creates a high probability that some cleaners and other chemicals will enter the water (USEPA 1993). Copper-based antifouling paint is released into marina waters when boat bottoms are cleaned in the water (USEPA 1993). Tributyl-tin, which is a major environmental hazard, has been largely banned except for use on military vessels. Fuel and oil are often released into waters during fueling operations and through bilge pumping. Oil and grease are commonly found in bilge water, especially in vessels with inboard engines, and these products may be discharged during vessel pump out (USEPA 1993).

Sewage and other wastes discharged from recreational boats may be most problematic in marinas and anchorage sites where vessels are concentrated. Despite existing federal and state regulations involving discharges of sewage and other materials, detection and control of these activities are difficult and discharges still occur. According to the 1989 American Red Cross Boating Survey, there were about 19 million recreational boats in the U.S. (USEPA 1993). About 95% of these boats were less than 26 feet in length and a large number of these boats used a portable toilet, rather than a larger holding tank. Given the large percentage of smaller boats, facilities for the dumping of portable toilet waste should be provided at marinas that service significant numbers of boats under 26 feet in length (USEPA 1993).

Increased recreational boating activity may contribute significantly to pollution of southeastern coastal waters by petroleum products. All two-cycle outboard engines require that oil be mixed with gasoline, either directly in the tank or by injection. That portion of the oil that does not burn is then ejected, along with other exhaust products, into the water. In 1990, 52,030 boats were registered in coastal North Carolina (North Carolina Wildlife Resources Commission, personal communication). Based on this number, conservative estimates indicate that about 84,549 gallons per year of oil (in fuel) is discharged annually into North Carolina’s coastal waters (Hoss and Engel 1996). For comparison purposes, hydrocarbon discharges for coastal North Carolina in 1982, from boating and urban runoff are about 470 and 2,270 tons, respectively. Increased use of personal water craft such as jet skis has added to the volume of hydrocarbon being introduced into southeastern waters since the engine exhaust from these vessels is discharged directly into the propellant water jet. Similar problems are inferred for other states and areas having high concentrations of boats.

The chronic effects of vessel grounding, prop and jet ski scarring, and anchor damage are generally more problematic in conjunction with recreational vessels. While grounding of ships and barges is less frequent, individual incidents can have significant localized effects. Propeller damage to submerged bottoms occur in all areas where vessels ply shallow waters. In addition, direct damage to multiple life stages of associated organisms, including egg, larvae, juveniles, and through water column de-stratification (temperature and density), resuspending sediments, and increasing turbidity (Stolpe 1997; Goldsborough 1997) have been observed in connection with vessel operation. This damage is particularly troublesome in North Carolina and Florida, the two South Atlantic states with submerged rooted vegetation in their coastal waters. In North Carolina, no official quantitative estimate of SAV damage has been performed; however, preliminary observations indicate that damage to the state's 135,000 acres of SAV is localized around marinas or other boat access points (R.L. Ferguson, personal communication). Scarring estimates for Florida indicate that about 173,000 of the state's 2.7 million acres of SAV are scarred (Sargent et al. 1995). On the Atlantic coast of Florida there are about 69,360 acres of SAV and 3,770 acres (18%) have been scarred by prop and other water craft action.

The ever increasing number of registered power boats along the South Atlantic coastal zone, and those temporarily entering coastal areas through tourism ensure that this threat is likely increase over time. Power boat registrations on Florida's east coast, not including sailboats, totaled 108,048 vessels in 1992-93. Of these, 95% were pleasure craft (Sargent et al. 1995).

The rapid increase in popularity of jet skis or "personal water craft" is also problematic. While these vessels are not propeller driven, the water jet removes sediment from seagrass roots and rhizomes and can cause damage. Further, these craft can operate in shallower waters and can access seagrass areas with relative ease, in addition to direct impacts to grassbeds. These machines are exceedingly loud and can create large wakes. It is reasonable to hypothesize that the audio and physical environment of shallow nursery areas may be disrupted in manners which stress postlarval life stages. The degree of stress is currently uninvestigated.

Incidences of commercial groundings are few, but where they occur on hard bottom habitats damage may be extensive and long-term. For example, groundings in the Florida Keys National Marine Sanctuary have caused extensive damage to coral reefs and signs of recovery are slow to appear.

The cumulative effect of anchor scarring in seagrass beds is not as damaging as that caused by propeller and jet powered vessels. On coral reefs, however, damage caused by anchoring of recreational boats is significant (Davis 1977). Dragging or pulling anchors

through coral beds breaks and crushes the coral, destroying the coral formation. Most reef damage of this type occurs in the Florida Keys and in nearshore waters.
The effects of vessel induced wave damage have not been quantified, but may be extensive. The most damaging aspect relates to the erosion of intertidal and SAV wetlands located adjacent to marinas, navigation channels, and boating access points such as docks, piers, and boat ramps. Wake related erosion in places along the Atlantic Intracoastal Waterway and elsewhere is readily observable and has undoubtedly converted substantial areas of emergent wetlands to less important habitat such as submerged bottom. In heavily trafficked areas bottoms may become unstable and colonization by bottom dwelling organisms may not be possible. Indirect effects may include the resuspension of sediments and contaminants that can affect EFH. Where sediments flow back into existing channels, the need for maintenance dredging, with its attendant impacts, may increase.

The introduction of exotic species by vessel operations is linked largely to the world wide movement of commercial vessels. Exotic species may be brought into the U.S. by several methods, but capture and release in ballast waters is of most concern. With the introduction of the zebra mussel into the Great Lakes and its rapid dispersal into other waters, considerable attention is being directed at this problem. According to one estimate, two million gallons of foreign ballast water are released every hour into U.S. waters (Carlton 1985). This possibly represents the largest volume of foreign organisms released on a daily basis into North American ecosystems. The introduction of exotic organisms threatens native biodiversity and could lead to changes in relative abundances of species and individuals that are of ecological and economic importance. This has already been observed in other parts of the world. While EFH has not been directly affected, recent introduction of a brown mussel into the Gulf of Mexico is of concern and is being investigated. It is anticipated that technology such as use of filters or open ocean exchange of bilge waters can be used to reduce the spread of non-native species. Considering the extent of port development and shipping along the South Atlantic, addressing this issue is of paramount importance.

6.1.1.8 Inshore Mining

Inshore mining, as a category of EFH threats, is generally confined to a few specific locations where associated effects may be substantial. Between 1981 and 1996 the NOAA Fisheries Service received only 434 of these proposals for review. Of these, 307 were from Florida and involved phosphate mining. While these activities undoubtedly have a dramatic effect on local landscapes and wetlands, the majority are well inland of most EFH locations. Where these activities occur along the coast, phosphate rock, sand, gravel, stone, and marl are generally mined. Phosphate rock is sought mostly for fertilizer production and the other materials are used mostly for fill, roadbed construction, and concrete production. The products of mining operations may eventually be transported to other locations and construction and operation of shipping facilities and navigation channels could involve EFH.

<u>Threats to EFH from Inshore Mining Activities</u>

Potential threats include conversion of wetlands to mine pits and uplands, or to reclaimed aquatic sites and uplands that lack pre-mine habitat and fishery production values; direct and/or non-point-source discharge of fill, tailings, chemicals, cooling and processing water, and surface and ground waters into streams, rivers and estuaries; hydrological modifications including those associated with ditches, dikes, water and waste lagoons, intake and discharge systems; and cumulative and synergistic effects associated with other mining and non-mining activities. Related shipping, storage, and processing facilities also can threaten EFH.

Where mining activities occur in areas identified as EFH, the local effect is often dramatic and extremely damaging. In eastern North Carolina phosphate mining has essentially eliminated an entire estuarine creek ecosystem in Beaufort County. The only phosphate mine in North Carolina is found in Beaufort County and located adjacent to the estuarine waters of Pamlico and South Rivers which are tributaries of Pamlico Sound. A 2006 proposal for continuation of mining would result in the loss of about 3,000 acres of wetlands of a variety of types, including the loss of approximately 30 acres of fresh and brackish estuarine emergent wetlands and freshwater/brackish water submerged aquatic vegetation located in the upper reaches of 5 estuarine creeks whose headwaters would be within the proposed mine expansion's footprint. Wetlands losses of this magnitude are significant on an ecosystem scale and the extent to which mitigation would offset these losses is uncertain at best. Alternative mining plans are available to the applicant that would be less damaging to wetlands and EFH; however, the company was opposed to these alternatives based on economic issues including profit margin.

In Dade and Monroe Counties, Florida, limestone removal operations have converted large areas of wetlands to open pits. The majority of these operations occur in the "Lake Belt", which is an approximately 57,515-acre area that was established by the Florida Legislature in 1997 for the purpose of implementing the Miami-Dade County Lake Belt Plan. The area lies west of Miami and east of Everglades National Park. To date, mining in the Lake Belt area has thus far converted approximately 4,900 acres of freshwater wetlands into lakes. The Clean Water Act Section 404 permits authorized by the COE require the mining industry to fund acquisition, restoration, and long-term management of lands in the Pennsuco wetlands, which is the area sandwiched between the Lake Belt and the Florida Everglades.

While most state and federal regulations require restoration of mine sites, such action is costly and often fails to produce environments that are similar in ecological character and productivity to those that were destroyed. EFH designation could further fishery management opportunities in certain locations and in the case of certain mining activities. In locations where suitable mitigation cannot be provided, the creation of new mines and expansion of existing operations may be curtailed or prohibited. Other less intrusive mining operations, such as minor removal of sand and gravel, are likely to continue, but needed environmental protection measures (e.g., seasonal work restrictions) could be specified to minimize impacts to fishery resources and prevent significant harm to EFH. However, this is not always the case as illustrated by a proposed 750 acres mineral mining project in New Hanover County, North Carolina that would adversely impact about 300 acres of tidally influenced forested wetlands located adjacent to the northeast Cape Fear River. The wetlands to be impacted and the adjacent waters in the river are designated as fish management areas by the North Carolina Division of Marine Fisheries and are therefore EFH. While approval of wetland losses of this type is unlikely, the frequency of this type of mining activity is likely to increase given the increase in development in coastal states and the need for aggregate fill for highway and commercial construction.

The construction and operation of mining-related facilities such as storage, processing, and shipping facilities and other related infrastructure such as roads, also presents a threat to EFH. Discussions found in Sections 6.1.1.6 and 6.1.1.7 address these factors.

6.1.1.9 Hydrologic Modifications

Alteration of freshwater flows into coastal marine waters, typically via the construction of canals, has changed temperature, salinity, and nutrient regimes, reduced the extent of wetlands, and degraded estuarine and nearshore marine habitats (Reddering 1988; Whitfield and Bruton 1989). The following summary is largely taken from Serafy et al. (1997). Profound changes to the south Florida ecosystem have occurred with the construction of an extensive inland and coastal canal system by the COE which began as early as 1917 (Hoffmeister 1974; Teas et al. 1976). Today, the system constitutes a 1400-mile network of canals, levees, locks and other flood control structures which modulates fresh water flow from Lake Okeechobee, the Everglades, and coastal areas. These areas, which serve as nursery areas for a wide diversity of organisms, have experienced drastic changes in both the amount of freshwater they receive, and in the fashion in which it is delivered. For example, in southern Biscayne Bay, Florida, canal locks are all that separate this occasionally hypersaline lagoon from the entirely freshwater canal systems. When the locks open, the salinity of marine waters downstream often drops 20 ppt within 60 minutes before recovering as rapidly (Wang and Cofer-Shabica 1988). This may occur several times a day and over several months, particularly during the rainy season (i.e., May to October) when water temperatures are also at maximum levels.

<u>Potential Threats to EFH from Hydrologic Modifications</u>

Most hydrologic modifications are performed with other activities that are identified as having potential to adversely impact EFH. As such, the activities involved are similar or identical to those identified in other sections. Other threats are possible with mosquito control, aquaculture, wildlife management, and flood control projects and activities. Hydrologic modification can involve entire watersheds and drainage basins for large scale water diversion projects, where silviculture and/or agriculture activities are large in scale and/or intensity, and where runoff from urban and suburban development is substantial. Threats related to hydrologic modification can involve any activity that alters water quality or the rate, duration, frequency, or volume at which water enters or moves through an aquatic system. Consequently, activities associated with industrial, urban, and suburban development (including those occurring on uplands), ditching, *draining, diking, and impounding may all qualify as hydrologic modification related threats.*

Rapid salinity fluctuations can represent a significant stress for a marine organism, depending on its osmoregulatory ability and/or its behavioral response (Serafy et al. 1997). In fishes, abrupt salinity changes can cause mineral imbalances in the blood which tends to become diluted as salinity drops, and concentrated as it rises -- either of which can be lethal (Mazeaud et al. 1977). Rectification of proper osmotic balance in response to salinity stress requires energy expenditure, often at the cost of growth, reproduction and/or resistance to other stressors, including high temperature (Moore 1972; Schreck 1990). The combination of high temperatures and low salinity pulses on marine organisms has received only limited attention (Moore 1972; Albertson 1980). Only one study has examined the combined effects of high temperature and freshwater pulses on subtropical marine fishes of the Western Atlantic. Serafy et al. (1997) combined a field survey of nearshore fishes in Biscayne Bay, Florida, with a series of laboratory-based freshwater pulse experiments. A 13-month trawl project was supplemented with high temperature - low salinity challenge experiments on eight fishes: five species that dominated canal-influenced habitats (*Eucinostomus gula*, *Lagodon rhomboides*, *Haemulon sciurus*, *Opsanus beta*, and *Lucania parva*) and three species that were less common in these areas (*Cynoscion nebulosus*, *Haemulon favolineatum*, and *Cyprinodon variegatus*). Of the five fishes that dominated the nearshore habitats, three exhibited no mortality when subjected to freshwater pulses, while *L. rhomboides* and *L. parva* exhibited 12.5% and 50% mortality rates, respectively. Mortality was 100% for the three species that were less common in habitats influenced by canals. These laboratory and field results support the hypothesis that anthropogenic changes to fresh water delivery regimes can play a partial role in determining the species compositions of nearshore fish assemblages within Biscayne Bay, Florida.

Holland et al. (1996) found that salinity was a major factor in controlling the distribution and abundance of living marine resources in South Carolina estuaries. In watersheds having the greatest areas of roofs, roads, and parking lots it was found that surface water discharges tended to be “flashier” and that recruitment and colonization by benthic fauna in these areas was less predictable than in more stable environments.

Mosquito control activities and associated threats to EFH have become better understood in recent years. Between 1996 and 2006, NOAA Fisheries Service reviewed 203 applications for mosquito control and related activities in the South Atlantic area. Although efforts to alleviate the hydrologic modifications resulting from this activity are underway (27,000 acres of reconnected impoundments in the Indian River Lagoon) much of the area altered by ditching and draining of saltmarsh throughout the east coast has not been addressed. Although tidal water still flows into most of these saltmarsh areas it flows in prescribed dredged channels and does not interact with much of the marsh surface expect through extreme high tide events. Without sheet flow of water across the marsh surface much of the ecological benefit of saltmarsh is underutilized. Some of these areas are receiving hydrological restoration but efforts have been under funded and go largely unrecognized.

6.1.1.10 Dams, Impoundments, and Other Barriers to Fish Passage

Natural river systems throughout the world have been extensively modified for a variety of societal purposes including withdrawals for irrigation, public water supplies, navigation, flood control, and hydroelectric power. Over half of the world's large river systems (172 of 292) are affected by dams constructed in the past century (Nilsson et al. 2005). Approximately 800,000 dams have altered riverine habitats worldwide, with approximately 2 major dams constructed each day for the past 50 years (World Commission on Dams 2000). In the United States the total number of dams built during 1700- present is not known with certainty. The National Inventory of Dams (FEMA and U.S. Army Corps of Engineers 1994, 1996) listed approximately 76,000 dams including those deemed to be a threat to life and property downstream, those greater than 6 feet high with more than 50 acre-feet of storage, and those 25 feet or greater in height with more than 15 acre-feet of storage. The National Research Council estimated well over 2.5 million dams existed in the United States in 1992. All of the watersheds tributary to the South Atlantic Shelf Ecosystem are highly affected by large mainstem flood control and hydropower dams and many small dams constructed for various purposes. Bush, et al. (1998) in a review of existing dam location data identified 6,944 dams in South Atlantic watersheds (North Carolina to Florida).

Thousands of wetland acres have been impounded each year in the southeast for purposes such as waterfowl habitat creation, aquaculture, agriculture, flood control, and mosquito control. Historically, large areas of wetlands were impounded in South Carolina for rice production. Projects range in size from minor, such as repair of existing embankments, to large-scale projects where constructing dikes and water- control structures may affect relatively large wetland tracts.

Numerous dams and other structures have been built on major rivers for industrial water uses, hydropower facilities, reservoirs, and as part of flood control projects. Those facilities near the coast can have an adverse effect by blocking fish passage, and modifying hydrology and sediment and nutrient flows to coastal waters. Dams affect or disrupt many natural processes including upstream and downstream movements of fish and other aquatic species, export of organic carbon, natural hydrological variability and seasonal flow patterns, seasonal temperature, dissolved oxygen and nutrient export patterns, and riverine, estuarine, and coastal geological processes (Freeman et al. 2003; World Commission on Dams 2000).

<u>Potential Threats to EFH from Dams, Impoundments, and Other Barriers to Fish Passage</u>
Direct effects of impoundments and other barriers are removal of habitat, conversion of habitat away from historic usage, alteration of hydrology, and modification of water quality by modification of temperature, salinity, and nutrient and sediment fluxes. Flow regimes often are controlled and differ substantially from pre-impoundment flows. This can adversely affect anadromous fish migration and spawning as well as food production for prey species needed by larvae and juveniles. Riverine, estuarine, and coastal marine ecosystems have evolved in synchrony with natural seasonal river flow variability and

discharge patterns. Species life cycles, reproduction, and sustainable populations may be disrupted by man-made barriers and their many effects as described previously.

Large acreages of coastal wetlands have been impounded along the southeast Atlantic. Reasons vary, but include aquaculture, waterfowl production, mosquito control, and in the Old South prior to 1912, rice production. The overall amount of impounded coastal wetlands is not known, but probably exceeds 200,000 acres. Between 1981 and 1996, the NOAA Fisheries Service reviewed 721 proposals of varying sizes that blocked or impounded EFH (Tables 26-29). A review of 190 of these projects revealed that about 7,131 acres of EFH would be adversely altered through these projects. From 1996-2006, the NOAA Fisheries Service Habitat Conservation Division received 465 applications for barriers and impoundments.

A primary biological concern for barriers and impoundments is the impact on estuarine-dependent marine fisheries production. Most impoundments are managed for resources other than fish (e.g., waterfowl). The management regimes, based largely on seasonal consideration, may exclude or severely restrict access by fish and invertebrates. This decreases habitat area and proportionately, the production of fishery resources. Even if fisheries gain access, conditions within impoundments may not be hospitable and organisms may not be able to escape and enter harvestable and reproductively active populations found in surrounding waters. Other management regimes, such as marsh burning, may adversely affect fishery resources. Water quality and nutrient outflow also may be compromised.

However, it is important to note that existing impoundments can be managed to reduce their impacts on estuarine habitat, although some impacts may remain, (e.g., blockage of ingress-egress, reduction of carbon and nutrient export). New impoundments pose a potential risk to EFH and fish production and must be carefully evaluated. However, within the South Atlantic, some positive aspects are evident related to existing impoundments. Because wetlands have been extensively damaged, these areas (especially old rice fields) provide a wealth of available habitat. Further, production of fisheries organisms within these areas is often excellent. Crab production, for example, has been shown to be high in some areas and the production of many estuarine-dependent species has been observed.

New impoundments pose a potential risk to EFH and fish production and must be carefully evaluated. However, within the South Atlantic, some positive aspects are evident related to existing impoundments. Because wetlands have been extensively damaged, these areas (especially old rice fields) provide a wealth of available habitat. Further, production of fisheries organisms within these areas is often excellent. Crab production, for example, has been shown to be high in some areas and the production of many estuarine-dependent species has been observed. Strides have been made in revising existing management regimes to better accommodate fishery production and these early efforts are producing positive results. In Florida, the Subcommittee on Managed Marshes, an interagency ad hoc group is making impressive strides in reestablishing fisheries access to impounded wetlands. These types of efforts provide a positive solution for better integrating the uses associated with these areas.

The effects of riverine dams and impoundments on riverine and coastal ecosystem processes, habitats, and health may be profound. Ecological functions of riverine ecosystems affected by dams may be grouped into five primary components: hydrology, biology, geomorphology, water quality, and connectivity (Instream Flow Council 2002). Each of the five components is strongly linked with physical habitat structure, important nutrient and carbon cycles, and health and productivity of estuarine and coastal marine ecosystems. Explained in simplest terms, the effects of dams are manifested through the broad impact categories of habitat fragmentation and flow regulation, in addition to alteration of morphological processes.

With respect to coastal ecosystems and managed fisheries, arguably the most critical effects of dams include blockage and consequent reduction in available reproductive habitat for sea-run diadromous fishes, and large-scale alteration of the distribution and periodicity of freshwater inflows.

Diadromous fishes including shad, herring and other alosines are important components of estuarine and marine food webs. Prior to construction of dams in Atlantic river basins large annual spawning runs of shad and herring and other diadromous species supported important coastal and river fisheries. Early accounts described annual spawning runs of shad and river herring in rivers including the Potomac, Susquehanna, Roanoke, and Savannah in the tens of millions (Baird 1887) with landings in individual river basins exceeding today's total Atlantic Coast managed fishery landings by a wide margin. Baird was among the first marine scientists to suggest the relationship between diadromous fish biomass and support for stocks of other commercially important marine species. Construction of dams in Atlantic Coast river basins began soon after European colonization in the early 1700s and continued in cycles through the early 1970s (Watson 1996). Nearly all large river basins in the South Atlantic were closed to significant diadromous fish spawning runs by mainstem dams by the 1960s and 1970s. Busch et al. (1997) estimated the reduction in Atlantic Coast riverine habitats for diadromous species due to construction of dams. In the North Atlantic region (Maine to Connecticut) stream access for diadromous species has been reduced by 91%, and the corresponding reduction for the South Atlantic Region (North Carolina to Florida) is 77%. As dam construction progressed, along with unregulated exploitation and increasing pollution, the Atlantic Coast shad fishery remained one of the most economically important fisheries into the 1940s prior to construction of the last major mainstem dams after the Second World War (Hightower 1997). Today the formerly large spawning runs of shad, river herring, striped bass and sturgeon are reduced to small remnant populations or have disappeared entirely in some rivers. Because of the drastic reductions in abundance of shad and other alosine species, their importance in food web support has also diminished and may represent a significant limiting factor in recovery of some federally managed species.

The timing, duration, and frequency of river flows are critically linked to the health and function of riverine, estuarine and coastal marine ecosystems and fisheries (Taylor et al., 1990). Estuarine and coastal marine wetlands and deepwater habitats are highly dependent upon inputs of freshwater and associated nutrients and sediments from rivers (Berkamp et al. 2000). Seasonal periods of increased river discharge and consequent inflow to estuaries and coastal waters may serve as biological triggers for fish and invertebrate migrations and reproductive cycles. More prominent examples include upstream spawning movements of shad, striped bass, and sturgeon to spawning habitats in river channels; and movements of spawning blueback herring and Atlantic menhaden into floodplain forested wetlands and deepwater sloughs (Rulifson 1982; Pardue 1983; Meador 1982). Natural seasonal patterns and variations in freshwater inflows to estuarine and coastal marine habitats provide suitable salinity and nutrient conditions for reproduction and growth of oysters, blue crabs, shrimp and many estuarine-dependent species. Regulation of river flows by dams, particularly for flood control and hydropower production, may significantly alter natural patterns of river discharge to which many species life cycles have adapted during their evolutionary history. River regulation may affect seasonal salinity patterns over large areas of estuarine and coastal marine habitats. Dams with large storage capacity can reduce downstream flows during critical late winter and spring diadromous fish migrations, resulting in reduced water level and duration and areal extent of inundation, severely limiting fish production. Dams and reservoirs trap river-borne sediments, resulting in reduction of nutrient-rich sediment deposition in downstream floodplain wetlands and alluvial deltas. Resulting disruption of alluvial delta and wetland formation processes may cause large scale floodplain and wetland subsidence, adversely affecting habitat stability and productivity for estuarine and coastal marine fisheries.

Thermal stratification of large reservoirs during summer months often results in biological oxygen depletion of the cooler water of the hypolimnion, with consequent discharge of cooler water with low dissolved oxygen downstream of the dam. Fish and other aquatic life may be eliminated or adversely affected in riverine or estuarine areas downstream as far as the deoxygenation persists. Large, shallow impoundments lacking thermal stratification may result in solar warming with consequent release of water with elevated temperatures to downstream riverine and estuarine habitats. During warmer summer months, the resulting elevated water temperatures may exceed the tolerance levels for fish species adapted to naturally occurring seasonal temperature regimes. Where dams and river regulation have been in place for many years, the continuing cumulative effects of habitat fragmentation, altered flows, water temperatures, and dissolved oxygen conditions may result in shifts in aquatic species community structure and composition. Populations of federally managed diadromous, estuarine and marine species may be limited by the continuing effects of dams and river regulation.

Dams and other barriers have been constructed on almost every major southeastern river. They serve multiple purposes including hydropower production, water supply, and flood attenuation. Dams located on the Roanoke and Neuse Rivers in North Carolina, the Cooper and Santee Rivers in South Carolina and on the Savannah River on the South Carolina-Georgia border are major impediments to anadromous fish migrations, as mentioned above. Most of these structures are old and were built either before their effects on fish and other wildlife were known, or at a time when environmental concerns were of lesser importance than economic and political factors. Considering the present level of knowledge of their effect on fish migration and production, water quality, and flow alteration, it is unlikely that major new structures will be built. The present challenge is to revisit older structures to determine their usefulness and where their negative impacts outweigh their benefits, they should be removed or modified. An example is removal of the Quaker Neck Dam on the Neuse River in North Carolina. Where removal is not feasible then consideration must be given to providing for, or improving fish passage and for modifying flow regimes to mimic pre-impoundment flows. These considerations will rely on new research and improvements in fish passage technologies.

6.1.1.11 Other sources of nonpoint-source pollution

Potential Threats to EFH from Other Sources of Nonpoint Source Pollution
Potential threats include reduced water quality, erosion, increased contaminants, increased sedimentation, and disease.

The more common sources of NPS pollution include runoff from agriculture, pasture lands, silviculture, mining, and developed areas as well as erosion created from modifying rivers, streams, and shorelines. These sources have separate sections in the Fishery Ecosystem Plan. Three additional sources of NPS runoff deserve brief mention and include construction sites, marinas, and septic systems

Runoff from construction sites can be considerable sources of NPS pollution (Carpenter et al. 1998). Construction sites occupy a relatively small percentage of land surface area, but rates of erosion from these sites can be high leading to a large amount of pollution coming from these small areas. Erosion rates from watersheds under development can approach 50 times the rate from agriculture lands and 500 times the rate from areas with undisturbed plant cover. Eroded material from construction sites contributes to siltation of water bodies as well as eutrophication. Best management practices for controlling runoff from construction sites are well known and should be followed to avoid impacting fishery resources.

Understanding NPS pollution associated with marinas can be difficult because marinas can be both a source of pollutants generated by activities occurring within the marina as well as the place where pollutants generated elsewhere collect (Flory 2005; USEPA 2001). Construction of the basins, docks, jetties, and bulkheads needed for marina operations typically reduce water circulation, and this reduced circulation promotes the settling of fine sediments that often have organic material, metals, or other pollutants attached to them. These materials concentrate in marina sediments and, at times, also can concentrate in marina waters. The pollutants that might be generated at a marina or accumulate within a marina basin include nutrients and pathogens (from pet waste and overboard sewage discharge), sediments (from parking lot runoff and shoreline erosion), fish waste (from dockside fish cleaning), petroleum hydrocarbons (from fuel and oil drippings and spills and from solvents), toxic metals (from antifouling agents and debris from boat maintenance), and liquid and solid wastes (from engine and hull maintenance and general marina activities).

Many contaminants generated from boat maintenance and general marina use (e.g., oil and grease drippings from cars) are insoluble in water. In the slow flowing, protected waters of the marina, the fine particles that these materials adhere to settle and accumulate in the sediments. While these sediments may then release their contaminants into the water in response to physical disturbance (such as dredging, propeller wash, or storms) or from changes in water chemistry (such as pH or dissolved oxygen concentration), effects upon benthic organisms and fishery resources are of greatest concern. Most benthic organisms either burrow into the sediment or feed by sorting through large volumes of sediment in search of prey items or detritus. Both behaviors bring benthic organisms into close contract with any contaminants that may be present and these contaminants can then accumulate in the bodies of the benthic animals. Fishery species that feed upon these benthic organisms are then exposed to concentrated doses of the contaminants, which may reduce the health or reproduction of the fishery individuals or make them unsuitable for consumption by humans.

Pollutants from marinas can cause pollution problems in the water column. These problems usually take the form of decreased levels of dissolved oxygen and increased levels of metals and petroleum hydrocarbons. Pollutants that cause these problems get into the water through storm water runoff, discharges from boats, and spills of fuel or bilge water. Low levels of dissolved oxygen can be a problem any place where organic material accumulates. The decay of organic material consumes oxygen from surrounding water. If the low circulation promotes accumulation of organic material while at the same time hindering exchange with oxygen-laden waters outside the marina, the result can be insufficient oxygen for fishery species.

In addition to pollutants that reduce the quality of sediment or the water, marinas often are associated with silt that can impair seagrass, oyster, or other habitats that support fishery resources. Increased boat traffic within and near a marina can erode shoals and the shoreline suspending large amounts of sediment into the water that fall upon fishery habitats. Waves generated by boat wakes can wash away seagrass that is loosely rooted in sediments and the benthic organism living at the sediment surface.

NPS pollution associated with marinas can be reduced by ensuring marinas are designed to flush regularly with adjacent waters; locating marinas close to tidal inlets and away from the headwaters of tidal creeks is part of these design decisions. Shorelines should be vegetated to reduce erosion. Stormwater runoff can be controlled by well designed and maintained stormwater management systems. Marina fueling and sewage collection stations should be maintained and designed to make cleanup of spills easier.

Septic systems include the underground system of pipes and tanks designed to use naturally occurring bacteria and microorganisms to treat bathroom, kitchen and laundry wastewater. In older homes, a septic system may be little more than a cesspool and a pipe that connects the cesspool to the house. In newer homes, a septic system usually includes a septic tank, distribution box, drain field, and pipes that connect these elements. Passing sewage and household wastewater through a septic system protects the environment from contamination. Microorganisms and insects living within the drain field help decontaminate waste materials by consuming leftover waste particles. Improperly maintained septic systems can allow nutrients and pathogens to enter ground waters and surface waters that flow into coastal ecosystems. The excess nutrients can lead to eutrophication and low levels of dissolved oxygen, both of which can impair habitats used by fishery species. The pathogens can spread disease that reduce the health of fishery species.

NPS pollution from septic systems can be reduced by ensuring the systems are inspected annually and pumped regularly. Pumping out every three to five years is recommended for a three-bedroom house with a 1,000-gallon tank; smaller tanks should be pumped more often. Storm drains should not be diverted into septic systems because the extra load on the systems will overwhelm its ability to process nutrients and eliminate pathogens. Any measure that decreases water use within a home can help a septic system protect coastal water quality by reducing the likelihood of overflow from the system.

6.1.1.12 Non-native or nuisance species

Update on Aquatic Invasive Species Management in the Southeast-March 2008
Marilyn Barrett-O'Leary Southeast Aquatic Resources Partnership (SARP)

Aquatic invasive species are a part of fisheries and wildlife management in all of the Southeast Aquatic Resources Partnership (SARP) states. Many of the states manage specific species cooperatively, but we do not have comprehensive regional management. For example, Texas and Louisiana partnered with some federal agencies to bring massive chemical control to reduce a giant salvinia infestation on Caddo Lake, a popular angling lake on the two states' shared border. Florida, a state with better funding resources than many of its neighbors, routinely shares research results and outreach products (on many invasive plants and animals) to promote regional control. All of the states are members of at least one regional Aquatic Invasive Species (ANS) panel, providing biannual meetings to share information and committees to work on problems regionally.

Every SARP state has developed an ANS management plan. Most have completed that process, which involves forming a task force, gathering information, identifying overlapping jurisdictions, setting priorities, and devising action plans. Most important, these activities lead to governor's buy in and signature, interagency agreements such as MOUs, and continuation of the task force in some form to facilitate management. As of this date, every SARP state has at least one agency person with ANS as part of his/her scope of work. Some have individuals with ANS as his/her exclusive scope of work. The states of Louisiana, Texas, Florida, Virginia and Missouri have officially accepted plans. Kentucky, South Carolina, Alabama, Tennessee and Mississippi are in the final, official stages of seeking national acceptance of their plans. They have effectively identified the problem and are already integrating solutions into their agency activities. Oklahoma, Georgia, North Carolina, and Arkansas are still developing their plans. Both

Georgia and North Carolina are developing plans that combine management of terrestrial and aquatic invasive species. All states are aware of the need to work in that direction. All of these states face similar issues. Below are a few of them:

1. Invasive species are not all bad or all good – they may cause problems in certain circumstances but actually benefit certain groups or situations. Management (treatment, regulation, education) requires ecological and economic evaluation on local, regional, and national levels and cooperation among state, local, and federal agencies.

2. Invasive species almost always alter the ecosystem; they seldom simply slip into an unfilled niche. They thrive in disturbed systems. Therefore, ecological management can contribute to invasive species prevention and control. Unfortunately, states are not funded or equipped to manage all state waters at that level, and every state has many water bodies that are managed privately or by federal agencies.

3. The general population has only fleeting knowledge of this problem, and often, unwittingly, contributes to it. Consistent, continuous education is needed over the long term. SARP agencies are trying to educate one of the most involved segments of the population – the recreational fisher – to clean off boats before leaving the dock, place unused live bait into the trash rather than dumping it into the water, and to refrain from moving live fishes in an attempt to 'stock' for certain fish. Similar, targeted education efforts need to be made towards many other population segments. Tax dollars need to be earmarked for this management.

6.1.2 Marine/offshore processes

6.1.2.1 Navigation

Offshore maintenance dredging for navigation is mainly limited to inlet bar channels and other port entrances; (e.g., Port Canaveral, Florida). The sediments are typically coarse and the bottom communities are low diversity reflecting the dynamic nature of these areas. Bottom organisms occupying this zone are generally sparse and adapted to the dynamic nature of the habitat they occupy. As such, dredging in these locations generally does not pose the same magnitude or type of impact incurred when working in nearshore environments. The same is true for vessel operations, although to some degree the problems discussed in Section 4.1.1.6 also apply. Vessel operation impacts are mainly linked to sinking, grounding, routine disposal trash and wastes, and the accidental release or spillage of cargo and fuel.

However, offshore new dredging, namely widening and deepening existing port entrance channels to accommodate super-carriers, i.e., Post-Panamax vessels an impact complex hard bottom communities along channel walls in addition to reef trends. For example, the Jacksonville District COE in conjunction with Port Everglades is presently completing a feasibility study in part to evaluate the widening and deepening of the Port Everglades Outer Entrance Channel. The project could impact offshore marine habitats, including hard bottom and coral reef communities located offshore Fort Lauderdale, Florida (Broward County). In total, 11.9 acres of hard bottom habitat on the outer reef (Reef 3) may be removed during construction (COE 2006).

Potential Threats to EFH from Navigation

Potential threats include excavation and burial of EFH in connection with creation, expansion and maintenance of navigation channels; elevation of turbidity and resuspension of toxic and harmful components of dredged materials (includes material that cause elevated sediment and dissolved oxygen demands); interruption of coastal sand movement and sub-adult fish migration through construction of channel stabilization structures such as jetties; potentially harmful vessel operations such as discharge or spillage of fuel, oil, grease, paints, solvents, trash, and cargo; grounding/sinking/prop scaring in ecologically/environmentally sensitive locations; exacerbation of shoreline erosion due to wakes; and transfer and introduction of exotic and harmful organisms through ballast water discharge.

With a few exceptions, offshore dredging is performed using hopper dredges. Hopper dredges generally dump accumulated material through a split hull; however, the use of these dredges in connection with pipelines and vessel pump out is becoming more commonplace, especially where sand is needed for beach fill. Closer inshore, sidecast dredges may be used where wave amplitude is slight and dredging volumes are relatively minor. In protected waters pipeline dredges are almost always used since they provide the most effective and efficient means for removing and redepositing bottom sediments. On rare occasion, as in the case of the Cape Canaveral Ship Channel, pipeline dredges may be used in open waters but their vulnerability to wave damage generally precludes this. Bucket dredges and scows are employed in some locations, but such use is usually limited to situations where other dredges cannot operate due to water depth and pumping distances (for pipeline dredges).

In connection with offshore waters, threats to EFH are most significant in terms of possible burial of benthic communities in the vicinity of dump sites and in connection with turbidity from dumped materials. Contamination of the water column and bottoms is also possible if the dredged material is contaminated. Sediments may also be re-dispersed after being dumped in offshore sites and burial of productive bottoms is possible. On occasion, designated dump sites are not adequately studied or they change and high quality benthic habitat may be damaged or destroyed.

Although most ports are located in estuarine waters, navigation related threats can also be severe in offshore waters. As the shipping industry moves towards super containerships, the many eastern seaboard ports are evaluating the need to widen and deepen offshore entrance channels. Currently, only a limited number of ports can accommodate Post-Panamax vessels. The Port of New York/New Jersey is the only port along the Atlantic seaboard that is undergoing expansion work to support super-carriers.

Additional threats to EFH from offshore navigation occur through the overboard disposal of trash, cargo, and wastewater from ocean going vessels, and disposal of dredged

material (see Section 7.4.2.1). Although comparisons are unavailable, it is likely that most vessel-related disposal occurs on the open ocean, rather than in estuarine and nearshore waters where such activities are likely to be observed.
Within Florida waters, particularly in the Florida Keys and Fort Lauderdale, vessel groundings represent a chronic threat to live coral habitat. Anchoring is also a problem, however, it has become less of a threat through wide spread use of single point mooring buoy systems. Vessel groundings can be broken into two broad categories: large vessel and ship groundings that often result in severe injury to live coral colonies and non-living reef framework; and small recreational boat groundings that result in numerous strikes to individual coral colonies in both inshore and offshore areas. Large vessel and ship groundings occur infrequently, but result in far more significant injury to coral reefs and other habitat types. Recreational boat groundings are much more frequent. Between 1993 and 1997, 2089 groundings were reported in the Florida Keys National Marine Sanctuary. Many more are likely unreported.

Table 6.1-1 Reported Vessel Groundings* in Florida Keys National Marine Sanctuary (FKNMS) 1993 to 1997.

Year	Total Reported Vessel Groundings
1993	280
1994	550
1995**	400
1996**	399
1997**	460
Total	2089

*Data from FKNMS & Florida Marine Patrol Computer Assisted Dispatch Report
** Grounding data for 1995 through 1997 are incomplete and require further data analysis.
Note: The above numbers do not represent coral reef groundings alone. Reported groundings occur in all types of habitats found in the FKNMS.

Accurate baseline data for live coral coverage exist mainly for reefs in the Florida Keys but not for the remaining habitat that contains stony corals that do not form reefs. In some cases though, sufficient data are available to allow calculation of the actual extent of a grounding incident. For example, on August 10, 1994, the R/V *Columbus Iselin*, a 154-foot research vessel, was conducting survey work for the University of Miami when it struck Looe Key, a spur and groove reef. Approximately 345 square meters of living coral and 338 square meters of non-living coral reef framework were destroyed.

Injuries to coral from groundings take several forms and include crushing, splitting and fragmentation, dislodging colonies, and depending on the severity of the incident, sedimentation and/or burial. In general, groundings occur on or near the reef crest where coral formations are closest to the water surface. Species commonly injured in the reef crest include elkhorn coral (*Acropora palmata*), staghorn coral (*A. cervicornis*), fire coral (*Millepora complanata*), starlet coral (*Siderastrea siderea*), mustard hill coral (*Porites astreoides*), and knobby zoanthidean (*Palythoa mammillosa*). Species that inhabit deeper areas such as brain coral (*Diploria strigosa*), star coral (*Montastrea annularis*), and large star coral (*Montastrea cavernosa*) are at risk from deep draft vessels. Small individual groundings may recover over time, but the loss of live coral coverage is likely to take decades. Catastrophic groundings involving large ships or freighters may never fully recover.

Since 1994, there have been at least 10 reported large-scale groundings near the existing anchorage off Port Everglades (in Florida) that have collectively damaged over 3 acres of coral reef habitat. The existing shallow water anchorage is located between two lines of reef. Dozens of undocumented anchor and anchor chain drag impacts have also occurred damaging an undetermined amount of reef. The U.S. Coast Guard has proposed anchorage rulemaking to revise the existing anchorage locations to strengthen existing anchoring requirements and guidelines in order to provide a higher degree of protection to the reef resources.

6.1.2.2 Dumping

Dredged material disposal in ocean waters generally involves disposal of sediments dredged from inshore areas such as port facilities. Where navigation approaches from offshore and inlets are involved these materials may also be placed in offshore sites. Most of the sediments taken from inshore areas are fine, contain some degree of contamination, and produce at least short-term impacts such as turbidity plumes when removed or deposited. The overall effects of dumping on or near EFH can range from immeasurable to significant and are not well studied. Therefore, dredging and disposal are typically evaluated on a case-by-case basis. The SAFMC policy on dumping provides additional detail on the subject. The principal authority for designating ocean disposal sites for placement of dredged material is the Regional Administrator of the EPA. The EPA develops and publishes Environmental Impact Statements (EIS) and the rule making paperwork for ocean dredged material disposal site (ODMDS) designations. Corps of Engineer Districts provides the EPA with the necessary information to prepare the EIS and to identify significant issues to be addressed in the site designation process. Information required from the Districts includes: zone or siting feasibility data, justification for the need for ocean disposal, and alternatives to ocean disposal. The purpose of the EPA site designation process is to establish sites that minimize impacts to the environment, economize disposal site management and monitoring activities, and support multiple users (C. McArthur personal communication).

Under provisions of the Marine Protection Research and Sanctuaries Act (MPRSA), ocean disposal of hazardous and toxic materials, other than dredged materials, is prohibited by U.S. flag vessels and by all vessels operating in the U.S. territorial sea and contiguous zone. The EPA may issue emergency permits for industrial waste dumping into ocean waters if an unacceptable human health risk exists and no other alternative is feasible. The MPRSA assigns responsibility the ocean disposal of dredged material to the EPA and the COE. This involves designating ocean sites for disposal of dredged material; issuing permits for the transportation and disposal of the dredged material; regulating times, rates, and methods of disposal and the quantity and type of dredged material that may be dumped; developing and implementing effective monitoring programs for the sites; and evaluating the effect of dredged material disposed at the sites (C. McArthur, personal communication).

To date, offshore ocean dumping sites have been approved for ports at Wilmington, North Carolina; Brunswick and Savannah, Georgia; Georgetown, Charleston and Port Royal, South Carolina; and Miami, Palm Beach, Port Everglades, Fort Pierce, Jacksonville, and Fernandina Beach, Florida (C. McArthur, personal communication). The COE has identified Jacksonville Harbor as possibly needing a new or expanded ODMDS.

Table 6.1-2 Region IV of the U.S. Environmental Protection Agency identifies the following concerns in connection with existing South Atlantic Ocean Dredged Material Disposal Sites (ODMDS):

Ocean Dredged Material Disposal Site	Site Specific Concerns
Charleston, SC ODMDS	Live bottom areas proximal to the site subject to possible impact.
Miami, FL ODMDS	Effect of disposal plumes on nearshore coral reefs are under investigation.
Port Everglades, FL ODMDS	Burial of deepwater hard bottoms and shelf edge zones that support managed species. Conversion of sediment type could affect tilefish burrows. Possible presence of deepwater corals (e.g. *Oculina varicosa*).
Palm Beach, FL ODMDS	Burial of deepwater hard bottoms and shelf edge zones that support managed species. Conversion of sediment type could affect tilefish burrows. Possible presence of deepwater corals (e.g. *Oculina varicosa*).
Fort Pierce, FL ODMDS	Offsite transport of disposed dredged material and subsequent burial of nearby hard bottom communities is of concern to local community.
Jacksonville, FL ODMDS	Lies within Northern Right Whale Critical Habitat and site may be undersized.
Fernandina, FL ODMDS	Lies within Northern Right Whale Critical Habitat.
Brunswick, GA ODMDS	Lies within Northern Right Whale Critical Habitat.
Wilmington, NC ODMDS	Wood debris in dredged material suspected of

	migrating off site into shrimping grounds.

Dumping of trash, wastewater, and unwanted cargo is more likely to occur on the open seas since it is less observable here than in inshore waters. Prior to passage of the Marine Plastic Pollution Research and Control Act (MPPRCA) of 1987 (PL 100-220), an estimated 14 billion lbs of garbage were being dumped into the ocean each year. More than 85% was believed to have come from the world's shipping fleet in the form of cargo-related wastes. See section 6.1.2.2.3 below.

Potential Threats to EFH from Dumping

Potential threats include burial of habitats and their flora and fauna, introduction of contaminants and toxic substances into waters and substrates, increased and harmful turbidity levels, and creation of hazards to fishing and navigation.

Threats associated with ocean dumping sites include covering of live bottom or hard bottom areas in or near a dump site; disposal of fish processing wastes; converting the sediment type in areas that support tilefish; impacts to nearshore coral reefs and live bottoms by disposal plumes; offsite transport of disposed dredged material and subsequent burial of nearby hard bottom communities; designated sites that are too small to handle the load; migration of debris (e.g., wood) to fishing grounds; derelict vessel disposal; and the location of dumping sites within critical habitat of endangered species such as the northern right whale.

Because monitoring of disposal activities is sometimes inadequate, there are reports of dredged material dumping outside of designated dump sites (short dumping). One recent example of a possible short dumping event involves the excavation associated with the Fort Pierce Harbor, Florida, expansion project. In this case, over 400,000 cubic yards of dredged material from this project was dumped at a mid-shelf site. Numerous complaints arose thereafter from fisherman and divers that the fill was short-dumped and large areas of reef habitat had been covered. These sites had previously served as productive snapper/grouper fishing locations. EPA Region IV undertook a number of studies into this issue. EPA monitoring reports are available at http://www.epa.gov/region4/water/oceans/sites.htm#ftpierce. Reed (1996) summarizes information available at the time regarding the mud deposits potentially derived from this event.

Another documented example of dumping occurring outside the designated ODMDS occurred during the Charleston Harbor Deepening Project. A total of 53 documented incidents of unauthorized disposal activity outside the ODMDS were reported subsequent to dredging for the Charleston Harbor Deepening Project. The unauthorized dumps were first detected during a routine assessment of the ODMDS and surrounding area using side scan sonar (Jutte et al. 2001). The documented dumps placed large quantities of mud and clay on sandy bottom habitat, with some located very near hard bottom reef habitat. Subsequent surveys over a four year period to determine whether movement of material from these sites or the ODMDS was having an adverse impact on nearby reef habitats did not identify clear loss of habitat with the exception of one site located closest to the ODMDS. The abundance finfish and large sessile invertebrates, such as sponges and corals also did not appear to be adversely affected during the survey period (Crowe et al. 2006).

In areas that have been suspect of short-dumping, such as the ODMDS located offshore the Port of Miami, the EPA Region IV and NOAA Fisheries Service habitat office have developed additional permit conditions that include:
1. The permittee shall use an electronic positioning system to navigate to and from the ODMDS;
2. The permittee shall certify the accuracy of the electronic positioning system proposed for use during disposal operations at the ODMDS;
3. The permittee shall not allow any water or dredged material placed in a hopper dredge or disposal barge or scow to flow over the sides or leak from such vessels during transportation to the ODMDS;
4. A disposal operations inspector and/or the captain of any tug boat, hopper dredge, or other vessel used to transport dredged material to ODMDS shall ensure compliance with disposal operation conditions defined in this permit;
5. If the disposal operations inspector or the captain detects a violation, he or she shall immediately report the violation to the relevant county Seaport Department, the Corps of Engineers District, and to NOAA Fisheries Service;
6. When dredged material is disposed, no portion of the hopper dredge or disposal barge or scow shall be farther than 500 feet of the center of the ODMDS;
7. The permittee shall use an automated disposal verification system that will continuously track (1 minute intervals) the horizontal location and draft condition of the disposal vessel (hopper dredge or disposal barge or scow) to and from the ODMDS;
8. The required digitally recorded data should include: date, time, vessel name, dump number, beginning and ending coordinates of the dredging area for each load, location at points of initiation and completion of disposal, description of material disposed (rock rubble, sand, clay or silt), volume of load, and disposal technique;
9. The permittee shall conduct a bathymetric survey of the ODMDS within 30 days following project completion;
10. The number and length of the survey transects shall be sufficient to encompass the ODMDS and a 0.25 nautical mile wide area around the site. The transects shall be spaced at 500_foot intervals or less;
11. Vertical accuracy of the survey shall be ±0.5 feet; and
12. At the dredge site, barges must be either lashed to dredges or cables must be floated to avoid impact to submerged resources.

Similarly, at the Charleston ODMDS site a number of constraints similar to those used in Miami were adopted, and it also included limiting the barge traffic to areas that were outside know hard bottom habitat.

Even with the use of approved practices and disposal sites, ocean disposal of dredged materials is expected to cause environmental harm since contaminants will continue to be released, productive bottoms will still be buried, and localized turbidity plumes and reduced oxygen zones will persist. Further, analyses are needed for use in dump site designation. For example, there have already been observed cases (e.g., at Charleston) where dump sites were designated and then, after dumping had been initiated, it was determined that valuable hard bottom habitats were located in or near the dump site. However, at the Charleston Harbor site, while it was determined that valuable hard bottom habitat is located adjacent to the dump site, monitoring has confirmed that construction of a berm along the edges of the disposal site is containing the majority of the dredged material, with the exception of occasional missed targeting and these are generally in the vicinity of the adjacent channel from which the vessel is traversing.

The effects of new disposal techniques such as creation of nearshore berms and “beneficial uses” of dredged material such as creation of shallow water habitats and emergent wetlands are, in many cases, unclear and may cause long-term geomorphological and ecological change that is harmful to certain species and environments. In the Charleston ODMDS, the deepening project included the construction of large berms along the border of the ODMDS that were composed primarily of cooper-marl material that would stay in place. The logic for constructing these berms was to inhibit significant movement of the disposed material within the ODMDS to sensitive bottom habitats located nearby. This effort appeared to be successful based on subsequent monitoring activities (Crowe et al. 2006). The SAFMC recognizes offshore berm construction as a disposal activity. As such, its policies regarding disposal of dredged materials apply. The SAFMC also recommends that research should be conducted to quantify larval fish and crustacean transport and use of inlets prior to any consideration of placement of underwater berms. Until the impacts of berm creation in inlet areas on larval fish and crustacean transport are determined, the SAFMC recommends that disposal activities should be confined to an approved ODMDS. The SAFMC further believes that new offshore and near shore underwater berm creation activities should be reviewed under the most rigorous criteria and on a case-by-case basis.

In the absence of MPRSA and MPPRCA repeal or weakening, major dumping threats to EFH within federal waters should be limited mostly to illegal dumping and accidental disposal of material in unapproved locations. However, many agencies lack sufficient staff and funds to carry out mandated responsibilities and the opportunity for illegal and accidental dumping may be substantial. The effect of insufficient monitoring and enforcement is evident by the tons of debris, sometimes including hazardous materials such as syringes and medical wastes that are deposited along the nation’s beaches every year.

As noted in Section 7.4.2.1 the SAFMC has developed Policies for disposal of dredged material in waters under its jurisdiction. With regard to use of ODMDSs, the policy provides that:

- The ODMDS should be designated or re-designated so as to avoid the loss of live or hardbottom habitat and minimize impacts to all living marine resources.

- Notwithstanding the fluid nature of the marine environment, all impacts from the disposal activities should be contained within the designated perimeter of the ODMDS.
- The final designation of the ODMDS should be contingent upon the development of suitable management plans and a demonstrated ability to implement and enforce that plan.
- The Council encourages EPA to press for the implementation of such management plans for all designated ODMDSs.
- All activities within the ODMDS are required to be consistent with the approved management plan for the site. The Council's Habitat and Environmental Protection Advisory Panel when requested by the Council will review such management plans and forward comment to the Council. The Council may review the plans and recommendations received from the advisory sub-panel and comment to the appropriate agency.
- ODMDS management plans should specify those entities/ agencies which may use the ODMDS, such as port authorities, the U.S. Navy, the Corps of Engineers, etc. Other potential users of the ODMDS should be acknowledged and the feasibility of their using the ODMDS site should be assessed in the management plan.
- Feasibility studies of dredge disposal options should acknowledge and incorporate the ODMDS in the larger analysis of dredge disposal sites within an entire basin or project. For example, Corps of Engineers' analyses of existing and potential dredge disposal sites for harbor maintenance projects should incorporate the ODMDS as part of the overall analysis of dredge disposal sites.

6.1.2.3 Marine Debris

One of the more conspicuous byproducts of commercial and recreational boating activities in coastal environments is the discharge of marine debris, trash, and organic wastes into coastal waters, beaches, intertidal flats, and vegetated wetlands. The debris ranges in size from microscopic plastic particles (Carpenter et al. 1972), to mile-long pieces of drift net, discarded plastic bottles, bags, aluminum cans, etc. In laboratory studies, Hoss and Settle (1990) demonstrated that larvae of estuarine-dependent fishes including Atlantic menhaden, spot, mullet, pinfish, and flounder consume polystyrene microspheres. Investigations have also found plastic debris in the guts of adult tuna, striped bass, and dolphin (Manooch 1973; Manooch and Mason 1983). Based on the review of scientific literature on the ingestion of plastics by marine fish, Hoss and Settle (1990) conclude that the problem is pervasive. Most media attention given to marine debris and sea life has focused on threatened and endangered marine mammals and turtles, and on birds. In these cases, the animals become entangled in netting or fishing line, or ingest plastic bags or other materials. Recently, a 35-foot- long sperm whale stranded and died in North Carolina due to ingestion of a plastic float, plastic jugs, a large piece of rubber, 50 feet of nylon rope, and a large plastic bag (D. Engel, personal communication).

The production of plastic resin in the U.S. increased from 6.3 billion lbs in 1960 to 47.9 billion lbs in 1985. The increased production, utilization, and subsequent disposal of petro-chemical compounds known as plastics has created a serious problem of persistent marine debris. Marine ecosystems have, over the years, become the final resting place for a variety of plastics originating from many ocean and land-based sources including the petroleum industry, plastic manufacturing and processing activities, sewage disposal, and littering by the general public and government entities (commercial fishing industry, merchant shipping vessels, the U.S. Navy, passenger ships, and recreational vessels) (Department of Commerce 1988c).

Effective January 1, 1989, the disposal of plastic into the ocean is regulated under the Plastic Pollution Research and Control Act of 1987, implementing MARPOL Annex V. Recognizing worldwide concern for preservation of our oceanic ecosystems, the Act prohibits all vessels, including commercial and recreational fishing vessels, from discharging plastics in U.S. waters and severely limits the discharge of other types of refuse at sea. This legislation also requires ports and terminals receiving these vessels to provide adequate facilities for in-port disposal of non-degradable refuse, as defined in the Act.

The utilization of plastics to replace many items previously made of natural materials in commercial fishing operations has increased dramatically. The unanticipated secondary impact of this widespread use of plastics is the creation of persistent marine debris. Commercial fishing vessels have historically contributed plastics to the marine environment through the common practice of dumping garbage at sea before returning to port and the discarding of spent gear such as lines, traps, nets, buoys, floats, and ropes. Two types of nets are routinely lost or discarded drift gill nets and trawl nets (Department of Commerce 1988c). These nets are durable and may entangle marine mammals and endangered species as they continue to fish or when lost or discarded.

An estimated 16 million recreational boaters utilize the coastal waters of the United States (Department of Commerce 1988c). Disposal of spent fishing gear (e.g. monofilament fishing line), plastic bags, tampon applicators, six pack yokes, styrofoam coolers, cups and beverage containers, etc. is a significant source of plastic entering the marine environment.

In the mid 1970s, the National Academy of Science (NAS) estimated that approximately 14 billion lbs of garbage was disposed of annually into the world's oceans. Approximately 85% of total trash is produced from merchant vessels, with 0.7% of that total, or eight million lbs annually being plastic. The use of plastics has risen dramatically since the NAS study. In 1987, 20% of all food packaging was plastic and by the year 2000 this figure was expected to rise to 40% (CEE 1987).

The main contribution of plastic to the marine environment from cruise ships is the disposal of domestic garbage at sea. Ships operating today carry between 200 and 1,000 passengers and dispose of approximately 62 million lbs of garbage annually, of which a portion is plastics (CEE 1987).

The U.S. Navy operates approximately 600 vessels worldwide, carrying about 285,000 personnel and discharging nearly four tons of plastic refuse into the ocean daily (Department of Commerce 1988a). The U.S. Coast Guard and NOAA operate 226 vessels which carry nearly 9,000 personnel annually and have internal operating orders prohibiting the disposal of plastic at sea. MARPOL Annex V does not apply to public vessels although the Plastic Pollution Research Control Act of 1987 requires all Federal agencies to come into compliance by 1994 (CEE 1987).

6.1.2.4 Offshore Sand and Mineral Mining and Beach Fill

To date, offshore mining for minerals has not been a significant issue in the South Atlantic region (oil and gas mining is discussed separately). However, several pending proposals are under regulatory consideration. Earlier consideration of mining for manganese nodules and removal of useable materials and metals from seawater have not materialized, probably due to market conditions. Recent discovery of large phosphate deposits in waters off North Carolina could eventually lead to requests to mine these deposits. As readily available upland sources of minerals and other materials are depleted, the extraction of marine deposits will become more feasible and likely to occur. The mining of sand for beach nourishment presents a large, complex, and politically charged threat to EFH in the southeast. Between 1981 and 1996, the NOAA Fisheries Service reviewed more than 200 dredge proposals to nourish beaches. Between 1996 and 2006, NOAA Fisheries Service reviewed an additional 312 dredge proposals to nourish beaches. Most of these projects are large in scope and affect miles of coastline and nearshore habitats. Where sand is removed from nearshore environments, channels, and inlets, additional EFH alteration is possible due to a number of factors such as down drift erosion and removal of materials that eventually nourish shallow waters located behind barrier islands. A survey of 120 of the more than 200 beach nourishment projects received by the NOAA Fisheries Service showed that about 5,735 acres of aquatic sites were subject to excavation and filling.

The Federal Outer Continental Shelf (OCS) contains large sand deposits that MMS anticipates could serve as long-term sources of borrow material for beach nourishment projects. In the last few years, the potential for exploitation of these resources has rapidly grown with identification of suitable sand resource areas in some OCS regions. At the same time, the demand for high quality sand suitable for beach nourishment, coastal protection, and other public and private projects is anticipated to increase during coming years (Hammer et al. 2004). However, the SAFMC is concerned that excavation of the offshore shoals could have significant adverse consequences to the shoreline and living marine resources.

<u>Potential Threats to EFH from Offshore Sand and Mineral Mining</u>

Potential threats include: removal of substrates that provide habitat for fish and invertebrates; creation (or conversion) of habitats to less productive or uninhabitable sites such as anoxic holes or silt bottom; burial of productive habitats in the vicinity of the mine site or in nearshore disposal sites (as in beach nourishment); release of harmful *or toxic materials either with actual mining, or in connection with machinery and materials used for mining; creation of harmful turbidity levels; and modification of hydrologic conditions that cause erosion of desirable habitats.*

Offshore mining of sand for beach nourishment has steadily increased along the South Atlantic coast. Presently, sand mining and beach nourishment activities are performed along the entire South Atlantic coast from North Carolina to Florida. Major projects include those at Wrightsville Beach, North Carolina; Myrtle Beach and Folly Beach in South Carolina; and many of Florida's beaches such as Palm Beach, Boca Raton, Fort Lauderdale and Miami Beach. Large-scale beach nourishment has also been performed at Tybee Island in Georgia; however, the material for that project was obtained from the Savannah Harbor deepening project. In addition to the larger projects that can involve millions of cubic yards of material, a substantial number of smaller projects involving beach scraping and removal of nearshore and inlet sand deposits are performed annually. While most of the larger projects are publicly funded and performed by the COE, many of these smaller projects are paid for with local revenues and/or private funds.

Although some of the environmental effects of sand mining and beach nourishment are documented there is much that is not known or studied (National Research Council 1995). NOAA Fisheries Service and the FWS began raising questions over related effects as long as twenty years ago. In North Carolina and South Carolina concern over nearshore populations of mole crab (*Emerita talpoida*) and donax (*Donax spp.*) was raised with several projects. Although frequently requested, no long term studies on impacts to these and other beach fauna were ever performed. The fate of these species, from a population perspective, is of concern since they are important food items for transitory and resident fishes (e.g., Florida pompano, kingfishes, and spot) that are of economic and recreational importance (Hackney et al. 1996). Limited studies performed by Reilly and Bellis (1978) showed significant reductions in occurrence and biomass of mole crabs and Donax at nourished beaches. Considering that many miles of southeastern beach front are now filled and/or subjected to scraping and sand relocation each year the cumulative effect of this activity could be substantial. Reviews of numerous beach nourishment projects suggest that the overall infaunal communities recover relatively rapidly (months to less than 1yr) although some species may remain adversely affected (NRC 1995). Much depends on the compatibility of the material placed on the beach relative to what was present prior to the project.

In Florida, beach nourishment projects require the dredging and filling of millions of cubic yards of fine sediments among shallow cross-shelf habitats, repetition or these activities at 3-10 year intervals, and tens of millions of dollars in annual expenditures (ACOE 1996). A U.S. Fish and Wildlife report (2004) prepared pursuant to Resolution 4 from the 8th Coral Reef Task Force meeting held on October 2-3, 2002, in San Juan, Puerto Rico, concluded that projects involving filling and dredging for beach nourishment and port development have caused the most impacts to coral reef habitats in southeast Florida since 1985. Among mid-shelf sand plains, often having nearby reef habitats, dredges create large craters and increased turbidity. At both dredge and fill sites, acres of shallow water hard bottom, worm reef, seagrass, or other habitats can be directly buried or subjected to elevated turbidity. Nearshore reefs buried or indirectly affected by dredging in south and central Florida can be utilized by over 325 invertebrate species (Nelson 1989), 190 fish species, and serve as nursery habitats for many managed species (Lindeman et al. 2000). The timing of burial and anthropogenic turbidity spikes may have important effects upon the recruitment of settlement-stage fishes and invertebrates. Early spring through early fall dredge related burial of hard bottom may eliminate habitat required by larvae of many marine organisms during peak recruitment periods (Hackney et al. 1996; Lindeman and Snyder 1999).

Based primarily on summary tabulations of data for southeast Florida within ACOE (1996), Lindeman (1997) estimates that:

- At least 47 large-scale offshore dredge and inshore fill projects have occurred since 1960.
- Approximately 97 additional large-scale dredge projects are conservatively planned to occur between 1997 and 2046.
- Over 48,000,000 cubic yards of offshore sediments have been dumped within an intertidal/subtidal corridor of approximately 500 feet x 110 miles in the last 36 years.
- Over 80,000,000 additional cubic yards of excavated offshore material may be dumped within the same corridor of subtropical southeast Florida in the next 50 years.

Long-term estimates of mean turbidity values under natural conditions are not available for most areas. Therefore, the percentages of affected animals and algae that can tolerate repetitious (e.g., 2 to 4 hours to 4 to 6 times a day for three months) sedimentation and elevated turbidity events (that may approximate continuous three-month storms), are unknown. With exception of hurricanes, highly turbid nearshore conditions in southeast Florida are typically the product of winter storms and heavy runoff during the rainy season. Near Miami, Florida turbidity in the nearshore hard bottom habitat is highly variable, and affected by winds, longshore currents, swell condition and upland runoff. Summer-fall months normally show lower turbidity levels of 1-4 NTUs (Nephelometric Turbidity Units) and winter-spring months show higher average levels (3-7 NTUs) (Miami-Dade DERM unpublished). Direct effects of dredging activities on corals have been discussed by Marszalek (1981), Goldberg (1988) and Blair et al. (1990). Although sublethal effects of elevated turbidity are poorly known in tropical marine environments, some information is available. Bak (1978) showed that a relatively short period of dredge-induced turbidity stress created an abrupt decrease in growth in two species of hard corals (*Agaricia* and *Madracis*). From both the magnitude and duration of suppressed calcification, he concluded that such metabolic shock may have long-term consequences on reproduction. Long-term resuspension of bottom sediments has been shown to adversely affect an important hard coral, *Montastrea annularis* (Dodge et al. 1974). Teleniski and Goldberg (1995a; 1995b) have recently demonstrated negative effects of sediment loads on hard corals at turbidity levels of approximately 18 NTUs. This is noteworthy, as the Florida state administrative threshold for temporary shut-downs of dredge operations is substantially higher (29 NTUs). Such work is needed for other taxa and would provide a scientific basis for maximum turbidity thresholds (Goldberg 1988; Teleniski and Goldberg 1995b). Herrnkind et al. (1988) demonstrated that increased siltation can cause direct loss of critical habitat for spiny lobster recruitment. Enhanced resuspension of sediments over time and chronic turbidity may lower key growth and reproduction rates of some algal and invertebrate populations which are a basis for primary and secondary production on an ecosystem scale (Lindeman 1997b). The potential for management decisions to multiply over time and impact unintentionally large spatial scales is of concern (Odum 1982; Rothschild et al. 1994) and is particularly relevant when affected species are also over harvested (Ault et al. in press).

Adopting 15 NTU above background as a threshold level for turbidity in Florida and other areas where waters are naturally not turbid is supported by sound science and appropriate for the following additional reasons:

1. Research associated with investigations by Telesnicki and Goldberg (1995) examined the effects of turbidity measured as an absolute value. In southeast Florida, turbidity standards are based on relative conditions (i.e., above background conditions);
2. We do not have adequate statistical competency to conclude that turbidity monitoring stations would be positioned in a manner that would capture the densest portion of the turbidity plume. Inherent risks associated with this warrant adoption of a more conservative threshold level; and
3. Although elevated turbidity levels may not directly or instantaneously kill corals, construction-induced turbidity may have long-term adverse impacts on corals (e.g., reduced reproductive health) that cannot be detected without carefully designed long-term monitoring.

In other areas of the southeast where waters are more naturally turbid and sensitive bottom fauna such as reef habitat are not present, a higher NTU criteria may be desired. For example, the South Carolina Department of Health and Environmental Control has adopted a threshold of 25 NTU for impaired versus non-impaired estuarine and marine waters. While monitoring of turbidity plumes associated with beach nourishment operations in South Carolina have been limited, Van Dolah et al. (1994) monitored sediment plumes associated with a beach nourishment operation on Folly Beach, South Carolina to determine the both the amount and extent of turbidity. During calm seas, values of about 100NTU were measured in the surf zone at the pipeline outfall. Turbidity levels dropped to less than 50 NTU in the upcurrent direction over a fairly short distance (less than 200 m), and more slowly in the downcurrent direction 500-1000 m. Under more turbulent conditions of strong winds and rough seas, turbidity levels increased to over 200 NTU directly in front of the pipeline and higher turbidities were documented over a larger extent of the beach. However, turbidities in South Carolina's surf zone are naturally turbid, and turbidity values of about 100NTU were occasionally recorded at a reference beach in the Folly Beach study.

In addition, resource management agencies are examining the value of integrating Acoustic Current Doppler Current Profile (ADCP) technology into water quality monitoring protocols. ADCP is an instrument with capability of collecting acoustic backscatter data through the full depth of the water column and has demonstrated utility in other projects, especially in areas that are characterized by shifting currents (e.g., a project in Long Island Sound in which ADCP was utilized in the turbidity monitoring program in order to accurately locate the plume so that targeted water column sampling could be accomplished). We note that the nature of a plume in open water can be highly variable both spatially and temporally and can be further complicated by winds and seas. Therefore, to overcome these challenges and position the monitoring in the right place at the right time, full depth profiling with ADCP may be essential to the integrity of the monitoring performed. Use of third party environmental inspectors for water quality monitoring has also been included in recent large scale offshore construction project Corps of Engineers permits.

The SAFMC is concerned that excavation of the offshore shoals could have significant adverse consequences to the shoreline and living marine resources. Between 1995 and 2006, the Minerals Management Service (MMS) provided approximately 14 million cubic yards of material from the Outer Continental Shelf (OCS) for 9 coastal projects in Florida (8) and South Carolina (1). Although many offshore shoals have not been thoroughly studied with respect to fish utilization, SAFMC believes the shoals serve as a benthic nursery area, refuge, and feeding ground for a variety of fishery resources. The SAFMC identifies sandy shoals as EFH for migratory pelagic fish, including king mackerel, Spanish mackerel, cobia, and dolphin. Clarke et al. (1988) and Michel et al. (2001) note the geomorphology of offshore shoals provide a unique assembly of micro-habitats that facilitate high biological productivity.

The MMS and Corps of Engineers are evaluating the St. Lucie Shoal (located offshore St. Lucie and Martin Counties, Florida) as a potential excavation site for beach renourishment in Dade and St. Lucie Counties. Anecdotal evidence suggests that the shoal is biologically unique and diverse, supporting fisheries that are economically and recreationally important, such as the migratory species listed above, sailfish, and prey species consumed by these fishery species.

In South Carolina, a survey of multiple sites dredged for beach nourishment purposes identified that most sites were slow to refill (average of 7 yrs among 5 sites) and generally refilled with non-beach compatible material (Van Dolah et al. 1998).

The SAFMC is concerned that mining shoals for sand may alter the local wave climate bringing about erosion that could affect EFH. Through an evaluation of the potential impacts from dredging linear shoals in the U.S. Gulf and Atlantic continental shelves, Hayes and Nairn (2004) concluded that the deflation of a shoal feature could change wave patterns between the shoal and the shoreline. In turn, such dredging could change longshore and cross-shore sand-transport patterns and erosion and accretion rates along the shore. Kelley et al. (2004) verified this conclusion in their examination of a borrow site offshore Martin County (depths were approximately 8 to 10 m), and recommend application of wave transformation numerical modeling tools that recognize the random nature of incident waves as they propagate onshore when examining incremental and cumulative changes from sand dredging on the continental shelf.

Furthermore, the SAFMC is concerned that excavation of nearshore borrow areas in addition to the placement of fill in nearshore areas could adversely affect hardbottom reefs in the area that are known to support corals and worm reefs colonized by *Phragmatopoma lapidosa*. Nearshore hardbottoms and worm reefs are also identified as EFH and HAPC by the SAFMC. These reefs reduce wave energy and stabilize shorelines (Kirtley 1967; Kirtley and Tanner 1968) and provide structural habitat for hundreds of fishery organisms (Gore et al. 1977; Nelson 1989; Lindeman and Snyder 1999). Avoidance and minimization of impacts to hardbottom resources is needed. Due to the importance of these concerns, SAFMC recommends that MMS and the COE continue to coordinate closely with the NOAA Fisheries Service Habitat Conservation Division to ensure the EFH assessments and NEPA documents contain sufficient detail to support federal decision making.

Other offshore mineral and mining does not presently occur along the South Atlantic coast. Extensive phosphate deposits have been located in Onslow Bay in North Carolina and large quantities of mineral nodules containing manganese and other metals are abundant along the continental shelf floor. It is reasonable to conclude that mining of these and other materials could become economically feasible. If initiated, mining of marine bottoms would cause substantial bottom disturbance that could impact productive hard bottom communities, shellfish beds, and wintering grounds for demersal fish. Since related port and processing facilities do not presently exist, new mooring and dockside facilities would be needed and related secondary impacts would be expected. These impacts are discussed in detail in Section 7.4.2.1 of this document.

6.1.2.5 Oil and Gas Exploration, Development, and Transportation

Extensive areas of the South Atlantic have been designated and blocked off for oil and gas development. Prior to 2003, this activity had been relatively dormant, unlike the pipelines and liquefied natural gas (LNG) facilities that proliferate in the Gulf of Mexico. Initial exploration in the vicinity of Cape Hatteras several years ago did not advance due to environmental and other concerns including consistency issues associated with North Carolina’s Coastal Zone Management Program. As of this writing, interest in the potential for renewed oil and gas exploration off North Carolina is again being considered. Environmental Impact Statements have been prepared for Mid-Atlantic Sale 121 and South Atlantic Sale for the exploration of oil and gas offshore of Cape Hatteras, North Carolina. Should gas or oil be found, the laying of pipe to North Carolina’s shoreline facilities would likely have to traverse barrier islands and associated wetlands. As oil and gas levels decline, exploration will undoubtedly resume and if economically viable reserves are located, this activity could expand and inshore and offshore EFH could be at risk.

There are currently three natural gas pipeline proposals in Florida that propose to construct pipelines from the Bahamas to southeast Florida. Between 1996 and 2006, NOAA Fisheries Service reviewed 548 applications and support documents associated with pipelines in the South Atlantic area. The NOAA Fisheries Service Southeast Region Habitat Conservation Division (HCD) office is engaged in three separate EFH consultations for natural gas pipeline projects proposed to be constructed from southeast Florida to the Bahamas. One of three projects (AES Ocean Express) has received Department of the Army (DA) authorization and a Federal Energy Regulatory Commission (FERC) license to proceed with construction. However, to our knowledge, all of these projects are still awaiting the necessary approvals from the Bahamian government.

One pipeline company (Calypso), recently filed an application with the U.S. Coast Guard to construct a deepwater port located approximately 5 to 10 off the eastern coast of Florida to the northeast of Port Everglades in a water depth of approximately 640 to 950 feet.

<u>Potential Threats to EFH from Oil and Gas Exploration, Development, and Transportation</u>

Potential threats include elimination or damage to bottom habitat due to drill holes and positioning of structures such as drilling platforms, pipelines, anchors, etc., water intake and impacts to ichthyoplankton, release of harmful and toxic substances form extracted muds, oil, and, gas and from materials used in oil and gas recovery; discharges of potentially large volumes of drilling fluids (muds) used during the well drilling process and produced (brine) water from the extraction phase; damage to organisms and habitats due to accidental spills; damage to fishing gear due to entanglement with structures and debris; and damage to fishery resources and habitats including deep water habitats, due to anchoring and effects of blasting (used in platform support removal); and indirect and secondary impacts to nearshore aquatic environments affected by product receiving, processing, and distribution facilities.

The various threats to EFH that would result from natural gas pipeline installation and construction depend on project location and construction methods proposed. Horizontal directional drilling was one of the primary nearshore construction methods evaluated, but eventually ruled out due to concerns that pertain to frac-outs, which are generally caused when the drill head moves through an area of unconsolidated sediments. Frac-outs are typically monitored through monitoring the hydrostatic pressure differential. Considering that frac-outs can occur anywhere along or near the pipeline route, pressure monitoring alone was not sufficient in areas that support reef. Frac-outs can occur as a slight release of mud or an uncontrolled flow of drilling muds.

According to Stauber et al. (2003), with sufficient geotechnical information it is possible to calculate a maximum allowable borehole pressure curve for a given HDD bore profile. Using this information, preliminary bore plans could be developed that provide reasonable assurance that the bore could be completed without incident. Therefore, SAFMC recommends that pipeline applications include an HDD Risk Analysis to ensure that the bore paths identified are the least likely to contribute to a frac-out.

Other threats to EFH could occur as a result of offshore dredging of exit pits and direct burial of resources through the pipeline placement, movement, and/or articulated concrete mats which are typically proposed for use in water depths of less than 200 feet for pipeline stabilization. In addition, drilling muds and the use of additives, such as Envis (a mixed metal hydroxide) or StaFlo (a polyanionic cellulose) are commonly used during drilling operations to control drilling mud flow and fluid loss. Another potential threat is hydrostatic testing which is typically proposed to verify that the pipeline was properly installed and structurally sound. Chemicals may be proposed for use in hydrostatic testing and can include corrosion inhibitors, biocides, oxygen scavengers, and leak detection dye that would be used for pipe treatment and as seawater additives.

Another nearshore construction approach involves tunneling, which is preferred over HDD but has not been tested yet in nearshore areas of southeast Florida. Tunneling poses less risk to the marine environment because it may be possible to conduct operations independent of weather and it reduces or eliminates the risk of frac-outs because the operation is conducted under much less pressure and at greater depths. However other issues are still being evaluated, such as the potential for localized slumping or heave, tunnel failure, a higher probability of a frac-out near the tunnel exit location, and hydrostatic testing, as mentioned above.

To date, only one deepwater LNG port has been proposed in the South Atlantic. However, the Federal Energy Regulatory Commission has received three applications (including Calypso) to construct pipelines from southeast Florida to the Bahamas. To date, none of the applications has received approval from the Bahamian government to construct regassification facilities. Therefore, SAFMC is concerned about the potential for multiple deepwater ports to be proposed offshore southeast and east-central Florida. The September 2006 Calypso application states that approximately 273 acres of deepwater habitats could be impacted as a result of anchoring activities. Benthic organisms may be adversely affected from direct crushing and disturbance of sediments in the immediate vicinity of the anchors. The Calypso LNG terminal is proposed to be located on or adjacent to the Miami Terrace, which is a proposed deepwater coral HAPC. Hardbottom and coral resources found along the Miami Terrace and Escarpment are identified as EFH and HAPC by the SAFMC. Reed et al. (2006) characterized the fauna on the Miami Terrace and Escarpment as consisting of gorgonacean octocorals, colonial scleractinian corals (including thickets of *Lophelia pertusa*, *Madrepora oculata*, and *Enallopsammia profunda*), stylasterine hydrocorals, and Antipatharia. Diverse populations of the sponges Hexactinellida and Demospongia also occur along the Miami Terrace and Escarpment. In addition, based on studies conducted for the Calypso Pipeline Final Environmental Impact Statement, side-scan sonar results from the area show highly reflective signatures, which suggests the substrate is hardbottom mixed with medium carbonate sands and silty sands.

Unlike the open loop LNG facilities proposed and in operation in the Gulf of Mexico, the Calypso LNG facility is proposed to be a closed loop system (it should be noted, however, that Calypso could have chosen to use open loop regasification technologies and, given cost considerations, so might any other LNG company that looks at the Atlantic coast off Florida). Open loop systems use seawater for the regasification of LNG and water intakes can exceed 100 million gallons of water per day. However water intake associated with closed loop systems is only for engine cooling and can range from approximately 30-60 million gallons per day depending on the number, type, and duration of vessels at Port. With the closed loop system proposed in the South Atlantic, the discharge water would be approximately 13 degrees Fahrenheit warmer than the intake water.

Applications for LNG facilities should adequately consider potential impacts to fishery resources and the project's proximity to the Gulf Stream. The conditions and flow of the Gulf Stream are variable on time scales ranging from two days to entire seasons. Important spawning locations can occur along the Gulf Stream front (e.g., *Coryphaena*, *Xiphius*) (SAFMC 1998). Movement of the Gulf Stream front also affects the distribution of adult fishes (Magnuson et al. 1981); hook-and-line fishermen and longliners target much of their fishing effort in these frontal zones.

Biological and economic analyses of impacts related to impingement and entrainment of the various life stage histories of fishery resources are needed to allow the SAFMC, public, and NOAA to assess the costs of lost fisheries production from the water intake/discharge component of the Calypso LNG deepwater port. Such examinations should include detailed comparisons of the environmental impacts and environmental costs of alternative closed-loop regasification technologies to understand more fully the potential impacts to fishery resources. Analyses should be based on an assumption of 100% zooplankton mortality that would result from water intake, unless the applicant can show applicable studies demonstrating otherwise. In addition, surveys of the ichthyoplankton communities within project areas are needed because in many areas, including water off Fort Lauderdale, there are no site-specific data regarding ichthyoplankton resources. Such surveys should be designed to provide a quantitative assessment of the impacts to fishery resources. In addition, the surveys should be designed to support the monitoring of impacts from port operations on fishery resources so that adjustments to those operations can be made in a timely manner. Although the continental shelf of the South Atlantic Bight has been the focus of moderate interest for exploration of oil and gas resources, there are presently no ongoing related activities in the region with exception of that mentioned above.

In addition to what is presented above and considering the current status of the industry, a brief overview of the facilities that might be emplaced on the Outer Continental Shelf (OCS) to facilitate oil and gas exploration, development, and production is also presented. This includes drilling vessels (jack-ups, semi-submersibles, and drill ships), production platforms, offshore moored terminals, and pipelines.

Oil and gas related activities are inherently intrusive and pose a considerable level of threat to marine and estuarine ecosystems, including EFH. As discussed below, exploration and recovery operations may cause substantial localized bottom disturbance. Where large scale development is undertaken the area of impact may be greatly expanded and become regional in scale. The toxic nature of hydrocarbon products and certain drilling materials (e.g., drilling muds), spill cleanup chemicals, and the large volume of unrefined and refined products that must be moved within the coastal zone places large areas and resource bases as risk.

Structure emplacement can be expected to disturb some bottom area and, if anchors are deployed, the area of disturbance could be expanded. Jack-up rigs and semi-submersibles are generally used in water depths not exceeding 400 meters and disturb about 1.5 ha (3.7 ac) of bottom each. Conventional fixed platforms are also employed where water depths are less than 400 meters and they disturb about 2 ha (4.9 ac). Where water depths exceed 400 meters, dynamically-positioned drill ships may be used and sea floor disturbance is usually limited to the well site. Tension leg platforms may also be employed at these depths and the potential bottom disturbance area associated with these structures is about 5 ha (10.25 ac).

Each exploration rig, platform, terminal, and pipeline emplacement on the OCS can be expected to disturb surrounding areas. Exploration rigs, platforms, and pipe laying barges use an array of eight 9,000 kg anchors to position a rig and barge, and to move the barge along the pipeline route. These anchors are continually moved as the pipe laying operation proceeds and the total area actually affected by the anchors will depend on water depth, wind, currents, anchor chain length, and the size of the anchors and chain (MMS 1996). With conventional, fixed multi-leg platforms, which are anchored to the sea floor by steel pilings, explosives are generally used to sever conductors and pilings. These support structures are substantial in size since they must withstand hurricane conditions and have an average lifespan of about 20 years. The Minerals Management Service requires severing support structures at five meters below the sea floor surface so as to preclude interference with commercial fishing operations.

Possible injury to biota from use of explosives extends horizontally to 900 meters from the detonation site, and vertically to the surface. Based on MMS data, it is assumed that approximately 80% of removals of conventional fixed platforms in the Gulf of Mexico, in water less than 400 meters in depth, will be performed with explosives (MMS 1996). Alternative methodologies such as mechanical cutting and inside burning are often ineffective and are hazardous to workers.

Associated bottom debris commonly associated with over water oil and gas operations includes cable, tools, pipe, drums, assorted trash, and structural parts of platforms. The amount of bottom debris deposited around a site may vary and may be measured in tons. Extensive analysis of remotely-sensed data within developed lease blocks indicates that the majority of ferromagnetic bottom debris falls within a 450 meter radius of the site. The Fisherman's Contingency Fund, which was established by the oil and gas industry, provides recourse to commercial fishing interests for recovery of equipment losses due to shrimp net entanglement (MMS 1996).

Blowouts occur when improperly balanced well pressures result in sudden, uncontrolled releases of petroleum hydrocarbons. Blowouts can occur during any phase of development: exploratory drilling, development drilling, production, or workover operations. About 23% of all blowouts will have associated oil spills, of which 8% will result in oil spills greater than 50 barrels, and 4% will result in spills greater than 1000 barrels. In subsurface blowouts, sediment will be resuspended and bottom disturbance will generally occur within a 300 meter radius. Whereas larger grain sediment will settle first, fined grained material may remain in suspension for periods of up to thirty days or longer. Fine grained material may be redistributed over a significantly large area depending on the volume of sediment disturbed, bottom morphology, and currents (MMS 1996).

The major operational wastes associated with offshore oil and gas exploration and development include drilling fluids and cuttings, and produced waters. Other important wastes include: from drilling--waste chemicals, fracturing and acidifying fluids, and well completion and workover fluids; from production--produced sand, deck drainage, and miscellaneous well fluids; and from other sources--sanitary and domestic wastes, gas and oil processing wastes, ballast water, storage displacement water, and miscellaneous minor discharges (MMS 1996). Major contaminants or chemical properties of materials used in oil and gas operations may include those that are highly saline; have a low ph.; contain suspended solids, heavy metals, crude oil compounds, organic acids, priority pollutants, and radionuclides; and those which generate high biological and chemical oxygen demands. Pierce et al. (1980) documented that wild fish have been injured by petroleum pollutants. Grizzle (1983) suggested that larger liver weights in fish collected in the vicinity of production platforms versus control reefs could have been caused by increased toxicant levels near the platforms. He also suspected that severe gill lamella epithelium hyperplasia and edema in red snapper, vermilion snapper, wenchman, sash flounder, and creole fish were caused by toxicants near the platforms. These types of lesions are consistent with toxicosis.

Accidental discharge of oil can occur during almost any stage of exploration, development, or production on the OCS or in near shore base areas. Oil spills may result from many possible causes including equipment malfunction, ship collisions, pipeline breaks, human error, or severe storms. Oil spills may also be attributed to support activities associated with product recovery and transportation. In addition to crude oil spills, chemical, diesel, and other oil-product spills can occur with OCS activities. Of the various potential OCS-related spill sources, the great majority are associated with product transportation activities (MMS 1996).

As of this writing, only test wells have been drilled in the South Atlantic Bight area and these have been confined to inshore areas. All of these wells were capped immediately after drilling. No production or transportation facilities such as offshore terminals and pipelines have been built, nor are any such facilities currently planned in South Atlantic

Bight waters. Despite this, millions of barrels of crude oil and refined product transit South Atlantic Bight waters by tank vessel every year and the potential exists for the discharge of thousands of barrels of oil due to vessel collision or sinking. Discharge of untreated ballast water from transiting vessels is also a chronic low level source of petroleum-based pollution.

6.1.2.6 Commercial and Industrial Activities

Direct physical encroachment into offshore environments by industrial activities is relatively limited along the South Atlantic seaboard. Notable exceptions include thermal intake and outfall structures associated with power plants in North Carolina and Florida, and sea walls that are used to protect commercial and industrial development. Several municipal sewage outfalls which discharge commercial and possibly light industrial wastes also exist. Although direct physical impacts may be minor on a regional scale, water quality effects are largely unknown. Indirect effects, such as those associated with point and nonpoint-source discharges are thought to be substantially greater since it has been shown that discharges, including trash and debris, from land based activities may reach coastal waters and food webs.

Commercial development for hotels, motels, and related infrastructure along the South Atlantic shoreline has been extensive. Because many of these developments are located on unstable and shifting coastlines, maintaining associated buildings, revetments, bridges, causeways, beaches etc. has, and will continue to have an adverse effect on nearshore and offshore processes and environments.

<u>Potential Threats to EFH from Commercial and Industrial Activities</u>
Potential threats include: direct and/or non-point-source discharge of chemicals, placement of intake structures, and protective sea walls (often used in connection with commercial establishments), and cumulative and synergistic effects caused by these and other industrial and non-industrial related activities.

Future exploration and recovery of marine resources and placement of offshore mooring and unloading facilities could substantially threaten offshore EFHs. Although none of these activities or facilities are presently being planned, it is likely that continued economic growth, depletion of limited natural resources, and use of limited coastal lands will eventually lead to greater exploitation of offshore resources.

Electric power generation is needed for commercial and industrial development, and for residential purposes (See Section 4.1.1.4). Between 1996 and 2006, NOAA Fisheries Service evaluated 85 proposals to construct new or expand existing electric generation facilities. When located in coastal waters, power generation facilities may adversely affect EFH and associated biota. Potential threats include direct displacement of wetlands, submerged bottoms, and vegetated upland buffer areas for generation facilities and ancillary uses such as fossil fuel storage, cooling towers, and water intake and outfall structures; construction of navigation channels and docks for unloading coal, oil, and other materials needed for operation of generators and equipment; discharge of toxic substances from air emissions; cooling waters (e.g., chlorine); and from point and nonpoint-source discharges emanating from impervious surfaces and coal and slag piles; discharge of thermal discharges that may be lethal to flora and fauna, or that serve as attractants that subject fish, invertebrates, and marine mammals to thermal stress when changes in plant operation or weather occur; and entrainment and impingement of living marine resources in which organisms succumb to or are damaged as a result of entrapment in intake structures or capture on screens.

An example of an electric power generation plant and threats to EFH is the Florida Power and Light's Turkey Point Power Plant, located along Biscayne Bay in Dade County Florida, which directly impacted over 24 acres of estuarine emergent wetlands, including mangrove wetlands, seagrass, and open water habitat in order to construct a natural gas-fired electric generating facility to provide electricity to meet the projected 2007 demand in southeast Florida. An additional 10.7 acres of wetlands were impacted through secondary effects. The wetlands at the subject site are high quality, uncommon, and provide direct benefits to the fishery resources of Biscayne Bay. The bay's extensive seagrass beds, mangrove wetlands, and hardbottom communities support a diverse array of fishes and invertebrates including over 512 species of fishes and over 800 species of invertebrates which have widely variable environmental requirements for growth and reproduction.

Although relatively minor in its present scale, the commercial harvest of *Sargassum* from coastal waters off North Carolina is of concern. *Sargassum* weed lines and associated frontal zones provide cover, trophic, and other attributes needed to sustain endemic fish and invertebrates of the pelagic *Sargassum* community and associated fauna. The weed lines may be especially important during early life stages of sea turtles and certain fish and they are important sites for the North Carolina and South Carolina offshore recreational fishery.

The occurrence of methyl mercury in the flesh of the large piscivorous fish such as king and Spanish mackerel and other large pelagic and demersal species such as amberjack, wahoo, snapper, and grouper has been documented and is of concern largely with respect to human consumption of these species (D. Engel, personal communication). The probable source of these contaminants is atmospheric input from worldwide inventories associated with emissions from incinerators, fossil fueled power plants, automobiles, and industry. As such, the regulation of surface water contamination from atmospheric pollution may require local, regional, and international efforts.

Effects related to commercial development are similar to those from urban and suburban development and the discussions in Section 4.1.1.4 apply. Further, effects of shoreline modifications such as beach nourishment are found in Section 4.1.2.3.

6.1.2.7 Artificial Reefs

Artificial reef construction in the South Atlantic has substantially increased over the last 10 years. Project scales range from single family homeowners applying to place reef balls under docks for lobster recruitment to 3,000 acre areas located in offshore areas. Project applications typically state that the purpose of the project is to "further develop three artificial reef sites to increase the marine flora and fauna within the area for local fishermen and SCUBA divers without detriment to the existing reef structures or fish populations." However, artificial reefs are also constructed to replace natural reef habitats. Construction at the larger scale sited typically involves the placement of a variety of materials including concrete, limestone boulders, submerged vessels, and other approved items.

Potential Threats to EFH from Artificial Reefs

Potential threats to EFH include permanent conversion of one habitat type to another, introduction of predators, possible increased fishing activity and relic gear on structures.

Although the SAFMC recognizes and appreciates applicant's efforts to provide additional marine habitat, information regarding the level of impact this project would have on EFH resources is needed in the application process. This information need includes a thorough assessment of environmental impacts and details concerning its design and specifications. The type of information that should be contained in an artificial reef application includes:

- It should be demonstrated that the project will provide enhanced marine fisheries habitat. This may be achieved through (but not limited to):
  - Identifying the specific fisheries and life history stages that will be enhanced by the proposed work.
  - Demonstrating a clear link between the structural design and the fisheries the artificial reef will support.

- The applicant should demonstrate full consistency with NOAA's *National Artificial Reef Plan* (1985) and the draft plan revision (2001)[1], including, but not limited to, the following provisions:
  - Demonstrated consistency with the applicable state's artificial reef plan (e.g., the State of Florida's Artificial Reef Plan). Through this, the applicant should:
  - Have a specific objective for fisheries management or other purpose stated in the goal of the statewide, or site-specific plan;
  - Have biological justification relating to present and future fishery management needs;
  - Have minimal negative effects on existing fisheries, and/or conflicts with other uses;
  - Have minimal negative effects on other natural resources and their future use;
  - Use materials that have long-term compatibility with the aquatic environment;

[1] National Artificial Reef Plan (revised 2001). National Marine Fisheries Service. Available on-line at: http://www.nmfs.noaa.gov/irf/Revised_PLAN_11_16.pdf

    - Conduct monitoring during and after construction to determine whether the reef meets permit terms and conditions and is functioning as anticipated.
- The applicant should ensure that the proposed artificial reef structure will not threaten the integrity of natural habitats in the area, including live/hardbottoms, corals, seagrasses, and macroalgae;
- The application should verify that any vessels deployed have been cleaned in accordance with Environmental Protection Agency Guidelines;
- The constructed reef should remain stable during a 100-year storm event;
- The applicant should identify the most extreme sea state and wave surge conditions under which work will be undertaken; and
- An entity should be identified to demonstrate the capability of assuming long-term financial liability for the deployment, biological and stability monitoring, and maintenance of the artificial reef.

Artificial reefs can serve as effective fishery management tools (when coupled with additional fishery management measures, for example the designation of no-take zones) to attract fish and, in some situations, mitigate for anthropogenic and natural damage to coral and hardbottom reefs. The SAFMC concurs with the leading artificial reef researchers in this region (see Bohnsack 1989) that artificial reefs are unlikely to benefit heavily exploited or overfished populations without other management actions. Conversely, if not properly sited they may have only minimal habitat value and could even degrade existing reef resources if placed on or in close proximity to such habitats. Artificial reefs are also constructed as mitigation reefs. A U.S. Fish and Wildlife report (2004) prepared pursuant to Resolution 4 from the 8th Coral Reef Task Force meeting held on October 2-3, 2002, in San Juan, Puerto Rico, concluded that projects involving filling and dredging for beach nourishment and port development have caused the most impacts to coral reef habitats in southeast Florida since 1985. The 26 Florida projects (16 completed; 10 pending) reviewed in this report impacted 217 acres of reef, and mitigated with 113 acres of artificial reef. However, a study is needed that would provide information as to impacts to hard bottom communities of shoreline projects, including whether proposed mitigations are adequate to offset the environmental impacts of the activities. General practice in Florida is to permit mitigation for shallow hard bottom communities in deeper waters is contributing to a substantial net loss of the shallow communities and related functions.

6.1.2.8 Alternative Energy Technologies

Sections below excerpted from MMS Alternative Energy Synthesis report: Michel, J., Dunagan, H., Boring, C., Healy, E., Evans, W., Dean, J.M., McGillis, A. and Hain, J. 2007. Worldwide Synthesis and Analysis of Existing Information Regarding Environmental Effects of Alternative Energy Uses on the Outer Continental Shelf. U.S. Department of the Interior, Minerals Management Service, Herndon, VA, MMS OCS Report 2007-038. 254 pp. <u>*See Report for references in following sections.*</u>

Offshore wind turbines

An offshore wind farm is a set of turbines that generate electricity from the mechanical force that the wind imparts upon an object and are specifically designed for their oceanic location. Each modern oceanic turbine is capable of producing up to 4.5 megawatts of power (some older turbines installed in the 1990s produced less than 1 megawatt, newer turbines under development may produce 5 to 10 megawatts), and the hub of the turbine is 180 feet or more above the sea surface. Present proposals include systems with blades that will reach more than 510 feet above the sea surface. The number of turbines in a farm varies and will be affected by economics, space, and demand for the electricity generated. The number of turbines in proposed farms ranges from three units in a proposed research setting to over 150. The turbines need to be separated from each other by a distance of 0.25 mile or more in order to reduce the effect one turbine has upon the wind field experienced by adjacent turbines. Wind farms include a distribution platform that serves as a hub for the cables that collect power from each turbine and the fewer, but larger, cables that carry the power to shore.

A recent study conducted by the Minerals Management Service (MMS 2007) cites the following as the current primary economic and technical feasibility determinants that affect the choice of sites for offshore wind parks:

- Availability of a substantial, relatively constant wind resource
- Shallow water (less than 30 meters deep)
- Proximity to an area of high electricity consumption
- Distance to shore

Water depth is a critical design element that currently limits installation in deeper waters because of technology and economic constraints. Existing wind parks in Europe are installed in very shallow water (up to 15 m deep). Most North American wind resources are in water greater than 30 m deep, requiring development of economically feasible new technologies for wind turbine structures that can withstand wave and wind action in deeper areas (MMS 2007).

In addition to the water depth limitations of technology as of 2007, significant economic concerns are associated with the distance from shore and the length of subsea electrical cable required to reach the onshore electrical grid. Although available wind turbine designs allow installation in waters less than 30 m deep, wind parks operating in Europe are in shallower coastal areas (water depths of approximately 15 m). In the United States, wind parks are likely to be developed along the Atlantic seaboard and the Gulf of Mexico (MMS 2007).

The Cape Wind project offshore of Massachusetts and the Long Island Offshore Wind Park (LIOWP) offshore New York are in the environmental impact statement (EIS) stage, and other projects are planned along the northern and central U.S. coast. In addition, two leases have been granted by the State of Texas to develop wind parks off the coastline of Padre Island and Galveston Island. Additional projects are in the early planning stages along the U.S. east coast and Gulf of Mexico (MMS 2007).

Potential threats to EFH from Offshore Wind Turbines

Operational characteristics of each turbine design and its size are influenced by the minimum sustained winds occurring in an area and needed to make the wind farm profitable. Studies from the northeastern U.S. conclude a minimum wind speed of 16 mph or more is needed, studies from the southeastern U.S. conclude wind speeds of 11 to 13 mph are sufficient (Stewart 2005). Analyses are not simple; wind persistence, direction and natural turbulence can limit a turbine's ability to produce electricity even though its blades are spinning. Analyses must also consider the efficiency of the turbines and the number of days in a year when the wind reaches or exceeds the minimum speed required to produce electricity. Other factors that influence the feasibility of establishing a wind farm include proximity to an established electrical grid and water depth, because market availability and water depth affect construction cost. Some authorities suggest 180 feet is a maximum depth; developers of the wind farm off Cape Cod, MA, actively sought waters less than 50 feet deep. Lloyd's Insurance has set 12 fathoms as their insurance risk limit. The occurrences of high winds are an issue since they can damage the turbine systems. Wind speeds that cause the blades to rotate above 14 revolutions per minute trigger most systems to shutdown.

In the United States, there are no offshore wind farms in operation, although six projects are currently being considered (Dennehey 2006; Ludwig 2006). Two are off the coast of Cape Cod, MA, two of the coast of Texas, one off the coast of Long Island, NY, and one is being considered off the Pacific Northwest Coast. Evaluations of the general environment off North Carolina and Georgia by universities conclude that wind farms warrant further investigation in these areas (Halks et al. 2005; Stewart 2005). Offshore wind farms have been established in Europe, especially in Denmark, and business forecasts indicate additional farms are likely due to tax and business incentives that focus on renewable energy (Danish Energy Authority 2005, see also http://home.planet.nl/~windsh/offshoreplans.html).

There are three general designs currently in use for anchoring turbines to the sea bottom, and the design chosen affects the extent of the environmental impacts (Danish Energy Authority 2005). A gravity foundation uses a large base (much broader than the pylon) with supplemental mass being placed on the base structure to anchor the pylon on the seafloor. A monopile base is a piling driven deep into the sea floor to create the stable anchor and is similar in diameter to the pylon itself; monopiles are currently used in water depths up to 60 feet. Multi-pole bases consist of piling systems similar to those used in small offshore oil and gas platforms; pilings are driven into the sea bottom over an area that is broader than the pylon that supports the turbine and the pylon is attached to a framework and platform that links the pilings. When commenting on a proposal by Cape Wind Associates for a wind farm on Nantucket Sound, MA, NOAA Fisheries Service indicated a preference for the 46-ft diameter, monopole design because it impacts less sea bottom and fishing gear is less likely to snag on this type of structure. Research being done in Europe is examining the feasibility of floating foundations and hybrids between monopile and gravity foundations that will allow farms to be located in deeper water without requiring a foundation that occupies a large amount of sea bottom. One of the wind farms proposed for New York plans to investigate the stability of a jack-up barge as its base, and the wind farms proposed for Texas are exploring use of oil and gas platforms that are no longer needed by the petroleum industry.

Long-term impacts to coastal ecosystems from wind farms are unclear because only a few offshore wind farms have existed for more than 10 years. However, all the wind farms recently constructed or authorized in Europe include substantial monitoring programs, so lack of data should not remain a problem for long. U.S. Army Corps of Engineers (2004) and the Danish Energy Authority (2005) provide initial lists and summaries of the impacts that can be expected from an offshore wind farm and the latter also provides Internet links to Web sites planned for distributing future study results.

Direct impacts to coastal ecosystems include usurpation of seafloor habitat(s) by the pilings, distribution platforms, and cables that connect the turbines to the onshore power grid. Especially when the monopile design is used, the cumulative area impacted is small; for example, Cape Winds Associates estimates the pylons from their farm of 130 turbines would occupy less than one acre of sea bottom. Construction equipment impacts during cable and system installations would add to this acreage. Direct effects to the sea bottom also may occur from alteration of current fields moving past the foundations, but these impacts to be manageable in most circumstances.

The most obvious affect of the pilings on marine biota will be from the structures serving as fish habitat. Many fish are attracted to any structure that provides relief from the otherwise featureless sea floor. Benthic organisms, which may adhere to a pylon or its base, depending on local conditions and construction materials, may add to the attractiveness of the structure to fish. Although unlikely to be an issue, there is some concern that electromagnetic fields (EMF) may disrupt the movements of sharks and other aquatic resources that navigate by sensing the earth's electromagnetic fields. Wind farms can transmit direct current, which has a greater capacity than alternating current to create localized EMF. Recent research indicates the severity of this impact may be small. Vibrations transmitted from the structures and systems to the water column and affecting the behavior of fish is a concern but not much is known about the severity of this impact. Monitoring in Europe has not found evidence of either EMF or vibration impacting aquatic resources (Ludwig 2006). Indirect impacts to marine biota may result from wind farms shifting navigation away from preferred routes into areas where marine mammals or fishery resources are more concentrated. The Federal Aviation Administration and military have recently identified that wind farms create a shadow effect on near ground, tracking radars.

Socioeconomic impacts have been controversial. Many members of the public object to the expected deteriorations in the vistas caused by the wind farms as well as wind farms occupying preferred fishing grounds. However, the Europeans have experienced a sharp increase in eco-tourism at their wind farm sites. The public also has been focused on impacts to seabirds, although impacts to birds seem uncommon based on preliminary evidence (Danish Energy Authority 2005).

Ocean current technology

(Excerpted from MMS 2007 report)
Ocean current technology is similar to wind technology, only underwater. Instead of wind, ocean current pushes turbine blades to transfer kinetic energy. Similar to wind turbines, the blades of the current turbines move at a very slow speed. For example, one type of design has vertical turbine rotors that rotate 10 to 30 revolutions per minute, which is approximately 10 times slower than ship propellers. Although the rotors move slowly, they produce a significant amount of energy because of the density of water moving them.

In the United States, no operating commercial systems using ocean current technology are connected to an electrical grid at this time (MMS 2006). However, the technology to harness ocean current energy as an alternative energy source is in the developmental stage. Demonstration and pilot studies of different prototypes are taking place throughout the world. Marine current velocities are lower than those of wind, but because water is 835 times denser than air, a 3-knot current has the kinetic energy of 161 km/h wind. The total potential energy contained in marine currents worldwide is estimated at approximately 5,000 GW (MMS 2006).

Available data indicate that current velocities between 2 and 5 meters per second (m/s) would be required to make ocean current energy technology economically viable at a particular site (MMS 2006).

In the United States, the most promising sources of ocean current energy include the Florida Current (part of the Gulf Stream) and the California Current (MMS 2006). These ocean current resources are located relatively close to shore and near centers of high electricity demand, making ocean current energy an attractive resource. In addition, ocean currents tend to be significantly more constant than wind resources, which can fluctuate greatly over relatively short periods of time.

A number of turbine designs exist, some of which have been through field testing while others are still in the development phase (MMS 2007). Florida Hydro is testing a disk-like design called the Open Center Turbine for use in the Florida Current (**Figure 6.1-1**).The moving parts of this technology are encased within the unit. Designed to produce 2.5 MW, the turbine was tested off Palm Beach, FL.

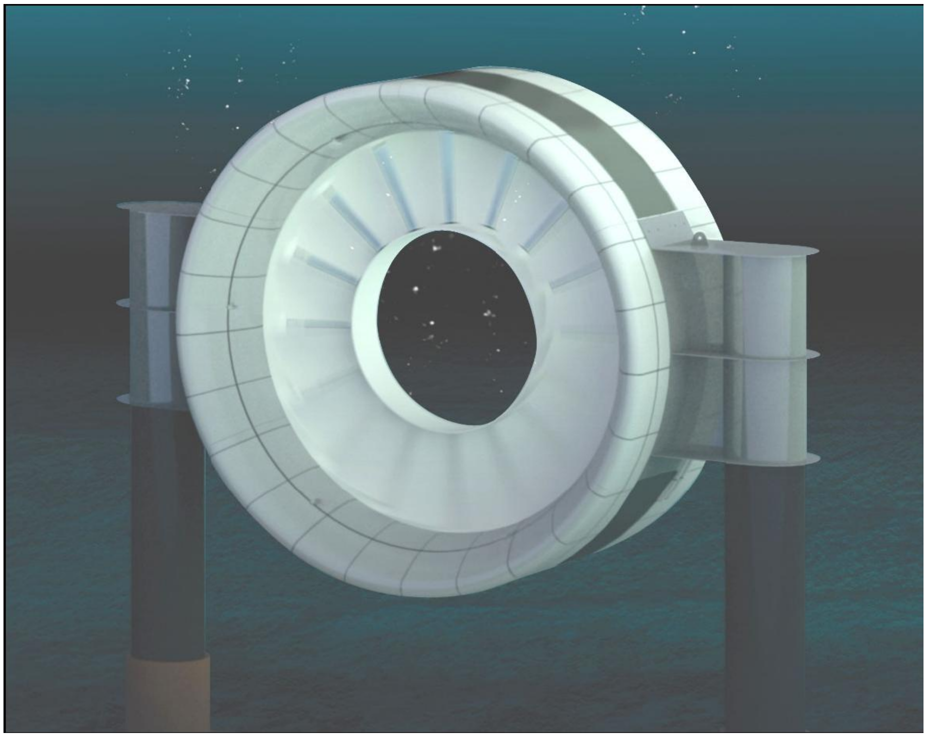

Figure 6.1-1. Open center current/tidal turbine with encased moving parts (Source: Open Hydro Group Limited).

Several other ocean current technologies are being developed. Those designs are tethered to the seabottom using anchors or on poles that extend from seabed foundations (ABP, 2004). These technologies are in the very early stages of development; however, they may be the most promising design for deeper, offshore applications on the OCS.

Solar technology

(Excerpted from MMS 2007 final report)
Solar energy technology has been producing useable energy from land-based, full-scale, grid connected power plants for more than a decade, but use of solar energy technology on the OCS is very limited. Economically feasible installation of full-scale solar energy projects on the OCS will depend on producing significant amounts of transmittable energy.

The possibilities for solar technology are not limited to large offshore solar plants; solar energy technology could be collocated with other alternative energy technologies. For example, solar collectors could be installed near the base of a wind turbine, and then used to augment energy output. Solar technology also could be installed as an alternative use for decommissioned oil and gas platforms on the OCS. Already some small, unmanned oil and gas platforms use solar panels for electricity needs. Solar panels are also used on buoys, platforms, and meteorological stations.

The potential for annual average solar power varies greatly by latitude and cloud cover; solar radiation is significantly greater in the lower latitudes. In the United States, solar radiation is greatest in southern parts of the country. A literature review yielded no information on solar radiation levels offshore and along the OCS (MMS 2006). However, unpublished solar radiation data may exist as shipboard information collected during routine or research operations.

Solar energy is converted into useable energy through two basic technologies: thermal and photonic. Thermal technologies convert solar energy to heat. Photonic technologies absorb solar photons, which are then converted into electricity through photovoltaic (PV) cells. Technology is also in the early stages of development to store the photonic energy as hydrogen for later use, rather than convert it directly to electricity (MMS 2006).

Some solar technologies use concentrating mechanisms to focus heat or photonic solar energy into a collector. Technology and application of concentrated PV are not as advanced as concentrated thermal technology, but it is under development. Concentrated PV and thermal systems use mirrors or lenses configured to concentrate solar radiation on receiving panels.

Current solar energy technology has limited application on the OCS. It is distributed only to power buoys, weather stations, and small, unmanned oil and gas platforms. A literature review revealed no solar energy projects on the OCS at any stage of planning or development. Any offshore solar energy project would need to be mounted onto some sort of large floating or fixed structure (MMS 2006). The number of solar panels, and therefore, the size of the structure necessary to support an offshore commercial solar energy facility would vary depending on the solar radiation level at the location, the orientation of the panels, and weather conditions.

Thermal solar technologies require dry, warm locations, and thus, current technologies likely would not be feasible on the OCS where humidity is high. PV solar technology surface area requirements also limit their application at OCS locations, where a floating platform would be required. Approximately 8 to 12 square meters is required for each kilowatt of capacity, meaning 0.8 to 1.2 hectares (0.008 to 0.012 km^2) of PV cells would be required for each 1 MW of power output (MMS 2006). Concentrated PV systems developed for thermal solar projects are in early development. Efficient concentrated PV technologies may increase the economic feasibility of OCS solar applications because PV is more effective in humid environments.

Hydrogen Technology

Hydrogen technology would be used on the OCS as a transport or storage mechanism for energy produced by one of the other alternative energy technologies (wind, wave, current or solar). No projects were identified at any stage of planning or implementation for this type of technology. The best source of information on the possibilities of using hydrogen technology for storage or transport of energy on the OCS is the MMS (2006) white paper.

Since the application of hydrogen technology is so undefined at this stage, and because there are no current plans or prototypes for OCS application, the potential impacts were not included in the MMS report (2007).

6.1.2.9 Non-native or nuisance species

Indo-Pacific Lionfish

Lionfish (*Pterois volitans/miles* complex) are venomous coral reef fishes from the Indian and western Pacific oceans, that are now found in the western Atlantic Ocean (Whitfield et al. 2002; Hare and Whitfield 2003; Meister et al. 2005; Ruiz-Carus et al. 2006; Whitfield et al. 2006). Adult lionfish have been observed from the Turks and Caicos Islands throughout the northern Bahamas and from Florida to Cape Hatteras, North Carolina, including Bermuda. There is also recent evidence to suggest that lionfish have been found near Tampa Bay, Florida in the Gulf of Mexico (Ramon Ruiz-Carus, pers. Comm.). Juvenile lionfish have been observed in increasingly high numbers off New Jersey, New York and Rhode Island, generally in the fall of the year. Lionfish reports from the public (beginning in 2000) combined with quantitative surveys conducted from Florida to North Carolina (2004-2006) suggest that the number of lionfish continues to increase along the east coast and their distribution is expanding both in the northern (juveniles in northeast) and southern range (Whitfield et al. 2006; Whitfield unpublished data). Due to the large geographic range now inhabited by lionfish this invasion is likely irreversible as removal of this invader across this region would be expensive and take unprecedented resources.

Introductions of marine species occur in many ways. Ballast water discharge is a very common method of introduction for marine invertebrates, and is responsible for many freshwater fish introductions. In contrast, most marine fish introductions have resulted from intentional stocking for fishery purposes. In the case of lionfish, all evidence points to an unintentional or intentional aquarium release (Hare and Whitfield 2003).

Currently no management actions have been taken to limit the effect of lionfish on the southeast United States continental shelf ecosystem. Under this scenario we predict that; 1) the lionfish population and geographic range will continue to increase; 2) as a result of this increasing abundance, the impacts of lionfish on the southeast United States continental shelf ecosystem will become more noticeable; 3) eventually, human impacts from lionfish ‘stings’ will occur along the southeast United States coast (Hare and Whitfield 2003; Whitfield et al. 2006).

The introduction and success of lionfish along the east coast may change the long-held perception that marine fish invasions are a minimal threat to marine ecosystems. The magnitude of this invasion as a stressor on marine ecosystems presently has not been quantified, but NOAA scientists have made a great deal of progress in understanding the lionfish introduction into the Western Atlantic. We have also made significant inroads in our understanding of many aspects of lionfish biology and ecology including reproduction, diet, population demographics and genetics. This section summarizes the current state of knowledge regarding the Atlantic lionfish population within five main topic areas: 1) Description and Distribution, 2) Reproduction, 3) Development, growth movement patterns and genetics, 4) Ecological relationships/Potential Impact and 5) Abundance and status of the stock.

Description and Distribution

The Indo-Pacific lionfish (*Pterois volitans/miles* complex, Scorpaenidae) is a venomous predator (Halstead 1970) native to the sub-tropical and tropical regions of the South Pacific, Indian Oceans and the Red Sea (Schultz, 1986). Lionfish are generally well known and recognized as a popular aquarium fish. Lionfish have venomous dorsal, anal, and pelvic spines, similar to other members of the family Scorpeanidae. The venomous spines are not known to be used in prey capture but are generally thought to be for self-defense and male/male agonistic displays during spawning (Fishelson 1975).

The present distribution (October 2006) of Indo-Pacific lionfish within the Atlantic is from southeast Florida to North Carolina, including Bermuda, the Bahamas, Turks and Caicos and along the northeast U.S. shelf as juveniles. Lionfish may have originated off the east coast of Florida in the early 1990's, but the actual source of the lionfish invasion remains unknown. In 2000, lionfish were first reported in North Carolina and Bermuda. In 2004, lionfish were first reported in the Bahamas, and in 2006 they were reported in the Turks and Caicos. Public reports combined with quantitative surveys suggest that both the number and geographic extent of the population continues to grow (Whitfield et al. 2006).

Within their native range lionfish are found on coral reefs and rocky outcrops from the surface to 50 meters (Schultz 1986). Within the South Atlantic Bight lionfish are widespread in abundance, found on all types of habitat (low relief hard bottom to high relief artificial structures) within water depths from 115 to 300 ft deep (Whitfield et al. 2006). By all accounts lionfish were already established (reproducing and dispersing) by the time the first surveys were conducted in 2004 and lionfish captures by hook and line are also on the rise within the past two years but these captures still vastly under-represent the extent of the lionfish population within the Atlantic. The large geographic extent of the lionfish distribution and the speed with which they occupied this area (since 2000) suggest they are very successful colonizers and competitors within their 'new' ecosystem (Atlantic).

At present the primary factors that can potentially limit their distribution are available habitat, availability of prey and winter bottom water temperatures. Both habitat and prey appear to be plentiful, especially with the potential increase in prey resources made available through overfishing of many grouper species (likely competitors for prey) (Huntsman et al. 1999; NMFS 2004). Thus the minimum bottom water temperatures remain the single most important factor in controlling the present lionfish distribution within the Atlantic. This is not only evidenced by the shift in depth distribution from their native habitat (shallower) to the Atlantic (deeper) but also by winter bottom water temperature data collected in both nearshore (colder) and offshore (warmer; Gulf Stream influenced) locations (Whitfield et al. 2002; Whitfield et al. unpublished data). Minimum winter bottom water temperatures collected from locations where lionfish are known to over-winter support the thermal minimums found in laboratory studies (Kimball et al. 2004). Based on laboratory thermal minimums, lionfish would not survive water temperatures that dip below 10º C (Kimball et al. 2004). In North Carolina, this equates to an inshore depth limit of approximately 80 to 90 ft, depending on winter temperatures overall. Nevertheless, lionfish can still recruit into shallower areas but they are not expected to over-winter in shallow water (less than 80-90ft) north of Florida (see Figure 5, Kimball et al. 2004). However, since the thermal tolerance of fishes is known to change with changes in fish size and age (Wootton 1992), a series of mild winters could interact with the advancing size and age of Atlantic lionfish, eventually establishing subpopulations inshore of those currently surveyed. Therefore, the actual inshore limit remains unresolved off the Mid-Atlantic states. At their southern limit (southeast Florida, Bahamas, Turks and Caicos and Gulf of Mexico) there are no such depth or temperature constraints as water temperature remains warm year round. Thus lionfish have been reported in water depths as shallow as 3 ft in the Bahamas and Jacksonville, FL (Ruiz-Carus et al. 2006).

It is important to mention that although connectivity between the Bahamas and the Caribbean is low, there are certain locations such as the Turks and Caicos where connectivity is higher (Cowen et al. 2006). Since lionfish have free-floating eggs and larvae even minimal larval connectivity from the southeast U.S. and Bahamas could lead to invasion of the Caribbean and the Gulf of Mexico through a stepping-stone effect (Carr & Reed 1993; Cowen et al. 2006).

Reproduction

Lionfish can be characterized as gonochoristic, iteroparous, asynchronous, indeterministic batch spawners. This mode of reproduction is consistent with other members of the *Pterois* and *Dendrochirus* genera. Lionfish appear to be summer spawners off North Carolina with a resting period lasting throughout the winter. The lionfish spawning season is likely to increase at the southern range of their distribution (i.e., Florida/Bahamas).

From observations in the Red Sea, Fishelson (1975) has reported that lionfish are pair-spawners exhibiting a complex courtship during mating. Laboratory and shipboard observations indicate that lionfish release two buoyant egg balls during each spawning event consisting of a batch fecundity of approximately 30,000 eggs. Lionfish eggs are released while encased in a gelatinous mucus which breaks apart releasing the developing embryos within 48 hours. Lionfish do not exhibit sexual dimorphism; however, males do grow significantly larger than females. Sex ratio of lionfish in the Atlantic is approximately 1:1. Female lionfish appear to be sexually mature within two years of age corresponding to approximately 150 mm standard length (Morris, J.A., Jr., pers. comm.).

In their native range lionfish are reported as being solitary defending their home range against conspecifics; groups were typically observed only during mating (Fishelson 1975). In contrast within the Atlantic, lionfish are regularly found in groups, but, to our knowledge no mating behavior has been observed (Whitfield, pers. obs.).

Development, growth, age, movement patterns and genetics

The early life history stages of lionfish are poorly known. Mito and Uchida (1958) and Fishelson (1975) describe the development and early larval stages of congenerics, while Imamura and Yabe (1996) describe five *P. volitans* larvae collected in the water column off of northwestern Australia. Lionfish settle from the water column to benthic habitats at about 10-12 mm. Laidig and Sakuma (1998) reported a larval growth rate of 0.3 mm d-1 for *Scorpaena*, a genus in the same family as lionfish, Scorpeanidae. Using this growth rate, the estimated planktonic larval duration (PLD) of lionfish is 25 to 40 d, which means that larvae may be in the water column and susceptible to transport by ocean currents for approximately one month. However, confirmation of PLD specific to *P. volitans* is needed as PLD can vary widely, even within members of the same genus (Victor 1986).

In 2004, a total of 149 lionfish were collected off North Carolina for life history analyses, These ranged in length from 5 to 45 cm (average length = 30.5 cm) and in weight from 25 to 1380 grams (3 lbs) with average wt of 480 grams. Several lionfish collected in this study were larger (45 cm) than the reported maximum length from their native range (38 cm) (Schultz 1986; Randall et al. 1997; Myers 1999), suggesting that lionfish growth along the southeast U.S. is not resource limited (Elton 1958). The growth rate of lionfish in the Atlantic or in their native habitat remains unknown.

Although preliminary, analyses of annual zones on sagittal otoliths suggest that the lionfish population off North Carolina is relatively young, (max. age 7 years old; 43 cm specimen). If confirmed, these results would support our general timeline of the invasion which we believe began around the year 2000, off North Carolina. However, age validation is still required to confirm this result.

As in most reef fishes, the major dispersal phase of lionfish probably occurs while eggs and larvae are in the plankton. The northward dispersal (i.e., from Florida to NC) of lionfish is thought to be greatly facilitated by the strong northerly flowing Gulf Stream currents. Dispersal further into the northeast is most likely facilitated by Gulf Stream eddies (e.g., cross shelf transport, Hare and Cowen 1996). Once settled to the benthos, observations from their native habitat suggest that lionfish exhibit site fidelity and do not migrate (Fishelson 1975, 1997; McBride and Able,1998.) In the Atlantic, however, the question of lionfish movement or migration, especially in response to cold water incursions, remains an important area of research but to date is unknown. If lionfish did move offshore in the winter in response to cold bottom water temperatures, this may increase their ability to survive thereby decreasing their natural mortality.

Genetics analyses of the Atlantic lionfish specimens revealed the presence of two closely related sister species *Pterois volitans* and *P. miles* within the Atlantic but 93.5% of collected specimens were *P. volitans*. We also found that the complexity of the haplotype network for Atlantic specimens was greatly simplified when compared to specimens in their native range. Twenty-eight different haplotypes were found within 43 native range *P. volitans* as opposed to 3 haplotypes within the 160 Atlantic *P. volitans* specimens. In addition, 95% of the Atlantic *P. volitans* shared the same haplotype. These data indicate a large decrease in genetic diversity within the Atlantic population most likely caused by a small founder population, but of no less than 3 female specimens. These data may indicate that a small release in the right environment can result in an invasion of impressive proportions.

Ecological relationships – Potential Impact

Within their native habitat the ecology of lionfish is not well known. A few studies on lionfish found they consumed a wide variety of smaller fishes, shrimps and crabs (Fishelson 1975), and occupy the upper levels of the food chain (Fishelson 1997). Moreover, few predators of lionfish have been reported in their native range (but see, Bernadsky and Goulet 1991; Moyer and Zaiser 1981). Although, potential lionfish predators along the southeast United States have no experience with the venomous spines of the lionfish (Ray and Coates 1958; Halstead 1967) there are other native venomous fishes such as scorpionfishes (same family as lionfish) which are consumed by native predatory fishes (Randall 1967; Ebert et al. 1991; Roel and Macpherson 1998; Bowman et al. 2000). However, the potential role of predation in decreasing the number of lionfish is unknown, as is the effect of lionfish on predators.

Lionfish could impact native ecosystems through direct predation, competition and overcrowding. Preliminary data on the diet of Atlantic lionfish specimens suggest that they are primarily generalist piscivores, similar to their native counterparts. The Atlantic lionfish diet is comprised mainly of prey from a variety of fish families including members of the Serranidae, Pomacentridae, Labridae, Scaridae, Blenniidae, Bothidae, Carangidae, and Monacanthidae. Ninety eight percent of stomachs examined contained fishes, and other prey items (decapod crustaceans, cephalopod and bivalve mollusks) make up only a fraction of prey contents by volume (approx. 0.5 % or less). The small serranids (sea basses) were substantially more important in terms of volume than other families of fishes (41% vs. 15% and lower for other prey families) (Munoz et al. in prep). Since lionfish are opportunistic predators feeding primarily on smaller fishes, there is potential for trophic overlap with native fishes (Sano et al. 1984; Naughton 1985; Matheson et al. 1986; Fishelson 1997) such as groupers in the genus Mycteroperca. Groupers comprising this genus feed almost exclusively on fishes (Dodrill et al. 1993). In particular, gag (*Mycteroperca microlepis*) and scamp (*M. phenax*) groupers are present in significant numbers off the North Carolina coast and scamp occur at size classes that appear to overlap size classes of lionfish. Serranids form one of the most important food items in the scamp diet (Matheson et al. 1986) so similarly sized scamp and lionfish may be targeting similar prey. In addition, lionfish have been confirmed to prey upon scad (Carangidae), one of the dominant fish species in the diet of gag (Naughton & Saloman 1985). If these prey fishes are already or became a limiting resource, a growing lionfish population could negatively impact the scamp and gag populations via competition for food resources. The style of lionfish predation, (i.e., ambush predator) is not unique on southeast United States reefs and wrecks (e.g., red grouper, frog fish, scorpion fish), but the lack of experience of prey species may increase the predation efficiency of lionfish. Moreover, continued mortality of groupers and other native predators through overfishing

(Huntsman et al. 1999; NMFS 2004) may open niche space and further increase resources for lionfish (Davis 2000).

Lionfish may also affect the use of habitat by other species through physical overcrowding and aggressive tendencies. Lionfish are often described as 'standing their ground' and male-male aggression is extremely high prior to and during reproductive activities, during which lionfish will even threaten divers (Thresher 1984; Myers 1991). If this behavioral characteristic was extended towards other organisms in their introduced range, the threat might be expected to increase with lionfish abundance and potentially cause native species displacement into sub-optimum habitats (Schumacher and Parrish 2005; Taylor et al. 1984).

<u>Abundance and status of the stock</u>
The total population abundance of lionfish in the Atlantic is currently unknown. Quantitative surveys combined with public reports suggest the population is growing in number and increasing in geographic extent and may potentially colonize the entire Caribbean and Gulf of Mexico (Whitfield et al. 2006). Within the last two years quantitative surveys at the same nineteen locations off North Carolina (95 to 150 fsw) indicate that lionfish densities have doubled. Moreover, yearly surveys from the same nineteen locations, off North Carolina, suggest lionfish densities may be similar to many native fish species (i.e., *Cephalopholis cruentatus*, *Epinephelus guttatus*, *E. adscensonis*, *Mycteroperca interstitialis*, *M. microlepis*) (Whitfield et al. 2006). At this point there is every expectation that the total population and geographic extent of lionfish will continue to increase. More information is clearly needed to determine the status of the entire population, but traditional fishery sampling methods are not appropriate because lionfish are not captured effectively in this manner. More detailed information on the amount and type of benthic habitat within the southeast region combined with a random program of quantitative visual surveys over a broad geographic area (Bahamas to NC) will assist in estimating the total population size of lionfish.

Summary
The southeast United States continental shelf ecosystem is already undergoing change. Many important reef fish predators are overfished (Huntsman et al. 1999). In the Snapper-Grouper Management Unit of the South Atlantic Fisheries Management Council, approximately half of the stocks for which the status is known are classified as overfished. The reef fish fauna of the southeast United States continental shelf is also becoming more tropical (Parker and Dixon 1998). From the 1970's to the 1990's, the number of tropical species and the abundance of individual tropical species increased off the coast of North Carolina. Both of these large-scale changes favor the continued growth and dispersal of the lionfish population along the southeast United States. The effect of climate change, overfishing and invasive species have been implicated in ecosystem decline and collapse in several marine ecosystems, (Harris & Tyrrell 2001; Stachowicz et al. 2002; Frank et al. 2005). Along the southeast U.S. shelf the high number of stressors acting in synergism may eventually have unexpected and irreversible consequences for the native communities and economically valuable fisheries in this region.

6.1.3 Natural Events and Climate Change

Potential Threats to EFH from Natural Events and Climate Change

Potential threats: Coastal and inland storms can cause severe acute and chronic perturbations including habitat erosion, burial of habitat and organisms by sediment deposition; creation of strong currents that alter habitats and remove biota; damage by wind and waves; creation of turbidity levels that can cause physiological damage and disrupt feeding, spawning migration, and other vital processes; and abrupt changes in salinity and other water quality characteristics such as fecal coliform levels and harmful algal blooms. Long-term climatological changes, such as, changes in weather patterns and ocean currents, can bring about similar changes by increasing storm activity, changing fresh water inputs and salinity in coastal systems, increasing ocean acidification which affects coral reef building, and changing water column productivity that can affect certain fish population. For example, the Atlantic Multidecadal Oscillation can cause large scale ecological changes called regime shifts where temperature alterations favor or harm a particular species or group. Changes that cause relocation of frontal boundaries, weed lines, and stratification and temperature boundaries may also cause substantial and undesirable environmental change.

Coastal processes may be dramatically altered by natural events. These include short term events such as severe storms, hurricanes, floods, etc. Effects vary from potentially positive to catastrophic. For example, a moderate storm may provide needed freshwater, flush and recharge stagnant water bodies, and transfer nutrients from uplands and high marsh surfaces to tidal waters. On the other hand, shoreline erosion, wetlands destruction and subsidence and substantial changes in the structure of coral communities (e.g., Bythyell et al. 1993) are possible.

Hurricanes and other severe climatological events and change can drastically alter shorelines and associated environments including wetlands. Some changes may be positive such as the flushing of stagnant systems. However, wind induced erosion and overwash can remove and fill large areas of SAV and emergent wetlands. In overwash areas, newly created "uplands" are often quickly developed and stabilized and geomorphological processes that lead to rebuilding of wetlands and shallow water areas may be precluded. As storm activity increases in severity and regularity, emergency shoreline protection response threatens coastal nearshore habitats primarily through burial by beach restoration efforts. Littoral sand drift has interrupted by the development of stabilized inlet jetties, which has reduced sand budgets. Decreased sand budgets coupled with increased severe storm activity (a known result of increased rates of global warming) necessitate an increase in large-scale beach dredge and fill projects. The direct, secondary and cumulative effects of these activities are known to have a profound effect on EFH through burial of nearshore hard bottom, worm reef, coral reef and sand bottom habitat areas. Loss of habitat areas utilized by various life stages of federally managed species and their prey species will continue to have a negative effect. As the need for such projects increases and the time between projects decreases adverse effects will be amplified.

Hurricanes also cause vertical mixing in coastal waters that results in cooling and nutrient enrichment of surface water and stimulation of algal growth. In estuaries, hurricanes suspend sediment and increase terrestrial runoff that can result in algal blooms and hypoxia in bottom waters (NOAA 2005). Algal blooms and hypoxia can cause fish die-offs and spread disease to other plants and animals.

Climate Change

This section was excerpted from the *Summary Report for Policymakers* based on the assessment carried out by the three Working Groups of the Intergovernmental Panel on Climate Change (IPCC). It provides an integrated view of climate change as the final part of the IPCC's Fourth Assessment Report, released in fall 2007. A complete elaboration of the topics covered in this summary can be found in this Synthesis Report and in the underlying reports of the three Working Groups available online at (http://www.coastalclimate.org/).

<u>Observed changes in climate and their effects</u>

Warming of the climate system is unequivocal, as is now evident from observations of increases in global average air and ocean temperatures, widespread melting of snow and ice, and rising global average sea level (**Figure 6.1-2**)**.**

Eleven of the last twelve years (1995-2006) rank among the twelve warmest years in the instrumental record of global surface temperature (since 1850). The 100-year linear trend (1906-2005) of 0.74 [0.56 to 0.92]°C 1 is larger than the corresponding trend of 0.6 [0.4 to 0.8]°C (1901-2000) given in the Third Assessment Report (TAR) (**Figure 6.1-2**). The temperature increase is widespread over the globe, and is greater at higher northern latitudes.

Land regions have warmed faster than the oceans (**Figure 6.1-3**). Rising sea level is consistent with warming (**Figure 6.1-2**). Global average sea level has risen since 1961 at an average rate of 1.8 [1.3 to 2.3]mm/yr and since 1993 at 3.1 [2.4 to 3.8]mm/yr, with contributions from thermal expansion, melting glaciers and ice caps, and the polar ice sheets. Whether the faster rate for 1993 to 2003 reflects decadal variation or an increase in the longer-term trend is unclear.

Observed decreases in snow and ice extent are also consistent with warming (Figure SPM.1). Satellite data since 1978 show that annual average Arctic sea ice extent has shrunk by 2.7% (2.1 to 3.3) per decade, with larger decreases in summer of 7.4% (5.0 to 9.8) per decade. Mountain glaciers and snow cover on average have declined in both hemispheres.

From 1900 to 2005, precipitation increased significantly in eastern parts of North and South America, northern Europe and northern and central Asia but declined in the Sahel, the Mediterranean, southern Africa and parts of southern Asia. Globally, the area affected by drought has likely increased since the 1970s.

It is very likely that over the past 50 years: cold days, cold nights and frosts have become less frequent over most land areas, and hot days and hot nights have become more frequent. It is likely that: heat waves have become more frequent over most land areas, the frequency of heavy precipitation events has increased over most areas, and since 1975 the incidence of extreme high sea level has increased worldwide.

There is observational evidence of an increase in intense tropical cyclone activity in the North Atlantic since about 1970, with limited evidence of increases elsewhere. There is no clear trend in the annual numbers of tropical cyclones. It is difficult to ascertain longer-term trends in cyclone activity, particularly prior to 1970.

Average Northern Hemisphere temperatures during the second half of the 20th century were very likely higher than during any other 50-year period in the last 500 years and likely the highest in at least the past 1300 years.

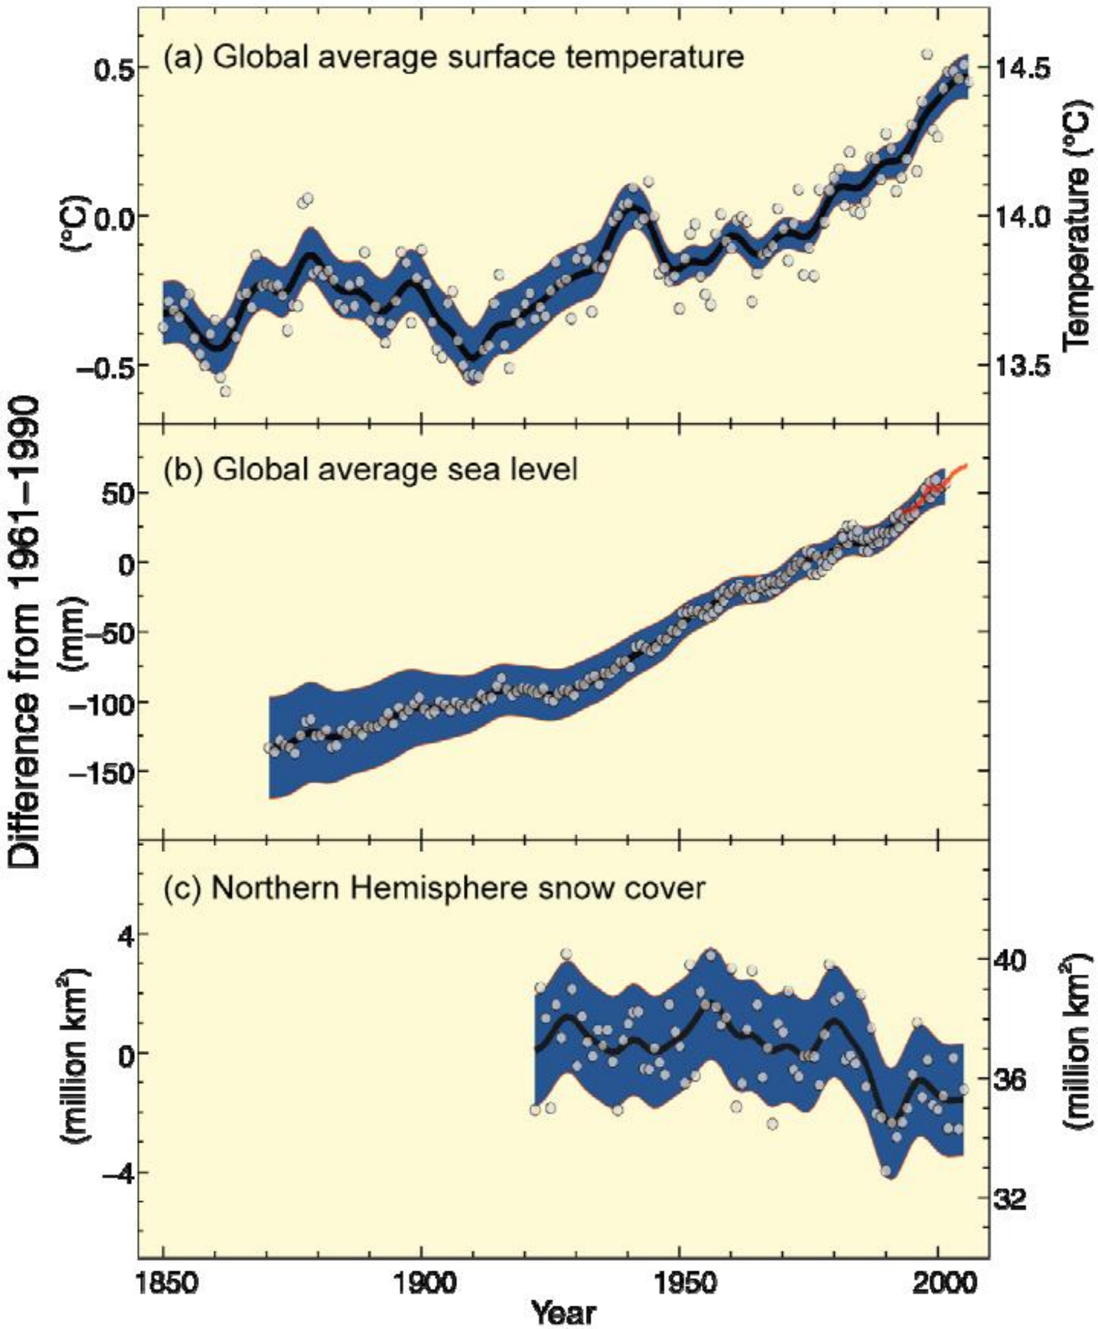

Figure 6.1-2. Observed changes in (a) global average surface temperature; (b) global average sea level from tide gauge (blue) and satellite (red) data and (c) Northern Hemisphere snow cover for March-April. All differences are relative to corresponding averages for the period 1961-1990. Smoothed curves represent decadal averaged values while circles show yearly values. The shaded areas are the uncertainty intervals estimated from a comprehensive analysis of known uncertainties (a and b) and from the time series (c).

Observational evidence from all continents and most oceans shows that many natural systems are being affected by regional climate changes, particularly temperature increases. Changes in snow, ice and frozen ground have with high confidence increased the number and size of glacial lakes, increased ground instability in mountain and other permafrost regions, and led to changes in some Arctic and Antarctic ecosystems.

There is high confidence that some hydrological systems have also been affected through increased runoff and earlier spring peak discharge in many glacier- and snow-fed rivers, and effects on thermal structure and water quality of warming rivers and lakes.

In terrestrial ecosystems, earlier timing of spring events and poleward and upward shifts in plant and animal ranges are with very high confidence linked to recent warming. In some marine and freshwater systems, shifts in ranges and changes in algal, plankton and fish abundance are with high confidence associated with rising water temperatures, as well as related changes in ice cover, salinity, oxygen levels and circulation.

Of the more than 29,000 observational data series, from 75 studies, that show significant change in many physical and biological systems, more than 89% are consistent with the direction of change expected as a response to warming. However, there is a notable lack of geographic balance in data and literature on observed changes, with marked scarcity in developing countries.

There is medium confidence that other effects of regional climate change on natural and human environments are emerging, although many are difficult to discern due to adaptation and non-climatic drivers. They include effects of temperature increases on:

- agricultural and forestry management at Northern Hemisphere higher latitudes, such as earlier spring planting of crops, and alterations in disturbance regimes of forests due to fires and pests
- some aspects of human health, such as heat-related mortality in Europe, changes in infectious disease vectors in some areas, and allergenic pollen in Northern Hemisphere high and mid-latitudes
- some human activities in the Arctic (e.g., hunting and travel over snow and ice) and in lower-elevation alpine areas (such as mountain sports).

<u>Causes of change</u>

Changes in atmospheric concentrations of greenhouse gases (GHGs) and aerosols, land-cover and solar radiation alter the energy balance of the climate system.

Global GHG emissions due to human activities have grown since pre-industrial times, with an increase of 70% between 1970 and 2004. Carbon dioxide (CO_2) is the most important anthropogenic GHG. Its annual emissions grew by about 80% between 1970 and 2004. The long-term trend of declining CO_2 emissions per unit of energy supplied reversed after 2000.

Global atmospheric concentrations of CO_2, methane (CH_4) and nitrous oxide (N_2O) have increased markedly as a result of human activities since 1750 and now far exceed pre-industrial values determined from ice cores spanning many thousands of years. Atmospheric concentrations of CO_2 (379ppm) and CH_4 (1774 ppb) in 2005 exceed by far the natural range over the last 650,000 years. Global increases in CO_2 concentrations are due primarily to fossil fuel use, with land-use change providing another significant but smaller contribution. It is very likely that the observed increase in CH_4 concentration is predominantly due to agriculture and fossil fuel use. Methane growth rates have declined since the early 1990s, consistent with total emissions (sum of anthropogenic and natural sources) being nearly constant during this period. The increase in N_2O concentration is primarily due to agriculture.

There is very high confidence that the net effect of human activities since 1750 has been one of warming.

Most of the observed increase in globally-averaged temperatures since the mid-20th century is very likely due to the observed increase in anthropogenic GHG concentrations. It is likely there has been significant anthropogenic warming over the past 50 years averaged over each continent (except Antarctica) (Figure SPM.4).

During the past 50 years, the sum of solar and volcanic forcings would likely have produced cooling. Observed patterns of warming and their changes are simulated only by models that include anthropogenic forcings. Difficulties remain in simulating and attributing observed temperature changes at smaller than continental scales.

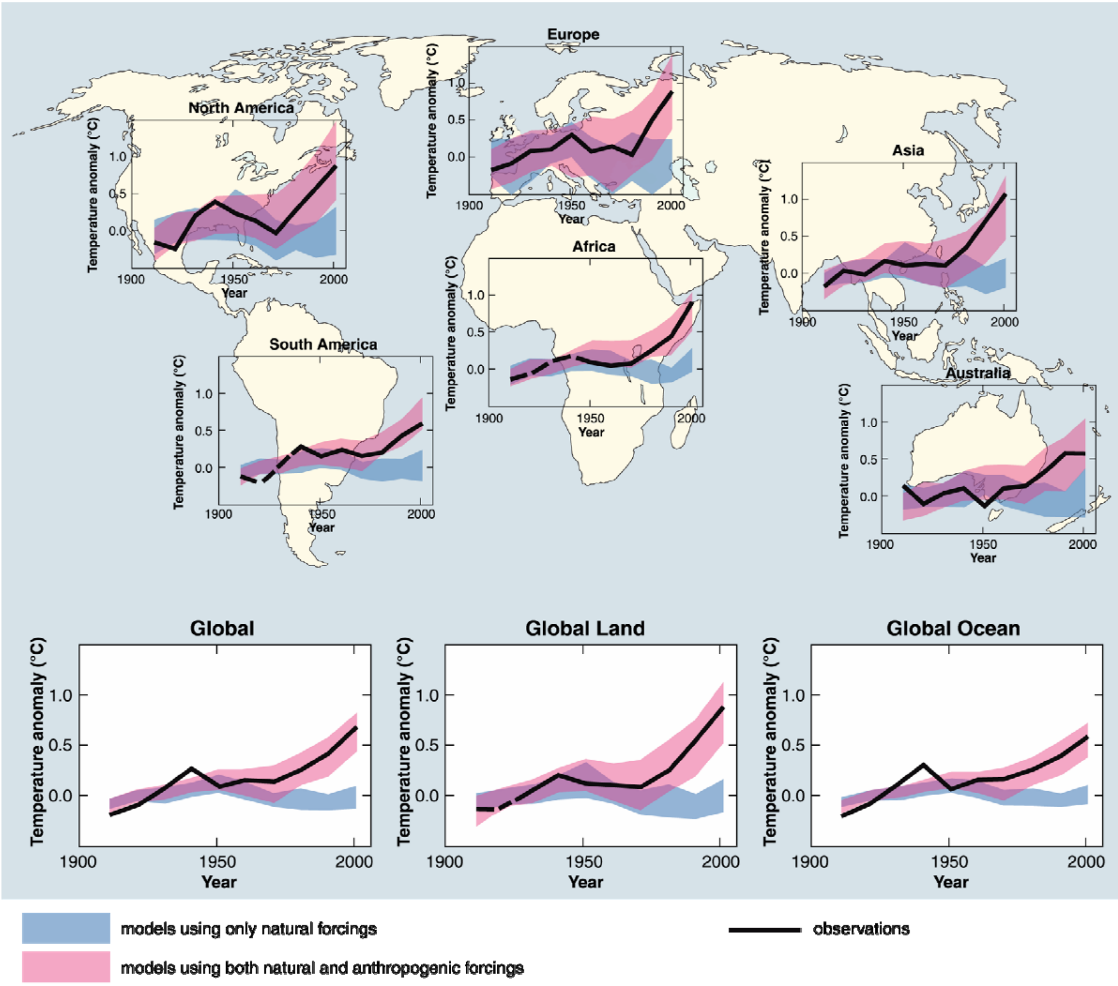

Figure 6.1-3. Comparison of observed continental- and global-scale changes in surface temperature with results simulated by climate models using either natural or both natural and anthropogenic forcings. Decadal averages of observations are shown for the period 1906-2005 (black line) plotted against the centre of the decade and relative to the corresponding average for the period 1901-1950. Lines are dashed where spatial coverage is less than 50%. Blue shaded bands show the 5-95% range for 19 simulations from 5 climate models using only the natural forcings due to solar activity and volcanoes. Red shaded bands show the 5-95% range for 58 simulations from 14 climate models using both natural and anthropogenic forcings.

Advances since the TAR show that discernible human influences extend beyond average temperature to other aspects of climate.

Human influences have:

- very likely contributed to sea level rise during the latter half of the 20th century
- likely contributed to changes in wind patterns, affecting extra-tropical storm tracks and temperature patterns

- likely increased temperatures of extreme hot nights, cold nights and cold days
- more likely than not increased risk of heat waves, area affected by drought since the 1970s and frequency of heavy precipitation events.

Anthropogenic warming over the last three decades has likely had a discernible influence at the global scale on observed changes in many physical and biological systems. Spatial agreement between regions of significant warming across the globe and locations of significant observed changes in many systems consistent with warming is very unlikely to be due solely to natural variability. Several modeling studies have linked some specific responses in physical and biological systems to anthropogenic warming.

More complete attribution of observed natural system responses to anthropogenic warming is currently prevented by the short time scales of many impact studies, greater natural climate variability at regional scales, contributions of non-climate factors and limited spatial coverage of studies.

Projected climate change and its impacts

There is high agreement and much evidence that with current climate change mitigation policies and related sustainable development practices, global GHG emissions will continue to grow over the next few decades.

The IPCC Special Report on Emission Scenarios (SRES, 2000) projects an increase of global GHG emissions by 25-90% (CO_2-eq) between 2000 and 2030, with fossil fuels maintaining their dominant position in the global energy mix to 2030 and beyond. More recent scenarios without additional emissions mitigation are comparable in range.

Continued GHG emissions at or above current rates would cause further warming and induce many changes in the global climate system during the 21st century that would very likely be larger than those observed during the 20th century. For the next two decades a warming of about 0.2°C per decade is projected for a range of SRES emission scenarios. Even if the concentrations of all GHGs and aerosols had been kept constant at year 2000 levels, a further warming of about 0.1°C per decade would be expected. Afterwards, temperature projections increasingly depend on specific emission scenarios.

For an explanation of SRES emission scenarios, see Box 'SRES scenarios' in Topic 3 of this Synthesis Report. These scenarios do not include additional climate policy above current ones; more recent studies differ with respect to UNFCCC and Kyoto Protocol inclusion.

There is now higher confidence than in the TAR in projected patterns of warming and other regional-scale features, including changes in wind patterns, precipitation, and some aspects of extremes and sea ice. Regional-scale changes include:

- warming greatest over land and at most high northern latitudes and least over Southern Ocean and parts of the North Atlantic Ocean, continuing recent observed trends **(Figure 6.1-4)**;

- contraction of snow cover area, increases in thaw depth over most permafrost regions, and decrease in sea ice extent; in some projections using SRES scenarios, Arctic late-summer sea ice disappears almost entirely by the latter part of the 21st century;
- very likely increase in frequency of hot extremes, heat waves, and heavy precipitation;
- likely increase in tropical cyclone intensity; less confidence in global decrease of tropical cyclone numbers;
- poleward shift of extra-tropical storm tracks with consequent changes in wind, precipitation, and temperature patterns; and
- very likely precipitation increases in high latitudes and likely decreases in most subtropical land regions, continuing observed recent trends.

There is high confidence that by mid-century, annual river runoff and water availability are projected to increase at high latitudes (and in some tropical wet areas) and decrease in some dry regions in the mid-latitudes and tropics. There is also high confidence that many semi-arid areas (e.g., Mediterranean basin, western United States, southern Africa and northeast Brazil) will suffer a decrease in water resources due to climate change.

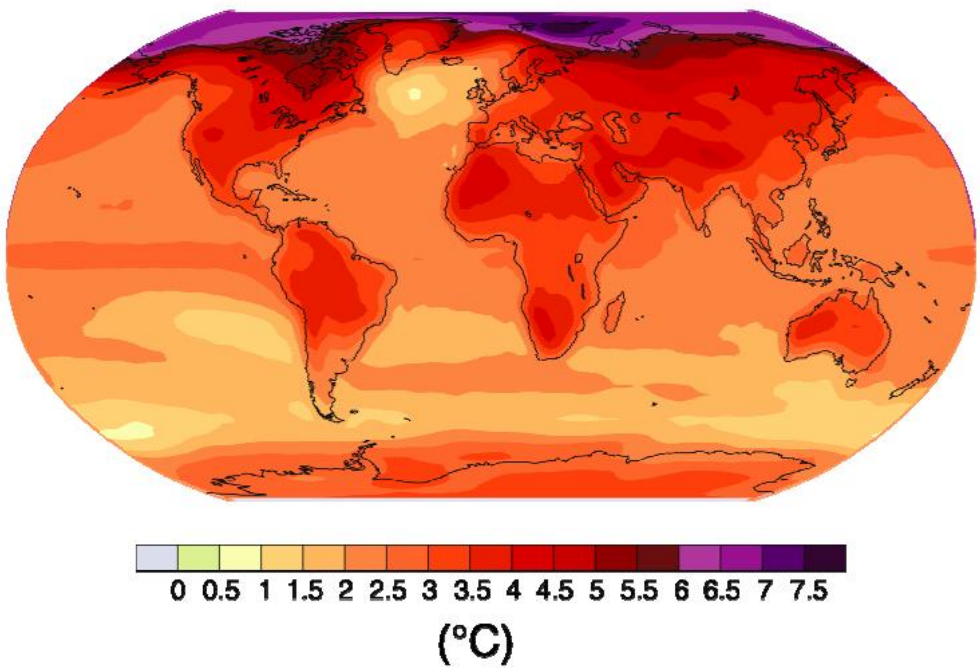

Figure 6.1-4. Projected surface temperature changes for the late 21st century (2090-2099). The map shows the multi- AOGCM average projection for the A1B SRES scenario. All temperatures are relative to the period 1980-1999.

Studies since the TAR have enabled more systematic understanding of the timing and magnitude of impacts related to differing amounts and rates of climate change.

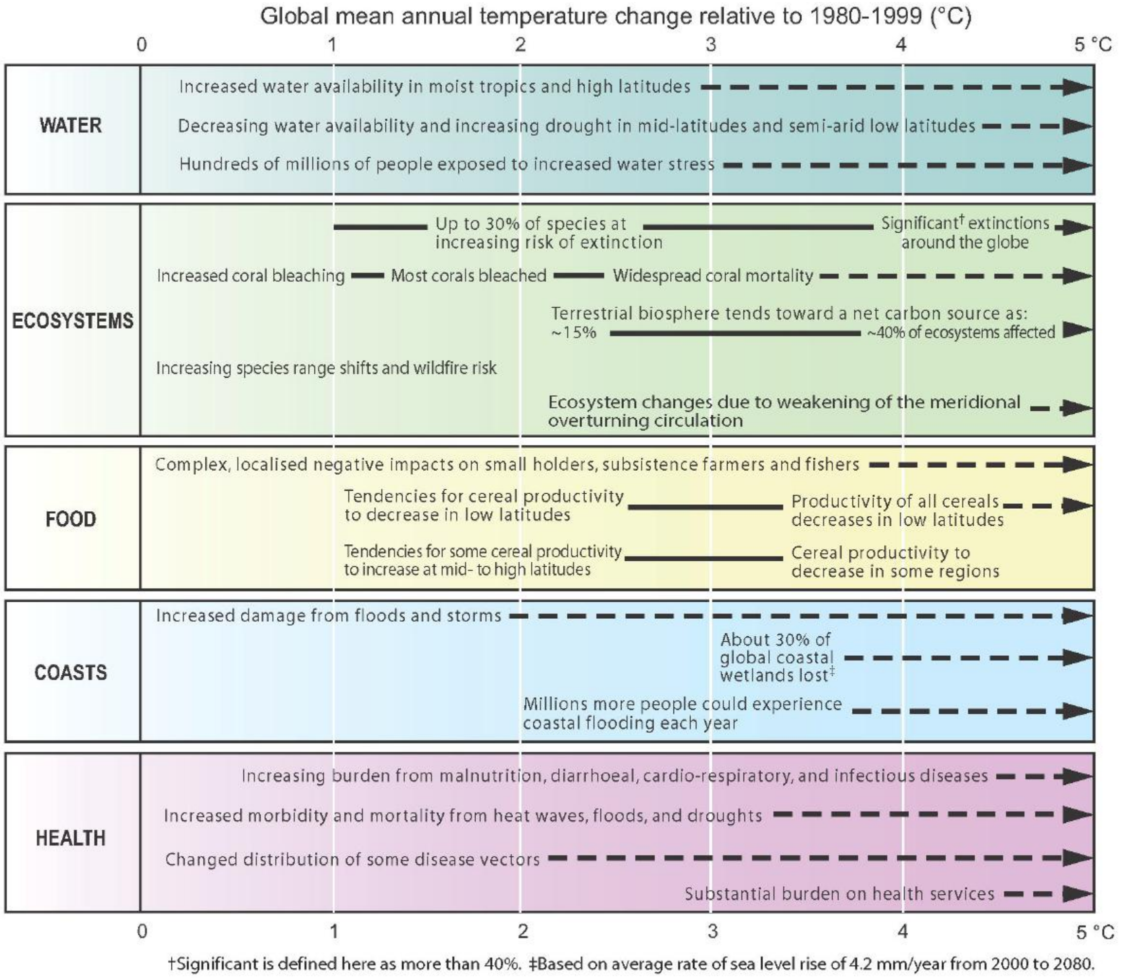

Figure 6.1-5. Illustrative examples of global impacts projected for climate changes (and sea level and atmospheric CO_2 where relevant) associated with different amounts of increase in global average surface temperature in the 21st century.

The black lines link impacts; broken line arrows indicate impacts continuing with increasing temperature. Entries are placed so that the left hand side of text indicates the approximate level of warming that is associated with the onset of a given impact. Quantitative entries for water scarcity and flooding represent the additional impacts of climate change relative to the conditions projected across the range of SRES model scenarios. Adaptation to climate change is not included in these estimations. *Confidence levels for all statements are high.*

Examples of some projected regional impacts in North America:

- Warming in western mountains is projected to cause decreased snowpack, more winter flooding, and reduced summer flows, exacerbating competition for over-allocated water resources.

- In the early decades of the century, moderate climate change is projected to increase aggregate yields of rain-fed agriculture by 5-20%, but with important variability among regions. Major challenges are projected for crops that are near the warm end of their suitable range or which depend on highly utilized water resources.
- During the course of this century, cities that currently experience heat waves are expected to be further challenged by an increased number, intensity and duration of heat waves during the course of the century, with potential for adverse health impacts.
- Coastal communities and habitats will be increasingly stressed by climate change impacts interacting with development and pollution.

Moreover, some systems, sectors and regions are likely to be especially affected by climate change.

- Particular ecosystems
    - terrestrial: tundra, boreal forest and mountain regions because of sensitivity to warming; Mediterranean-type ecosystems because of reduction in rainfall; and tropical rainforests where precipitation declines
    - coastal: mangroves and salt marshes, due to multiple stresses
    - marine: coral reefs due to multiple stresses; the sea ice biome because of sensitivity to warming
- Water resources in some dry regions at mid-latitudes and in the dry tropics, due to changes in rainfall and evapotranspiration, and in areas dependent on snow and ice melt agriculture in low-latitudes, due to reduced water availability.
- Low-lying coastal systems, due to threat of sea level rise and increased risk from extreme weather events.
- Human health in populations with low adaptive capacity.

Altered frequencies and intensities of extreme weather, together with sea level rise, are expected to have mostly adverse effects on natural and human systems.
Examples for selected extremes and sectors are shown in **Table 6.1-3.** These do not take into account any changes or developments in adaptive capacity. The likelihood estimates in column two relate to the phenomena listed in column one.

Table 6.1-3. Examples of possible impacts of climate change due to changes in extreme weather and climate events, based on projections to the mid- to late 21st century.

Phenomenon[a] and direction of trend	Likelihood of future trends based on projections for 21st century using SRES scenarios	Examples of major projected impacts by sector			
		Agriculture, forestry and ecosystems	Water resources	Human health	Industry, settlement and society
Over most land areas, warmer and fewer cold days and nights, warmer and more frequent hot days and nights	*Virtually certain*[b]	Increased yields in colder environments; decreased yields in warmer environments; increased insect outbreaks	Effects on water resources relying on snowmelt; effects on some water supplies	Reduced human mortality from decreased cold exposure	Reduced energy demand for heating; increased demand for cooling; declining air quality in cities; reduced disruption to transport due to snow, ice; effects on winter tourism
Warm spells/heat waves. Frequency increases over most land areas	*Very likely*	Reduced yields in warmer regions due to heat stress; increased danger of wildfire	Increased water demand; water quality problems, e.g. algal blooms	Increased risk of heat-related mortality, especially for the elderly, chronically sick, very young and socially isolated	Reduction in quality of life for people in warm areas without appropriate housing; impacts on the elderly, very young and poor
Heavy precipitation events. Frequency increases over most areas	*Very likely*	Damage to crops; soil erosion, inability to cultivate land due to waterlogging of soils	Adverse effects on quality of surface and groundwater; contamination of water supply; water scarcity may be relieved	Increased risk of deaths, injuries and infectious, respiratory and skin diseases	Disruption of settlements, commerce, transport and societies due to flooding; pressures on urban and rural infrastructures; loss of property
Area affected by drought increases	*Likely*	Land degradation; lower yields/crop damage and failure; increased livestock deaths; increased risk of wildfire	More widespread water stress	Increased risk of food and water shortage; increased risk of malnutrition; increased risk of water-and food-borne diseases	Water shortage for settlements, industry and societies; reduced hydropower generation potentials; potential for population migration
Intense tropical cyclone activity increases	*Likely*	Damage to crops; windthrow (uprooting) of trees; damage to coral reefs	Power outages causing disruption of public water supply	Increased risk of deaths, injuries, water- and food-borne diseases; post-traumatic stress disorders	Disruption by flood and high winds; withdrawal of risk coverage in vulnerable areas by private insurers, potential for population migrations, loss of property
Increased incidence of extreme high sea level (excludes tsunamis)[c]	*Likely*[d]	Salinisation of irrigation water, estuaries and freshwater systems	Decreased freshwater availability due to saltwater intrusion	Increased risk of deaths and injuries by drowning in floods; migration-related health effects	Costs of coastal protection versus costs of land-use relocation; potential for movement of populations and infrastructure; also see tropical cyclones above

Notes:
a) See WGI Table 3.7 for further details regarding definitions.
b) Warming of the most extreme days and nights each year.
c) Extreme high sea level depends on average sea level and on regional weather systems. It is defined as the highest 1% of hourly values of observed sea level at a station for a given reference period.
d) In all scenarios, the projected global average sea level at 2100 is higher than in the reference period. The effect of changes in regional weather systems on sea level extremes has not been assessed.

Anthropogenic warming could lead to some impacts that are abrupt or irreversible, depending upon the rate and magnitude of the climate change. Partial loss of ice sheets on polar land could imply meters of sea level rise, major changes in coastlines and inundation of low-lying areas, with greatest effects in river deltas and low-lying islands. Such changes are projected to occur over millennial time scales, but more rapid sea level rise on century time scales cannot be excluded.

Climate change is likely to lead to some irreversible impacts. There is medium confidence that approximately 20-30% of species assessed so far are likely to be at increased risk of extinction if increases in global average warming exceed 1.5-2.5°C (relative to 1980-1999). As global average temperature increase exceeds about 3.5°C, model projections suggest significant extinctions (40-70% of species assessed) around the globe.

Based on current model simulations, the meridional overturning circulation (MOC) of the Atlantic Ocean will very likely slow down during the 21st century; nevertheless temperatures over the Atlantic and Europe are projected to increase. The MOC is very unlikely to undergo a large abrupt transition during the 21stcentury. Longer-term MOC changes cannot be assessed with confidence. Impacts of large-scale and persistent changes in the MOC are likely to include changes in marine ecosystem productivity, fisheries, ocean CO_2 uptake, oceanic oxygen concentrations and terrestrial vegetation. Changes in terrestrial and ocean CO_2 uptake may feedback on the climate system.

The five “reasons for concern” identified originally in the IPCC’s Third Assessment Report (TAR) remain a viable framework to consider key vulnerabilities. These “reasons” are assessed here to be stronger than in the TAR. Many risks are identified with higher confidence. Some risks are projected to be larger or to occur at lower increases in temperature.

Understanding about the relationship between impacts (the basis for “reasons for concern” in the TAR) and vulnerability (that includes the ability to adapt to impacts) has improved. This is due to more precise identification of the circumstances that make systems, sectors and regions especially vulnerable, and growing evidence of the risks of very large impacts on multiple century time scales.

- **Risks to unique and threatened systems.** There is new and stronger evidence of observed impacts of climate change on unique and vulnerable systems (such as polar and high mountain communities and ecosystems), with increasing levels of adverse impacts as temperatures increase further. An increasing risk of species extinction and coral reef damage is projected with higher confidence than in the TAR as warming proceeds. There is medium confidence that approximately 20-30% of plant and animal species assessed so far are likely to be at increased risk of extinction if increases in global average temperature exceed 1.5-2.5°C over 1980-1999 levels. Confidence has increased that a 1-2°C increase in global mean temperature above 1990 levels (about 1.5-2.5°C above pre-industrial) poses significant risks to many unique and threatened systems including many biodiversity hotspots. Corals are vulnerable to thermal stress and have low adaptive capacity. Increases in sea surface temperature of about 1-3°C are projected to result in more frequent coral bleaching events and widespread mortality, unless there is thermal adaptation or acclimatization by corals. Increasing vulnerability of indigenous communities in the Arctic and small island communities to warming is projected.

- **Risks of extreme weather events.** Responses to some recent extreme events reveal higher levels of vulnerability than the TAR. There is now higher confidence in the projected increases in droughts, heat waves, and floods as well as their adverse impacts.
- **Distribution of impacts and vulnerabilities.** There are sharp differences across regions and those in the weakest economic position are often the most vulnerable to climate change. There is increasing evidence of greater vulnerability of specific groups such as the poor and elderly in not only developing but also developed countries. Moreover, there is increased evidence that low-latitude and less-developed areas generally face greater risk, for example in dry areas and megadeltas.
- **Aggregate impacts.** Compared to the TAR, initial net market-based benefits from climate change are projected to peak at a lower magnitude of warming, while damages would be higher for larger magnitudes of warming. The net costs of impacts of increased warming are projected to increase over time.
- **Risks of large-scale singularities.** There is high confidence that global warming over many centuries would lead to a sea level rise contribution from thermal expansion alone which is projected to be much larger than observed over the 20th century, with loss of coastal area and associated impacts. There is better understanding than in the TAR that the risk of additional contributions to sea level rise from both the Greenland and possibly Antarctic ice sheets may be larger than projected by ice sheet models and could occur on century time scales. This is because ice dynamical processes seen in recent observations but not fully included in ice sheet models assessed in AR4 could increase the rate of ice loss.

There is high confidence that neither adaptation nor mitigation alone can avoid all climate change impacts; however, they can complement each other and together can significantly reduce the risks of climate change.

Adaptation is necessary in the short and longer term to address impacts resulting from the warming that would occur even for the lowest stabilization scenarios assessed. There are barriers, limits and costs, but these are not fully understood. Unmitigated climate change would, in the long term, be likely to exceed the capacity of natural, managed and human systems to adapt. The time at which such limits could be reached will vary between sectors and regions. Early mitigation actions would avoid further locking in carbon intensive infrastructure and reduce climate change and associated adaptation needs.

Many impacts can be reduced, delayed or avoided by mitigation. Mitigation efforts and investments over the next two to three decades will have a large impact on opportunities to achieve lower stabilization levels.

Delayed emission reductions significantly constrain the opportunities to achieve lower stabilization levels and increase the risk of more severe climate change impacts.

In order to stabilize the concentration of GHGs in the atmosphere, emissions would need to peak and decline thereafter. The lower the stabilization level, the more quickly this peak and decline would need to occur.

Sea level rise under warming is inevitable. Thermal expansion would continue for many centuries after GHG concentrations have stabilized, for any of the stabilization levels assessed, causing an eventual sea level rise much larger than projected for the 21st century. The eventual contributions from Greenland ice sheet loss could be several meters, and larger than from thermal expansion, should warming in excess of 1.9-4.6°C above pre-industrial be sustained over many centuries. The long time scales of thermal expansion and ice sheet response to warming imply that stabilization of GHG concentrations at or above present levels would not stabilize sea level for many centuries.

Ocean Acidification

another global change issue relates to changes in the earth's carbon budget and cycle. Carbon cycles through the earth's ecosystems in organic and inorganic forms. Recent increasing trends in carbon dioxide in the earth's atmosphere is shifting the cycle of carbon in the ocean and increasing carbonic acid and a gradual decrease in ocean pH and calcium carbonate. Experimental evidence suggests that if these trends continue, key marine organisms, such as corals and some plankton, will have difficulty maintaining their external calcium carbonate skeletons (Orr et al. 2005).

According to the Intergovernmental panel on Climate Change (2007), the uptake of anthropogenic carbon since 1750 has led to the ocean becoming more acidic with an average decrease in pH of 0.1 units. Increasing atmospheric CO_2 concentrations lead to further acidification. Projections based on SRES scenarios give a reduction in average global surface ocean pH of between 0.14 and 0.35 units over the 21st century. While the effects of observed ocean acidification on the marine biosphere are as yet undocumented, the progressive acidification of oceans is expected to have negative impacts on marine shell-forming organisms (e.g., corals) and their dependent species.

6.2 Adverse impacts of fishing activities under South Atlantic Council Fishery Management Plans

(excerpted from Barnette 2001)

All fishing has an effect on the marine environment, and therefore the associated habitat. Fishing has been identified as the most widespread human exploitative activity in the marine environment (Jennings and Kaiser 1998), as well as the major anthropogenic threat to demersal fisheries habitat on the continental shelf (Cappo et al. 1998). Fishing impacts range from the extraction of a species which skews community composition and diversity to reduction of habitat complexity through direct physical impacts of fishing gear.

The nature and magnitude of the effects of fishing activities depend heavily upon the physical and biological characteristics of a specific area in question. There are strict limitations on the degree to which probable local effects can be inferred from the studies of fishing practices conducted elsewhere (North Carolina Division of Marine Fisheries 1999). The extreme variability that occurs within marine habitats confounds the ability to easily evaluate habitat impacts on a regional basis. Obviously, observed impacts at coastal or nearshore sites should not be extrapolated to offshore fishing areas because of the major differences in water depth, sediment type, energy levels, and biological communities (Prena et al. 1999). Marine communities that have adapted to highly dynamic environmental conditions (e.g., estuaries) may not be affected as greatly as those communities that are adapted to stable environmental conditions (e.g., deep water communities). While recognizing the pitfalls that are associated with applying the results of gear impact studies from other geographical areas, due to the lack of sufficient and specific information within the Southeast Region it is necessary to review and carefully interpret all available literature in hopes of improving regional knowledge and understanding of fishery-related habitat impacts.

In addition to the environmental variability that occurs within the regions, the various types of fishing gear and how each is utilized on various habitat types affect the resulting potential impacts. For example, trawls vary in size and weight, as well as their impacts to the seabed. Additionally, the intensity of fishing activities needs to be considered. Whereas a single incident may have a negligible impact on the marine environment, the cumulative effect may be much more severe. Within intensively fished grounds, the background levels of natural disturbance may have been exceeded, leading to long-term changes in the local benthic community (Jennings and Kaiser 1998). Collie (1998) suggested that, to a large extent, it is the cumulative impact of bottom fishing, rather than the characteristics of a particular gear, that affects benthic communities. Unfortunately, a limitation to many fishing-related impact studies is that they do not measure the long term effects of chronic fishing disturbance. Furthermore, one of the most difficult aspects of estimating the extent of fishing impacts on habitat is the lack of high-resolution data on the distribution of fishing effort (Auster and Langton 1999).

The effects of fishing can be divided into short-term and long-term impacts. Short-term impacts (e.g., sediment resuspension) are usually directly observable and measurable while long-term impacts (e.g., effects on biodiversity) may be indirect and more difficult to quantify. Even more difficult to assess would be the cascading effects that fishery-related impacts may have on the marine environment. Additionally, various gears may indirectly impact EFH. Bycatch disposal and ghost fishing are two of the more well-documented indirect impacts to EFH. While recognizing that these are serious issues that pertain to habitat, this review does not attempt to discuss these due to the secondary nature of the impacts.

The majority of existing gear impact studies focus on mobile gear such as trawls and dredges. On a regional scale, mobile gear such as trawls impact more of the benthos than any other gear. However, other fishing practices may have a more significant ecological effect in a particular area due to the nature of the habitat and fishery. Yet there are few studies that investigate other gear types, especially static gear. Rogers et al. (1998) stated that there are few accounts of the physical contact of static gear having measurable effects on benthic biota, as the area of sea bed affected by each gear is almost insignificant compared to the widespread effects of mobile gear. Regardless, static gear may negatively affect EFH and, therefore, must be considered.

The exact relationship that particular impacts have on the associated community and productivity is not fully understood. While it is clear that fishing activities impact or alter EFH, the result of those impacts or the degree of habitat alteration that still allow for sustainable fishing is unknown (Dayton et al. 1995; Auster et al. 1996; Watling and Norse 1998). Hall (1994) noted that not all impacts are negative. A negative effect at one level may sometimes be viewed as a positive effect at a higher level of biological organization – particular species may be removed in small-scale disturbances yet overall community diversity at the regional scale may rise because disturbance allows more species to coexist.

6.2.1 Fishing Gear Regulations under Council FMPs

The following is a list of gear currently in use (or regulated) in fisheries managed under the South Atlantic Council fishery management plans. In general, if gear is not listed it is prohibited or not commonly used in the fishery:

Snapper Grouper Fishery
Vertical hook-and-line gear, including hand-held rod and manual or electric reel or "bandit gear" with manual, electric or hydraulic reel (recreational and commercial).

Spear fishing gear without rebreathers (recreational and commercial).

Powerheads, except where expressly prohibited in Special Management Zones (SMZs). In addition, the use of explosive charges, including powerheads, is prohibited in the EEZ off South Carolina (recreational and commercial).

Bottom longlines (commercial). Prohibited south of a line running east of St. Lucie Inlet, Florida (27° 10' N. lat.) and in depths less than 50 fathoms north of that line. May not be used to fish for wreckfish.

Sea bass pots (commercial). May not be used or possessed in multiple configurations. Pot size, wire mesh size and construction restrictions. May not be used in the EEZ south of a line running due east of the NASA Vehicle Assembly Building, Cape Canaveral, Florida (28° 35.1' N. lat.).

Special Management Zones (created under the Snapper Grouper FMP). Sea bass pots are prohibited in all Special Management Zones. Fishing may only be conducted with hand-held hook-and-line gear (including manual, electric, or hydraulic rod and reel) and spearfishing gear in specified Special Management Zones; however, in other specified Special Management Zones a hydraulic or electric reel that is permanently affixed to a vessel ("bandit gear") and/or spear fishing gear (or only powerheads) are prohibited.

Shrimp

Penaeid shrimp trawls (commercial). The Shrimp Fishery Management Plan allows North and South Carolina, Georgia and east Florida to request a closure in federal waters adjacent to closed state waters for brown, pink or white shrimp following severe cold weather that results in an 80% or greater reduction in the population of white shrimp (whiting, royal red and rock shrimp fisheries are exempt from a federal closure for white shrimp). During a federal closure, a buffer zone is established extending seaward from shore to 25 nautical miles, inside of which no trawling is allowed with a net having less than 4" stretch mesh. Vessels trawling inside this buffer zone cannot have a shrimp net aboard (i.e., a net with less than 4" stretch mesh) in the closed portion of the federal zone. Transit of the closed federal zone with less than 4" stretch mesh aboard while in possession of penaeid (white, brown and pink) species will be allowed provided that the nets are in an unfishable condition, which is defined as stowed below deck. Specified areas are closed to trawling for rock shrimp.

Rock shrimp trawls (commercial). The minimum mesh size for the cod end of a rock shrimp trawl net in the South Atlantic EEZ off Georgia and Florida is 1-7/8 inches (4.8 cm), stretched mesh. This minimum mesh size is required in at least the last 40 meshes forward of the cod end drawstring (tie off strings), and smaller mesh bag liners are not allowed. A vessel that has a trawl net on board that does not meet these requirements may not possess a rock shrimp in or from the South Atlantic EEZ off Georgia and Florida.

Bycatch Reduction Devices (BRDs). On a penaeid shrimp trawler in the South Atlantic EEZ, each trawl net that is rigged for fishing and has a mesh size less than 2.5", as measured between the centers of opposite knots when pulled taut, and each try net that is rigged for fishing and has a headrope length longer than 16.0 ft. must have a certified BRD installed. The following BRDs are certified for use by penaeid shrimp trawlers in the South Atlantic EEZ: extended funnel, expanded mesh and fisheye.

As of January 12, 2007, on a vessel that fishes for or possesses rock shrimp in the South Atlantic EEZ, each trawl net or try net that is rigged for fishing must have a certified BRD installed.

Turtle Excluder Devices (TEDs). TEDs are required for the penaeid and rock shrimp fisheries.

<u>Red Drum</u>
No harvest or possession is allowed in or from the EEZ (no gear specified).

<u>Golden Crab</u>
Crab traps (commercial). May not be fished in water depths less than 900 feet in the northern zone and 700 feet in the middle and southern zones. Rope is the only allowable material for mainlines and buoy line. Max. trap size equals 64 cubic feet in volume in the Northern zone and 48 cubic feet in volume in the Mid and Southern zones. Traps must have at least 2 escape gaps or rings and an escape panel. Traps must be identified with a permit number.

Coral, Coral Reefs, and Live/Hard Bottom Habitat
Hand harvest only for allowable species (recreational and commercial). A toxic chemical may not be used or possessed in a coral area in the EEZ. A power-assisted tool may not be used to take prohibited coral, allowable octocoral or live rock.

Oculina Bank Habitat Area of Particular Concern: Fishing with bottom longlines, bottom trawls, dredges, pots or traps is prohibited. Fishing vessels may not anchor, use an anchor and chain, or use a grapple and chain.

Coastal Migratory Pelagics
Hook and line gear, usually rod and reel or bandit gear, hand lines, flat lines etc. (recreational and commercial).

Run-around gillnets or sink nets (commercial). A gillnet must have a float line less than 1,000 yards in length to fish for coastal migratory pelagic species. Gillnets must be at least 4-3/4 inch stretch mesh.

Purse seines for other coastal migratory species (commercial) with an incidental catch allowance for Spanish mackerel (10%) and king mackerel (1%).

For Atlantic king mackerel (commercial) north of the Cape Lookout, NC Light (34° 37.3' N. lat.) all gear is authorized except for drift gillnets and long gillnets. South of the Cape Lookout Light the following gear is authorized: **automatic reel, bandit gear, handline, rod & reel.**

For Spanish mackerel (commercial) **automatic reel, bandit gear, handline, rod & reel, cast net, run around gill net and stab net**. Minimum size of 3.5" stretch mesh required for all run around gill nets.

Spiny Lobster
Traps, hand harvest, dip nets and bully nets (recreational and commercial). No poisons or explosives are allowed. No spear, hooks or piercing devices are allowed. A degradable panel is required on non-wooden traps. Traps may not be tended at night. Buoy and trap identification is required.

Dolphin and Wahoo
Pelagic longline, hook and line gear including manual, electric, or hydraulic rod and reels, bandit gear, handline and spearfishing gear (including powerheads). Surface and pelagic longline gear for dolphin and wahoo is prohibited within any "time area closure" in the Atlantic EEZ which is closed to the use of pelagic gear for highly migratory pelagic species (HMS) (commercial).

Sargassum
Nets used to harvest Sargassum be constructed of 4" stretch mesh or larger fitted to a frame no larger than 4 x 6 feet.

6.2.2 Gear Descriptions

6.2.2.1 Mobile Gear

(excerpted from Barnette 2001)

Crab Scrape

A crab scrape is composed of a net bag attached to a rigid frame with short teeth (Figure 1). This gear, used exclusively in state waters, is dragged in the shallow water of bays and estuaries to catch crabs. There are no studies available that document potential damage to habitat. However, due to their design, their use in SAV would likely result in the potential uprooting of some plants, as well as leaf shearing (Barnette, personal observations). However, crab scrapes are not typically employed in vegetated areas due to the amount of plant litter that would fill the net. Penetration of the benthos by the teeth would result in sediment resuspension.

Frame Trawl

Roller frame trawls are primarily utilized to harvest bait shrimp in the State of Florida. They consist of a frame that holds open a net and supports slotted rollers that grip the bottom and turn freely. This motion prevents the scouring and scraping impacts primarily associated with otter trawls. Because participants in the fishery usually operate in shallow water, 9.14 m (30 ft) or less, frame trawls are typically limited to state waters.

A study by Futch and Beaumariage (1965) found that while frame trawls gathered large amounts of unattached algae and deciduous *Thalassia testudinium* leaves, no SAV with roots attached were found in the trawl catch.

Trawls with larger rollers (20.3cm; 8 in diameter) reduced the amount of bycatch material, with most drags uprooting SAV. Damage to SAV beds was noted on several occasions when the boats ran aground. The study concluded that side frame trawls do negligible damage to SAV beds. This conclusion was supported by Meyer et al. (1991; 1999), who found no significant trawl impacts on shoot density, structure, or biomass with increased trawling on turtlegrass (*Thalassia testudinium*). However, these studies did not evaluate the effects of repetitive trawling.

Woodburn et al. (1957) noted that the roller on the bottom of the trawl does cause the leaves ripe for shedding to break off, though this would not negatively impact the plant itself. Higman (1952) concluded that frame trawling is not sufficient to denude vegetated areas permanently or to damage the ecology of such locations. Additionally, Tabb and Kenny (1967), while not explicitly investigating habitat impacts, believed that roller frame trawls do no significant damage to habitat. In contrast to studies that assessed impacts to SAV, Tilmant (1979) found a high incidence of damage to stony corals in a study that investigated frame trawl impacts to hard bottom habitat in Biscayne Bay. Frame trawls turned over or crushed 80% of *Porites porites* and *Solenastrea hyades* and damaged over 50% of sponges and 38% of gorgonians in the trawl path. Macroalgae, including *Halimeda* and *Sargassum*, were heavily damaged. The primary impact on

Sargassum was that it was torn loose from the bottom resulting in an early release to the free floating state. Tilmant (1979) found it doubtful that this action was harmful to *Sargassum* unless it occurred during early column formation. It was concluded that frame trawls have a significant impact on certain benthic organisms (Tilmant 1979).

Furthermore, within dense SAV communities, removal of epibenthic algae, tunicates, sponges, and other primary producers may also be significant. Futch and Beaumariage (1965) recommended that the diameter of the rollers be no less than 15.2cm (6in) and that the teeth of the rakes on the trawls should not extend below the roller. Furthermore, they recommend that boats employed in the frame trawl fishery that operate in shallow water should be of tunneled construction to prevent damage to SAV from propeller scarring. Tabb (1958) recommended that strainer bars should be rigid and aimed into the roller so that regardless of how far forward the net frame tips, the bars cannot dig into the bottom. The results from Tilmant (1979) indicated that extensive damage occurs to hardbottom habitat from frame trawls.

A logical recommendation that can be extrapolated from this study is the prohibition of frame trawling in areas where hardbottom habitat exists. Frame trawls, while causing negligible damage to SAV, are not compatible with hardbottom areas due to the damage it causes to complex vertical habitat (e.g., sponges, corals, gorgonians).

Prohibition on the use of bottom trawls
The use of trawl gear to harvest fish in the directed snapper grouper fishery south of Cape Hatteras, North Carolina (35°15' N. Latitude) and north of Cape Canaveral, Florida (Vehicle Assembly Building, 28°35.1' N. Latitude) is prohibited (SAFMC 1987). A vessel with trawl gear and more than 200 lbs of fish in the snapper grouper fishery on board will be defined as a directed fishery. The amendment also establishes a rebuttable presumption that a vessel with fish in the snapper grouper fishery on board harvested its catch of such fish in the Exclusive Economic Zone.

The Council based the trawl prohibition on habitat destruction and the desire to prevent overfishing of vermilion snapper. Fishes present in live bottom areas are described by Grimes et al. (1982) and include 113 species representing 43 families of predominantly tropical and subtropical fishes. Vermilion snapper were more abundant on the shelf edge than on the open shelf (Grimes et al. 1982). Miller and Richards (1980) described the distribution of live bottom habitat in the South Atlantic Bight and reported the most productive area of the shelf for commercial reef fish as being in the open shelf zone between 33 and 40 meters. Parker et al. (1983) reported on a survey of the areas from Cape Canaveral, Florida to Cape Fear, North Carolina and from Cape Fear to Cape Hatteras, North Carolina. From Cape Hatteras to Cape Fear 14,486 square km between 27 and 101 m were surveyed and contained 2,040 square km (14%) of reef habitat of which only 204 square km (10%) had one meter or more relief (distance from the highest point of the live bottom to the ocean floor). In the area from Cape Fear to Cape Canaveral, 24,826 square km between 27 and 101 m were surveyed and contained 7,403 square km (30%) of reef habitat of which 1,743 square km (7%) had one meter or more relief. The Oregon II cruise report (Anon. 1978) supports the scattered nature of live bottom in the South Atlantic from Cape Canaveral, Florida to Cape Hatteras, North Carolina. The Fishery Management Plan reported that in terms of the entire shelf area, current data suggest that from three to 30% of the shelf is suitable bottom for snapper grouper species (SAFMC 1983a).

The report on effects of a research trawl on live bottom (Van Dolah et al. 1987) documents that habitat damage does occur from the use of trawl gear even in the case of one pass through an area in a controlled study. The abstract is as follows:

"The effects of a research trawl on several sponge and coral species was assessed in a shallow-water, hard-bottom area located southeast of Savannah, Georgia. The study entailed a census of the numerically dominant species in replicate 25-square meter quadrants located along five transects established across a trawling alley. The density of undamaged sponges and corals was assessed in trawled and non-trawled (control) portions of each transect immediately before, immediately after, and 12 months after a 40/54 roller-rigged trawl was dragged through the alley once. Some damage to individuals of all target species was observed immediately after trawling, but only the density of barrel sponges (*Cliona* spp.) was significantly reduced. The extent of damage to the other sponges (*Ircinia campana, Haliclona oculata*), octocorals (*Leptogorgia virgulata, Lophogorgia hebes, Titanideum frauenfeldii*) and hard corals (*Oculina varicosa*) varied depending on the species, but changes in density were not statistically significant. Twelve months after trawling, the abundance of specimens counted in the trawled quadrants had increased to pre-trawl densities or greater, and damage to the sponges and corals could no longer be detected due to healing and growth. Trawl damage observed in this study was less severe than the damage reported for a similar habitat in a previous study. Differences between the two studies are attributed to (1) differences in the roller-rig design of the trawls used, and (2) differences in the number of times the same bottom was trawled."

The authors point out that in a study by Tilmant (1979) looking at the effects of commercial bait shrimping with roller-frame trawls in a shallow-water area of Biscayne Bay, Florida damage was much more severe: "Tilmant observed severe damage (specimens crushed or torn loose) to more than 80% of the stony corals, 50% of the sponges and 38% of the soft corals along the trawl path." It should be noted however, that this frame trawl consists of a solid, rectangular frame to which a net is attached and is used to fish grass bed areas; it was not designed to "roll over" live bottom and would be expected to cause significant damage to corals, etc.

Importantly, habitat damage described by Van Dolah et al. (1987) resulted from one tow of trawl gear through the study area. That study was designed to evaluate the effects of a research trawl that does not typically cross the same bottom area more than once. Commercial trawling does not operate in this manner. Under commercial fishing conditions, a live bottom area would be fished over and over until the catches from such an area become unprofitable. Under such conditions, habitat damage would be expected to be much greater than is indicated from the above study.

The *Oregon II* cruise report (Anon. 1978) indicated that drags with a trawl yielded a total catch of 476 lbs which included 424 lbs of finfish and 46 lbs of sponges and corals (10% of the total catch). This area was reported to have been on a mud bottom but turned out to be a low profile live bottom of sand ridges, clumps of sponges and scattered corals. Further indication of habitat damage is reported by Wenner (1983):

"The 3/4 Yankee trawl net effectively covers a much wider area of the bottom than the measured sweep (8.7 m) due to the configuration of the otter doors, ground cables, and bottom leg lines. Although this arrangement cannot increase the actual spread of the net beyond the headrope length, the passage of these cables over the substrate creates a disturbance that serves to herd fish in the path of the net (Baranov 1969). This net does, however, damage the sponge-coral habitat by shearing off sponges, soft corals, bryozoans, and other attached invertebrates. The 56 trawl tows made in the sponge-coral habitat for this study collected 2,351 kg of attached invertebrates (including sponges, soft corals, tunicates, bryozoans, and hydroids) yielding an average 42 kg/tow. This is only the amount of bottom material actually removed from the habitat. An estimate of the total amount of bottom destroyed by the doors, ground cables, and leg lines cannot be ascertained from the current study.

Personal observations and interviews with commercial fishermen attest to the productivity of the sponge-coral habitat. Most studies indicate the importance of habitat availability and space in determining the abundance and diversity of reef fishes (Emery 1978). With this in mind, and given the knowledge that 1) the use of the 3/4 Yankee trawl net reduces the amount of attached invertebrate growth (the amount damaged by doors and ground cables is presently not quantifiable); 2) the places where the invertebrates had been attached may be sanded over and rendered unsuitable for recolonization; and 3) the removal of these attached invertebrates reduces refugees for decapods, polychaetes, etc., that are food items for *Centropristis striata* and other benthic feeders, one must conclude that the continued use of this trawl net reduces the amount of productive fish habitat. For these reasons, in addition to the ineffectiveness of the gear in sampling commercially important species, alternate nondestructive methods, such as direct observations or the use of mark-recapture techniques with trap catches, should be employed in assessment surveys of the commercially important species of this habitat."

Results of trawl survey work in Australia provide some insight into what can happen to catches in an area after the continued use of commercial trawl gear. Young and Sainsbury (1985) report that "At moderate to low levels of fishing effort, the main effect of fishing on the relative abundance of bottom shelf fishes is by alteration of the relative frequency and spatial distribution of habitat types. In particular this refers to the conversion of areas with dense epibenthos (sponge, corals, hydroids, gorgonians) to areas with sparse epibenthos. (It may be noted that even at the relatively low intensity of trawling of the past few years the fishing effort exerted on the main trawl grounds is sufficient to sweep 50 to 100 per cent of the area of those grounds per year.)." These results are from trawling conducted in 1982 as compared to trawl catches in 1966 from the same locations and at the same time of year. The catch composition shifted from species associated with sponges, soft corals, etc. (during 1966) to those associated with open sandy bottom (during 1982).

A similar type of scenario for the South Atlantic was suggested by Bob Low (pers. comm.):
"Parker et al. (1983) estimated that, in the area they surveyed between Cape Fear and Cape Canaveral, there were 7,403 square km of reef habitat. Of this, 1,743 square km had an average profile exceeding 1 m. Assuming that such ground could not be trawled, this leaves about 5,660 square km (1,398,000 acres) of trawlable reef habitat. The average boat might pull a net with a footrope of 120 feet, giving an effective sweep of the roller gear of about 72 feet maximum. A typical tow over open bottom is perhaps 3 hours at 2 knots. The area swept by the roller gear per tow is then about 20 acres/hour or 60 acres/tow. Assume that 20 boats participate for 4 months (January-April) each year. [Note: The actual number of vessels during 1987 was seven.] The average vessel makes 3 trips/month, with 3 days of fishing each trip. The average (24 hr) fishing day includes perhaps 4 tows. A typical trip therefore consists of 12 tows or 36 hr of fishing. The 20 boats make an aggregate of 240 trips. This equates to 2,880 tows, covering around 172,800 total acres. If each tow was over a previously unswept area, the total area covered by the roller gear would then amount to about 12% of the trawlable reef habitat estimated by Parker et al. (1983). Under one set of assumptions, the area affected by the doors, bridles, and warps would add to this. Under a second set, repetitive trawling over identical areas would reduce the total area impacted. Van Dolah et al. (1987) noted a substantial renewability within a year. There are likely to be 8 months of recovery time between trawling seasons. Doesn't that allow for significant restoration in many of the trawled areas?"

The above scenario indicated that about 12% of available habitat between Cape Fear and Cape Canaveral would be impacted annually by trawling, whereas in the Australian work the area impacted was between 50 and 100%. The Council has concluded that the level of damage to the live-bottom habitat in the South Atlantic is significant and that our available knowledge is not sufficient to risk impacting the long-term abundance of snapper and groupers by reducing their habitat. The results shown by Van Dolah et al. (1987) indicated that regeneration of tissue sufficient to have rounded off the tops of partially severed sponges and to have closed wounds on other sponges occurs within a year but that additional growth is limited as indicated by some of the sponges being obviously shorter than before the trawling damage. This supports the Council's concern because in a four month trawling season there would be a net loss of habitat (i.e., more damage than regrowth) with the effects being cumulative over time. By destroying habitat we destroy the productivity of the resource being harvested and we are in essence drawing on the principal, not just taking the interest so that next year the same amount of trawling will represent more than 12% of the habitat and the year after even more. Given this information, the South Atlantic Fishery Management Council concluded that over the long-term there would be a net loss of existing habitat, which is counter to the Council's habitat policy and the Magnuson-Stevens Act.

Indirect evidence of habitat damage is provided in Christian et al. (1985) where they report on attempts to use crab nets rigged with light chain and plastic mud rollers. These nets proved to be inadequate for offshore fish trawling on broken bottom because the light molded plastic mud rollers were not durable and did not prevent net damage. They further reported that captains who tried crab nets soon switched to nets with heavy netting, properly rigged sweep systems and steel vee-doors for trawling over rough bottom. Further indication of habitat damage was presented in Section II of Snapper Grouper Amendment 1 with the numerous references to gear damage, gear loss and the need to use rollers and modified doors to be able to trawl in rough and broken areas.

An additional reference concerning potential habitat damage is provided by Moore and Bullis (1960) when they reported on the discovery of a deep water reef in the Gulf of Mexico. The MV *Oregon* was cruising over the continental slope about 40 nautical miles due east of the Mississippi Delta and observed an unusual tracing on the depth recorder. They sampled this bottom area using a shrimp trawl and reported the following: "A drag, made over the area with a shrimp trawl, contained a large mass of coral, other invertebrates, and fish. The netting of the trawl was torn and most of its contents were lost, but about three hundred lbs of coral remained in the bag. A sample was brought back to the laboratory where it was identified by Moore as *Lophelia prolifera*."

Invertebrates associated with sponges and corals occur in disproportionately high densities which suggest that they may use sponges and corals as a food source or a refuge from predation (Wendt et al. 1985). These invertebrates in turn serve as a food source for various snapper and grouper species. In addition, corals are very slow growing with some such as *Oculina* sp. only growing between 11 and 16 mm per year (Reed 1981). Damage to these areas can negatively affect the food and shelter available to snappers and groupers. Further, Grimes et al. (1982) note the importance of the live bottom and shelf edge habitats in serving as reservoirs for recruits in shallow areas (less than 30 m).

The best estimate of the number of boats operating in the fishery during the winter of 1986/87 was four boats (one South Carolina boat fishing in South Carolina and three North Carolina boats fishing in South Carolina, Georgia and Florida). The number of vessels increased to seven during the winter of 1987/88. These vessels fished during the slow period for shrimp which is normally January to March/April. Even though the actual number of boats is small, the amount of habitat damage is significant when one realizes that these boats fish directly on the limited live bottom habitat in these areas. Productive snapper grouper habitat on the continental shelf is limited and trawl gear is fished repeatedly in these areas over this three to four month period. Most, if not all, fishermen use Loran which allows them to return to the exact spot and trawl a particular rock out-cropping repeatedly. The data previously described from Australia points out the changes to bottom habitat and catches resulting from such a fishery.

Vermilion snapper in the early 1980s were experiencing growth overfishing (see SAFMC 1983a p. 44-58 for a more detailed discussion). Yield per recruit (or yield per individual) analysis indicated that a 12 inch minimum size will increase yield per recruit from 132 g to 177 g which is equivalent to a 34% increase in yield if recruitment is constant.

Confidential data available to the South Atlantic Council indicated that the minimum mesh size of 4 inches is not being adhered to and as a result the Council's prior action establishing the mesh restriction has not been effective in releasing small vermilion (less than 12 inches). The trawl prohibition will result in an increase in yield for vermilion snapper. Catch data from South Carolina (Bob Low, pers. comm.) show a slight negative correlation between trawl landings and hook & line landings (r = -0.13). A good fishery independent index of abundance would allow us to examine the affect of trawl catches on abundance of vermilion snapper. Given the available information, the South Atlantic Fishery Management Council concluded that the trawl prohibition would increase yield; however, our ability to measure this increase is lacking.

The potential existed for more vessels to enter the fishery particularly if the calico scallop, shrimp and sea scallop fisheries have not been productive or are not active during this time period. The actual number of vessels during 1987/88 was seven, greater than the number expected. This further supported the Council's concern that effort could have increased rapidly.

Impacts on affected vessels from prohibiting use of trawl gear in the snapper grouper fishery were not significant. Input from public hearings, committee and Council meetings indicated that income from fish trawling made up a small portion of total income. No trawl fishermen came forward with information during the public hearing process indicating that impacts would be significant. Fishermen used this fishing method primarily as a fill-in activity and had the ability to utilize other gear (e.g., electric & hydraulic reels, black sea bass traps, longlines, etc.) to fish snappers and groupers. These general conclusions are supported by the following in Christian et al. (1985):

“The major seafood industry in the South Atlantic Bight is based on shrimp, and this dependence on one crop has made the industry financially precarious....Therefore, fishermen have looked to other activities such as bottom trawling for finfishes to supplement their income. This is not the single salvation for the whole industry. Although fish trawling can offer an alternative which may aid some shrimpers in maintaining year-round income, suitable trawling bottom in this area is limited, and target species of such a fishery (snapper, grouper, and porgies) are relatively long-lived, slow-growing, and can sustain only limited fishing pressure.”

Hydraulic Escalator Dredge

Hydraulic escalator dredges have been utilized since the 1940s to harvest shellfish such as clams and oysters and are designed expressly for efficient commercial harvest (Coen 1995). The dredge consists of a water pump supplying a manifold with numerous water jets mounted in front of a conveyer belt that dislodges buried organisms from the sediment (Figure 3). Hydraulic escalator dredges are currently only employed in a limited shellfish fishery in South Carolina state waters. Hydraulic escalator dredges may penetrate the benthos approximately 45.7cm (18in), thus disturbance to the sediment may be substantial (Coen 1995). Increased turbidity, burial/smothering, release of contaminants, increased nutrients, and removal of infauna were offered as potential effects from dredging activities (Coen 1995). Turbidity was found to be elevated only in the immediate vicinity of the harvester operation and downcurrent of the study area to a distance of between 1.5-1.75km. Turbidity values returned to baseline levels within a few hours (Maier et al. 1998). Manning (1957) stated that hydraulic clam dredging can result in severe damage to oysters within a distance of 7.6m (25ft) downcurrent from the site of dredging. Enough sediment was displaced and redeposited to a distance of at least 15.2m (50ft), but not more than 22.9m (75ft) downcurrent, to cause possible damage to oyster spat. Beyond about 22.9m (75ft) there was no visible or measurable change in the experimental area. Sediment plumes caused by dredge activity were found by Ruffin (1995) to range from less than 1 to 64 hectares. Although sediment plumes increased turbidity and light attenuation at all depths, plumes in shallow water (less than 1.0 m) caused greater increase in turbidity and light attenuation over background than did plumes in deeper waters. Plume decay is based largely on sediment size, with sand particles settling quickly while the silt/clay particles remain in suspension longer. Sites were monitored for storm disturbance to compare against dredge impacts. Storm events increased turbidity and light attenuation com pare d to calm days but not to the extremes obtained in sediment plumes.

Storm events affect a large area at a low intensity while dredging intensely affects a more localized area. SAV subjected to decreased light penetration will inhibit reproduction, reduce propagule abundance, and structurally weaken SAV due to the need of plants growing higher into the water column (Ruffin 1995). Ruffin (1995) concluded that clam dredging increased light attenuation to the point of inhibiting SAV growth. As may be expected, hydraulic clam dredges are highly destructive t o SAV within the immediate area of intensive dredging (Manning 1957; Godcharles 1971). Due to the capability of the water jets to penetrate the substrate to a depth of 45.7cm (18in), virtually all attached vegetation in its path is uprooted (Godcharles 1971). As the use of this gear is limited to a fishery in South Carolina where SAV does not exist, discussion of SAV impacts are included only to provide information on potential impacts should this gear type be considered in the future for other geographic area s where SAV may be found. Although there may be physical impacts associated with escalator dredge activity, the chemical effects apparently are not as dramatic. Dissolved oxygen, pH, and dissolved hydrogen sulfide were measured throughout the harvesting process at varying distances. No consistent patterns of depression or release were noted. Only in the direct plume of the harvester did they measure even a temporary reduction in dissolved oxygen and pH (Coen 1995). While it is recognized that there is infaunal and epifaunal species mortality associated with escalator dredge activity, based on all evidence, these community impacts appear to be short-term (Godcharles 1971; Peterson et al. 1987a; Coen 1995). Coen (1995) noted that the escalator possibly provides a tilling effect of the bottom that has been observed to be beneficial to subtidal oyster and clam populations. Typically, shellfish dredging operations have typically not been considered to have deleterious results, since its effects are perceived to be negligible compared to natural environmental variation (Godwin 1973). Coen (1995) concluded that based on all direct and indirect evidence, the short-term effects of subtidal escalator harvesters are minimal, with no long-term chronic effects, even under worst case scenarios. Observed effects were often indistinguishable from ambient levels or natural variability.

Recovery of the benthos may vary greatly depending on sediment composition. Shallower trenches with shorter residency times are typical of coarse sediments (i.e., sand), whereas trenches generated in muddy, finer sediments are typically deeper, often persisting for greater than 18 months (Coen 1995). Godcharles (1971) observed that trenches had filled in between 1 to 10 months, depending on bottom type. In regard to SAV, no trace of *Thalassia testudinium* recovery was evident after more than 1 year, though *Caulerpa prolifera* began to re-establish itself in dredge areas within 86 days (Godcharles 1971).

Otter Trawl

Perhaps the most widely recognized and criticized type of gear employed in the southeast region is the otter trawl. Utilized in both state and Federal waters of the Gulf of Mexico and South Atlantic, otter trawls pursue invertebrate species such as shrimp and calico scallops, as well as finfish species such as flounder and butterfish. As the most extensively utilized towed bottom-fishing gear (Watling and Norse 1998), trawls have been identified as the most wide-spread form of disturbance to marine systems below depths affected by storms (Watling and Norse 1998; Friedlander et al. 1999).

Jones (1992) broadly classified the way a trawl can affect the seabed as: scraping and ploughing; sediment resuspension; and physical habitat destruction, and removal or scattering of non-target benthos. The following discussion attempts to group documented impacts into either physical-chemical (e.g., sediment resuspension, water quality) or biological impact categories. In many instances documented habitat impacts overlap these categories.

Physical-Chemical Repercussions

The degree to which bottom trawls disturb the sediment surface depends on the sediment type and the relationship between gear type, gear weight, and trawling speed (ICES 1991). Various parts of trawl gear may impact the bottom including the doors, tickler chains, footropes, rollers, trawl shoes, and the belly of the net. While the components of trawl gear are similar, trawl design may vary greatly. Potential impacts may be shared by all otter trawls, but differences in the weight of trawl doors, footrope design, and operation (tow times), will result in a broad spectrum of impact severity. Furthermore, the number and weight of tickler chains vary the degree of disturbance. Margetts and Bridger (1971) concluded that the cumulative effect of tickler chains is likely to emulsify the sediment to a depth proportional to the number of chains. Additionally, the cumulative effect of intense otter trawling is as important as gear weight and design in impacting the benthos (Ball et al. 2000). Although the effect of one passage of a fishing (trawl) net may be relatively minor, the cumulative effect and intensity of trawling may generate long-term changes in benthic communities (Collie et al. 1997). Trawl gear disturbs the benthos as it is dragged along the bottom. Otter trawl doors, mounted ahead and on each side of the net, spread the mouth of the net laterally across the sea floor. The spreading action of the doors results from the angle at which they are mounted, which creates hydrodynamic forces to push them apart and, in concert with the trawl door's weight, also to push them toward the sea bed (Carr and Milliken 1998). The doors, due to their design and function, are responsible for a large proportion of the potential damage inflicted by a trawl. The footrope runs along the bottom of the net mouth and may be lined with lead weight and rollers. On relatively flat bottom, it is expected that the footrope would not have a major effect on the seabed and its fauna (ICES 1995). However, in areas of complex benthic habitat the footrope would likely have more impact with the benthos.

The South Atlantic Draft Calico Scallop FMP noted that during the early years of the calico scallop fishery, large quantities of benthic material were removed by trawlers. Reports were received during numerous meetings about entire “rocks” being removed. One individual provided a print-out from a depth sounder which indicated a large amount of bottom relief in a particular area prior to the calico scallop fishery. Similar bottom plots after the calico scallop fishery operated in that area indicated a relatively flat bottom (SAFMC 1998b). Additionally, while the footrope generally causes little physical substrate alteration aside from smoothing of bedforms and minor compression on relatively flat bottoms (Brylinsky et al. 1994), these minor compressions can lead to sediment “packing” after repeated trawling activity on the same general areas (Schwinghammer et al. 1996; Lindeboom and de Groot 1998). Further compression can result from the dragging of a loaded net (cod end) along the bottom. The remaining path of the trawl is influenced by the ground warps which, while not in direct contact with the seabed, can create turbulence that resuspends sediment (Prena et al. 1999).

Trawl gear, particularly the trawl doors, penetrates the upper layer of the sediments which liquefies the affected sedimentary layers and suspends sediment in the overlying water column. This sediment “cloud” generated by the interaction of the trawl gear with the benthos and the turbulence created in its wake contributes to fish capture (Main and Sangster 1979; 1981). The appearance of the sediment cloud, but not its size, is governed by the type of seabed. Brief observations on different seabed types show that soft, light-colored mud produces the most opaque and reflective type of cloud and the fine mud remains in suspension much longer than coarse sand. Studies of sediment disturbance by trawls vary greatly, though it can be concluded that benthic habitat areas composed of fine sediments (e.g., clay, mud) are affected to a greater degree than those with coarse sediments (e.g., sand). In sandy sediments, otter boards cannot penetrate deeply due to the mechanical resistance of the sediment, and the seabed in sandy areas is more rapidly restored by waves and currents (DeAlteris et al. 1999). Short-term alterations to sediment size distribution result from the various rates of redeposition of suspended sediments; as noted before, coarse grains (i.e., sand) settle out rapidly while fine grains (i.e., silt) settle out relatively slowly. In general, resuspended sediments settle out of the water column at a rate inversely proportional to sediment size (Margetts and Bridger 1971). Transport of fine-grained sediments away from trawled area s due to this slow settling period may result in permanent changes to the sediment grain size of a trawled area. Again, this effect will be more pronounced in mud/silt habitats than in habitat areas consisting of heavier sand. For example, suspended sediment concentrations of 100-500mgl-1 were recorded 100m astern of shrimp trawls in Corpus Christi Bay, Texas (Schubel et al. 1979), an estuary dominated by muddy sediments. The same study estimated that the total amount of sediment disturbed annually as a result of shrimp trawling was 25-209,000,000m^3, which is 10-100 times greater than the amount dredged during the same period for maintenance of shipping channels in the same area.

ICES (1973) concluded that the physical effects of trawling in tidal waters cannot be permanent. However, it is possible that frequently repeated trawling of one ground with a mixed sediment type bottom in strongly tidal waters might ultimately alter the nature of the bottom towards being predominantly coarse sand because the finer particles are carried away to settle elsewhere. In deeper waters, impacts may be more profound and longer lasting. Engel and Kvitek (1998) investigated two adjacent areas in 180m of water to determine the differences between a heavily trawled site and a lightly trawled site. The data indicated that intensive trawling significantly decreased habitat heterogeneity. Rocks and mound s were less common and sediments and shell fragments were more common in the highly trawled area. Rocks and mounds were more abundant in the lightly trawled area, as well as the amount of flocculent matter and detritus. They theorized that less trawling most likely results in an area with more topographical relief and allows for the accumulation of debris, whereas consistent trawling removes rocks, smoothes over mounds, and resuspends and removes debris. Likewise, Kenchington (1995) found that sand ripples were flattened and stones were displaced after a trawl passage. Churchill (1989) modeled sediment resuspension by trawling and found that this may be a primary source of suspended sediment over the outer shelf where storm-related bottom stresses are weak.

Otter trawl doors were found to have a maximum cutting depth of 50 - 300mm (Drew and Larsen 1994) and, according to Schubel et al. (1979), the footropes of shrimp trawlers in Texas disturbed approximately the upper 50mm of the sediment. Schwinghamer et al. (1996) observed that while the trawl doors may leave scours or depressions, trawling activity reduces the overall surface roughness. Ripples, detrital aggregations, and surface traces of bioturbation are smoothed over by the mechanical action of the trawl and the suspension and subsequent deposition of the surface sediment. In general, the passage of an otter trawl was found to have a minor physical and visual impact on the soft sedimentary sea bed, represented by a flattening of the normally mounded sediment surface and some disturbance of the sessile epifauna (Lindeboom and de Groot 1998). The potential to suspend sediments varies greatly, in large part due to the type of sediment a trawl is working on. Regardless, the suspension of sediments, whether fine silt or coarse sand, impacts the chemical and physical attributes of water quality. The resuspension of sediments may influence the uptake or release of contaminants and, depending on the frequency of disturbance, the nature of the contaminant(s). Clearly, such effects may be more significant where contaminant burdens are relatively high, (e.g., near areas affected by major industrialization,) (ICES 1995). Repetitive trawling on the same ground may enhance nutrient release from sediments and that estimates of average trawling effort for large areas may be unsuitable for estimating these effects (ICES 1995). This has important implications on nutrient cycling in areas that are regularly trawled. Pilskaln et al. (1998) found that impacts include burial of fresh organic matter and exposure of anaerobic sediments; large nutrient delivery to the water column, possibly impacting primary production; increase in nitrate flux out of the sediments; and reduced denitrification (conversion of remineralized nitrogen into $N2$ gas). All of these may have desirable or undesirable ecosystem impacts. An increase in nitrate fluxes to the water column may alter primary production (phytoplankton), potentially benefiting fisheries, or stimulating deleterious phytoplankton growth that results in harmful algal blooms (Pilskaln et al. 1998).

Increased water turbidity as a result of trawling activity has the potential to compress the width of the euphotic zone, wherein light levels are sufficient to support photosynthesis (North Carolina Division of Marine Fisheries 1999). The magnitude of this effect depends on sediment size, duration and periodicity of the trawling event, gear type, season, and site-specific hydrographic and bathymetric features (Paine 1979; Kinnish 1992).

Dredging studies would indicate that the effect of turbidity is greatly dependent on local conditions. Windom (1975) found that sediment resuspension caused by dredging operations significantly reduced phytoplankton growth in a naturally clear estuary (south Florida) but not in a naturally turbid estuary (Chesapeake Bay). Additionally, increased turbidity resulting from trawling activities may reduce primary production of benthic microalgae. This may have serious consequences as benthic microalgae support a variety of consumers and can be a significant portion of total primary production (Cahoon and Cooke 1992; Cahoon and Tronzo 1992; Cahoon et al. 1990; 1993). Increased turbidity also has may reduce the foraging success of visual predators (Minello et al. 1987) and contribute to the mortality of organisms by impeding the normal functioning of feeding and respiratory structures (Sherk et al. 1975). Sediment resuspension may increase the amount of organic matter resulting from enhanced primary production and may stimulate heterotrophic microbial production. If the amount of resuspended organic material is copious, sustained proliferation of heterotrophic microflora will reduce the dissolved oxygen content within the water, and widespread hypoxia or anoxia could ensue to the detriment of benthic and pelagic fauna (West et al. 1994). Conversely, oxygen penetration into the sediment might be enhanced through trawling activity, resulting in shifts in mineralization patterns and redox-dependent chemical processes. Among other consequences, a change from anaerobic to aerobic conditions facilitates the degradation of hydrocarbons. As Kaiser (2000) pointed out, bottom trawls are designed to stay in close contact with the seabed and an inevitable consequence of their design is the penetration and resuspension of the seabed to some extent. While it is possible to reduce the direct physical forces exerted on the seabed by modifying fishing practices, the benefits are questionable and catches would most certainly suffer. Despite attempts to improve gear design, as long as bottom dwelling species are harvested using towed gear, there will be inevitable sediment resuspension.

Biological Repercussions

The physical disturbance of sediment, such as the ones previously discussed, can also result in a loss of biological organization and reduce species richness (Hall 1994). In general, the heavier the gear and the deeper its penetration of the sediment, the greater the damage to the fauna. Impacts also will vary depending on type of habitat the gear is working. Gibbs et al. (1980) determined that shrimp trawling occurring within a sandy estuary had no detectable effect on the macrobenthos. After repeated trawls the sea bottom appeared only slightly marked by the trawl's passage. However, Eleuterius (1987) noted that scarring due to shrimp trawls in Mississippi SAV was common, especially in deeper water. Trawling activities left tracks and ripped up the margins of the beds, and great masses of seagrass were often observed floating on the surface following the opening of shrimp season. Furthermore, Wenner (1983) noted that the use of an otter trawl on hardbottom habitat may inflict considerable damage. The net damages the sponge-coral habitat by shearing off sponges, soft corals, bryozoans, and other attached invertebrates. Therefore, it is not necessarily that trawl gear is doing a constant level of damage, but rather particular habitats are more vulnerable to impacts than others.

Numerous studies cite specific, direct biological impacts to habitat such as the reduction of algal and SAV biomass (Tabb 1958; Fonseca et al. 1984; Bargmann et al. 1985; Peterson et al. 1987a; Sánchez-Lizaso et al. 1990; Guillén et al. 1994; Ardizzone et al. 2000). Gelatinous zooplankton and jellyfish, which provide habitat to juvenile and other fish species, are greatly impacted as they pass through the mesh of mobile gear (Auster and Langton 1999). Fishing activity may reduce the size and number of zooplankton aggregations and disperse associated fishes. Furthermore, there is a directed trawl fishery for cannonball jellyfish in the Gulf of Mexico.

While this fishery removes jellyfish which may provide habitat for juvenile fish, otter trawls utilized in this fishery do not interact with the benthos. Trawls in the Gulf of Mexico and South Atlantic have been noted to impact coral habitat, damaging and destroying various colonies (Moore and Bullis 1960; Gomez et al. 1987; Bohnsack, personal observation). Loss of sponges and associated cnidarian benthos has been documented to lead to a reduction in fish catch (Sainsbury 1988; Hutchings 1990). Sponges are particularly sensitive to disturbance because they recruit periodically and are slow growing in deeper waters (Auster and Langton 1999). Bradstock and Gordon (1983) observed that trawling virtually destroyed large areas dominated by encrusting coralline growths (bryozoans), reducing colony size and density. Probert et al. (1997) documented the bycatch of benthic species that occurs in a deep-water trawl fishery and noted the vulnerability of pinnacle communities and deepwater coral banks such as the Oculina habitat area of eastern Florida. Van Dolah et al. (1983; 1987) conducted experimental trawl surveys over hard bottom habitat consisting of coral and sponge off the coast of Georgia. A single pass of an otter trawl on this habitat damaged all counted species (Van Dolah et al. 1983; 1987).

However, only the density of barrel sponges was significantly decreased by trawling activities. It should be noted that these studies did not investigate the cumulative impacts of trawls. The repetitive effects of trawling over the same area can be expected to have more severe consequences to benthic habitat. While Moran and Stephenson (2000) estimated that a demersal otter trawl reduced benthos (greater than 20cm in maximum dimensions) density by 15.5% in a single pass, Cappo et al. (1998) estimated that complete denuding of the sea bottom structure occurs after 10-13 trawl passes over the same area. Of equal importance are the observations of Moran and Stephenson (2000), who noted variations among trawl studies, possibly due to differences of employed ground ropes. These variations are a warning against generalizations about the impact of otter trawls on attached benthos. As many epifaunal and infaunal organisms create structures which provide habitat for other species, summaries of these studies and their findings are included. For example, many infauna species and other bioturbators have an important role in maintaining the structure and oxygenation of muddy sediment habitats. Consequently, any adverse effects on these organisms would presumably lead to changes in habitat complexity and community structure (Jennings and Kaiser 1998). Furthermore, the loss of biogenic epifaunal species (epibenthic habitat) increases the predation risk for juveniles of other species, thereby lowering subsequent recruitment to adult stocks (Bradstock and Gordon 1983; Walters and Juanes 1993; Jennings and Kaiser 1998). Therefore, reduction in biomass of epifaunal species may be considered a reduction or degradation of habitat in certain instances and trawling has been documented to decrease mean individual biomass of epibenthic species (Sainsbury et al. 1993; Prena et al. 1999). While it may be hard to quantify the impact this loss presents to habitat-dependent organisms, it should be noted nonetheless. In a long-term study of Corpus Christi Bay, Texas, Flint and Younk (1983) noted that the continual minor and random disturbance, both in time and space, of channel sediments by large tanker traffic and shrimp trawling probably was sufficient to keep these communities in a state of constant disruption. This allowed the opportunists to persist more successfully than other species. The disturbed channel sites of the study, though viable, consistently had lower densities, lower numbers of species and corresponding low diversities contrasted to the lesser impacted shoal sampling sites (Flint and Younk 1983). Engel and Kvitek (1998) investigated two adjacent areas in 180 m of water to determine the differences between a heavily trawled site and a lightly trawled site.

They concluded that high-intensity trawling apparently reduces habitat complexity and biodiversity while simultaneously increasing opportunistic infauna and the prey of some commercial fish. The data indicated that intensive trawling significantly decreased habitat heterogeneity. All epifaunal invertebrates counted were less abundant in the highly trawled area. Bergman and Santbrink (2000) estimated direct mortality on various species of benthic megafauna from a single pass of an otter trawl (sole fishery) at between 0-52% for silty sediments and between 0-30% for sandy sediments. In general, small-sized species tend to show lower direct mortalities, when compared with larger sized species and smaller individuals of megafaunal species tend to show lower mortalities than larger-sized ones. Krost and Rumohr (1990) noted damage directly resulting from otter trawl doors. Benthic organisms were found to be reduced in number by 40 to 75% in otter board tracks, as compared to control sites. Biomass was also generally reduced. However, they found almost no differences in epibenthic species such as crustaceans. In shallow areas with densely packed sediments, inhabitants of the upper sediment layer were found to suffer most by the trawling impact.

In contrast to the above studies, there are several studies that document no significant habitat impact. Van Dolah et al. (1991) found no long-term effects of trawling on an estuarine benthic community; five months of shrimp trawling in areas previously closed to fishing were found to have no pronounced effect on the abundance, diversity, or composition of the soft bottom community when compared to nearby fished areas. They concluded that seasonal reductions in the abundance and numbers of species sampled had a much greater effect than fishing disturbance. In a power analysis of their sampling strategy, Jennings and Kaiser (1998) noted that Van Dolah et al. (1991) only considered changes in the abundance of individuals and the number of species. This assumes that the response of the infauna to trawling disturbance was unidirectional, whereas a consideration of changes in partial dominance might have been more sensitive to subtle changes in the fauna. Yet, Jennings and Kaiser (1998) stated that the results of Van Dolah et al. (1991) were plausible and that light shrimp trawls probably do not cause significant disturbance to communities in poorly sorted sediments in shallow water. Sanchez et al. (2000) determined that sporadic episodes of trawling in muddy habitats may cause relatively few changes in community composition. They found similar infaunal community changes in both fished and unfished control areas through time. Sanchez et al. (2000) also noted that the decrease in the abundance of certain species in the unfished control areas may indicate that the natural variability at the experimental site exceeds the effect s of fishing disturbance. Regardless, Ball et al. (2000) commented that epifauna are generally scarce in muddy sediment habitats, and detection of fishing effects on such species has therefore been limited.

While the passage of a trawl may damage or destroy macroinfauna, Gilkinson et al. (1998) suggested that smaller infauna are resuspended or displaced by a pressure wave preceding otter trawl doors and are redeposited to the sides of the gear path. Due to a buffer effect caused by a displacement field of sediment (sand), bivalves incur a low level of damage (5%) by the passing of a trawl door. In contrast to coarse sediment communities where the infauna are found within the top 10 cm, organisms in soft mud communities can burrow up to two meters deep (Atkinson and Nash 1990). Due to their depth, it is likely that these organisms are less likely impacted by passing trawls (Jennings and Kaiser 1998), though it should be noted that the energetic costs of repeated burrow reconstruction may have long-term implications for the survivorship of individuals.

Studies documenting impacts to habitat from successive trawling are not prevalent. However, a few studies suggest that shifts in species abundance and diversity are a result of the cumulative effects of trawling. Over a longer time scale (i.e., 50 years), Ball et al. (2000) suggested that fishing disturbance may ultimately lead to an altered, but stable, community comprising a reduced number of species, and hence, diversity. Sainsbury et al. (1993; 1997) noted that composition of a multispecies fish community in Australia was at least partially habitat-dependent and that historical changes in relative abundance and species composition in this region were at least in part a result of the damage inflicted on the epibenthic habitat by the demersal trawling gear. In summary, trawling has the potential to reduce or degrade structural components and habitat complexity by removing or damaging epifauna; smoothing bedforms which reduces bottom heterogeneity; and removing structure producing organisms. Trawling may change the distribution and size of sedimentary particles; increase water column turbidity; suppress growth of primary producers; and alter nutrient cycling. The magnitude of trawling disturbance is highly variable. The ecological effect of trawling depends upon site-specific characteristics of the local ecosystem such as bottom type, water depth, community type, gear type, as well as the intensity and duration of trawling and natural disturbances. It should also be noted that there is not a direct relationship between the overall amount of trawling effort and the extent of subsequent impacts or the amount of fauna removed because trawling is aggregated and most effort occurs over seabed that has been trawled previously (Pitcher et al. 2000). Yet, several studies indicate that trawls have the potential to seriously impact sensitive habitat areas such as SAV, hardbottom, and coral reefs. In regard to hard bottom and coral reefs, it should be recognized that trawlers do no t typically operate in these areas due to the potential dam age their gear may incur.

While trawl nets have been documented to impact coral reefs, typically resulting in lost gear (Bohnsack, personal observation), these incidents are usually accidental. Partially in response to accusations of trawl activity on hard bottom habitat, a recent research effort to investigate potential impacts on the Florida Middle Ground Habitat Area of Particular Concern concluded that there was no evidence of trawl impacts or other significant fishery related impacts to the bottom (Mallinson, unpublished report). However, low-profile, patchy hard bottom or sponge habitat areas are more likely impacted from trawls due to the gear's ability to work over these habitat types without damaging the gear. Regardless, while it may be concluded that trawls have a minor overall physical impact when employed on sandy and muddy substrates, the available information does not provide sufficient detail to determine the overall or long-term effect of trawling on regional ecosystems.

Recovery of substrate depends on sediment type, depth, and natural influences such as currents and bioturbation. Schoellhamer (1996) investigated sediment resuspension within Tampa Bay, a shallow estuary with fine non-cohesive material (muds absent), and found that sediment concentrations returned to pre-trawl conditions approximately 8 hours after disturbance. The cumulative effects of several trawlers operating were not investigated. DeAlteris et al. (1999) found that scars similar to those that occur from otter trawl boards disappear relatively quickly in a shallow sand environment, while those occurring in a deeper mud habitat took as long as two months to disappear. DeAlteris et al. (1999) also found that natural disturbances to mud substrate in 14 m of water are rarely capable of disturbing the seabed. Therefore, recovery of fishery-related impacts in deeper water may be protracted due to the lack of natural events that help deposit sediments and fill trawl scars. Ball et al. (2000) determined that intensive demersal trawling over muddy seabeds leads to apparent long –term alteration of the seabed. Trawl tracks in muddy sediments may last up to 18 months; however, in areas of strong tidal or wave action, they are likely to disappear rapidly. Also, in areas where levels of bioturbation are high, and regular turnover of sediment produces large numbers of mounds on the seabed, trawl tracks will be filled relatively quickly (Ball et al. 2000). Habitats in deeper water tend to recover at a slower rate. Berms and furrows generated by trawl doors generally disappeared within one year in sandy habitats in depths of approximately 120-146 m (Schwinghamer et al. 1998; Prena et al. 1999). More dramatic is the estimate of 50-75 years to fill a typical trawl mark (~15 cm scour depth) in deep water (greater than 175m) by Friedlander et al. (1999). The greater the water movement, the faster the scars will be filled in (Jones 1992). Churchill (1989) and Krost et al. (1990) reported an increase in the frequency of tracks attributed to trawl doors in deeper water, presumably where water movement and natural impacts are less pronounced.

In general, few studies document recovery rates of habitat. Those that do investigate recovery usually only do so after a single treatment which does not reflect the reality of fishing impacts which are ongoing and cumulative. For example, Van Dolah et al. (1983; 1987) noted that hard bottom habitat in his trawl study recovered within one year. However, the experiment did not investigate the cumulative and repetitive effects of trawling at commercial intensities. As noted by an ICES (1995) study, due to the cumulative effects of trawling, focus on the scale of individual trawl impacts may be inadequate for estimating the importance of impacts on benthic communities. ICES (1994) stated that deep water coral banks (e.g., *Oculina varicosa*), due to their fragility, long life spans, and infrequent recruitment, may be nearly exterminated by a single passage of a trawl and are unlikely to recover "within a foreseeable future." Likewise, SAV would also have a protracted recovery time in comparison to sediments. SAV recovery may vary by species and can be greater than two years if the rhizomes of the plant are removed (Homziak et al. 1982). Regardless, the majority of studies concur that shallow communities have proved to be resilient due to their adaptation to highly variable environmental conditions and thus, recovery is usually swift. Kaiser et al. (1996a) found epifaunal communities in 35m of water that were experimentally trawled were indistinguishable from control sites after six months.

In areas of low current or great tidal exchange (e.g., deep ocean), where the benthos is not adapted to high sediment loads, the adverse effects of sediment resuspension by gear could persist for decades (Jones 1992). Recovery of small epibenthic organisms may be relatively rapid, but recovery of larger epibenthic organisms would be expected to be much slower. Though they did not discuss depth as a controlling factor, Sainsbury et al. (1993; 1997) indicated that there would be a considerable time lag after trawling ceases before recovery of large epibenthic organisms is substantial. Boesch and Rosenberg (1981) predicted that recovery times for macrobenthos of temperate regions would be less than five years for shallow waters (including estuaries) and less than ten years for coastal areas of moderate depth.

The majority of management recommendations indicate that marine reserves or gear zoning may be the most effective at reducing habitat impacts. However, other specific recommendations can be extracted from several studies. Tabb (1958) recommended that otter trawls not be permitted to operate in the bait shrimp fishery due to potential impact to SAV communities. Van Dolah et al. (1987) suggested that trawls with doors attached directly to the nets would greatly reduce the bottom area damaged by trawling activities. The use of artificial reefs to protect the seabed, in particular along the perimeter of SAV habitat areas, from trawling has also been offered (Guillén et al. 1994; Ardizzone et al. 2000). The use of semi-pelagic trawls would avoid the majority of habitat impacts that demersal trawls are associated with. However, while the use of semi-pelagic nets does not significantly impact the benthos, catch efficiency may be greatly reduced.

Furthermore, enforcement on the use of semi-pelagic nets remains difficult (Moran and Stephenson 2000). Carr and Milliken (1998) offered more straightforward recommendations: target certain species and modify gear appropriately; encourage the use of lighter sweeps; reduce the sea bottom available to trawlers that fish very irregular terrain; and opt for stationary gear over mobile gear. It is suggested that where fishing effort is constrained within particular fishing grounds, and where data on fishing effort are available, studies that compare similar sites along a gradient of effort have produced the types of information on effort impact that will be required for effective habitat management (Collie et al. 1997; Auster and Langton 1999). Additionally, the use of an indicator species (e.g., quahogs) that provides a historical record of fishing disturbance events could greatly enhance the interpretation of perceived changes ascertained from samples of present-day benthic communities (Macdonald et al. 1996; Kaiser 1998). Finally, the use of tracking devices (VMS) would provide a means for identifying the most heavily fished areas and those, if any, that are presently unfished (Macdonald et al. 1996; Kaiser 1998).

Comprehensive mapping of benthic habitats may provide the necessary information to determine what areas are at risk from fishery-related impacts. Utilized in conjunction with information that details fishing effort and area, gear zoning that limits the vulnerability of sensitive habitats while minimizing economic impacts to fishery participants should be considered.

Oyster Dredge

An oyster dredge consists of a metal rectangular frame to which a bag-shaped net of metal rings is attached. The frame's lower end is called the raking bar, and is often equipped with metal teeth used to dig up the bottom. The frame is connected to a towing cable and dragged along the seabed. Oyster dredges are widely utilized in state waters along the Gulf of Mexico, as well as the South Atlantic. Mechanical harvesting of oysters using dredges extracts both living oysters and the attached shell matrix and has been blamed for a significant proportion of the removal and degradation of oyster reef habitat (Rothschild et al. 1994; Dayton et al. 1995; Lenihan and Peterson 1998). Lenihan and Peterson (1998) observed that less than one season of oyster dredging reduced the height of restored oyster reefs by ~30%. Reduction in the height of natural oyster reefs is expected to be less than that of restored reefs because the shell matrix of natural reefs is more effectively cemented together by the progressive accumulation of settling benthic organisms, while restored reefs are initially loose piles of shell material. Regardless, it is likely that the height of natural reefs is also reduced by dredging because a large portion of extracted material from natural reefs by dredges is shell matrix. Lenihan and Peterson (1998) stated that it was probable that reduction in reef heights in a Neuse River, North Carolina estuary was due to decades of fishery-related disturbances caused by oyster dredging. At an annual removal rate of 30%, restored reefs would be completely destroyed after less than 4 years of harvesting. Furthermore, they determined that the height reduction of oyster reefs through fishery disturbance impacted the quality of habitat due to the seasonal bottom-water hypoxia/anoxia which caused a pattern of oyster mortality and influenced the abundance and distribution of fish and invertebrate species that utilize this temperate reef habitat (Lenihan and Peterson 1998). Their results illustrated that tall experimental reefs – those mimicking natural, ungraded reefs – were more dependable habitat for oysters and other reef organisms than short reefs – those mimicking harvest-degraded reefs – because tall reefs provided refuge above hypoxic/anoxic bottom waters. Chestnut (1955) also documented that intensive dredging over a period of years resulted in the removal of the productive layer of shell and oyster, leaving widely scattered oysters and little substrate for future crop of oysters.

Glude and Landers (1953) noted that dredges mixed the sandy-mud layer and the underlying clay. Fished areas were found to be softer and have less odor of decomposition than the unfished control site. Glude and Landers (1953) also found a decrease in benthic fauna in the fished sites versus the unfished control sites. Conversely, a study conducted by Langan (1998) which looked at the impacts oyster dredging had on benthic habitat, as well as sediment resuspension resulting from dredging activity, concluded with different results. He noted that the size-frequency of oysters from the control site was biased towards older and larger specimen s with poor recruitment. Oysters from the dredged site illustrated good recent recruitment, while larger specimens were not as abundant as the control site. No significant differences between the two areas were found in number, species richness, or diversity of epifaunal and infaunal invertebrates, indicating that dredge harvesting had no detectable effect on the benthic community. Sediment suspension resulting from dredging activity appeared to be localized. It should be noted that the study failed to evaluate fishing activity (number of participants, effort) on the dredged site.

Due to overfishing and disease, oysters may now be more economically valuable for the habitat they provide for other valued species than they are for the oyster fishery (Lenihan and Peterson 1998). Rothschild et al. (1994) suggested the establishment of broodstock sanctuaries that includes the designation of “no-fishing” restrictions in specific areas. Lenihan and Micheli (2000) also recommended the closure of some oyster reefs to harvest. Maintaining high densities of oysters on some intertidal reefs may help to preserve future oyster harvests and broodstock. Furthermore, protecting some reefs will also preserve the ecological functions that oyster reef provide such as improving water quality and providing essential recruitment, refuge, and foraging habitat for numerous marine species.

Scallop Dredge (Inshore)

Scallop dredges are similar to crab scrapes, though scallop dredges utilized in the southeast generally do not have teeth located on the bottom bar. Scallop dredges are predominately used on SAV beds where bay scallops can be efficiently harvested, and thus, are primarily limited to state waters. Popular bay scallop fisheries exist both off Florida and North Carolina. This gear, while similar, is not the same type of dredge utilized offshore to harvest calico scallops (*Argopecten gibbus*) or Atlantic sea scallops (*Placopecten magellanicus*).

Though scallop dredges do not have teeth that would easily uproot SAV, studies have noted a reduction of algal and SAV biomass from their use (Fonseca et al. 1984; Bargmann et al. 1985). The reduction of SAV (*Zostera marina*) biomass was linearly related to the number of times a particular area was dredged, and the effects of dredging were proportionately greater on soft bottom than hard bottom (Fonseca et al. 1984). The Fonseca et al. (1984) study utilized an empty dredge that was 60% of the legal limit for a commercial dredge, and was not employed in conjunction with a boat as the commercial fishery does. Hand dredging was done to eliminate propeller scour which commonly occurs in shallow SAV beds. In commercial scalloping, the added dredge and scallop weight, as well as the propeller wash, could be expected to have a greater imp act (Fonseca et al. 1984). In general, more damage from scallop dredging occurred to SAV in soft substrates (i.e., mud) than hard substrates (i.e., sand). In softer sediments, plants were uprooted and damage to underground plant tissues, including meristems, occurred. In harder sediments, damage was found to be generally greater for above ground parts; underground meristems were left intact and able to begin to repair shoots or produce new ones after impacts had ceased (Fonseca et al. 1984).

Fonseca et al. (1984) determined that in a lightly harvested SAV area, with less than 25 % biomass removal, recovery occurred within a year. In areas where harvesting resulted in the removal of 65% of SAV biomass, recovery was delayed for two years. After four years, preharvesting biomass levels were still not obtained. These estimates were based on termination of fishery-related impacts. Continued fishing activity would likely lead to prolonged recovery and continued degradation. Homziak et al. (1982) estimated that SAV recovery can be greater than two years if the rhizomes of the plant are removed.

Due to the importance of SAV beds as a nursery area to other species, loss of eelgrass meadows should be avoided. Fonseca et al. (1984) suggested that harvest area rotation may minimize habitat impact.

Scallop Dredge (Offshore)

Scallop dredges (Figure 7) utilized to harvest calico or sea scallops consist of a metal frame that supports tickler chains and a metal ring bag that collects the shellfish. Though not widely utilized in the southeast, the gear has been included in this review due to their inclusion as an approved gear in the South Atlantic. The majority of studies on scallop dredge impacts originate from areas with extensive scallop fisheries such as the northwest and northeast Atlantic.

Due to the potential for the gear to have considerable weight and the fact that it is dragged along the bottom, habitat impacts are expected to occur. Drew and Larsen (1994) estimated that a scallop dredge maximum cutting depth would be 40 - 150mm. Kaiser et al. (1996a) found that scallop dredging greatly reduced the abundance of most species, causing significant changes in the community. It was noted that a large proportion of some animals (such as echinoderms) were not captured or passed through the mesh of the gear. The scallop dredge catches contained a low proportion of non-target species which indicates that the belly rings allow the bycatch to escape. However, the study did not investigate the extent of damage/injury to organisms that were not captured. Likewise, Collie et al. (1997) found areas on Georges Bank that were impacted by scallop dredges to have lower species diversity, lower biomass of fauna, and dominated by hard-shelled bivalves, echinoderms, and scavenging decapods. Areas less impacted by dredges had higher diversity indices. However, it should be noted that portions of Georges Bank consist of cobble habitat which is encrusted with a diverse array of epibenthic species.

Perhaps more applicable to the areas in the southeast where calico scallops are harvested off North Carolina and Florida, would be a study conducted by Butcher et al. (1981), who determined that scallop dredges had little or no environmental effect when they were used on large-grained, firm sand bottom that was shaped in roughly parallel ridges. The area in this study was also noted to be a fairly uniform, low species diversity community. Turbidity caused by the turbulence of the dredge quickly dissipated due to the nature of the substrate. Additionally, Jolley (1972) found no detrimental dredging effects on sand substrates. Yet, there is a potential for dredges to impact coral adjacent to scallop beds, especially the scallop grounds which occur in close proximity to the Oculina Bank off eastern Florida. Should a scallop dredge impact *Oculina* coral, there would be severe results, similar to the conclusion s reached by ICES (1994) for trawls. This study determined that deep water coral banks such as those composed of *Oculina varicosa*, due to their fragility, long-life spans, slow growth, and infrequent recruitment, may be nearly exterminated by a single passage of a trawl. Recovery of this habitat area, "within a foreseeable future," is unlikely (ICES 1994).

Skimmer Trawl

Skimmer trawls are positioned along the side of a boat and pushed through the water to harvest shrimp. Two nets are typically used, one on each side of the boat. Skimmer trawls are supported by a tubular metal frame that skims over the bottom on a weighted metal shoe or skid. Tickler chains are also utilized along the base of the net. Because of the construction attributes of this gear type, skimmer trawls are generally restricted to water 3.05m (10 ft) or less which would limit them to state waters.

Skimmer trawls work on mud bottoms in water generally 3.05m (10ft) or less. The weighted shoe and tickler chains impact the bottom, resulting in sediment resuspension. Skimmer trawls may cause bottom damage due to improperly tuned or poorly designed gear (skids and bullets) or prop damage in shallow areas (Steele 1994). Furthermore, because skimmer trawls are used in shallow water, they may have a detrimental impact on critical nursery areas such as the marsh/water interface, SAV, or other sensitive submerged habitats. However, skimmer trawls are expected to impact the bottom less than otter trawls due to the absence of doors (Nelson 1993; Steele 1993). Coale et al. (1994) believed that the skimmer trawl would not have any greater effects on SAV than the otter trawl. They found it doubtful that the inside weight and outer shoe of the skimmer trawl would cause greater detrimental effects to the benthos than the heavy doors of an otter trawl. Based on underwater observations, Coale et al. (1994) suggested that the weight and shoe combination may be less-damaging than otter trawls. However, habitat such as sponges and SAV are cut off by tickler chains and lead lines whereas otter trawl doors can dig in and tear up the bottom. Given the difference in the amount of area covered by each on normal tows, Kennedy, Jr. (1993) found it doubtful that there would be much difference in the amount of habitat loss between skimmer trawls and otter trawls.

Kennedy, Jr. (1993) recommended that the use of skimmer trawls in Florida should be restricted to those areas currently approved for otter trawls. Due to the associated impacts to SAV, a prudent recommendation would be to limit skimmer trawl use to non-vegetated substrates.

6.2.2.2 Static Gear

Channel Net

Channel nets are fixed to pilings, docks, or shore installation and utilize current flow to capture shrimp, therefore, channel nets are limited to use within state waters. Though impacts of channel nets were not discussed specifically, it may be inferred from Higman (1952) that channel nets have negligible impact on habitat due to catch composition and the lack of interaction with the benthos.

Gillnet and Trammel Net

Gillnets (Figure 9) consist of a wall of netting set in a straight line, equipped with weights at the bottom and floats at the top, and is usually anchored at each end. As fish swim through the virtually invisible monofilament netting, they become entangled when their gills are caught in the mesh, hence the name. Gillnets may be fixed to the bottom (sink net) or set midwater or near the surface to fish for pelagic species. A trammel net is made up of two or more panels suspended from a float line and attached to a single lead line. The outer panel(s) are of a larger mesh size than the inner panel. Fish swim through the outer panel and hit the inner panel which carries it through the other outer panel, creating a bag and trapping the fish. Smaller and larger fish become wedged, gilled, or tangled. Gillnet s are widely used in numerous fisheries, both in state waters and in Federal waters. Trammel nets are primarily used in state waters, though they are an authorized gear in the Caribbean for both the spiny lobster and shallow water reef fish fisheries.

The majority of the studies that have investigated impacts of fixed gillnets have determined that they have a minimal effect on the benthos (Carr 1988; ICES 1991; ICES 1995; Kaiser et al. 1996b). An ASMFC (2000) report determined that impacts to SAV from gillnets would be minimal. Likewise, West et al. (1994) stated that there was no evidence that sink net (gillnet) activities contributed importantly to bottom habitat disturbance. However, Carr (1988) noted that ghost gillnet s in the Gulf of Maine could become entangled in rough bottom. He observed one net that had its leadline and floatline twisted around each other and tightly stretched between boulders. Furthermore, Williamson (1998) noted that gillnets can snag and break benthic structures. Gomez et al. (1987) noted that gill nets set near reefs occasionally results in accidental snaring often resulting in damage to coral. Bottom set gillnets have led to habitat destruction in different regions (Jennings and Polunin 1996). Bottom gillnets set over coral may cause negative impacts as the weighted lines at the base of the net often become entangled with branching and foliaceous corals. As the nets are retrieved, the corals are broken (Öhman et al. 1993). This observation has also been noted in a study by Munro et al. (1987), which documented that reefs are frequently damaged by the hauling of set (gill) nets, and the problem has been exacerbated by the use of mechanical net haulers or power blocks. Aside from the potential impacts cited on coral reef communities, the available studies indicate that habitat degradation from gillnets is minor.

Several studies note that lost gillnets are quickly incorporated by marine species. Cooper et al. (1988) found ghost gillnets in the Gulf of Maine covered with a heavy filamentous growth, exceeding 75% coverage on some nets. Anemones, stalked ascidians and sponges were attached to and growing to the net float lines (Carr et al. 1985; Cooper et al. 1988). Erzini et al. (1997) found that lost trammel nets and gill nets in shallow water (15-18m) on rocky habitat (analogous to coral reefs and hard bottom habitat) were colonized by various species, primarily macrophytes, which after three months completely blocked the meshes of some parts of the nets. Some netting would contact reef habitat, becoming heavily overgrown and eventually blended into the background. After a year, most of the netting was destroyed; those remnants that remained were completely colonized by biota (Erzini et al. 1997). Erzini et al. (1997) also noted that the nets eventually became incorporated into the reefs, acting as a base for many colonizing plants and animals. The colonized nets then provided a complex habitat which was attractive to many organisms. For example, large schools of juvenile fish were often observed in the vicinity of these heavily colonized nets, which may provide a safe haven from predators. Johnson (1990) and Gerrodette et al. (1987) noted that as gillnets tend to collapse and "roll up" relatively quickly, they may form a better substrate for marine growths and thereby attract fish and other predators which may get entangled, ultimately causing the net to sink. Therefore, one may assume that gillnets may be more of a ghostfishing problem and entanglement hazard to marine life than as an impact to habitat.

Catch by entanglement nets during 1988 was 1,398 lbs from North Carolina through Georgia (less than 1% of the combined state catch) and 253,739 lbs from the Florida East Coast (6% Florida East Coast catches). Much of the Florida landings are from a directed stab net fishery for gray snapper that operates in the EEZ. The Gulf Council and the State of Florida have prohibited entanglement nets. Florida regulations read as follows: "No person shall harvest in or from state waters any snapper of the family of Lutjanidae or any member of the genera *Epinephelus* or *Mycteroperca* by or with the use of any gear other than those types of gears specified in Subsection 1, provided however that snapper and grouper harvested as an incidental bycatch of other species lawfully harvested with other types of gears shall not be deemed to be unlawfully harvested in violation of this section, if the quantity of snapper/grouper so harvested does not exceed the bag and possession limits as specified elsewhere." The South Atlantic Council's actions track the Florida regulations in intent with respect to limiting possession to the bag limit and for species without a bag limit, no possession is allowed. Florida prohibited entanglement nets because it is an inappropriate gear to use on live bottom. Some of the reef fish are not necessarily found on the live bottom, however, many are and fishermen use stab nets to catch gray snapper on the live bottom areas.

The Council has concluded that entanglement nets are not an appropriate gear for the snapper grouper fishery and the prohibition will prevent use and/or expansion from North Carolina through Florida's East Coast. Entanglement nets targeting species other than those included in the management unit are limited to the bag limit if the species is under a bag limit, and if no bag limit is applicable, then no retention is allowed.

SAFMC Prohibition on the Use of Entanglement Nets
Snapper Grouper Amendment 4 prohibits the use of entanglement nets including, but not limited to, gill nets and trammel nets, for the harvest of species in the snapper grouper management unit (SAFMC 1991a). The simultaneous possession of entanglement nets and species in the management unit is prohibited.

Hoop Net

A hoop net is a cone-shaped or flat net which may or may not have throats and flues stretched over a series of rings or hoops for support. The net is set by securing the cod or tapered end to a post or anchored to the bottom. The net is played out with the current until fully extended, and then is allowed to settle to the bottom. The net is marked with a buoy for easy retrieval and identification purposes. The duration of time that a hoop net is set depends on the same factors that influence the duration of the set of a gill net and should be determined in a similar fashion. To harvest, the hoop net is raised at the cod end and the fish are removed.

While there are no studies that document the effect of hoop nets on habitat, due to its use primarily on flat bottoms the gear probably has less of an impact than traps.

Longline

Longlines use baited hooks on offshoots (gangions or leaders) of a single main line to catch fish at various levels depending on the targeted species. The line can be anchored at the bottom (Figure 12) in areas too rough for trawling or to target reef associated species, or set adrift, suspended by floats (Figure 13) to target swordfish and sharks. Longlines are widely utilized in numerous fisheries throughout the southeast region.

When a vessel is retrieving a bottom longline it may be dragged across the bottom for some distance. The substrate penetration, if there is any, would not be expected to exceed the breadth of the fishhook, which is rarely more than 50mm (Drew and Larsen 1994). More importantly is the potential effect of the bottom longline itself, especially when the gear is employed in the vicinity of complex vertical habitat such as sponges, gorgonians, and corals.

Bottom longlines in the snapper grouper fishery
The Council prohibited the use of bottom longline gear for snapper grouper in the South Atlantic EEZ within 50 fathoms (SAFMC 1994). Catch by bottom longlines during 1988

was 470,306 lbs from North Carolina through Georgia (6% of the combined state catches) and 576,310 lbs from the Florida East Coast (13% Florida East Coast catch). The Council was concerned about the use of bottom longline gear targeting species in the snapper grouper management unit in live bottom areas. Habitat damage and intense competition among users are problems that arise when this gear is used within 50 fathoms where significant live bottom occurs and where competition with hook and line vessels occurs. The Council concluded that this gear is appropriate for use in the deep-water snowy grouper/tilefish fishery where much of the bottom is mud with sparse live bottom areas. Allowing use of this gear deeper than 50 fathoms would preserve the traditional fishery which takes place in deeper water out to 50 fathoms. Based on information from South Carolina, up until 1983 the snapper grouper fishery was limited to vertical hook and line or bandit reels. Bottom longlines were introduced in the Gulf of Mexico after hook and line gear became less effective due to decreases in resource abundance; use of the gear grew rapidly. Up until this point there has been no gear prohibition on bottom longlines. After the golden tilefish and snowy grouper fisheries were developed, bottom longlines became the predominant gear, again as resource abundance declined. For species like snowy grouper and tilefish, it was not very efficient to use vertical hook and lines as the resource abundance declined from unfished levels. As the tilefish and snowy grouper stocks off South Carolina declined, the number of people using longlines decreased. Off South Carolina virtually all of the golden tilefish occurred well outside the 50-fathom mark and there was more than enough gear to adequately harvest these resources in the mid-depth zone. Vertical lines are much more environmentally acceptable and less damaging than bottom longlines.

This regulation essentially segments the mid-shelf and the deep-water complex to the bottom longlines. This measure was supported during the public hearing process and the Council concluded that prohibiting use of longline gear within 50 fathoms will prevent the problems of habitat damage and intense competition while at the same time allow fishermen using this gear to continue fishing in deeper water. This action effectively limits longlines to targeting the deep water component of the snapper grouper fishery and keeps the use of longlines outside of the rough bottom habitat.

The Council very briefly considered moving the line in to the 40 fathom contour but was concerned that there are substantial Oculina coral banks along this depth zone. It was further noted that the 50 fathoms was a compromise from the 100 fathom contour (which was mentioned) and that the 50 fathom contour effectively separates the inshore and deep water snapper grouper complexes.

Impacts on habitat

Observations of halibut longline gear off Alaska included in a North Pacific Fishery Management Council Environmental Impact Statement (NPFMC 1992) provide some insight into the potential interactions longline gear may have with the benthos. During the retrieval process of longline gear, the line was noted to sweep the bottom for considerable distances before lifting off the bottom. It snagged on whatever objects were in its path, including rocks and corals. Smaller rocks were upended and hard corals were broken, though soft corals appeared unaffected by the passing line. Invertebrates and other light weight objects were dislodged and passed over or under the line. Fish were observed to move the groundline numerous feet along the bottom and up into the water column during escape runs, disturbing objects in their path. This line motion has been noted for distances of 15.2m (50ft) or more on either side of the hooked fish. Based on these observations, it is logical to assume that longline gear would have a minor impact to sandy or muddy habitat areas. However, due to the vertical relief that hardbottom and coral reef habitats provide, it would be expected that longline gear may become entangled, resulting in potential impacts to habitat. Due to a lack of interaction with the benthos, pelagic long lines would have a negligible habitat impact.

SAFMC Prohibition on the Use of Bottom Longlines
The Council prohibits bottom longlining in the wreckfish fishery in the entire South Atlantic EEZ (SAFMC 1991a). A bottom longline is a stationary, buoyed, and anchored groundline with hooks attached. Regulations prohibit simultaneous possession of wreckfish and all the necessary components for bottom longlining.

The Council was concerned about wastage of fish, gear loss, gear conflict, habitat damage, and negative economic effects (both short and long run) attributable to the use of bottom longline gear in the wreckfish fishery. The bottom habitat on the wreckfish fishing grounds, which comprise an area of the Blake Plateau of approximately 50-75 square nautical miles, is characterized by a rocky ridge system having a vertical relief greater than 50 meters and a slope greater than 15° (SAFMC 1993). The depth range in this area is 450-600 meters; the substrates in areas of the Blake Plateau exhibiting significant relief are generally characterized as composed of manganese phosphate pavements, phosphorite slabs and coral banks (Pratt and McFarlin 1966; Stetson et al. 1969). This high relief, in conjunction with the strong tidal effects, makes gear loss probable (as reported by fishermen who have already tried longlines in the wreckfish fishery) which results in the loss of all fish on the gear as well as those which get hooked subsequently. Testimony from fishermen indicated gear loss on wreckfish longline sets was as great as 100% of the gear taken out on a single trip. According to accounts from fishermen, extensive lengths of lost longline gear have been observed on their fathometers. Fishermen can apparently see fish hooked on parted longline gear but are unable to recover the parted gear and its catch. Wreckfish fishermen use circle hooks that virtually prevent fish from working the hook free. The Council recognized that there was also some ghost fishing potential from lost vertical gear but believes that the extent of potential loss with vertical gear is much smaller by virtue of the fewer number of hooks used and the greater control over the gear.

Although the area is 50-75 square nautical miles, virtually all wreckfish fishing takes place along limited, high relief ledge areas within this area because wreckfish are found along the ledges and are not evenly distributed over the wider area. The sub-areas that produce wreckfish are typically 300 yards wide and 1-4 nautical miles long. Thus far, fishermen fishing vertical drop gear have been able to work in relatively close proximity without any major conflicts. If bottom longlines had been allowed to be used in this area, vessels would have not only lost gear due to the rough bottom, but this lost gear would create a hazard for those using vertical lines which would result in loss of that gear. This problem would have become progressively worse over time as more gear was lost, the more hangs were created for both longline and vertical gear, creating even more gear loss. This condition could have continued until much of the ground is unfishable. The wire cable that is used will remain a hazard for many years as the rate of decay is slow. While extensive hangs may ultimately provide protection for the resource due to much of the fishing grounds being unfishable, it may well result in the loss of the fishery. The use of longlines will result in gear losses to vertical hook and line fishermen that far exceed their losses prior to the introduction of longlines. This will serve to reduce benefits to those fishing with the traditional vertical gear.

The potential for gear entanglement and gear conflict also raised the issue of vessel safety. It was the Council's opinion that this situation would have lead to conflicts that jeopardize the safety of the vessels and fishermen participating in the wreckfish fishery.

Longline cable on the bottom has the potential to break some of the ledges, overhangs and associated organisms, and otherwise damage the habitat on which the wreckfish depend. Habitat damage caused by the longlines would violate the SAFMC habitat policy and should be avoided.

The wreckfish fishery has employed efficient vertical gear since its inception, and the addition of longlines would have eroded benefits to the majority of fishermen and adversely impact the resource and habitat. If longlines had been allowed, then all or at least many wreckfish fishermen may have been forced to adopt the gear in order to compete resulting in more gear loss from parted longlines. The Council determined that bottom longlines were not in the best interest of the wreckfish resource, habitat, fishermen or society at large. Further, the problems outlined justified prohibiting this gear/fishing method in the wreckfish fishery.

Pound net

A pound net consists of a fence constructed of netting that runs perpendicular to shore which directs fish to swim voluntarily into successive enclosures known as the heart, pound, or pocket. Pound nets are exclusively utilized in state waters.

An ASMFC (2000) report determined that impacts to SAV from pound nets are expected to be minimal, unless the net is constructed directly on SAV. West et al. (1994) also stated that pound nets do not contribute to benthic disturbance. Due to the limited amount of space a pound net may impact, it is expected that pound nets have minimal impact on habitat.

Trap and Pot

Traps and pots are rigid devices, often designed specifically for one species, used to entrap finfish or invertebrates. Depending on the type of fishing a trap is used for, most traps are generally baited and equipped with one or more funnel openings, they are left unattended for some time before retrieval. Traps and pots are weighted to rest on the bottom, marked with buoys at the surface, and are sometimes attached to numerous other traps to one long line called a trot line. Traps and pots are widely used on a variety of habitats in both state and Federal waters to commercially harvest species such as lobster, blue crabs, golden crabs, stone crabs and black sea bass. Wire-mesh fish traps are one of the principal fishing gears used in coral reef areas in the Caribbean (Appledorn 2000).

SAFMC Prohibition on the use of fish traps

It should be noted that many of the studies used in forming this document refer to fish trap fisheries outside of the continental US. These fisheries are different from crustacean trap fisheries operating on the South Atlantic coast in that the traps are built to selectively capture crabs and lobster and avoid bycatch of untargeted finfish. There are few studies to date regarding the bycatch rate of finfish but anecdotal information from fishermen and fisheries managers point out that spiny lobster traps do not capture significant amounts of snapper, grouper and other ornamental reef fish.

The Council prohibited the use of fish traps in the South Atlantic EEZ; however, black sea bass traps may be used north of Cape Canaveral (Vehicle Assembly Building, 28° 35.1' N Latitude). Fish traps were banned in federal waters off the South Atlantic states in 1992 and banned in the Gulf of Mexico west of Cape San Blas (located at about the middle of the Florida Panhandle) in 1997.

In general, pots can cost anywhere between $30-$50 USD to construct. It does take some skill in determining an appropriate location for fishing trap gear, and efficiency is based on how many traps a fishermen can service in one working day. Traps will soak an average of 1-2 weeks before they are checked. While traps can catch a wide variety of marine organisms, fishermen place traps in specific areas to avoid bycatch of untargeted species. One downfall to trap fishing is that the gear can be lost in storm events, so to avoid “ghost fishing” most traps have degradable panels and escape rings that rot off allowing fish to exit the trap. While trap fishing gear has created user-group conflicts in the past, managers are in the process of choosing particular fishing zones which will help the general public become more aware of trap fishing areas.

Due to their use to harvest species associated with coral and hard bottom habitat, traps and pots have been identified to impact and degrade habitat. Gomez et al. (1987) noted the incidental breakage of corals on which traps may fall or settle constitute the destructive effects of this gear. Within the Virgin Islands State Park, Garrison (1998) found 86% of the fish traps were set on organisms (live coral, soft coral, SAV) living on the sea floor. Damage to the live substrate has far-reaching negative effects on the marine ecosystem because the available amount of shelter and food often decreases as damage increases. Another study conducted by Garrison (1997) had similar results, as 82% of traps rested directly on live substrate, with 17% resting on stony corals. It is important to note that the aforementioned statistics (Garrison, 1987-1998) do not reflect the way trap based crustacean fisheries operate within the continental United States. Studies from the Florida Fish and Wildlife Conservation Commission (Tom Matthews, personal communication) confirm that only 2% of spiny lobster traps are fished on top of stony coral reef habitats.

Hunt and Matthews (1999) found that lobster and stone crab traps reduce the abundance of gorgonian colonies from rope entanglement. Furthermore, seagrass smothering occurs from trap placement on SAV beds, resulting in SAV "halos." ." Studies also confirm that traps set for no longer than a two week period do not pose an adverse threat to seagrass ecology as the seagrass subsequently recovers. Van der Knapp (1993) noted that fish traps set on staghorn coral easily damaged the coral. It appeared that in all observed cases of injury due to traps, the staghorn coral regenerated completely, although the time for regeneration varied from branch to branch. The greatest impact noted from the setting of traps was observed when the point of the trap's frame ran into coral formations. Several different species of coral were observed to suffer damage from fish traps. Observations of at least one damaged coral specimen noted that algae growth prevented regeneration in the damaged portion of the coral. Additionally, complete deterioration of a vase sponge was observed after it had been severely damaged by a trap. Traps are not placed randomly, rather they are fished in specific areas multiple times before fishing activity moves to other grounds. Therefore, the damage caused by wire fish traps in this study has a concentrated cumulative effect in particular areas rather than being uniform over all coral reef habitat

Appledorn et al. (2000) commented that fish traps may physically damage live organisms, such as corals, gorgonians, and sponges, which provide structure and in some cases, nutrition for reef fish and invertebrates. Damage may include flattening of habitats, particularly by breaking branching corals and gorgonians; injury may lead to reduced growth rates or death, either directly or through subsequent algal overgrowth or disease infection. During initial hauling, a trap may be dragged over more substrate until it lifts off the bottom. Traps set in trotlines can cause further damage from the trotline being dragged across the bottom, potentially shearing off at their base those organisms most important in providing topographic complexity.

Traps that are lost or set unbuoyed are often recovered by dragging a grappling hook across the bottom. This practice can result in dragging induced damage from all components (grappling hook, trap, trotline). The area swept by trotlines upon recovery is orders of magnitude greater than the cumulative area of the traps themselves. Appledorn et al. (2000) documented that single-buoyed fish traps off La Parguera, Puerto Rico, have an impact footprint of approximately 1 m^2 on hard bottom or reef. Of the traps investigated in the study, 44% were set on hard bottom or reef, resulting in 23% damage to coral colonies (70 cm^2 average), 34% damage to gorgonian colonies (56 cm^2 average), and 30% damage to sponges, though sponges were less frequently impacted due to their patchy distribution. Hauling these wire fish traps resulted in 30% of the traps inflicting additional damage to the substrate. In a similar study focusing on fish trap impacts conducted off St. Thomas, U.S.V.I., by Quandt (1999), 40% of all traps investigated were found to be resting on reef substrate. On average, 4.98% of all hard corals and 47.17% of all gorgonians were damaged; tissue damage averaged 20.03% to each gorgonian. Secondary impacts, such as trap hauling and movement due to natural disturbances were not investigated. However, the effects of pulling a string of two or more wire fish traps would most likely be much greater than one trap alone.

Eno et al. (1996) found pots that landed on, or were hauled through beds of bryozoans caused physical damage to the brittle colonies. It was noted that several species of sea pens bent in response to the pressure wave created by a descending pot and were lying flat on the seabed. When the pot was removed, the sea pens were able to reestablish themselves in the sediment. A species o f sea fan also was found to be flexible and specimens were not severely damaged when pots were hauled over them. This suggests that in some instances the direct contact of certain gears may not be the primary cause of mortality, rather the frequency and intensity may be more important. Additionally, Sutherland et al. (1983) cited little apparent damage to reef habitats inflicted from fish traps off Florida. The study found four derelict traps sitting atop high profile reefs with four other traps observed within a live-bottom area. There was no visual evidence that traps on the high profile reef killed or injured corals or sponges. One uprooted gorgonian was observed atop a ghost trap in a live bottom area. However, these observations were made on randomly located derelict traps. Thus, the primary impacts that may occur during deployment and recovery could not be evaluated.

Trap loss

Gear failure, theft, and improper placement are several of the many reasons why traps are lost both inshore and offshore. Gear failure can occur because of pot warp (line) parting, buoys separating from the pot warp, or buoys breaking up. Normal wear and tear, powerboat propellers, and sea turtles or sea gulls biting the buoys or pot warp can cause gear failure. Theft is also a major cause of lost traps in many areas. Losses also occur because of setting the traps too deep or on too steep a slope. Storm surge and wave action can cause loss of traps, particularly in shallow inshore waters during hurricane and foul weather events. Traps without buoys are less susceptible to storm damage, but may be moved from a site by currents or wave action and become irretrievable. In coralline areas, the buoy lines may become entangled on coral, chafe, and break. Offshore, losses are primarily caused by large vessels cutting or dragging gear, gear failure, and storms. Strong currents submerging buoys or sweeping traps away from the locations where they were set and traps becoming entangled with other fishing gear and anchors have also been cited as causes of trap loss.

The percentage of traps lost varies considerably among studies by both area and depth fished. Wolf and Chislett (1974) reported fish trap losses of 10-20% per trip in exploratory efforts in deep water shelf edges in the Virgin Islands. They attributed these losses to pots tumbling down steep slopes. Craig (1976) reported a fish trap loss rate of about 20% for a period of six months with some loss due to theft while trap fishing off Boca Raton, Florida. In Broward County, Florida, the same study reported that fish trap fishermen reported an average of 20.3% annual loss due mainly to strong currents, entanglement and theft. Dade County, Florida trap fishermen reported losing 1-5 traps per trip, with an annual loss of 100%. Losses were due to theft or loss of buoys. Trap theft was such a problem that traps were brought back to port at the end of each fishing day in Dade (Sutherland and Harper 1983).

Sutherland and Harper reported that Monroe County, Florida trap fishermen had estimated average annual trap losses of 63%. The losses were mainly from currents and severance of buoys by large ships in deep water and from vandalism inshore. Trap loss in the spiny lobster fishery was not a problem in Collier County, Florida with an annual loss of only 5% due to the fact that fishermen brought back traps to the dock after each trip (Taylor and McMichael 1983). About 85% of traps used off Key Biscayne, Florida were lost with most losses attributed to theft (Sutherland et al. 1987). Fish trap loss from theft and severed fouling lines was reported as a major problem in the Virgin Islands (Swingle et al. 1970; Olsen et al. 1974; Sylvester 1972).

In Jamaica, Munro and Thompson (1973) had such a theft problem in their study that the use of buoyed traps had to be abandoned. Losses due to theft, storms, and vessels cannot easily be controlled, but fish trap fishermen can inspect gear frequently for wear and tear and use more durable materials.

Fish traps that fishermen cannot locate and retrieve or that are abandoned but are still capable of catching fish, are often referred to as ghost traps. Ghost traps have long been a subject of concern, but opinions have changed considerably over time. Since Olsen et al. (1978) made their observations that if traps were lost, juvenile and forage species mortality could decimate a fishing ground, they suggested that considerable mortality could take place over the 1-2 years before the wire mesh corroded away, and indicated corrosion time would be longer and mortality would be greater for small sizes of mesh. A study by Harper and McClelland (1983) estimated the average fishing life of eight traps observed off Key Biscayne to be from 5.5 to 157 days before becoming unable to capture fish. They also found that 19.2% of the fish that entered the trap died (Harper and McClelland 1983). While the decay and catch rates of ghost traps are not well documented, at least some evidence indicates that lost traps quickly become damaged and ineffective (Sutherland et al. 1978). Most reports of injury and mortality from lost ghost traps are anecdotal but underwater video presented to the South Atlantic Fishery Management Council on June 11, 1990 documented dead and injured fish in ghost traps in the Florida Keys. The video was presented by Capt. Fernand Braun (a charter fishing guide) in an effort to persuade the Council to ban fish traps.

Derelict traps are lost or abandoned traps that are incapable of catching fish due to structural damage or deterioration. Derelict traps may have small holes or breaks and gaps between ceiling and floor panels and walls, or entire panels degraded or missing (Smolowitz 1978). Traps become derelict in a number of ways. Predator damage, corrosion, escape windows opening, and materials fastened to escape devices decomposing have all been documented.

Munro et al. (1971) speculated that lost fish traps that have accumulated large numbers of fish may be attacked and rendered ineffective by large predators such as nurse sharks (*Ginglymostoma cirratum*). Harper and McClelland (1983) found funnel openings enlarged with the prongs bent back and speculated that the damage was by large predators such as cubera snapper (*Lutjanus cyanopterus*), great barracuda (*Sphyraena barracuda*), yellow jacks (*Caranx bartholomae*), and lemon sharks (*Negaprion* *brevirostris*) attempting to escape and that mortality of these fish was high. Craig (1976) found that escapement through trap holes caused by predators became a problem if traps were not hauled after five or six days. Fish are rarely caught in traps with holes or breaks in the mesh and even small holes or breaks in the wire mesh apparently render them ineffective (Craig 1976; Sutherland and Harper 1983; Ward 1983).

Sutherland et al. (1983) found juvenile fish numerous in and around derelict fish traps. The derelict traps and other manmade objects appeared to serve as artificial reefs on barren sand sea floor areas (Sutherland et al. 1983; Harper and McClelland 1983). Sutherland et al. (1983) observed that fish were absent or rare near traps on or adjacent to reefs.

Impacts on habitat

The Council concluded that the issue of wire fish traps was a critical issue to the State of Florida and in the long term to the entire South Atlantic as well. Florida deliberated the issue of fish traps for many years and the Florida State Legislature prohibited the use of wire fish traps in 1980. The snapper grouper stocks are more overfished off Florida than they are anywhere else in the South Atlantic.

The Council concluded that fish traps are non-selective by size and by species (e.g., red grouper recruit to the hook and line fishery at around 19" and to the trap fishery at around 11"). Bohnsack et al. (1989) notes that modifications to mesh size will alter the size of fish caught. This study concluded that total value, species caught, number of individuals and mean total weight per haul declined with meshes larger or smaller than 1.5" hexagonal mesh. The mesh sizes required to correlate with the 20" minimum sizes would be so large as to result in de facto prohibition on use of fish traps.

Based on studies regarding fish traps between 1980-1990, the SAFM Council has concluded that wire fish traps capture a significant amount of bycatch. Information contained in Bohnsack et al. (1989) documents the bycatch of these species. Unfortunately, a variety of ornamental reef fish were not recorded separately in the commercial landings data until recently, thus the commercial landings data are not available to quantify the extent to which catches of these species have increased. We also expect that there has been a decline in the amount of ornamental reef fish caught as bycatch since wire fish traps were banned from federal waters (and state waters in Florida).

Since March 1, 1991 the State of Florida has prohibited the harvest of tropical fish: “The purpose and intent of this Chapter is to protect and conserve Florida’s tropical marine life resources and to ensure the continued health and abundance of these species. . The affect of selective removal of herbivores on the health of coral reefs was discussed by LaPointe (1989). These species were harvested by fish traps more frequently than by hook and line gear. Again, due to the fact that commercial statistics did not record these fish by species, data was unavailable to document the level of harvest by fish traps or by hook and line.

The further intent of this Chapter is to ensure that the harvesters in this fishery use non-lethal methods of harvest and that the fish, invertebrates and plants so harvested be maintained alive for the maximum possible conservation and economic benefits." Allowing fish traps in federal waters would make Florida's regulations difficult, if not impossible, to enforce and would not address Problem #5 which is, that "the existence of inconsistent state and federal regulation makes it difficult to coordinate, implement and enforce management measures and may lead to overfishing. Inconsistent management measures create public confusion and hinder voluntary compliance."

The way in which fish traps were used made enforcement extremely difficult. All other kinds of fishing gear are eventually brought back to the dock where they can be examined by state marine patrol officers or other law enforcement personnel. Once traps are placed in the water, they were seldom are brought back to the dock. Testimony documents the various kinds of violations recorded in the Key West area (e.g., biodegradable panel requirement violations). The loss of traps was high ranging from 20% to 63% and in certain sectors trap loss may be as high as 100%.

The SAFMC Law Enforcement Committee and Advisory Panel were established to advise the Council on enforceability of various management approaches. They noted that the existing system is difficult to enforce and is incompatible with Florida state law, that the 100-foot contour limitation is difficult to enforce and that poaching is a big law enforcement problem in the fish trap fishery. These two bodies recommended to the Council that a total prohibition on use of fish traps in the South Atlantic EEZ was the most enforceable of all alternatives considered.

The enforcement issue was summarized by Kelley (1990): "Enforcement is the largest problem of all. There are widespread abuses of the regulations governing the use of fish traps. There seems to be no effective way to enforce regulations in a fishery, such as fish trapping fishing, where gear can't be observed readily by enforcement officials. The largest present day problems in the Florida Keys and southeast Florida are the extensive trap poaching and the use of illegally constructed or deployed traps."

The Council recognized that gear that is not brought back to shore at the end of a fishing trip makes enforcement more difficult. The Council considered other, less drastic measures that would allow traps to be used but concluded that the at-sea enforcement required to effectively monitor and ensure compliance with existing regulations does not and will not exist. Therefore, the Council was persuaded that nothing short of a total ban on fish traps would be enforceable.

There is evidence that fish trapping causes habitat damage where fish traps are set in trawls on live bottom and where grappling hooks are dragged across live bottom to retrieve them. Testimony and video records of damaged *Oculina* reefs off Palm Beach County, provided to the Council at the February 1991 meeting, depicted significant and measurable damage to coral reef and live bottom communities. These activities leave an imprint of the trap upon the bottom communities and trenches caused by grappling hooks dragged over the bottom for the purpose of locating and recovering traps. Lost traps not only continue to fish, as it has been pointed out in the ghost trap discussion, but may contribute considerable secondary habitat damage by becoming mobilized at times of storm activity and impacting delicate bottom communities.

The affect of selective removal of herbivores on the health of coral reefs was discussed by LaPointe (1989). These species were harvested by fish traps more frequently than by hook and line gear. Again, due to the fact that commercial statistics did not record these fish by species, data was unavailable to document the level of harvest by fish traps or by hook and line.

Prohibiting fish traps was determined to be consistent with Florida's Coastal Zone Management Plan. Also, internationally, a number of countries (e.g., Bermuda) have tried to manage fish trap gear only to end up prohibiting their use. Bermuda has managed their snapper grouper fishery for a number of years and imposed a limited entry system with trap limitation. In addition, modifications to mesh size were also attempted. The Bermudian Government concluded that regulation the fish trap fishery was not effective and recently imposed a total ban on use of fish traps. The Council concluded that a total prohibition on the use of fish traps was the most effective alternative to address the stated problems and to achieve the plan's stated objectives.

6.2.2.3 Other Gear

Allowable Chemical

Collectors of live tropical reef fish commonly employ anesthetics such as quinaldine. Quinaldine (2-methy lquinoline, $C_{10}H_9N$) is the cheapest and most available of several substituted quinolines (Goldstein 1973). As a result of using this compound near corals where tropical species shelter, there may be residual effects which was discussed in a study by Japp and Wheaton (1975). Short-term impacts of quinaldine include increased flocculent mucus production, retraction of polyps and failure to re-expand with a five minute observation period, and tissue discoloration in certain species. At both study sites, octocorals were found to suffer no long-term impacts. However, a minority of Scleractinians displayed minor damage, including mild discoloration and small patches of dead tissue, three months after quinaldine treatment. Two of these specimens degraded to poor condition or displayed areas of dead tissue more than six months after initial treatment. Overall, Japp and Wheaton (1975) determined that quinaldine exposure resulted in minimal damage to corals.

Barrier Net

Barrier nets are used in conjunction with small tropical nets or slurp guns to collect tropical aquarium species. The net is deployed to surround a coral head or outcropping and may or may not have a pocket or bag that fish are “herded” into for capture. Barrier nets may be utilized by tropical fish collectors in both state and Federal waters.

The American Marine Life Dealers Association conducted a survey (Tullock and Resor 1996) that focused on tropical collection practices. The survey defined a sustainable fishing practice as one that a) does not cause physical damage to the reef environment; b) does not impair the captured specimen's longevity in a properly maintained aquarium environment; and c) does not damage non-target species such as coral polyps, other invertebrates, or non-aquarium fish. The survey concluded that barrier nets were a sustainable fishing practice. However, a study conducted by Öhman et al. (1993) summarized that moxy nets, a type of barrier net that is used in other regions to collect ornamental fish species, may break corals during their use. However, it is likely that damage inflicted by barrier nets would be infrequent and incidental in nature, and therefore, the gear would have a negligible effect on habitat.

Castnet

Used to capture baitfish and shrimp, castnets (Figure 18) are circular nets with a weighted skirt that is thrown over a schooling target. Castnets are primarily used in shallow areas such as estuaries, though they may be used to catch baitfish offshore in Federal waters. Castnets have the potential to dislodge organisms or become entangled if utilized over heavily encrusted substrates. Observations by the author have noted numerous castnets entangled amongst sponges and other growth around rough bottom. However, a study conducted by DeSylva (1954) determined that castnets have no detrimental effect on habitat.

Clam Kicking

Clam kicking is a mechanical form of clam harvest primarily practiced in the state waters of North Carolina. The practice involves the modification of boat engines in such a way as to direct the propeller wash downwards instead of backwards. The propeller wash is sufficiently powerful in shallow water to suspend bottom sediments and clams into a plume in the water column, which allows clams to be collected in a trawl net towed behind the boat (Peterson et al. 1987a).

Several studies have noted that the practice of clam kicking reduces algal and SAV biomass (Fonseca et al. 1984; Bargmann et al. 1985; Peterson et al. 1987a). Reduction of SAV biomass was noted to increase with harvest intensity. Intense clam kicking treatments reduced SAV biomass by approximately 65% (Peterson et al. 1987a). Because of the importance of SAV to coastal fisheries and estuarine productivity, Peterson et al. (1987a) noted that intense clam kicking could have long-lasting and serious impacts on many commercially important fisheries. However, clam harvesting had no detectable effect on the abundance of small benthic invertebrates and outside of SAV habitat, clam kicking does not appear to have any serious negative impacts on parameters of ecological value (Peterson et al. 1987a).

SAV recovery can be greater than two years if the rhizomes of the plant are removed (Homziak et al. 1982; Peterson et al. 1987a). Peterson et al. (1987a) observed that SAV had yet to recover after four years of an intense clam kicking treatment. Although Peterson et al. (1987a) designated their heavier clam kicking treatment as “intense,” they conceded that it probably falls well short of the effort that commercial clammers would apply to a productive SAV bed. Limiting the intensity of clam fishing in SAV habitat would probably be beneficial. Peterson et al. (1987a) offered that a restriction of mechanical clam harvesters to unvegetated bottoms may be a suitable mechanism to minimize habitat damage.

Clam Rake, Scallop Rake, Sponge Rake and Oyster Tong

Rakes are used to harvest shellfish and sponges from shallow areas such as bays and estuaries. Oyster tongs, similar to two rakes fastened together and facing each other like scissors, are used by fishermen from the deck of a boat. As these gears are limited by water depth, they are exclusively utilized in state waters.

Lenihan and Micheli (2000) reported that the harvest of shellfish utilizing clam rakes and oyster tongs significantly reduce oyster populations on intertidal oyster reefs. Both types of shellfish harvesting, applied separately or together, reduced the densities of live oysters by 50-80% compared with the densities of unharvested oyster reefs. While oysters are removed, Rothschild et al. (1994) concluded that hand tongs probably have a minor effect on the actual oyster bar structure. Peterson et al. (1987b) compared the impacts of two types of clam rakes on SAV biomass. The bull rake removed over 89% of shoots and 83% of roots and rhizomes in a completely raked area while the pea digger removed 55% of shoots and 37% of roots and rhizomes. Loss or impact on SAV by bull rake was estimated to be double the impact of the smaller pea digger rake. Peterson et al. (1987a) found raking with a pea digger rake reduced SAV biomass by approximately 25%. An earlier study conducted by Glude and Landers (1953) noted that bull rakes and clam tongs mixed the sandy-mud layer and the underlying clay. Fished areas were also softer and had less odor of decomposition than the unfished control site. A decrease in benthic fauna was noted in the fished sites versus the unfished control sites.

Sponges are an important fishery in the Florida Keys and along the west coast of Florida (NOAA 1996). Sponges are dominant organisms in deepwater passes and along hard bottom habitat communities. Sponges create vertical habitat which provides shelter and forage opportunities for other invertebrates and tropical fish species. The fishery in the Keys typically employs a four-pronged iron rake attached to the end of a 5–7 m pole, which hooks the sponges from the bottom. While no studies document the extent of habitat damage from this gear type, it may be concluded that the harvest of sponges directly reduces the amount of available habitat, and thus may present a negative localized impact.

Peterson et al. (1987a) found that SAV biomass recovered to equal and even exceeded expected values within one year. Lenihan and Micheli (2000) recommended the closure of some oyster reefs to shellfish harvest. Maintaining high densities of oysters on some intertidal reefs may help to preserve future oyster harvests and broodstock. Furthermore, protecting some reefs will also preserve the ecological functions that oyster reef provide such as improving water quality and providing essential recruitment, refuge, and foraging habitat for numerous marine species. Due to the extensive habitat that sponges provide, further ecological study on the directed harvest of these organisms should be conducted.

Dipnet and Bully Net

Widely utilized to catch baitfish, crabs, or lobster, varieties of dipnets (Figure 22) consist of a long pole with a bag of netting of varying mesh size that are lowered into the water. Dipnets may also be employed to capture tropical reef fish (Figure 23), though these utilize a short handle and very fine mesh. Additionally, landing nets or hand bully nets (Figure 24) used to capture lobster can be considered a form of dipnet. Varieties of dipnets may be used both in state and Federal waters.

DeSylva (1954) determined that dipnets have no detrimental effect on habitat. However, the use of small dipnets (i.e., tropical fish nets and lobster hand bully nets) may result in minor isolated impacts to coral species as individuals attempt to capture specimens (Barnette, personal observation).

Hand Harvest

Hand harvest describes activities that capture numerous species such as lobster, scallops, stone crabs, conch, and other invertebrates by hand. As many small biogenic structures occur on the sediment surface, even gentle handling by divers can destroy them easily. Movements by divers were observed to cause demersal zooplankters to exhibit escape responses (Auster and Langton 1999). A study that assessed recreational SCUBA activity in the US Caribbean (Garcia-Moliner et al. 2000) concluded that approximately 2% of the total recreational divers in the USVI and 1.9% of the total recreational divers in Puerto Rico were lobstering. Potential impact of approximately 13,532 units occurred in the USVI and 14,946 units occurred in Puerto Rico. In this study, impact units consisted of two hands and two feet (4 units per diver) and impact was broadly defined as ranging from touching coral with hands to the resuspension of sediment by fins. No assessment of habitat degradation or long-term impacts was discussed. Divers pursuing lobster along coral or hard bottom communities have been observed to impact gorgonians and other encrusting organisms (Barnette, unpublished observations).

Harpoon

Harpoons, thrown from the decks of a vessel, are utilized to target swordfish and tuna. As this gear is employed to harvest pelagic species, there is no contact with the benthos and, thus, no impact to habitat.

Haul Seine and Beach Seine

A haul seine is an active fishing system that traps fish by encircling them with a long fence-like wall of webbing. It is made of strong netting hung from a float line on the surface and held near the bottom by a lead line. They are fished either along the shoreline (beach seine) where they are deployed in a semi-circle to trap fish between shore and net or, more typically, fish are encircled away from shore, worked into an even smaller pocket of net and lifted onto a boat for culling (Sadzinski et al. 1996). The use of this gear is limited to state waters. Sadzinski et al. (1996) found no detectable effects from haul seining on SAV. However, possible damage from haul seining to sexual reproduction, such as flower shearing, was not examined. There are possible long-term or cumulative impacts at established haul-out sites, resulting in loss of SAV biomass (Orth personal communication). As the seine is generally used in flat benthic areas to prevent the net becoming damaged, in most cases the impact from seines would be expected to be minor and temporary.

Hook and Line, Handline, Bandit Gear, Buoy Gear and Rod and Reel

These gear types are widely utilized by commercial and recreational fishermen over a variety of estuarine, nearshore, and marine habitats. Hook and line may be employed over reef habitat or trolled in pursuit of pelagic species in both state and Federal waters.

Few studies have focused on physical habitat impacts from these gear types. Impacts may include entanglement and minor degradation of benthic species from line abrasion and the use of weights (sinkers). Schleyer and Tomalin (2000) noted that discarded or lost fishing line appeared to entangle readily on branching and digitate corals and was accompanied by progressive algal growth. This subsequent fouling eventually overgrows and kills the coral, becoming an amorphous lump once accreted by coralline algae (Schleyer and Tomalin 2000). Lines entangled amongst fragile coral may break delicate gorgonians and similar species. Due to the widespread use of weights over coral reef or hardbottom habitat and the concentration of effort over these habitat areas from recreational and commercial fishermen, the cumulative effect may lead to significant impacts resulting from the use of these gear types.

Patent Tong

Similar to hand tongs, hydraulic patent tong s (Figure 26) are much larger and are assisted with hydraulic lift, allowing them to purchase more benthic area in pursuit of oysters. Patent tongs are utilized in the oyster fisheries that occur in state waters. Rothschild et al. (1994) found that hydraulic-powered patent tongs are the most destructive gear to oyster reef structure because of their capability to penetrate and disassociate the oyster reef. The capability arises from the gear weight and hydraulic power. Patent tongs operate much like an industrial crane with each bite having the ability to remove a section of the oyster bar amounting to $0.25m^3$.

Due to overfishing and disease, oysters may now be more economically valuable for the habitat they provide for other valued species than they are for the oyster fishery (Lenihan and Peterson 1998). Rothschild et al. (1994) suggested the establishment of broodstock sanctuaries that includes the designation of “no-fishing” restrictions in specific areas. Lenihan and Micheli (2000) also recommended the closure of some oyster reefs to harvest. Maintaining high densities of oysters on some intertidal reefs may help to preserve future oyster harvests and broodstock. Furthermore, protecting some reefs will also preserve the ecological functions that oyster reef provide such as improving water quality and providing essential recruitment, refuge, and foraging habitat for numerous marine species.

Purse Seine and Lampara Net

Purse seines are walls of netting used to encircle entire schools of fish at or near the surface. Spotter planes are often used to locate the schools, which are subsequently surrounded by the netting and trapped by the use of a pursing or drawstring cable threaded through the bottom of the net. When the cable has pulled the netting tight, enclosing the fish in the net, the net is retrieved to congregate the fish. The catch is then either pumped onboard or hauled onboard with a crane-operated dip net in a process called brailing. Purse seines are utilized to harvest menhaden in the Gulf and South Atlantic. Similarly, the lampara net has a large central bunt, or bagging portion, and short wings. The buoyed float line is longer than the weighted lead line so that as the lines are hauled the wings of the net come together at the bottom first, trapping the fish. As the net is brought in, the school of fish is worked into the bunt and captured. In the Florida Keys a modified lampara net is used to harvest baitfish near the top of the water column. The wing is used to skim the water surface as the net is drawn in and fish are herded into the pursing section to be harvested with a dip net. Purse seines in the Gulf menhaden fishery frequently interact with the bottom, resulting in sediment resuspension. Schoellhammer (1996) estimated that sediments resuspended by purse seining activities would last only a period of hours.

Pushnet

Employed to harvest shrimp in shallow water, pushnets (Figure 30) consist of netting supported by a frame that is mounted on to a pole, which is then pushed across the bottom. Pushnets are generally utilized on SAV beds where shrimp can be harvested in abundant numbers. DeSylva (1954) determined that push nets have no detrimental effect on habitat.

Slurp Gun

A slurp gun is a self-contained, handheld device that captures tropical fish by rapidly drawing seawater containing such fish into a closed chamber. Slurp guns are typically employed on hardbottom and coral reef habitat in both state and Federal waters. It is possible that tropical collectors may impact coral or other benthic invertebrates in pursuit of tropical species that are harvested on hardbottom or coral habitat areas. However, due to the limited force applied by a diver in an errant fin kick or hand placement, the likely effects to habitat would be minor.

Snare

Recreational divers pursuing spiny lobster often use a long, thin pole that has a loop of coated wire on the end called a snare. The loop is placed around a lobster that may be residing in a tight overhang or other inaccessible location, and then tightened by a pull toggle at the base of the pole in order to capture and extract the lobster.

While there are no studies that evaluate this gear type, it is probable that use of this gear may minimize impacts to habitat in comparison to divers that use no additional gear (hand harvest). Due to the more surgical precision with the snare, divers likely impact the surrounding habitat to a lesser extent than if capturing by hand only due to the required leverage needed by the divers to capture a lobster by hand.

Spear and Powerhead

Divers use pneumatic or rubber band guns or slings to hurl a spear shaft to harvest a wide array of fish species. Reef species such as grouper and snapper, as well as pelagic species such as dolphin and mackerel, are targeted by divers. Commercial divers sometimes employ a shotgun shell known as a powerhead at the shaft tip, which efficiently delivers a lethal charge to their quarry. This method is commonly used to harvest large species such as amberjack.

Gomez et al. (1987) concluded that spearfishing on reef habitat may result in some coral breakage, but damage is probably negligible. A study that assessed recreational SCUBA activity in the US Caribbean (Garcia-Moliner et al. 2000) concluded that approximately 0.7% of the total recreational divers in the USVI and 28% of the total recreational divers in Puerto Rico are spearfishing. Potential impact would be approximately 4,736 units in the USVI and 220,264 units in Puerto Rico. In this study, impact units consisted of two hands and two feet (4 units per diver) and impact was broadly defined as ranging from touching coral with hands to the resuspension of sediment by fins. No assessment of habitat degradation or long-term impacts was discussed. It may be assumed that divers pursuing pelagic species have no effect on habitat due to the absence of any interaction with the benthos.

6.3 Cumulative impacts of fishing and non-fishing activities

This section analyzes cumulative impacts, which are defined by the Council on Environmental Quality (CEQ) as “impacts on the environment that result from the incremental impact of an action when added to other past, present, and reasonably foreseeable future actions, regardless of who undertakes such actions.” Increasing evidence suggests that the most severe environmental effects may not result from the direct impacts of a particular action, but rather from cumulative environmental effects. The incremental loss of important habitat can irreversibly alter the structure and function of the nearshore marine ecosystem and ultimately affect human activities (Jackson 1997). Further, regional problems are highly vulnerable to small decision effects – the tyranny of small decisions, as evidenced in the Florida Everglades (Odum 1982).

The overall cumulative impact of human-induced activities and natural events remains poorly documented, understood, and in dire need of more study. Nationally, one report noted that “federal agencies have struggled with preparing cumulative effect analyses since the CEQ issued its National Environmental Policy Act (NEPA) regulations in 1978.” (CEQ 1997).

It is evident that the effect of human activity on aquatic systems has been substantial in locations where access and economically profitable modification could be readily accommodated. Dahl (1990) reports that in the 1780's there were about 20.3 million acres of wetlands in Florida, about 6.8 million acres in Georgia, about 6.4 million acres in

South Carolina, and about 11.1 million acres in North Carolina. By the 1980's Florida's wetlands had been reduced to 11.0 million acres, Georgia's to 5.3 million acres, South Carolina's to 4.7 million acres, and North Carolina's to 5.7 million acres. Overall about 36.3% of all wetlands in states under SAFMC purview have been eliminated. On a state-by-state basis this includes 46% of Florida's wetlands, 23% of Georgia's wetlands, 27% of South Carolina's wetlands, and 49% of North Carolina's wetlands. A 2001 National Research Council report found that, as a result, by the 1980s the area of wetlands in the contiguous United States had decreased to approximately 53% of its extent one hundred years earlier (NRC 2001).

According to the FWS Status and Trends of Wetlands in the Conterminous United States 1998 to 2004 there was an estimated net gain in wetlands of 191,750 acres, however the report did not draw conclusion regarding the quality of the nation's wetlands and counted over 700,000 acres of open water ponds as wetlands. Intertidal wetlands declined by an estimated 28,416 acres, with the greatest percent change attributed to marine intertidal wetlands. The overriding factor in the decline of estuarine and marine wetlands was the loss of emergent saltmarsh to open saltwater systems due to manmade activities such as dredging, water control, and commercial and recreational boat traffic. There was an estimated 800 acre gain of estuarine shrub wetlands, however most of this gain came from areas formerly classified as estuarine emergent wetland. Estuarine vegetated wetlands have continued to decline over time as losses to the estuarine emergent category have overshadowed the small gains to estuarine shrub wetlands (Dahl 2006).
As an indication of the scope of developmental pressure, hence one aspect cumulative effect on EFH (coastal and tributary wetlands), NOAA Fisheries Service data show receipt of more than 20,778 individual development proposals (COE permit applications, federal projects, etc.) in North Carolina, South Carolina, Georgia, and Florida between 1981 and 1996 (See Tables 26, 27, 28, & 29). A subsample of 4,000 of these development proposals involved over 13,856 acres of various wetland habitats. Between 1996 and 2006, NOAA Fisheries Service reviewed an additional 20,896 applications to impact areas known to support EFH.

In addition to the substantial loss of wetlands in the southeastern United States, Nocholls et al. (1999) determined that by the 2080s, sea-level rise could cause the loss of up to 22% of the world's coastal wetlands. When combined with other losses due to direct human action, up to 70% of the world's coastal wetlands could be lost by the 2080s, although there is considerable uncertainty. Therefore, sea-level rise would reinforce other adverse trends of wetland loss.

While it is believed that most regulated activities are implemented as planned, Mager and Thayer (1986) report that limited monitoring indicate that about 20% of the projects they examined did not comply with provisions of the associated permits. Notably, most of the differences observed related more to design of structures and not the area of habitat affected. As shown in the following tables, individually and cumulatively significant impacts to EFH can be moderated through the COE regulatory program; however, significant wetland perturbations persist. This situation is largely perpetuated by (1) regulatory provisions that exempt regulation of certain wetland types and activities and

(2) by severe staffing limitations within regulatory and environmental review agencies. In the absence of substantial correction in these two areas, significant wetland areas will continue to be adversely altered or eliminated, and regulatory and review agency effectiveness will be limited.

In addition to the direct cumulative effect incurred by developmental type activities, EFH is also jeopardized by persistent increases in certain chemical discharges. In that case incremental change in habitats, hydrology, and chemical inputs produced, over time, an enormous and extremely harmful result whose negative economic and social implications may far exceed any benefits related to the causative factors. Unfortunately, the effect of adding ever greater volumes and varieties of chemicals to surface waters is often insidious and resulting declines in the abundance and quality of affected and harvested resources may be slow and difficult to identify. As illustrated by Scott et al (1997), the effects may be realized at rudimentary trophic and ecological association levels in key portions (including EFH) of estuarine environments.

The rate and magnitude of anthropomorphic change on EFH, whether cumulative, synergistic, or individually large, is influenced by natural parameters such as temperature, wind, currents, rainfall, salinity, etc. Consequently, the level of threat posed by a particular activity or group of activities may vary considerably from location to location. This situation may be most acute in locations that are subject to extreme weather and oceanic conditions such as hurricanes and large waves, or where the effects of periodic or global change are most prevalent.

Nutrient over-enrichment has become a large cumulative problem for southeastern EFH. Excessive nutrients may be directly toxic. Even relatively low nitrate-nitrogen levels (as low as 3.5 uM NO3-N) have been found to cause impacts on both growth and survival in eelgrass (*Z. marina*) during spring and fall growing seasons (Burkholder et al. 1992). In contrast, Cuban shoal grass (*Halodule wrightii*) and widgeon grass (*Ruppia maritima*) were stimulated by nutrient enrichment (Burkholder et al. 1994). Eelgrass provides important brackish water habitat element for finfish, crustaceans and molluscs in North Carolina (Thayer et al. 1984). Nitrate toxicity to eelgrass in the field has yet to be documented, although nitrate concentrations in the range found to have an impact in mesocosm experiments certainly occurs in many estuarine settings.

The effects of nutrient enrichment and stimulation of toxic dinoflagellates and other algae, especially *Pfiesteria piscidida*, have been widely reported by the news media. The high abundance of small heterotrophic algae in southeastern estuaries was well known among plankton researchers during the 1980s and earlier; however, the toxic nature of *Pfiesteria* was not reported until the late 1980s (Burkholder et al. 1992, 1993, 1995; Noga et al. 1993). Analyses suggest that a large suite of *Pfiesteria*-like small heterotrophic dinoflagellates exist in most southeastern estuaries (P. Tester, personal communication). These organisms include toxic forms, like *Pfiesteria*, and may be responsible for a significant number of fish kills associated with eutrophic estuaries (Burkholder et al. 1992). Fish kills in North Carolina and Maryland have been attributed, at least in part, to these organisms (Burkholder et al. 1995), and analyses suggest that toxic dinoflagellates (and related organisms) are on the rise at a global scale (Paerl 1988; Smayda 1989; Paerl et al. 1995a).

The stimulation of toxic organism population growth by nutrient enrichment may be related to factors outside the South Atlantic region. The most notable recent case was the transport of the toxic dinoflagellate *Ptychodiscus brevis* in 1989 by the Gulf Stream and associated eddies into Onslow Bay, North Carolina. Among other impacts offshore and inshore, this seriously impacted scallop production in Bogue Sound, North Carolina (Tester et al. 1989).

Enrichment of estuarine algal and bacterioplanktonic communities by excessive nutrients is probably the most often cited example of estuarine degradation globally (Nixon 1995; NRC 1994; Ryther and Dunstan 1971). In general, the ecological pathway involves enhanced algal or bacterial production and metabolism followed by excessive oxygen uptake and subsequent deoxygenation. Anoxia and hypoxia have been identified as the fundamental problems facing Chesapeake Bay, the Gulf of Mexico, the Tar-Pamlico and Neuse River Estuaries, and other locations throughout the world (Paerl 1988).

Associated processes may be complex. For example, nutrient uptake and excessive autotroph production may result in deposition of organic material into benthic sediments, where increased sediment oxygen demand may occur at some later time. In stratified estuaries, the process may even be exacerbated by the re-release of nutrients as sediment oxygen demand is exerted in bottom, anoxic waters. The ecological effects of modification of production patterns also includes hypercapnia (elevated levels of carbon dioxide), which exerts powerful effects on some organisms (Burnett 1997).

Algal blooms in southeastern waters represent a major threat to EFH. Important algal blooms have been documented in Albemarle Sound, the Chowan River, the Tar-Pamlico River, the Neuse River Estuary, the New River Estuary, Bogue Sound, the St. Johns River, and Indian River (NOAA 1996). Algal levels can be extremely high in grossly enriched waters. A one-day survey of the Pamlico Estuary in 1988 found chlorophyll a (an algal pigment) in excess of 200 ug/l, compared to a North Carolina Water Quality Standard of 40 ug/l (15A NCAC 2B.0200). Another type of algal community stimulation occurs when airborne nitrogen from all sources, including agriculture, is deposited through wet and dry deposition into distant oceanic waters. This phenomenon was largely unrecognized until recently (Paerl 1985, 1993). Consequences of this type of deposition, where the majority of “new” primary production comes from this source, can be quite significant, both on patterns in primary and secondary production and in the taxonomic makeup of that production, including the toxic forms cited above.

Among the most serious problems caused by algal blooms and other effects of over enrichment is the removal of oxygen from the water. The extent of deoxygenation in southeastern estuaries has been well documented (Rader et al. 1987; Stanley 1985). A more recent survey of the South Atlantic region found periodic hypoxic conditions in 13 of the 21 estuaries surveyed, with bottom-water anoxia in 11 locations. Only one instance of anoxia was found along the Sea Island Coast of South Carolina and Georgia, and this was linked to stratified conditions in the Savannah River. Major anoxic events were documented in the Neuse River, the Tar-Pamlico River Estuary, the Indian River and St. Helena Sound (NOAA 1996). Although seasonal low-oxygen events may be natural in southeastern stratified estuaries, expansion in the size or persistence of deoxygenated areas has been identified for some of the above listed waters (Breitburg 1990; Rabalais et al. 1996).

Effects of deoxygenation on resident and post-larval fish, crustacean, and mollusc communities can be significant. The enormous fish kills that have plagued the Tar-Pamlico and Neuse River Estuaries have received abundant popular press since the late 1980's, and have recently been systematically analyzed (Pietrafesa and Miller 1997). This study identified 246 kills in the Pamlico during the period 1985-1995, and 73 in the Neuse, including many over 1,000,000 fish. Fish kills have also been documented in the St. John River, Florida and Charleston Harbor, South Carolina (Burkholder et al. 1995). Another possible manifestation of nutrient over enrichment is the occurrence of chitonoclastic shell disease in blue crabs. This is believed by some to be related to water pollution (either stress incurred after exposure to anoxic conditions or cadmium). Little is known absolutely (Noga et al. 1990). In addition, fish diseases have been implicated throughout polluted estuaries, but the link to pollution remains uncertain (Noga et al. 1989).

The impact of fish kills from nutrient over enrichment is difficult to assess in terms of their effect on stocks of commercially important fish. Many of the fish killed are juveniles and Atlantic menhaden appear especially vulnerable. If these stocks are density independent, then kills translate directly into reduced adult population sizes. Vaughan (1986) found that in Atlantic menhaden, catastrophic kills, where 10% mortality events occur periodically, coupled to the accumulating 1% annual losses from permanent habitat loss, could cause a loss of 60% of the fishery within 30 years.

Impacts of atmospheric deposition of nutrients on inshore EFH is well documented, as cited above (and in Fisher and Oppenheimer 1991). Some studies suggest that nutrient enrichment from atmospheric and more traditional surface water sources can also modify planktonic and epibenthic algal communities to the detriment of fish. Changes in the phytoplankton community lead to changes in the grazer community, including the reduction or elimination of preferred prey items for planktivorous fish and fish larvae. One example is the plankton community of Western Albemarle Sound, North Carolina, where nanoplankton (the small-celled algae that are the principal food source for crustacean zooplankters) are replaced in part in some years by blue-green algae of low food value, with a concomitant elimination of the zooplankters preferred by some anadromous fish larvae and juveniles (Rulifson et al. 1986).

Besides fish, plankton, and algae, vascular marine plants also are adversely affected by excessive nutrients and their consequences. Eutrophication may cause the reduction in coverage of SAV due to shading associated with water column turbidity and the growth of epiphytic filamentous algae. Although significant die-offs of SAV have occurred in some locations in the southeast, including the Pamlico River Estuary, the direct causes of algal growth stimulation has not been established (Davis et al. 1985). NOAA's 1996 survey of impacts on SAV found declines in 5 of 21 estuaries of the southeast, including Albemarle/Pamlico Sounds, but increases in Biscayne Bay and Charleston Harbor (NOAA 1996).

A major problem with regard to assessing cumulative effects is that the majority of the methods developed to evaluate cumulative effects were developed in a terrestrial context and the applicability to marine resources and EFH is not clear. However, new analytical approaches may advance management evaluations of cumulative environmental effects. Ecological risk assessment procedures provide a useful frame for comprehensively structured analyses of anthropogenic effects (EPA 1992). These procedures involve the systematic evaluation of stressors and effects using flexible methods that foster detailed evaluations of effects (Harwell et al. 1995). The application of risk assessment principles to environmental assessments could result in more comprehensive scientific products that also carry more administrative weight. In addition, systematic applications of decision support systems can offer logically consistent methods to evaluate multiple policy alternatives. Decision support systems aid the objective identification of appropriate decision combinations according to multiple priorities and they support group-based policy evaluations (Saaty 1990; Keyes and Palmer 1993; Schmoldt et al. 1994). Combined utilization of these approaches may identify previously underemphasized factors and objective policy alternatives (Lindeman 1997b). Ultimately, they may foster more logical and explicit decision-making regarding cumulative effects issues.

A cumulative assessment of population-scale fishing effects in the Florida Keys documents that 13 of 16 grouper species, 7 of 13 snappers, and 2 of 5 grunts are recruitment overfished (Ault et al. 1998). The cumulative result of technologically enhanced fishing effort has been the accelerated removal of those top predators with most economic value. Therefore, intensive effort is now being expended to obtain species that are lower on the food chain (Pauley et al. 1998). This has serious implications; as the lower levels of the food chain decline, the chances of revival at the top of the food chain are diminished even further (Williams 1998). Top-down ecosystem degradation can result in a variety of unfavorable species abundance shifts (Goeden 1982) and, potentially, outright ecosystem collapse (Pauley et al. 1998). Further cumulative assessments of managed species in the South Atlantic may reveal long-term declines similar to those now identified in the Keys. Under such circumstances, traditional management measures (e.g., size and harvest limits), may not be adequate to rebuild sustainable fisheries for the most desirable species.

7.0 Essential Fish Habitat Evaluation and Recommendations

7.1 Conservation and restoration

7.1.1 Estuarine Marshes

Efforts to restore or create salt marsh habitat have been underway for over 20 years, as losses of coastal wetlands through erosion, land subsidence, sea level rise and coastal development have increased (Nixon 1980; Matthews and Minello 1994). Salt marsh restoration has received much attention in recent years. This is likely due to the considerable acreage of salt marsh that has been lost along U.S. coastlines, recent recognition of the important functions provided by salt marshes, and the relative ease in which tidal marsh vegetation can be propagated at restored sites. Restoration or creation of marsh habitat begins with designing a site with the appropriate hydrology, tidal exchange, and sediment properties to support the growth of salt marsh plants. Analyses of current and projected land-use patterns, and socioeconomic factors are necessary and may be a critical factor in the final selection of possible restoration sites. Salt marsh restoration projects that lack clearly defined goals and objectives are less likely to achieve success.

Often, restoration of tidal flushing, combined with the existence or creation of appropriate marsh morphology (i.e., elevation, slope, grade, substrate, etc.) will be enough to rapidly revegetate the area with native salt marsh communities (see Sinicrope et al. 1990). However, if the site is isolated from sources of recolonizing vegetation, planting may be required in order to decrease the length of time before natural revegetation occurs. Planting, though potentially costly, is beneficial in the restoration of sites damaged by pollution, (e.g., an oil spill) (Matsil & Feller 1996), and can hasten re-establishment of target salt marsh vegetative communities.

Subsequent to physical modification of the site, plantings are often made of *Spartina alterniflora* or, less frequently, of other marsh plants. Planting growing or dormant plants, or plant propagules, is the most reliable planting method for salt marsh restoration projects (Broome et al. 1988; Garbisch et al. 1975). Given appropriate site selection and preparation, successful establishment of *Spartina* and/or other marsh species can occur within a few growing seasons.

An important, and still unanswered, question relative to marsh habitat restoration is how long it takes to restore marsh habitat function, as opposed to simply the replacement of marsh plants; this evaluation of habitat function is complex and time-consuming. Examples of marsh functions to be evaluated are food web support, provision of fishery nursery grounds, and the transformation of nutrients (Smith et al. 1995). Research on monitoring methods often is focused on determining the functions provided by a restored habitat and comparing the functions to those provided by natural systems. Evidence to date suggests that the time it takes a transplanted salt marsh to attain the ecological function of a mature natural marsh may be 10 to 20 years. If the hydrology and tidal elevation of the site are not maintained, then the transplanted marsh may never supply equivalent habitat function as a natural marsh. This is particularly important to recognize in cases where marsh restoration or creation is undertaken to mitigate for the loss of natural marsh via development, dredging, or other permitted activities. Most studies indicate that overall restored salt marshes are providing fish access to usable habitat and the systems are functioning to increase growth, production, and resilience of fish populations. However, in some cases restored systems may be structurally or functionally different from natural marshes. Continued research will help determine whether improved restoration methods could improve functional equivalency.

7.1.2 Mangroves

Threats

While much of the mangrove forest area is protected in the U.S. under the jurisdictions of parks, sanctuaries and refuges (Gilmore and Snedaker 1993; Thayer et al. 1999), this coastal habitat and resource is being progressively diminished by a variety of natural and anthropogenic actions such as removal, severe pruning, deprivation of freshwater from upland watersheds, severe freezes, water pollution, competitive exclusion by exotic tree species (e.g., Australian pine, Brazilian pepper), coastal erosion and sea-level rise. Most of these aspects have been discussed and/or documented by Odum et al. (1982) and Gilmore and Snedaker (1993), and are discussed under the section Essential Fish Habitat.

Removal and alteration to freshwater flow are the top threats to mangrove forests in Florida. Although both federal wetland regulations and local ordinances are in place to protect mangroves, legislation has not proved very effective. A burgeoning human population has increased the realized and potential negative impacts of human activities on coastal habitats in regions with limited land mass and a fragile ecology. As of 1991, development in the Florida Keys had destroyed roughly 40 % of mangrove forests and reduced mean forest size by 69% (Strong and Bancroft 1994). Further north towards Miami, the acreage of mangrove forest in Biscayne Bay's watershed has declined by as much as 82% since the 1970's (Teas et al. 1976; Snedaker and Biber 1996).

Substantial area of mangrove habitat has been lost by impoundment. Impoundment involves the creation of a dike and ditch system around the perimeter of the wetland so that water levels in the wetland can be artificially raised to prevent ovideposition on the substrate by marsh mosquitoes. From the mid-1950s to today, over 16,000 hectares of mangrove forests and salt marshes along the Indian River Lagoon System (Florida) have been impounded, making this method the most common technique used to prevent new generations of mosquitoes in Florida (Rey & Kain 1990; Rey et al. 1991). Permanent impoundment and high water levels prevented the effective gas exchange through mangroves root systems and resulted in chronic mortality similar to that an oil spill might cause. Permanent impoundment also severed the connection between resident mangroves and the surrounding ecosystem (i.e., effective removal). Today, a rotational impoundment system (RIM) is used, and culverts fitted with flapgates can be seasonally opened and closed (Carlson et al. 1991). RIM is a much more ecologically benign system of mosquito control and coastal marsh management because it allows for the seasonal exchange of water, nutrients, and aquatic fauna.

Mangroves are considered resilient and display characteristics of some “pioneer species” in that they have broad tolerances to environmental factors, rapid growth and maturity, continuous or almost continuous flowering and propagule production, high propagule outputs in a wide range of environmental conditions, and adaptations for short and long distance dispersal by tides (Cintron-Molero 1992). Even with these “r-strategist”, characteristics, mangroves are sensitive and vulnerable to disturbance. Changes to the freshwater flow from the Everglades to coastal mangrove forests since the late 1800s have coincided with ecological declines in the region (Light and Dineen 1994; Sklar et al. 2001). Marine intrusion into traditionally freshwater areas has resulted in a several-kilometer expansion of the coverage of mangrove forests in the region (Ross et al. 2000). The replacement of a narrow fringe and riverine forest (comparatively high production forests) with an expansive dwarf forest (a comparatively low production forest) complicates assessment of the change over time in the total productivity of the region’s mangroves.

7.1.3 Seagrass

Threats

Like all other organisms and habitats in estuarine-near shore environments, seagrasses occur at the end of all watershed inputs: the juncture between riverine inflow and oceanic inputs as well as the interface between land and sea. This situation makes them extremely susceptible to perturbations by natural processes as well as being susceptible to damage by human activities (Short and Wyllie Echeverria 1996).

In the South Atlantic region seagrasses experience natural disturbances such as bioturbation (stingray foraging), storm or wave-related scour (tropical storms and surges), and disease or disease-associated perturbations (*Labyrinthula*), as well as man-related impacts (Short and Wyllie-Echeverria 1996). Especially problematic are excessive epiphytic loads and smothering by transient macroalgae, both of which are often associated with nutrient enrichment and coastal eutrophication. Excessive nutrient discharges and suspended sediments can also disrupt seagrass systems by causing water column algal blooms that diminish the amount of light available for benthic dwelling seagrasses (Dennison et al. 1993). Often, nutrient enrichment will have detrimental effects that cascade up and down the food webs of seagrass meadows by diminishing the dissolved oxygen concentrations and stressing the faunal communities. Also toxic concentrations of hydrogen sulfide may be formed which kills seagrass and diminish the ability of a meadow to filter and stabilize sediments, thus altering the water column environment for filter feeders and other primary producers.

Subtidal seagrasses have suffered little damage from oil spills whereas impacts on intertidal beds have been significant (Durako et al. 1993; Kenworthy et al. 1993). Oil spill-related impacts on the seagrass-associated fauna can range from smothering to lowered stress tolerance, reduced market values and incorporation of carcinogenic and mutagenic substances into the food chain. Other well-known impacts such as newly permitted dredge and fill operations are no longer a primary cause of major losses of seagrass habitat due to the recognition of their ecological role and vigilance of state and federal regulatory activities to limit permits. Dredging activities which are grandfathered into water management plans are potential problems causing turbidity, resuspension of toxic compounds and direct removal of seagrass. This human-related impact, although still present, is now being replaced by a larger issue, that associated with propeller scouring (Sargent et al. 1995), vessel groundings (Kenworthy et al. 2002), and some fishing gear-related impacts (Fonseca et al. 1984). This physical damage is long-lasting and often results in sediment destabilization and continued habitat loss (Kenworthy et al. 2002; Whitfield et al. 2002). The increasing number of small boats plying estuarine and coastal waters has made vessel impacts more widespread, and there has been a recognized need in some regions for both enhanced management of these systems and increased awareness by the boating public.

Water quality and, in particular, water clarity is now considered among the most critical, if not the most critical, factor in the maintenance of healthy SAV habitats (Dennison et al. 1993). In the past few years it has become increasingly evident that, with few exceptions, seagrasses generally require light intensities reaching the leaves of 15-25% of the surface incident light (Kenworthy and Fonseca 1996; Gallegos and Kenworthy 1996; Onuf 1996; Dixon 1999; Gallegos 2001). However, water transparency standards historically have been based on light requirements of phytoplankton which typically require only 1% of surface light (Kenworthy and Haunert 1991). Many factors act to reduce water column transparency, with excess suspended solids and nutrients being considered to be among the most important and most controllable through watershed management practices (Gallegos 1991).

The loss of seagrasses, regardless of the cause, leads to several undesirable, and often difficult to reverse, situations that reflect on aquatic vascular plant ecological values (Moore 2004). Losses can and have led to reduced sediment binding and water motion baffling capability of the habitat allowing sediments to be more readily resuspended and moved (Fonseca 1996), eventually disturbing other components of coastal ecosystems such as coral reefs. The physical ramifications include reef degradation, increased shoreline erosion (e.g., as occurred in some areas after the eelgrass die-off in the 1930's) and water column turbidity. The loss of seagrasses, of course, eliminates all important associated habitat functions pertinent to fisheries use.

Aspects of Conservation and Restoration

The recognition of the ecological role of seagrass habitats has prompted a need to conserve, and more recently protect these habitats by avoiding impacts (i.e., proactive management) (Fonseca et al. 1998; Kenworthy et al. 2005). This is a less costly and an environmentally sounder means of protecting this important resource than either mitigation or restoration. None-the-less, seagrass habitats have been and continue to be impacted or lost, and restoration efforts have broadened to include development and evaluation of new approaches to seagrass restoration and measurements of recovery of functional values (Fonseca et al. 1998; Fonseca et al. 2000). In addition, programs are being developed to plant seagrasses for purposes of sediment stabilization, nutrient uptake, and fishery habitat (Kirsch et al. 2004). These programs and projects, which consult with experts, utilize scientifically based guidelines, and monitor their restoration success. Research continues to evaluate current techniques and develop new approaches. However, we have not found a restoration or mitigation project that has returned seagrass habitat equal to that which has been lost. Much has been written on techniques and evaluation of restoration tools for seagrasses along the South Atlantic coast of the U.S. (Fonseca et al. 1998). Data are showing that if seagrass transplanting is successful we can expect a similar faunal community to return within a few years (2-4 possibly), depending on the geographic area and rate of development of the transplant (Fonseca et al. 1996). There are many uncertainties associated with seagrass mitigation and restoration such as impacts of herbivory, but experience is showing that efforts can be successful if the well-founded guidelines available are followed.

7.1.4 Oyster reefs and shell banks

Shell bottom restoration in North Carolina
(Source: NCCHPP)
State efforts to restore oyster habitat and enhance oyster fishery production began around the turn of the century (Marshall et al. 1999). These efforts relied mostly on planting a variety of natural cultch, including oyster, clam, and scallop shells, and, more recently, limestone marl. Experimental oyster cultch plantings began in 1900, and state-sponsored cultch planting began in 1915 (Marshall et al. 1999). Between 1915 and 1934, a total of 1,856,379 bushels of shells and seed oysters were planted in North Carolina's estuaries. The Oyster Rehabilitation Program officially began in 1947 and resulted in planting 838,088 bushels of shell and 350,734 bushels of seed oysters over its first 10 years. Since 1970, North Carolina has relied almost exclusively on cultch planting as a means of enhancing oyster production (Figure 3.5). From 1958 to 1994, 12,475,000 bushels of shell material were planted, for an annual average of 337,162 bushels (Marshall et al. 1999). Over the entire period of cultch planting from 1915-1994, about 15 million bushels of oysters were planted in North Carolina waters. This volume of shells would contain the equivalent of 4.5 billion 2-inch oyster shells. Using a minimum 30% area coverage (100 2-inch shells/m2) as defining shell bottom, the volume of shell cultch planted from 1915-1994 could cover as much as 11,120 acres (45,000,000 m2). However, this is an overestimate of actual shell bottom area gained, because the shell plantings consist of piles of variable thickness rather than a single uniform layer. Also, many of the cultch areas are replanted due to flattening by waves and/or commercial harvesting. Despite these planting efforts, the oyster harvest continued to decline (Marshall et al. 1999).

Similar to natural shell bottom, restored oyster reefs provide bottom habitat for economically important species (Breitburg 1998; Lenihan et al. 1998; Coen et al. 1999; Harding and Mann 1999; Grabowski et al. 2000; Lenihan et al. 2001; Peterson et al. 2003a). Recent studies have examined the habitat value of constructed oyster reefs compared to natural oyster reefs. The researchers found that landscape characteristics seemed to influence fish species' relative abundance (i.e., connectivity with SAV and/or salt marsh). Fish abundance was significantly greater on restored oyster reefs adjacent to SAV than on mud flat and/or salt marsh restored reefs (Grabowski et al. 2000). Restored intertidal oyster reefs produced significantly more economically valuable oysters ($95.68/10 m2) than estimates of oyster production on subtidal reefs ($11.61/10 m2). The value of legal oysters present on mud flat reefs ($129.38/10 m2) exceeded that for oysters on salt marsh ($50.50/10 m2) or SAV restored reefs ($24.25/10 m2). They estimated that the long-term value of commercial fisheries landings from restored reefs was greater than the oyster harvest for both intertidal and subtidal shell bottoms.

The habitat benefits of cultch plantings may only be limited or temporary if the shell bottom is removed or damaged by towed fishing gears or other harvesting gears (Marshall et al. 1999). Cultch plantings in the southern areas (Onslow, Pender and New Hanover counties) are frequently replanted after harvesting to replenish cultch material for recruitment (Marshall et al. 1999). It generally takes about 3-4 years before oysters on planted sites reach harvestable size in the Pamlico Sound system, while oysters reach the minimum legal size of 3 inches in about two years in the southern coastal area. Faster growth in this area is due to higher rates of water exchange caused by greater tidal flow than in most of Pamlico Sound. The increased flow brings in more food and prevents oxygen depletion problems.

The majority of cultch planting sites during 1990-1994 were in Pamlico Sound, lower Neuse River and lower Pamlico River (Marshall et al. 1999). The same general areas were also planted in 2001 and 2002 (Maps 3.4a-b). Most of the recent (2001-2002) oyster restoration effort has been conducted in large bays around Pamlico Sound and in smaller tributaries of other estuaries (Maps 3.4a-b). The majority of these sites are "new" plantings on basically barren sediment (Marshall et al. 1999). Criteria for site selection include suitable sediment types, currents, protection from storm damage, historical productivity, salinity patterns, and existing shellfish concentrations. The presence of bottom disturbing fisheries, such as trawling, hydraulic clamming, and long haul seining, is also considered. Recommended sites for cultch plantings are often narrow bands of mixed sand and mud sediment between shallow, hard, nearshore sediment and soft offshore sediment. In deep water, large oyster mounds are constructed to increase recruitment and reduce effects of low oxygen on the bottom. The planting sites are monitored for oyster recruitment and survival over a period of three years (DMF 2001a). Using vessels currently in operation, cultch can be planted in water as shallow as two feet (Marshall et al. 1999). Since the early 1980s, the DMF has concentrated primarily on cultch plantings and small-scale, high quality seed transplanting activities, also referred to as the "relay program." In the relay program, oysters are removed from dense oyster populations in prohibited areas and relocated to open harvest areas with depleted resources. The relay program is very small and concentrated in the south, where there is very little effect on the seed source areas (M. Street, DMF, pers. com., 2003).

The primary purpose of the DMF cultch-planting program since it began has been oyster fishery enhancement. The DMF enhancement efforts have also been directed at providing stable long-term oyster habitat because research in recent years shows that oyster reefs have important ecological and economic value as coastal fisheries habitat. This broadening of focus for the protection/restoration program has occurred since the late 1990s. As of 2001, there were five constructed/artificial reef sanctuaries in North Carolina located in Bogue Sound, West Bay (Tump Island), Deep Cove (Swan Quarter), Croatan Sound, and behind Hatteras Village (DMF 2001a). Work is currently underway to enhance several existing restoration sites and create additional sites. These areas are no-take, no-disturbance sanctuaries (C. Hardy, DMF, pers. com.). In other states, sanctuaries are a major component of restoration efforts (CBP 2000). Creation of additional "no take" subtidal oyster sanctuaries has been recommended by Frankenberg (1995), the Chesapeake Research Consortium (1999), and Lenihan et al. (1998). There are multiple ecological benefits of constructed and natural oyster sanctuaries, including the following (Breitburg et al. 2000):

- Protection of brood stock,
- Enhancement of oyster populations in surrounding harvested areas through larval dispersion,
- Protection of disease-resistant oysters, improving the genetic pool for disease resistance, and
- Protection of associated fisheries and other organisms from predation through development and maintenance of maximum vertical relief and structural complexity.

The first true oyster reef restoration project in North Carolina occurred in 1992-1993 when 13 acres of oyster producing habitat were created as mitigation for the loss of 16 acres of estuarine bottoms and 1.5 acres of wetlands in Roanoke Sound (Marshall et al. 1999). The DMF monitored the site as part of a mitigation agreement with the U.S. Army Corps of Engineers (COE). The DMF also performed mitigation projects for the North Carolina Department of Transportation, and additional projects creating more than 70 acres of shell bottom with the COE (Marshall et al. 1999). Research is continuing on how to better construct these sites to provide effective oyster habitat. However, in the Pamlico Sound region where spatfall continues to decline (Marshall et al. 1999), more planting and longer protection of sites may be required to achieve the same results as previous restoration efforts. Restoration efforts must use knowledge of larval availability in order to be most effective. In southern waters, the amount of shell habitat is generally stable, but the amount of harvestable area is decreasing as closures increase because of contamination from storm water runoff (R. Carpenter, DMF, pers. com.).

Restoration of shell bottom is also undertaken by non-profit groups. One such project has been initiated in Pamlico Sound by The Nature Conservancy, in cooperation with NOAA's Community-Based Restoration Program and several partners. The goal of the Project is to enhance the biological diversity of Pamlico Sound by establishing a self-sustaining complex of living oyster reefs throughout the estuary. The Conservancy has enlisted the cooperation of marine scientists to ensure the most up-to-date techniques for siting, construction and management are used. Some criteria for site selection include depth, salinity, shellfishing-prohibited status, disease-resistant salinities, reef footprints, presence of larvae, and proximity to SAV, salt marsh, fish nursery areas, or Military Protected Areas. States and territories containing anadromous, estuarine, and marine species are eligible to compete for Community-Based Restoration grants typically ranging from $25,000 to $75,000. As the number of oyster restoration projects grows, the need for an overall strategy for shell bottom restoration also increases.

Any expansions of the current restoration/enhancement effort will require additional sources and funding for oyster cultch or limestone marl. Funding for acquisition of cultch material must be increased to more efficiently use the existing planting capabilities of DMF. The DMF began a voluntary shell-recycling program in 2004 using local coordinators to collect discarded shells from individuals and businesses. The shells are later transferred to stockpile facilities before being planted in new or expanding oyster sanctuaries. The amount of cultch volunteered could somewhat offset the amount of funding needed for additional cultch material. However, the amount of cultch volunteered is probably secondary to the public awareness gained from a shell-recycling program.

Shell Bottom Restoration in South Carolina

Note: The following text is excerpted from the SCDNR website and from Walker (2005). Human activities, in concert with natural phenomena, have greatly affected the distribution and abundance of oysters in the United States. In many areas, oyster habitats have declined precipitously in recent years due to numerous causes, including over-harvesting, destruction of habitat, water pollution, and other effects related to coastal development.

South Carolina's shellfish resources, particularly its subtidal oyster beds, have diminished over the years due to salinity regime changes resulting from a variety of factors including Atlantic Intracoastal Waterway construction; Santee/Cooper River diversion and rediversion; and, accelerated freshwater inflow into estuaries caused by wetland drainage projects and the clearing of land for forestry and agricultural purposes (Walker 2005). While the intertidal oysters of South Carolina may still appear to be abundant there is increasing evidence of negative effects from anthropogenic (man-made) stressors such as nonpoint source runoff, construction of docks and marinas, improper harvesting techniques, and wakes from recreational boat traffic. In fact, in many of the more heavily utilized creek systems, essentially no oysters remain.

South Carolina oyster resources also suffer from a lack of husbandry (conservation), particularly in the common property grounds managed by the state. Appropriate husbandry includes replanting of oyster shell to provide substrate for subsequent generations. If removal of oysters by harvesting is not offset by replanting, the resource declines due to insufficient substrate. A shortage of shell for replanting and a lack of funds for staff and equipment have severely limited the scope of shell replanting by the state of South Carolina (Walker, 2005).

<u>Oyster Restoration Activities in South Carolina</u>

Oysters will readily recruit to planted shell substrate in areas that otherwise have little or no recruitment due to lack of suitable attachment sites. In South Carolina there are adequate breeding populations (adult stocks) but recruitment is limited by substrate.

Although a fully functional reef requires at least 3 to 5 years to develop, a remarkable suite of invertebrates (over 85 species) quickly colonizes the oyster reefs, providing food sources for larger invertebrates and finfish and beginning the natural process of stabilizing the reef.

Planting of shell can also help to trap sediments and absorb wave energy, reducing erosion of adjacent salt marshes. With careful site selection, replanting of shell can restore oyster habitat by providing substrate for juvenile oysters, which grow to form a self-sustaining reef.

Oyster restoration and enhancement efforts in South Carolina are conducted by the South Carolina Department of Natural Resources (SCDNR) and include large-scale replanting in public shellfish grounds supported by saltwater license revenues, small-scale community-based restoration through the SC Oyster Restoration and Enhancement (SCORE) program, and the shell recycling program. The latter two programs are described in greater detail below.

SCORE - South Carolina Oyster Restoration and Enhancement Program
The South Carolina Department of Natural Resources (SCDNR) is responsible for managing the state's oyster resources. Appropriate management includes the planting of material to provide substrate, known as cultch, for recruitment of juvenile oysters. The best cultch material is oyster shell.

In order to increase oyster habitat at the minimum cost to taxpayers, SCDNR has initiated the South Carolina Oyster Restoration and Enhancement (SCORE) program. There are two major components to the SCORE program: oyster shell recycling and community-based restoration. By working together, community members and biologists can restore oyster populations while 1) enhancing habitat for fish, shrimp, and crabs, 2) improving water quality of estuarine areas, and 3) informing and educating children, industry, and the general public.

Oyster Shell Recycling
Immature oysters at the free-swimming larvae stage require a solid surface or substrate for attachment, which is called "setting." Once attached, oysters cannot relocate. Not surprisingly, oysters have evolved a preference for setting on other oyster shell. Adult oysters and even shells of dead oysters emit chemicals that attract oyster larvae. By selecting oyster shells as a substrate, the larvae maximize the likelihood of setting near other oysters (a requirement for reproduction) and of setting in a suitable habitat.

Unfortunately, there is a nationwide shortage of oyster shell to be used as cultch. That which is available is often not readily accessible because it is spread out in many locations. SCDNR has initiated an effort to encourage the public to recycle oyster shell for use in resource management. Recycling centers have been established at several sites along the coast.

Consumers are encouraged to deposit clean shell (i.e., no trash) in designated bins at the recycling centers, which are periodically emptied by SCDNR. The shell collected in this manner is then used for restoration and enhancement of shellfish resources, thus reducing the cost of these activities. Community groups and youth organizations may wish to recycle shell as a community service project. An abundance of oyster shell ends up being discarded by restaurants, caterers, resorts, and from private oyster roasts, so it is important to recapture it before it is sent to the landfill.

Community-Based Restoration
The restoration component of the SCORE program depends on local citizen groups working closely with SCDNR staff to construct oyster reef habitat, and to monitor the success of those efforts. Since May 2001, more than 2000 volunteers have used more than 250 tons of recycled shell to construct approximately 2,369 m2 of oyster reef habitat at 30 sites along the South Carolina coast, from Murrells Inlet to Pinckney Island. After the reefs are constructed, volunteers are trained to monitor water quality, reef development, and reef/shoreline interactions. The overall goal of the SCORE program is to protect oyster reef habitats by increasing citizen awareness of the ecological importance of these habitats and the potential negative effects of human activities on these fragile ecosystems. By involving citizens in the restoration process the SCDNR hopes to accomplish the following:

- Develop a citizen constituency for oysters
- Initiate a grass-roots effort to restore oysters
- Increase public awareness of the value of oysters to the ecosystem
- Influence public policy to provide greater protection for oyster habitats
- Influence lawmakers to provide adequate funding for proper management of oyster resources
- Expand the scope of our endeavors by utilizing volunteer labor.

<u>Recommendations for shellfish management</u>
Intertidal oyster reefs serve to buffer shorelines from coastal erosion, improve water quality, and provide habitat for other species. Oysters are also highly prized for human consumption, and should be managed sustainably to allow for continued harvesting, as well as to provide ecological services. Walker (2005) lists recommendations for shellfish management changes in South Carolina, which are based on comparisons with other states and interviews with agency staff and other stakeholders within South Carolina. These recommendations include considering the importance of shellfish resources beyond their consumptive value when making management decisions, increasing the number of inter and intra-agency planning meetings to streamline management, increasing replanting funds and efforts, reviewing Culture Permit and State Shell Shellfish Ground management, and continuing information exchange with the industry.

7.2 Description and use of EFH, EFH-HAPCs and Coral HAPCs

7.2.1 Penaeid and deepwater shrimp

7.2.1.1 Essential Fish Habitat

Penaeid Shrimp
For penaeid shrimp, Essential Fish Habitat includes inshore estuarine nursery areas, offshore marine habitats used for spawning and growth to maturity, and all interconnecting water bodies as described in the SAFMC Habitat Plan (SAFMC 1998a). Inshore nursery areas include tidal freshwater (palustrine), estuarine, and marine emergent wetlands (e.g., intertidal marshes); tidal palustrine forested areas; mangroves; tidal freshwater, estuarine, and marine submerged aquatic vegetation (e.g., seagrass); and subtidal and intertidal non-vegetated flats. This applies from North Carolina through the Florida Keys.

Rock Shrimp
For rock shrimp, essential fish habitat consists of offshore terrigenous and biogenic sand bottom habitats from 18 to 182 meters in depth with highest concentrations occurring between 34 and 55 meters. This applies for all areas from North Carolina through the Florida Keys. Essential fish habitat includes the shelf current systems near Cape Canaveral, Florida which provide major transport mechanisms affecting planktonic larval rock shrimp. These currents keep larvae on the Florida Shelf and may transport them inshore in spring. In addition, the Gulf Stream is an essential fish habitat because it provides a mechanism to disperse rock shrimp larvae.

The bottom habitat on which rock shrimp thrive is thought to be limited. Kennedy et al. (1977) determined that the deepwater limit of rock shrimp was most likely due to the decrease of suitable bottom habitat rather than to other physical parameters including salinity and temperature. Cobb et al. (1973) found the inshore distribution of rock shrimp to be associated with terrigenous and biogenic sand substrates and only sporadically on mud. Rock shrimp also utilize hard bottom and coral or more specifically, Oculina coral habitat areas. This was confirmed with research trawls capturing large amounts of rock shrimp in and around the Oculina Bank HAPC prior to its designation.

Other than Kennedy et al. (1977), no characterization of habitat essential to rock shrimp has been conducted. A list of species associated with the benthic habitat inhabited by rock shrimp was compiled from research trawling efforts (1955-1991) that captured harvestable levels of rock shrimp. In addition, Kennedy et al. (1977), during research efforts sampling the major distribution area of rock shrimp off the east coast of Florida, compiled a list of crustacean and molluscan taxa associated with rock shrimp benthic habitat.

Royal Red Shrimp
Essential fish habitat for royal red shrimp include the upper regions of the continental slope from 180 meters (590 feet) to about 730 meters (2,395 feet), with concentrations

found at depths of between 250 meters (820 feet) and 475 meters (1,558 feet) over blue/black mud, sand, muddy sand, or white calcareous mud. In addition, the Gulf Stream is an essential fish habitat because it provides a mechanism to disperse royal red shrimp larvae.

7.2.1.2 Essential Fish Habitat-Habitat Areas of Particular Concern

Penaeid Shrimp

Areas which meet the criteria for essential fish habitat-habitat areas of particular concern (EFH-HAPCs) for penaeid shrimp include all coastal inlets, all state-designated nursery habitats of particular importance to shrimp (for example, in North Carolina this would include all Primary Nursery Areas and all Secondary Nursery Areas), and state-identified overwintering areas.

Estuarine tidal creeks and salt marshes that serve as nursery grounds are perhaps the most important habitats occupied by penaeid shrimp. The major factor controlling shrimp growth and production is the availability of nursery habitat. Remaining wetland habitat must be protected if present production levels are to be maintained. In addition, impacted habitats must be restored if future production is to be increased. Other areas of specific concern are the barrier islands since these land masses are vital to the maintenance of estuarine conditions needed by shrimp during their juvenile stage. Passes between barrier islands into estuaries also are important since the slow mixing of sea water and fresh water are also of prime importance to estuarine productivity.

In North Carolina, essential fish habitat-habitat areas of particular concern include estuarine shoreline habitats since juveniles congregate here. Seagrass beds, prevalent in the sounds and bays of North Carolina and Florida, are particularly critical areas. Core Sound and eastern Pamlico Sound, based on a preliminary aerial survey funded through the Albemarle-Pamlico Estuarine Study, have approximately 200,000 acres of seagrass beds making North Carolina second only to Florida in abundance of this type of habitat (Department of Commerce 1988b). In subtropical and tropical regions shrimp and spiny lobster postlarvae recruit into grass beds from distant offshore spawning grounds (Fonseca et al. 1992).

South Carolina and Georgia lack seagrass beds. Here, the nursery habitat of shrimp is the high marsh areas with shell hash and mud bottoms. In addition, there is seasonal movement out of the marsh into deep holes and creek channels adjoining the marsh system during winter. Therefore, the area of particular concern for early growth and development encompasses the entire estuarine system from the lower salinity portions of the river systems through the inlet mouths.

Section 600.815 (a) (8) of the final rule on essential fish habitat determinations recognizes that subunits of EFH may be of particular concern. Such areas, termed Essential Fish Habitat- Habitat Areas of Particular Concern (EFH-HAPCs), can be identified using Identification of habitat areas of particular concern. FMPs should identify specific types or areas of habitat within EFH as habitat areas of particular concern based on one or more of the following considerations: (i) The importance of the ecological function provided by the habitat; (ii) The extent to which the habitat is sensitive to human-induced environmental degradation; (iii) Whether, and to what extent, development activities are, or will be, stressing the habitat type; and (iv) The rarity of the habitat type. The following is a summary evaluation of the EFH-HAPC as it relates to the criteria:

Table 7.2-1. EFH-HAPC and Criteria Evaluation, Penaeid Shrimp

EFH-HAPC and Criteria Evaluation	Ecological Function	Sensitivity to Environmental Degradation	Threat from Development Activities	Rarity of Habitat
Coastal inlets	High	Low	Medium	Medium
State-designated nursery habitats	High	High	Medium	High
State-identified overwintering habitats	Medium	Low	Medium	Medium
Seagrass beds in NC and FL	High	High	Medium	High
High marsh areas with shell hash and mud bottom in SC and GA	High	Medium	Medium	Medium

Rock Shrimp

No essential fish habitat areas of particular concern have been identified for rock shrimp; however, deep water habitat (e.g., the rock shrimp closed area/proposed expanded Oculina Bank HAPC) may serve as nursery habitat and protect the stock by providing a refuge for rock shrimp.

Royal Red Shrimp

Although no essential fish habitats of particular concern have been identified specifically for royal red shrimp, they are caught in association with deep water corals on the continental slope. Deep sea corals support high levels of marine biodiversity by providing habitat for numerous benthic species. As structure-forming animals, deep sea corals enhance habitat complexity by growing in the form of "reefs", fans, stalks, and "bushes". The *Enallopsamia* reefs off South Carolina, the *Oculina* habitat off Florida, and the *Lophelia* reefs from North Carolina to Florida may be important in the life history of royal red shrimp. Bottom impacting mobile gear such as trawls will likely impact these important habitats.

To obtain maps of EFH-HAPCs please visit the Council's Internet Map Server on the South Atlantic Council's website at www.safmc.net.

7.2.2 Snapper Grouper

7.2.2.1 Essential Fish Habitat

EFH utilized by snapper grouper species in this region includes coral reefs, live/hard bottom, submerged aquatic vegetation, artificial reefs and medium to high profile outcroppings on and around the shelf break zone from shore to at least 183 meters [600 feet (but to at least 2,000 feet for wreckfish)] where the annual water temperature range is sufficiently warm to maintain adult populations of members of this largely tropical fish complex. EFH includes the spawning area in the water column above the adult habitat and the additional pelagic environment, including Sargassum, required for survival of larvae and growth up to and including settlement. In addition, the Gulf Stream is also EFH because it provides a mechanism to disperse snapper grouper larvae.

For specific life stages of estuarine dependent and near shore snapper grouper species, EFH includes areas inshore of the 30 meters (100-foot) contour, such as attached macroalgae; submerged rooted vascular plants (seagrasses); estuarine emergent vegetated wetlands (salt marshes, brackish marsh); tidal creeks; estuarine scrub/shrub (mangrove fringe); oyster reefs and shell banks; unconsolidated bottom (soft sediments); artificial reefs; and coral reefs and live/hard bottom habitats.

7.2.2.2 Essential Fish Habitat-Habitat Areas of Particular Concern

Areas which meet the criteria for essential fish habitat-habitat areas of particular concern (EFH-HAPCs) for species in the snapper grouper management unit include medium to high profile offshore hard bottoms where spawning normally occurs; localities of known or likely periodic spawning aggregations; nearshore hardbottom areas; The Point, The Ten Fathom Ledge, and Big Rock (North Carolina); The Charleston Bump (South Carolina); mangrove habitat; seagrass habitat; oyster/shell habitat; all coastal inlets; all state-designated nursery habitats of particular importance to snapper grouper (e.g., Primary and Secondary Nursery Areas designated in North Carolina); pelagic and benthic Sargassum; Hoyt Hills for wreckfish; the Oculina Bank Habitat Area of Particular Concern; all hermatypic coral habitats and reefs; manganese outcroppings on the Blake Plateau; and Council-designated Artificial Reef Special Management Zones (SMZs). Areas that meet the criteria for designating essential fish habitat-habitat areas of particular concern include habitats required during each life stage (including egg, larval, postlarval, juvenile, and adult stages).

Section 600.815 (a) (8) of the final rule on essential fish habitat determinations recognizes that subunits of EFH may be of particular concern. Such areas, termed Essential Fish Habitat- Habitat Areas of Particular Concern (EFH-HAPCs), can be identified using Identification of habitat areas of particular concern. FMPs should identify specific types or areas of habitat within EFH as habitat areas of particular concern based on one or more of the following considerations: (i) The importance of the ecological function provided by the habitat; (ii) The extent to which the habitat is sensitive to human-induced environmental degradation; (iii) Whether, and to what extent, development activities are, or will be, stressing the habitat type; and (iv) The rarity of the habitat type. The following is a summary evaluation of the EFH-HAPC as it relates to the criteria:

Table 7.2-2. EFH-HAPC and Criteria Evaluation, Snapper Grouper

EFH-HAPC and Criteria Evaluation	Ecological Function	Sensitivity to Environmental Degradation	Threat from Development Activities	Rarity of Habitat
The Point, NC	Medium	Low	Medium	High
The Ten Fathom Ledge, NC	High	Low	Low	High
Big Rock, NC	High	Low	Medium	High
Charleston Bump, SC	High	Low	Medium	High
Mangrove habitat	High	High	High	High
Seagrass habitat	High	High	High	High
Oyster/shell habitat	High	Medium	High	High
All coastal inlets	Medium	Low	Medium	Medium
All state-designated nursery habitats	High	High	High	High
Pelagic and benthic Sargassum	High	Low	Low	High
Hoyt Hills (wreckfish)	High	Low	Medium	High
Oculina HAPC, FL	High	Medium	Low	High
All hermatypic coral habitats and reefs	High	High	Low	High
Manganese outcroppings of the Blake Plateau	High	Low	Medium	High
Artificial reef SMZs	Medium	Low	Low	High

To obtain maps of EFH-HAPCs please visit the Council's Internet Map Server on the South Atlantic Council's website at www.safmc.net.

7.2.3 Coastal Migratory Pelagics

7.2.3.1 Essential Fish Habitat

Essential fish habitat for coastal migratory pelagic species includes sandy shoals of capes and offshore bars, high profile rocky bottom and barrier island ocean-side waters, from the surf to the shelf break zone, but from the Gulf stream shoreward, including Sargassum. In addition, all coastal inlets, all state-designated nursery habitats of particular importance to coastal migratory pelagics (for example, in North Carolina this would include all Primary Nursery Areas and all Secondary Nursery Areas).

For Cobia, essential fish habitat also includes high salinity bays, estuaries, and seagrass habitat. In addition, the Gulf Stream is an essential fish habitat because it provides a mechanism to disperse coastal migratory pelagic larvae.
For king and Spanish mackerel and cobia, essential fish habitat occurs in the South Atlantic and Mid-Atlantic Bights.

Refer to Section 3.0 in the Habitat Plan for a more detailed description of habitat utilized by the managed species. Also, it should be noted that the Gulf Stream occurs within the EEZ.

7.2.3.2 Essential Fish Habitat-Habitat Areas of Particular Concern

Areas which meet the criteria for essential fish habitat-habitat areas of particular concern (EFH-HAPCs) include sandy shoals of Capes Lookout, Cape Fear, and Cape Hatteras from shore to the ends of the respective shoals, but shoreward of the Gulf stream; The Point, The Ten-Fathom Ledge, and Big Rock (North Carolina); The Charleston Bump and Hurl Rocks (South Carolina); The Point off Jupiter Inlet (Florida); *Phragmatopoma* (worm reefs) reefs off the central east coast of Florida; nearshore hard bottom south of Cape Canaveral; The Hump off Islamorada, Florida; The Marathon Hump off Marathon, Florida; The “Wall” off of the Florida Keys; Pelagic Sargassum; and Atlantic coast estuaries with high numbers of Spanish mackerel and cobia based on abundance data from the ELMR Program. Estuaries meeting this criteria for Spanish mackerel include Bogue Sound and New River, North Carolina: Bogue Sound, North Carolina (Adults May-September salinity greater than 30 ppt); and New River, North Carolina (Adults May-October salinity greater than 30 ppt). For Cobia, they include Broad River, South Carolina; and Broad River, South Carolina (Adults & juveniles May-July salinity greater than 25ppt).

Section 600.815 (a) (8) of the final rule on essential fish habitat determinations recognizes that subunits of EFH may be of particular concern. Such areas, termed Essential Fish Habitat- Habitat Areas of Particular Concern (EFH-HAPCs), can be identified using Identification of habitat areas of particular concern. FMPs should identify specific types or areas of habitat within EFH as habitat areas of particular concern based on one or more of the following considerations: (i) The importance of the ecological function provided by the habitat; (ii) The extent to which the habitat is sensitive to human-induced environmental degradation; (iii) Whether, and to what extent, development activities are, or will be, stressing the habitat type; and (iv) The rarity of the habitat type. The following is a summary evaluation of the EFH-HAPC as it relates to the criteria:

Table 7.2-3. EFH-HAPC and Criteria Evaluation, Coastal Migratory Pelagics

EFH-HAPC and Criteria Evaluation	Ecological Function	Sensitivity to Environmental Degradation	Threat from Development Activities	Rarity of Habitat
Sandy shoals of Cape Lookout, Cape Fear and Cape Hatteras (from shore to the end of shoals but shoreward from Gulf Stream)	Medium	Low	Medium	Medium
The Point, NC	Medium	Low	Medium	High
The Ten Fathom Ledge, NC	Medium	Low	Medium	Medium
Big Rock, NC	Medium	Low	Low	Medium
Charleston Bump, SC	Medium	Low	Medium	Medium
Hurl Rocks, SC	Medium	Low	Medium	Medium
The Point off Jupiter Inlet, FL	Medium	Low	Low	Low
Phragmatopoma (worm reefs) reefs off central E. coast of FL	High	Medium	Medium	High
nearshore hardbottom south of Cape Canaveral, FL	High	High	High	High
The Hump off Islamorada, FL	Medium	Low	Low	Medium
The Marathon Hump, FL	High	Low	Low	Medium
Pelagic Sargassum	High	Low	Low	Medium
Bogue Sound and New River estuaries, NC (Spanish mackerel)	High	High	High	Medium
Broad River, SC (cobia)	High	High	High	Medium

To obtain maps of EFH-HAPCs please visit the Council's Internet Map Server on the South Atlantic Council's website at www.safmc.net.

7.2.4 Golden Crab

7.2.4.1 Essential Fish Habitat

Essential fish habitat for golden crab includes the U.S. Continental Shelf from Chesapeake Bay south through the Florida Straits (and into the Gulf of Mexico). In addition, the Gulf Stream is an essential fish habitat because it provides a mechanism to disperse golden crab larvae. The detailed description of seven essential fish habitat types (a flat foraminferan ooze habitat; distinct mounds, primarily of dead coral; ripple habitat; dunes; black pebble habitat; low outcrop; and soft-bioturbated habitat) for golden crab is provided in Wenner et al. (1987).

Refer to Section 3.0 in the Habitat Plan for a more detailed description of habitat utilized by the managed species. Also, it should be noted that the Gulf Stream occurs within the EEZ.

7.2.4.2 Essential Fish Habitat-Habitat Areas of Particular Concern

There is insufficient knowledge of the biology of golden crabs to identify spawning and nursery areas and to identify HAPCs at this time. As information becomes available, the Council will evaluate such data and identify HAPCs as appropriate through the framework.

7.2.5 Spiny Lobster

7.2.5.1 Essential Fish Habitat

Essential fish habitat for spiny lobster includes nearshore shelf/oceanic waters; shallow subtidal bottom; seagrass habitat; unconsolidated bottom (soft sediments); coral and live/hard bottom habitat; sponges; algal communities (Laurencia); and mangrove habitat (prop roots). In addition the Gulf Stream is an essential fish habitat because it provides a mechanism to disperse spiny lobster larvae.

Refer to Section 3.0 in the Habitat Plan for a more detailed description of habitat utilized by the managed species. Also, it should be noted that the Gulf Stream occurs within the EEZ.

7.2.5.2 Essential Fish Habitat-Habitat Areas of Particular Concern

Areas which meet the criteria for essential fish habitat-habitat areas of particular concern (EFH-HAPCs) for spiny lobster include Florida Bay, Biscayne Bay, Card Sound, and coral/hard bottom habitat from Jupiter Inlet, Florida through the Dry Tortugas, Florida.

Table 7.2-4. EFH-HAPC and Criteria Evaluation, Spiny Lobster

EFH-HAPC and Criteria Evaluation	Ecological Function	Sensitivity to Environmental Degradation	Threat from Development Activities	Rarity of Habitat
Florida Bay	High	High	Medium	Medium
Biscayne Bay	High	High	Medium	Medium
Card Sound	High	High	Medium	Medium
Coral/hardbottom habitat from Jupiter Inlet through the Dry Tortugas, FL	High	High	High	High

To obtain maps of EFH-HAPCs please visit the Council's Internet Map Server on the South Atlantic Council's website at www.safmc.net.

7.2.6 Coral, Coral Reefs and Live/Hard Bottom Habitat

7.2.6.1 Essential Fish Habitat

Essential fish habitat for corals (stony corals, octocorals, and black corals) must incorporate habitat for over 200 species. EFH for corals include the following:

A. Essential fish habitat for hermatypic stony corals includes rough, hard, exposed, stable substrate from Palm Beach County south through the Florida reef tract in subtidal to 30 m depth, subtropical (15°-35° C), oligotrophic waters with high (30 35o/oo) salinity and turbidity levels sufficiently low enough to provide algal symbionts adequate sunlight penetration for photosynthesis. Ahermatypic stony corals are not light restricted and their essential fish habitat includes defined hard substrate in subtidal to outer shelf depths throughout the management area.

B. Essential fish habitat for Antipatharia (black corals) includes rough, hard, exposed, stable substrate, offshore in high (30-35o/oo) salinity waters in depths exceeding 18 meters (54 feet), not restricted by light penetration on the outer shelf throughout the management area.

C. Essential fish habitat for octocorals excepting the order Pennatulacea (sea pens and sea pansies) includes rough, hard, exposed, stable substrate in subtidal to outer shelf depths within a wide range of salinity and light penetration throughout the management area.

D. Essential fish habitat for Pennatulacea (sea pens and sea pansies) includes muddy, silty bottoms in subtidal to outer shelf depths within a wide range of salinity and light penetration.

Refer to Section 3.0 in the Habitat Plan for a more detailed description of habitat utilized by the managed species.

7.2.6.2 Essential Fish Habitat-Habitat Areas of Particular Concern

Areas which meet the criteria for essential fish habitat-habitat areas of particular concern (EFH-HAPCs) for coral, coral reefs, and live/hard bottom include The 10-Fathom Ledge, Big Rock, and The Point (North Carolina); Hurl Rocks and The Charleston Bump (South Carolina); Gray's Reef National Marine Sanctuary (Georgia); The *Phragmatopoma* (worm reefs) reefs off the central east coast of Florida; Oculina Banks off the east coast of Florida from Ft. Pierce to Cape Canaveral; nearshore (0-4 meters; 0-12 feet) hard bottom off the east coast of Florida from Cape Canaveral to Broward County; offshore (5-30 meter; 15-90 feet) hard bottom off the east coast of Florida from Palm Beach County to Fowey Rocks; Biscayne Bay, Florida; Biscayne National Park, Florida; and the Florida Keys National Marine Sanctuary.

Table 7.2-5. EFH-HAPC and Criteria Evaluation, Coral, Coral Reefs, and Live/Hard Bottom Habitat

EFH-HAPC and Criteria Evaluation	Ecological Function	Sensitivity to Environmental Degradation	Threat from Development Activities	Rarity of Habitat
Ten Fathom Ledge, NC	Medium	Low	Medium	Medium
Big Rock, NC	Medium	Low	Medium	Medium
The Point, NC	Medium	Low	Medium	Medium
Hurl Rocks, SC	Medium	High	High	Medium
Charleston Bump, SC	Medium	Low	Medium	Medium
Gray's Reef NMS, GA	High	Low	Low	Medium
Phragmatopoma worm reefs, FL	Medium	High	Medium	High
Oculina Banks from Ft. Pierce to Cape Canaveral, FL	High	Low	Low	High
Nearshore hardbottom off from Cape Canaveral to Broward County, FL	High	Medium	High	Medium
Offshore hardbottom from Palm Beach County to Fowey Rocks, FL	High	Low	Medium	Medium
Biscayne Bay, FL	Medium	Low	Medium	Medium
Biscayne National Park, FL	Medium		Medium	Low
Florida Keys NMS, FL	High	High	High	High

To obtain maps of EFH-HAPCs please visit the Council's Internet Map Server on the South Atlantic Council's website at www.safmc.net.

7.2.7 Dolphin Wahoo

7.2.7.1 Essential Fish Habitat

EFH for dolphin and wahoo is the Gulf Stream, Charleston Gyre, Florida Current, and pelagic Sargassum.

Note: This EFH definition for dolphin was approved by the Secretary of Commerce on June 3, 1999 as a part of the South Atlantic Council's Comprehensive Habitat Amendment (SAFMC, 1998b) (dolphin was included within the Coastal Migratory Pelagics FMP). This definition does not apply to extra-jurisdictional areas. A detailed description of the pelagic habitats used by dolphin and wahoo is presented in Section 3.0 Affected Environment.

7.2.7.2 Essential Fish Habitat-Habitat Areas of Particular Concern

EFH-HAPCs for dolphin and wahoo in the Atlantic include The Point, The Ten-Fathom Ledge, and Big Rock (North Carolina); The Charleston Bump and The Georgetown Hole (South Carolina); The Point off Jupiter Inlet (Florida); The Hump off Islamorada, Florida; The Marathon Hump off Marathon, Florida; The "Wall" off of the Florida Keys; and Pelagic Sargassum.

Note: This EFH-HAPC definition for dolphin was approved by the Secretary of Commerce on June 3, 1999 as a part of the South Atlantic Council's Comprehensive Habitat Amendment (dolphin was included within the Coastal Migratory Pelagics FMP).

Section 600.815 (a) (8) of the final rule on essential fish habitat determinations recognizes that subunits of EFH may be of particular concern. Such areas, termed Essential Fish Habitat- Habitat Areas of Particular Concern (EFH-HAPCs), can be identified using Identification of habitat areas of particular concern. FMPs should identify specific types or areas of habitat within EFH as habitat areas of particular concern based on one or more of the following considerations: (i) The importance of the ecological function provided by the habitat; (ii) The extent to which the habitat is sensitive to human-induced environmental degradation; (iii) Whether, and to what extent, development activities are, or will be, stressing the habitat type; and (iv) The rarity of the habitat type. The following is a summary evaluation of the EFH-HAPC as it relates to the criteria:

Table 7.2-6. EFH-HAPC and Criteria Evaluation, Dolphin Wahoo

EFH-HAPC and Criteria Evaluation	Ecological Function	Sensitivity to Environmental Degradation	Threat from Development Activities	Rarity of Habitat
The Point	High	Medium	Medium	High
The Ten Fathom Ledge	High	Medium	Low	Medium
Big Rock	High	Medium	Medium	High
The Charleston Bump	High	Low	Medium	High

The Georgetown Hole	High	Low	Low	High
The Point off Jupiter Inlet	High	Medium	Low	High
The Hump off Islamorada	High	Low	Low	High
The Marathon Hump	High	Medium	Low	High
The Wall off of the Florida Keys	Medium	Medium	Low	Medium
Pelagic *Sargassum*	High	Medium	Low	High

The EFH-HAPCs for dolphin and wahoo all meet at least one or more of the above criteria. This action enables the Councils to protect these EFH-HAPCs effectively and take timely actions when necessary. This could prevent further decreases in biological productivity and may lead to possible increases in yield of fish stocks.
This evaluation is based in part on information presented in this Action and Section 3.3.1.2.1 describing the general characteristics of the unique habitat type and where available specific descriptions of the habitat associated with the area proposed for designation as an EFH-HAPC. In addition, supporting rationale for designation including identified threats from fishing and non-fishing activities is presented in Habitat Plan (SAFMC, 1998b), the Comprehensive Habitat Amendment (SAFMC, 1998c) and the Sargassum Fishery Management Plan (SAFMC 2002) and included by reference. The following figures present maps for areas which for dolphin and wahoo ranked high in terms of ecological function, sensitivity, probability of stressor introduction and rarity of habitat (criteria established for designation of EFH-HAPCs). Based on the criteria in Section 600.815 (a) (9), it is concluded that they represent Essential Fish Habitat-Habitat Areas of Particular Concern for species managed under the Fishery Management Plan for Dolphin Wahoo of the Atlantic Region.

To obtain maps of EFH-HAPCs please visit the Council's Internet Map Server on the South Atlantic Council's website at www.safmc.net.

7.2.8 Other managed species in the South Atlantic

7.2.8.1 Atlantic Menhaden

(ASMFC 2001)

Essential Fish Habitat

Almost all of the estuarine and nearshore waters along the Atlantic coast from Florida to Nova Scotia, serve as important habitat for juvenile and/or adult Atlantic menhaden. Spawning occurs in oceanic waters along the Continental Shelf, as well as in sounds and bays in the northern extent of their range (Judy and Lewis 1983). Larvae are carried by inshore currents into estuaries from May to October in the New England area, from October to June in the mid-Atlantic area, and from December to May in the South Atlantic area (Reintjes and Pacheco 1966). After entering the estuary, larvae congregate in large concentrations near the upstream limits of the tidal zone, where they undergo metamorphosis into juveniles (June and Chamberlin 1959). The relative densities of juvenile menhaden have been shown to be positively correlated with higher chlorophyll a levels in the lower salinity zones of estuaries (Friedland et al. 1996). As juvenile menhaden grow and develop, they form dense schools and range throughout the lower salinity portions of the estuary, most eventually migrating to the ocean in late fall-winter. Many factors in the estuarine environment affect the behavior and well-being of menhaden. The combined influence of weather, tides, and river flow can expose estuarine fish to rapid changes in temperature and salinity. It has been reported that salinity affects menhaden temperature tolerance, activity and metabolic levels, and growth (Lewis 1966; Hettler 1976). Factors such as waves, currents, turbidity, and dissolved oxygen levels can impact the suitability of the habitat, as well as the distribution of fish and their feeding behavior (Reintjes and Pacheco 1966). However, the most important factors affecting natural mortality in Atlantic menhaden are considered to be predators, parasites and fluctuating environmental conditions (Reish et al. 1985).

It is clearly evident that estuarine and coastal areas along the Atlantic coast provide essential habitat for most life stages of Atlantic menhaden. However, an increasing number of people live near the coast, which precipitates associated industrial and municipal expansion, thus, accelerating competition for use of the same habitats. Consequently, estuarine and coastal habitats have been significantly reduced and continue to be stressed adversely by dredging, filling, coastal construction, energy plant development, pollution, waste disposal, and other human-related activities.

Estuaries of the mid-Atlantic and South Atlantic states provide almost all of the nursery areas utilized by Atlantic menhaden. Areas such as Chesapeake Bay and the Albemarle-Pamlico system are especially susceptible to pollution because they are generally shallow, have a high total volume relative to freshwater inflow, low tidal exchange, and a long retention time. Most tributaries of these systems originate in the Coastal Plain and have relatively little freshwater flow to remove pollutants. Shorelines of most estuarine areas are becoming increasingly developed, even with existing habitat protection programs. Thus, the specific habitats of greatest long-term importance to the menhaden stock and fishery are increasingly at risk.

7.2.8.2 Anadromous and Catadromous Species

Alosine species (from ASMFC habitat docs on anadromous species)

Essential Fish Habitat-Habitat Areas of Particular Concern

Habitats described as EFH for other managed species (spawning adult, egg, larval, juvenile, sub-adult, and adult resident and migratory) are deemed essential to the sustainability of anadromous alosine stocks as they presently exist. Nursery habitat for anadromous alosines consists of areas in which the larvae, postlarvae, and juveniles grow and mature. These areas include the spawning grounds and areas through which the larvae and postlarvae drift after hatching, as well as the portions of rivers and adjacent estuaries in which they feed, grow, and mature. Juvenile alosines, which leave the coastal bays and estuaries prior to reaching adulthood also use the nearshore Atlantic Ocean as a nursery area (ASMFC 1999).

Sub-adult and adult habitat for alosines consists of the nearshore Atlantic Ocean from the Bay of Fundy, Canada to Florida; inlets, which provide access to coastal bays and estuaries; and riverine habitat upstream to the spawning grounds (ASMFC 1999). American shad and river herring have similar seasonal distributions, which may be indicative of similar inshore and offshore migratory patterns (Neves 1981). Although the distribution and movements of hickory shad are essentially unknown after they return to the ocean, (Richkus and DiNardo 1984) because they are harvested along the southern New England coast in the summer and fall, (Bigelow and Schroeder 1953) it is assumed that they also follow a migratory pattern similar to American shad (Dadswell et al. 1987).

Klauda et al. (1991) concluded that the critical life history stages for American shad, hickory shad, alewives, and blueback herring are the egg, prolarva (yolk-sac or prefeeding larva), postlarva (feeding larva), and early juvenile (through the first month after transformation). Critical habitat in the state of North Carolina is defined as "The fragile estuarine and marine areas that support juvenile and adult populations of economically important seafood species, as well as forage species important in the food chain." Among these critical habitats are anadromous fish spawning and anadromous nursery areas, in all coastal fishing waters (NCAC 3I.0101 (20) (NCDEHNR 1997). Although most states have not formally designated essential or critical alosine habitat areas, most states have identified spawning habitat, and some have even identified nursery habitat.

Tables 1-4 summarize significant environmental, temporal, and spatial factors that affect the distribution of American shad, hickory shad, alewife, and blueback herring. Tables 5-8 contain confirmed, reported, suspected, or historical state habitat for American shad, hickory shad, alewife, and blueback herring. Appendix C contains information about past, current, or proposed actions to restore alosine habitat by state. Appendix D contains a discussion of habitat in the Exclusive Economic Zone (EEZ) and international waters. Alosines spend the majority of their life cycle outside of state waters, and the Commission recognizes that all habitats used by these species are essential to their existence.

American eel

Essential Fish Habitat-Habitat Areas of Particular Concern

Habitat types that qualify as Habitat Areas of Particular Concern for American eel include the spawning and hatching area, nursery and juvenile habitat, and adult habitat.

Ocean - The spawning and hatching area for American eel occurs in the oceanic waters of the Sargasso Sea. This is the only suspected location of reproduction for American eel, and therefore, is essential to the survival of the species. Little is known about American eel habitat in the Sargasso Sea, and the exact location of spawning and hatching has not been identified.

Continental Shelf - The Continental shelf waters are important to the American eel because it is final stage of the larval eel migration route, where eels begin entering coastal waters, and is important to larval feeding and growth. It is also where American eel metamorphose into the glass eel stage.

Estuaries/Freshwater Habitat – Estuaries and any upstream freshwater habitat, including rivers, streams, and lakes serve as juvenile, sub-adult, and adult migration corridors, as well as feeding and growth areas for juveniles and sub-adults (ASMFC 2000). After American eel larvae transform into glass eels over the continental shelf, they enter estuaries, and ascend the tidal portions of rivers. Glass eels change into the elver life stage and either continue upstream movements, or cease migrating in the lower saline portions of estuaries and rivers. These estuaries and freshwater habitats serve as the foraging grounds for American eels and are important to the eel growth and maturation. American eels can remain in these systems for up to twenty years before maturing and returning to sea.

While estuarine/riverine habitats have been identified as important for the rearing and growth of American eels, many studies have failed to find specific American eel-habitat associations within them (Huish and Pardue 1978; Meffe and Sheldon 1988; Smogor et al. 1995; Bain et al. 1988; Wiley et al. 2004). Huish and Pardue (1978) found no difference in American eel abundance in relation to width, substrate, flow, and depth in North Carolina streams. Likewise, Bain et al. (1988) found that eel habitat use was not related to specific habitat features including depth, water velocity, and substrate in two Connecticut River tributaries. Wiley et al. (2004) also did not find any eel-stream habitat relations. They found that eel density was correlated with distance from the ocean. Since eels have the ability to survive in a wide variety of habitats, the phase of their lives when they live in estuarine, riverine, stream, and lake habitats are less limited, but water quality is an important factor in their health and survival.

Given the great variation in demographics that occurs across latitudinal and distance-inland gradients, it's unlikely that all areas contribute equally to eel production/recruitment. Despite this, geographic patterns of differential recruitment are unexplored. This problem needs to be addressed before identifying specific Habitat Areas of Particular Concern.

7.2.8.3 Red Drum

For red drum, important fish habitat includes all the following habitats to a depth of 50 meters offshore: tidal freshwater; estuarine emergent vegetated wetlands (flooded saltmarshes, brackish marsh, and tidal creeks); estuarine scrub/shrub (mangrove fringe); submerged rooted vascular plants (sea grasses); oyster reefs and shell banks; unconsolidated bottom (soft sediments); ocean high salinity surf zones; and artificial reefs. The area covered includes Virginia through the Florida Keys.

Other important habitats for red drum include all coastal inlets, all state-designated nursery habitats of particular importance to red drum (for example, in North Carolina this would include all Primary Nursery Areas and all Secondary Nursery Areas); documented sites of spawning aggregations in North Carolina, South Carolina, Georgia, and Florida described in the Habitat Plan; other spawning areas identified in the future; and habitats identified for submerged aquatic vegetation.

7.2.8.4 Bluefish

The following present life history and habitat characteristics in the EFH Source Document (NEFSC 2006).

Table 7.2-7. Summary of life history and habitat characteristics for bluefish, *Pomatomus saltatrix*.

Life History Stage	Habitat (Spatial and Temporal)	Temperature	Salinity	Light/Vertical Distribution	Currents/ Circulation	Prey	Estuarine Use
Eggs [1]	*spring cohort*: unknown. *summer cohort*: occurs across continental shelf, southern New England to Cape Hatteras. Most in mid-shelf waters.	*spring cohort*: unknown. *summer cohort*: most in 18-22°C.	*spring cohort*: unknown. *summer cohort*: 31.0 ppt or more (minimum 26.0 ppt).	*spring cohort*: unknown. *summer cohort*: peak spawning in the evening (1900-2100 hrs).	*spring cohort*: unknown. *summer cohort*: in southern MAB, surface currents transport eggs south and offshore.	--	None
Larvae [2]	*spring cohort*: near edge of continental shelf, Cape Hatteras-Cape Canaveral, FL. Peak April-May. *summer cohort*: most 30-70 m depths, May-Sept, peak in July.	*spring cohort*: smallest larvae in > 24°C. *summer cohort*: near Cape Hatteras 22.1-22.4°C; in MAB 18-26°C.	*spring cohort*: smallest larvae in > 35 ppt. *summer cohort*: in MAB in 30-32 ppt.	*spring cohort*: > 4 mm strongly associate with surface. *summer cohort*: near surface at night, mostly at about 4 m during day.	*spring cohort*: subject to northward advection by Gulf Stream. Some retained in SAB by southerly counter-current. *summer cohort*: southwest winds in MAB may facilitate cross-shelf transport.	*summer cohort*: mostly copepod life history stages. Guts full during day.	None
Pelagic Juveniles [3]	*spring cohort*: smallest near 180 m contour; larger near shore. April-May. *summer cohort*: cross MAB shelf from Slope Sea to shore, early- to mid-June.	*spring cohort*: 19.0-24.0°C (or higher well offshore). *summer cohort*: in MAB 15.0-20.0°C (most > 18.0°C). As low as 13.0°C when cross shelf.	*spring cohort*: Near 180 m contour, > 35.0 ppt. *summer cohort*: During June, range 36.0-31.0 ppt.	*both cohorts*: strongly associated with the surface.	*spring cohort*: shoreward movement with growth unless advected north. *summer cohort*: move shoreward with growth. Currents important, but active swimming indicated.	--	*both cohorts*: enter estuarine nurseries during this stage
Juveniles [4] ***(summer cohort only)***	Several estuarine study areas between Narragansett Bay, RI and Delaware Bay and Delaware River. Also coast beaches and surf zones.	In most studies, arrive > 20°C, remain in temperatures up to 30°C, emigrate when declines to 15°C. Can not survive below 10°C or above 34°C. Fall migration in 18-22°C on inner continental shelf.	Usually 23.0-33.0 ppt but can intrude to as low as 3.0 ppt.	Day: usually near shorelines or in tidal creeks. Night: usually in open bay or channel waters.	Can occur in surf zone or clear to turbid back-estuarine zones.	Atlantic silversides, bay anchovy, clupeids, striped bass, sand shrimp, mysids, other fish, invertebrates.	Mostly sand, particularly along coast, but some mud, silt, clay. Also uses *Ulva*, *Zostera* beds, and *Spartina* or *Fucus*. In Chesapeake Bay includes oyster bars and beds.
Adults [5]	Generally oceanic, nearshore to well offshore over continental shelf.	Warm water, usually > 14-16°C. Can tolerate 11.8-30.4°C but are stressed at either extreme.	Oceanic salinities.	--	--	Sight feeders, prey on other fish almost exclusively.	Not uncommon in bays, larger estuaries, as well as coastal waters.

7.2.8.5 Horseshoe Crab

(from ASMFC's Horseshoe Crab FMP 1998)
Beach areas that provide spawning habitat are considered essential habitats for adult horseshoe crabs. Nearshore, shallow water, intertidal flats are considered essential habitats for the juvenile development. Delaware Division of Fish and Wildlife's 16-foot bottom trawl survey data indicated that over 99% of juvenile horseshoe crabs (less than 160 mm prosomal width) were taken at salinities greater than 5 parts per thousand (Michels 1997).

Larger juveniles and adults use deep water habitats to forage for food, but these are not considered essential habitat. Of these habitats, the beaches are the most critical (Shuster 1994). Optimal spawning beaches may be a limiting reproductive factor for the horseshoe crab population. Based on geomorphology Botton et al. (1992) estimated that only 10% of the New Jersey shore adjacent to Delaware Bay provided optimal horseshoe crab spawning habitat. The densest concentrations of horseshoe crabs in New Jersey occur on small sandy beaches surrounded by salt marshes or bulkheaded areas (Loveland et al. 1996).

Prime spawning habitat is widely distributed throughout Maryland's Chesapeake and coastal bays, including tributaries. Horseshoe crabs are restricted to areas that exceed 7 ppt salinity (Maryland Department of Natural Resources 1998). In the Chesapeake Bay, spawning habitat generally extends to the mouth of the Chester River, but can occur farther north during years of above normal salinity levels. Prime spawning beaches within the Delaware Bay consist of sand beaches between Maurice River and the Cape May Canal in New Jersey and between Bowers Beach and Lewes in Delaware (Shuster 1994).

7.2.8.6 HMS Species – Species in SA

Tunas

(excerpted from the Consolidated HMS FMP, chapter 10, section titled "Tunas" under "Summary of Review and Findings.)"

In recent years, archival tags and popup satellite tags (PSATs) have been used to successfully monitor ocean-wide movements of giant bluefin tuna as well as other HMS (Block et al. 2001, 2005; Lutcavage et al. 1999). This technology has greatly expanded the understanding of migratory patterns, reproductive behavior, and habitat use for bluefin tuna as well as other HMS such as blue and white marlin (NMFS 2004). However, despite these advances, there are considerable gaps in the understanding of habitat requirements as they relate to identifying Essential Fish Habitat (EFH) for tunas. Accurate identification of certain species of tunas can be difficult unless one has sufficient knowledge to check for appropriate distinguishing characteristics. This is particularly true for planktonic larval stages of all tuna species and adult stages of bigeye and blackfin tuna. For example, bigeye tuna may easily be mistaken for blackfin or juvenile yellowfin tuna, and can only be positively distinguished from one another by examining the liver and gill rakers. Reviewers raised concerns regarding presence of a high number of bigeye tuna in the Gulf of Mexico, which are rarer than blackfin tuna, and which may have been misidentified. The distribution maps for bigeye tuna indicate a significant number of observations in the Gulf of Mexico that may need to be reviewed and reanalyzed for accuracy prior to any modifications being made to existing boundaries (J. Lamkin, pers. comm.).

The Tag A Giant (TAG) program is a collaborative effort among scientists from Stanford University, the Monterey Bay Aquarium, and NOAA Fisheries Service which continues to place electronic tags internally and externally on Atlantic bluefin tuna in the North Atlantic to continuously record data. Tag A Giant deployed 201 archival and 37 pop-up satellite archival tags (PSATs) over two years, during which time 21 archival tags were recovered, more than a third of which were recaptured east of the 45 degree management line. The program has collected over 13,000 geopositions obtained from 330 bluefin tuna. It is now possible to examine data in relation to year class, season, and spawning grounds visited. Bluefin tuna tagged in the western Atlantic have migrated to both the Mediterranean and Gulf of Mexico spawning grounds. Most migration to spawning grounds in the Gulf of Mexico occurred in the spring months where spawning fish appear to prefer mesoscale cyclonic eddies in the western Gulf. Results indicate that spawning occurs in the Gulf of Mexico primarily during the months of April to June (Block et al. 2005).

The results attained from the TAG program detail the movements and behaviors of Atlantic bluefin tuna. These data answer questions about habitat preferences, spawning and feeding grounds, spawning site fidelity, the level of mixing between eastern and western stocks, and how movements are influenced by age class and season. Linking biological data with environmental data can assist in understanding relationships between the bluefin's physical environment and its behavior, movements, abundance and distribution, leading to predictive models enabling researchers to estimate the abundance and distribution of bluefin based on oceanographic features, season, and year class. This information is being collected primarily for ICCATs consideration in updating management strategies and quotas that reflect the bluefin tunas life history in the Atlantic Ocean.

Data collected to date consistently show that spawning occurs primarily after the bluefin reach 10 years of age. Bluefin tuna that are 8.5 years and younger tend to remain near New England in the summer and fall whereas older fish move offshore, many traveling to the east of the 45 degree management zone to the Mid-Atlantic Bight and Flemish Cap. Seasonal patterns are also apparent. Bluefin tuna remained in the coastal and offshore waters of North Carolina and the South Atlantic Bight throughout the winter months, predominately over the shallow continental shelf. In the spring, most fish move north depending on age class, where they remain for the summer before returning to the south in the fall. The movements among regions appear to be dependent on temperature.
In 2002 and 2003, the TAG program expanded tagging efforts to New England, off the coast of Nantucket to spread efforts over a broader area. In 2003, efforts were expanded to the eastern Atlantic off the coast of Ireland where the program has obtained the first

data on a new group of fish that have not yet been studied with this technology. Deploying tags off Ireland also increases the likelihood of documenting the behaviors of fish spawning in the Mediterranean for comparison to those spawning in the Gulf of Mexico. The improved understanding of bluefin movements and behaviors has important applications for management and can serve as the basis for necessary changes in current management strategies.

Beginning in 1997, studies led by the New England Aquarium have implanted pop-up and pop-up archival satellite tags (PSATs) on western Atlantic bluefin tuna. Recent studies involved the implantation of PSATs into 68 Atlantic bluefin tuna in the southern Gulf of Maine and off the coast of North Carolina between July 2002 and January 2003 (Wilson et al., In Press). Most of the fish tagged in the southern Gulf of Maine in late summer/early fall remained in that area until late October, consistent with previous studies. Of the 33, 14 remained in northern shelf waters (between Maryland and Nova Scotia), 14 moved south to waters off the coasts of Virginia and North Carolina, and five were in offshore waters of the northwestern Atlantic Ocean. In the spring, six of the 11 fish either stayed in northern waters or moved to that area from Virginia and North Carolina waters, and the other five fish moved offshore into the Mid-Atlantic Ocean. Similar seasonal movement patterns have been shown by individuals tagged in coastal waters off North Carolina. During the winter months, these fish remained either on the Carolina shelf or in offshore waters of the northwestern Atlantic Ocean and moved offshore along the path of the Gulf Stream in spring. By summer, many were in northern shelf waters.

Swimming depth was significantly correlated with location, season, size class, time of day, and moon phase. The greatest depth recorded was 672 m (2,218 ft), and fish experienced temperatures ranging from 3.4° to 28.7°C (38° to 83.7° F). The data show that Atlantic bluefin tuna spend the majority of their time in the top 20 m (66 ft) of the water column, descending occasionally to depths in excess of 500 m (1,650 ft). The vertical behavior of bluefin tuna differed among locations, with shallower swimming depths occurring when the fish were in inshore waters.

A recent study of the diet and trophic position of bluefin tuna in coastal Massachusetts and the Gulf of Maine used stable isotope analyses to investigate feeding habits of bluefin tuna. The results suggest that bluefin tuna feed on a variety of schooling fish, including silver hake, Atlantic mackerel, and Atlantic herring (Estrada et al. 2005). Juvenile bluefin tuna appear to have isotopic nitrogen signatures similar to those of suspension feeders, suggesting that nektonic crustaceans or zooplankton may contribute significantly to the diet of juvenile bluefin tuna (Estrada et al. 2005).

Combined, all of the studies and data are providing a higher resolution of potential spawning, feeding, and other important habitat areas for bluefin tuna. Given that there is a considerable and growing body of science on bluefin tuna, it may be one of the species for which NOAA Fisheries Service may consider modifying the boundaries in the future. For example, although bluefin tuna spawning habitat has been described as encompassing nearly all of the Gulf of Mexico by Block et al. (2005), adult bluefin tuna EFH is limited to a smaller portion of the western Gulf of Mexico, and the adult EFH areas may not necessarily correspond to areas considered most likely as bluefin tuna spawning habitat (Block et al. 2005). NOAA Fisheries Service may need to reconsider these boundaries to account for new information being developed through PSAT technology and other means. Similarly, some of the highest individual counts of adult bluefin tuna (per 100 nm2) have been observed off of North Carolina, yet these areas are not currently included as adult bluefin tuna EFH. Furthermore, the SEFSC is currently conducting a comprehensive review of larval distributions from 1984 to the present from ichthyoplankton collections in the northern Gulf of Mexico. Once larval movement due to local currents is accounted for these data may prove useful in the review of potential modification of EFH boundaries for other tunas as well.

In addition, the distribution and abundance of other tuna species (i.e., albacore, bigeye, skipjack, and yellowfin tunas) have been attained through fishery data combined with other information, such as remote sensing data. Many of these species have similar bioecological responses (i.e., many species are specialized in high energy foraging strategies of sustained fast swimming, searching over large areas (Sharp and Dizon 1978; Au 1986) and therefore, have similar physiological responses to oceanographic conditions (Ramos et al. 1996). Skipjack and albacore are highly migratory tunas with active thermic exchanges with the environment (Sharp and Dizon 1978). Consequently, their distribution is influenced by changes in marine features at different spatial and temporal scales (Ramos et al. 1996). For instance, both species are visual predators and are unable to efficiently capture small pelagic prey in colder turbid upwelled waters (Ramos et al. 1996). Therefore, over small spatial and temporal scales, the most suitable areas based on the physiology and feeding strategies for these two species are the boundary between warm and cold water where food and other abiotic features are physiologically optimal (Ramos et al. 1996). Over longer temporal and spatial scales, such as migration pathways, sea surface temperatures generated by the Intertropical Zone of Convergence play an important role (Ramos et al. 1996). In addition, concentration of food and water quality (i.e., higher temperature, high concentration of oxygen and low level of turbidity) lead to the concentration of skipjack and albacore in their respective fishing grounds (the northeast Atlantic for albacore and Senegal waters 10° North to the Canarian area 28° North for skipjack; Ramos et al. 1996).

Yellowfin tuna is a cosmopolitan species mainly distributed in the tropical and subtropical oceanic water of the three oceans. In the Atlantic Ocean, tagging and catch-at-size data analyses have shown that yellowfin tuna move at different scales in the whole tropical Atlantic Ocean (Maury et al. 2001). Environmental conditions are probably the main causes driving migration phenomena and massive population movements (Mendelssohn and Roy 1986; Lehodey et al. 1997). Recent work by Maury et al. (2001) showed that on a large spatiotemporal scale (the whole ocean), low salinity was a good predictor of yellowfin habitat. Juveniles were mainly distributed in low-salinity waters (less than 35 parts per thousand) whereas adults extend their range to water of 36 parts per thousand. This can be due to two reasons; for young tuna (less than 3 yrs old), salinity could be a marker of favorable feeding areas, such as low salinity levels in the Gulf of Guinea where freshwater runoff contains high levels of nutrients. Secondly, the metabolic cost of osmotic regulation could prevent young yellowfin tuna from reaching high salinity levels (Maury et al. 2001). After breeding in the Gulf of Guinea, adults, however, disperse in an east-west fashion related to salinity and warmwater seasonal oscillations (Maury et al. 2001). On a mesoscale (1000 km), north-south seasonal movements are clearly related to warmwater seasonal oscillations. Such seasonal migrations should be due to surface water temperatures where adults preferentially stay in zones of water temperature between 26 to 29° C and where deeper waters are warmer than 15° C. Juveniles stay in surface waters where the sea surface temperature is 27° C or higher (Maury et al. 2001). Finally, at the local level (100 km), yellowfin tuna seem to be influenced by both local hydrological and biological features, such as tuna prey distribution and the spatial stability of water masses. For instance, the presence of floating objects, and the existence of small-scale hydrological events like local fronts or convergences can all be responsible for yellowfin concentrations (Bakun 1996).

Lastly, bigeye tuna are large epi-and mesopelagic fish that are found in surface waters ranging in temperatures from 13 to 29°C (Collette and Nauen 1983). However major concentrations coincide with the temperature range of the permanent thermocline, between 17 and 22°C. Therefore, temperature and thermocline depth appear to be important environmental factors governing the vertical and horizontal distribution of bigeye tuna (Alvarado Bremer et al. 1998). Such oceanographic features can have important implications for fisheries management; for instance, water temperature can prevent movement of fish between ocean basins, influencing stock structure (Alvarado Bremer et al. 1998). On the basis of fisheries data, geographic distribution, tagging results, and the location of spawning and nursery areas, a single population is assumed to inhabit the Atlantic Ocean (ICCAT 1997). For management purposes, both the Indian Ocean and Pacific populations are considered to be single units. Recent molecular work has indicated that the Atlantic and Indo-Pacific populations are two regions and genetically distinct (Alvarado Bremer et al. 1998), confirming a single spawning stock of bigeye in the Atlantic and a single spawning stock in the Indo-Pacific. In the Atlantic Ocean, juvenile bigeye tuna have been observed only in the Gulf of Guinea (ICCAT 1997). Tagging studies indicate trans-Atlantic movements of bigeye from the Gulf of Guinea to the central Atlantic north of Brazil, and northerly migration from the Gulf of Guinea to the eastern Atlantic (ICCAT 1997).

As with most other HMS, salinity and temperature appear to be primary factors influencing the distribution of tunas and may ultimately determine EFH. The challenge remains in identifying specific EFH areas based solely on environmental parameters; in most cases, distribution data may still provide the best indication of habitat preference of these different species.

Swordfish

(text below excerpted from the Consolidated HMS FMP, chapter 10, section titled "Swordfish" under "Summary of Review and Findings."

Based on a review of the swordfish maps and current distribution points, reviewers commented that additional research may be needed to validate the current size ranges for juvenile and adult swordfish. In addition, further analysis may be needed to determine whether certain areas have been used consistently over time. Analyzing spawning areas that are consistently used over a number of years may provide a better understanding of swordfish EFH. Several discrepancies in distribution points and EFH areas delineated in 1999 were noted, including a high concentration of observed occurrences of juvenile swordfish in an area north of Long Island Sound that was not defined as EFH in 1999. NOAA Fisheries Service may consider modifying swordfish EFH boundaries in the future, particularly in the Long Island Sound area, and conversely, areas currently delineated as EFH that have few if any observed occurrences in the data sets being analyzed.

Pinpointing definitive EFH for spawning swordfish is difficult because research indicates that presence of larvae may not always be a sign that spawning occurred in the vicinity of the collection. Adult swordfish, and HMS in general, may move significant distances during spawning, and eggs and larvae may be transported substantial distances by currents as well. Govoni et al. (2000) determined that since a swordfish egg's incubation period is 3 days at 24°C, with an additional three or four days for posthatch growth, along with an average velocity of the Gulf Stream of 1.5 m/s (Olson et al. 1994), larvae of four to five mm SL in the Atlantic could have been transported from as far away as 900 km. A similar trajectory was projected for small larvae of bluefin tuna (McGowan and Richards 1989).

Billfish

Similar to other HMS, billfish EFH is not easily identified due to a lack of association with readily identifiable features such as benthic habitat or other underwater structures. Billfish tend to aggregate in areas with dynamic features such as temperature gradients, ocean fronts or currents resulting from interactions between a number of factors. Many of these water column features are dynamic, making detailed delineation of billfish spawning, nursery, and feeding habitats difficult. Adding to the difficulty of designating billfish EFH is that most of the literature on billfish larvae and juveniles mention them as incidental catches in studies that were directed at other species or that were concerned with characterizing ichthyofaunal or plankton communities as a whole (NMFS, 2004). Comments received during the Draft FMP indicate that *Sargassum* may be an important component of billfish habitat, particularly during early life stages, and that NOAA Fisheries Service should investigate this further. If the NOAA Fisheries Service determines that EFH for some or all HMS needs to be modified, then that would be addressed in a subsequent rulemaking, at which point *Sargassum* could also be considered as potential EFH. With regard to harvest, the final South Atlantic Fishery Management Council FMP for Pelagic *Sargassum* Habitat in the South Atlantic Region was approved in 2003 and implemented strict restrictions on commercial harvest of Sargassum. The approved plan includes strong limitations on future commercial harvest. Restrictions include prohibition of harvest south of the NC/SC state boundary, a total allowable catch (TAC) of 5,000 lbs wet weight per year, limiting harvest to November through June to protect turtles, requiring observers onboard any vessel harvesting *Sargassum*, prohibiting harvest within 100 miles of shore, and gear specifications.

One of the key issues associated with delineating billfish EFH is the difficulty of accurately identifying billfish larvae. However, new molecular techniques are being developed that show promise (Luthy et al. 2005). Without accurate identification of larvae, it is difficult to draw conclusions on spawning areas, habitat associations, and requirements. Billfish larvae may be swept miles from actual spawning grounds before they are sampled. Thus, even though peak spawning periods for blue and white marlin are known to occur from May to June, there are significant issues related to positive identification of larvae that must be overcome to verify spawning locations. Research off Punta Cana, Dominican Republic, is one of the few instances on record where spawning by blue and white marlin was confirmed through simultaneous collections of both larvae and tracking of spawning adults using pop-up satellite tags (Prince et al. 2005).

Collaborative studies conducted by NOAA Fisheries Service and University of Miami scientists using PSATs while simultaneously conducting adult and larval sampling off the Dominican Republic in the spring of 2003 have revealed important information concerning white and blue marlin spawning locations as well as horizontal and vertical movements. Co-occurrence of larval blue marlin and white marlin in samples suggest that the two species share a spawning location in the vicinity of Punta Cana, Dominican Republic. Adult white and blue marlin caught in the area appear to have similar vertical and horizontal movement patterns in terms of time at depth, time at temperature, average horizontal displacement per day, net horizontal displacement, and directional dispersion (compass heading).

Displacements of seven white marlins tagged with PSATs ranged from 31.7 to 267.7 nm (58.7 to 495.8 km), while displacement of one blue marlin was 219.3 nm (406.2 km). In general, all marlin spent a high proportion of the monitoring time in the upper 25 m (82 ft) and at temperatures at or above 28°C (82°F). Minimum and maximum depth and temperatures monitored show that on most days marlin visited depths of 100 m (330 ft) or more, but generally stayed at these depths less that 10% of the time. Minimum temperatures ranged from 16.8° to 20.6°C (62.2° to 69°F), while maximum temperatures ranged from 28.2° to 30.0°C (82.7° to 86°F). Additional research in other areas of the Gulf of Mexico and U.S. Atlantic coast would help improve understanding and delineation of billfish EFH (Prince et al. 2005).

The characterization of adult movements and larval distribution in a potentially important spawning area is paramount for establishing improved management and rebuilding strategies for depressed Atlantic billfish stocks. However, more information on the distribution of reproduction and nursery areas and on adult movement patterns is needed to help managers make more informed decisions regarding conservation of the resource. Scientists at VIMS have been involved with electronic tagging of blue and white marlin since 1999, some of which has been conducted in conjunction with the NOAA SEFSC. More recently, VIMS deployed over 60 PSAT on white marlin from both recreational sport boats and a commercial pelagic longline vessel to determine post-release survival

(Prince et al. 2005). In addition to this work, VIMS is also in the process of updating information regarding habitat preferences and vertical movements of white marlin using environmental data obtained from the PSAT work as well as other environmental data. Most of the work at VIMS, however, remains focused on the interactions of billfish with the various fisheries.

There are a few considerations and limitations of these data that reviewers should keep in mind as they look at EFH determinations (E. Prince, pers. comm.). Inaccurate EFH maps for billfish can be created because of boat side misidentification of billfish, sexual dimorphism, and criteria used in defining groups can result in both under and overestimates and ultimately impact the accuracy of the maps. The CTS is the main source of data for most of the billfish EFH maps and it obtains size information of tagged, released, and recovered fish from constituents based mostly on boatside estimates of fish size. This approach introduces a significant amount of error.

In addition, most size estimates are made when the fish is underwater and the reflective index biases these estimates upwards by as much as 30% (E. Prince, pers. comm.). Billfish are sexually dimorphic (size difference between sexes), with this being most severe for blue marlin. The maps provided in this amendment do not include a consideration of sexually dimorphic differences in size and thus the characterization of juvenile size limits on the maps may be quite different for male and female marlin. The tagging data only infrequently have recoveries that include gender, so separating the maps into males and females would not likely be practical, even though it would probably be more accurate (E. Prince, pers. comm.). Furthermore, the accuracy of the maps for defining juvenile marlin based on size could vary depending on the criteria used in this definition.

Data from the CTS, which account for a significant portion of the overall data points for billfish, were historically recorded only to the nearest degree, and did not include minutes or seconds. As a result, reviewers will notice that certain data points that reflect a high number of observations are lined up along major lines of latitude or longitude, both in the Gulf of Mexico and the Atlantic coast. This may be an artifact resulting from the way in which tagging locations were recorded rather than the true points of highest observed occurrence. Depending on reviewer comments received on this aspect of the data, NOAA Fisheries Service may consider removing these data points during future considerations of EFH boundaries. Therefore, as a result of technical reviewer comments, several changes to EFH boundaries may be considered in the future. These include, but are not limited to, potential modifications of EFH boundaries for blue and white marlin for the reasons stated above (E. Prince, pers. comm.).

Sharks

Significant progress has been made in recent years in identifying habitat requirements and EFH for sharks. The proximity of nursery and pupping grounds to coastal areas has provided research opportunities that do not exist for other HMS that spawn much farther from shore. Sampling has increased in a number of different locations under the auspices of several different programs (Cooperative Atlantic States Shark Pupping and Nursery Survey (COASTSPAN), Cooperative Gulf of Mexico States Shark Pupping and Nursery Survey (GULFSPAN), and others). Considerable research has been devoted to determining the size ranges of the different shark life stages (neonate, juvenile, and adult). The size ranges for each species' lifestage used in this review as well as size ranges used in the 1999 FMP are presented in Table B.1, Appendix B. The table reflects new information and updates to the 1999 FMP size ranges. Based on these size ranges, the distribution data have been mapped for each species and life stage.

The 1999 FMP highlighted the importance of coastal nursery and pupping areas in maintaining viable shark populations. It also identified continued delineation of shark nurseries as a research priority. As a result, several studies and cooperative research projects aimed at improving NOAA Fisheries Service's understanding of EFH and shark reproductive habitat requirements have been undertaken since the 1999 HMS FMP.
In 2002, the COASTPAN project initiated a synthesis document of information on shark nursery grounds along the U.S. Atlantic east coast and the Gulf of Mexico. Researchers from universities and state and Federal agencies in twelve different states from Massachusetts to Texas contributed information to the preliminary report (McCandless et al. 2002; McCandless et al. 2005). This information was included in updates to EFH for several shark species in Amendment 1 to the FMP, and is being incorporated into the data for the current review. Results for the 2003 sampling year were compiled and synthesized, and the final report is currently under review. Participants in the 2003 COASTSPAN survey included the North Carolina Division of Marine Fisheries, the South Carolina Department of Natural Resources, Coastal Carolina University, the University of Georgia's Marine Extension Service and the University of Florida's Program for Shark Research. Researchers from the NOAA Fisheries Service's Apex Predators Program and the University of Rhode Island conducted the survey in Delaware Bay. A total of 3,698 sharks were sampled in the 2003 COASTSPAN survey. Juvenile sharks sampled, tagged and released during the survey were the Atlantic sharpnose, blacknose, blacktip, bonnethead, bull, dusky, finetooth, nurse, sandbar, sand tiger, scalloped hammerhead, silky, spinner, and tiger sharks, and also the smooth and spiny dogfish. Environmental parameters for each sampling location were also measured to indicate habitat preferences. There were a number of tag recaptures returned by fishery biologists and commercial and recreational fisherman in 2003 from sharks that were tagged by COASTSPAN cooperators in previous years.

A final synthesis document entitled "Shark Nursery Grounds of the Gulf of Mexico and the East Coast Waters of the United States" is currently under review for publication by the American Fisheries Society (AFS). It is a compilation of 20 individual papers documenting shark distributions in coastal habitats similar to the project described above, but expanded to include several new studies. This document provides valuable information for the possible modification or inclusion of additional shark EFH.

In 2003, NOAA Fisheries Service initiated the GULFSPAN Survey to expand upon the Atlantic COASTSPAN Survey. States involved in the program during 2004, the second year of the program, include Florida, Mississippi, Alabama, and Louisiana. Sharks sampled, tagged, and released during the surveys included the Atlantic sharpnose, blacknose, blacktip, bonnethead, bull, finetooth, great hammerhead, sandbar, scalloped hammerhead, and spinner sharks. In addition, environmental parameters were measured qualitatively. The most abundant sharks included the Atlantic sharpnose, blacktip, and bull sharks. Results of this study are under review in the AFS synthesis document as well.

In Florida waters, most species captured were juveniles and young-of-the-year. Among sharks for all areas combined, the Atlantic sharpnose shark, a member of the small coastal shark (SCS) management group, was the most abundant shark captured, while the blacktip shark was the most abundant species captured in the LCS management group. The bonnethead shark was the second most abundant species captured in the SCS group and overall was the third most encountered species. The remaining species commonly captured in decreasing order of abundance were the finetooth, spinner, scalloped hammerhead, blacknose, and sandbar sharks. Other species infrequently caught were bull shark, great hammerhead shark, and the Florida smoothhound.

In Mississippi and Alabama waters, 75% of the sharks captured were immature. The blacktip shark was the most abundant species caught, followed by the Atlantic sharpnose, finetooth, and bull sharks. In Louisiana in the 2004 sampling season, most species captured were juveniles. The blacktip shark was the most abundant species caught, followed by the bull shark. A single adult specimen of the finetooth shark in addition to young-of-the-year Atlantic sharpnose shark was also collected in 2004.

New information on habitat preferences is also emerging from this study. Juvenile bonnethead sharks appear to prefer habitat dominated by seagrass (in northwest Florida) or mangroves (Louisiana), although these areas have not yet been identified as EFH. In areas where neither of these habitat types is available, juvenile bonnetheads are in very low numbers or absent (i.e. Mississippi Sound). Adult bonnethead sharks, however, are found in diverse habitats ranging from areas with a mud or sand bottom to areas dominated by seagrass. Evidence indicates bull sharks are found among the most diverse environmental conditions with salinities ranging from 15 ppt (in Louisiana and Mississippi) to 33 ppt (in northwest Florida), and over all habitat types. Within the Gulf of Mexico, most juvenile sandbar sharks are still predominately caught in the northwest portion while blacktip, finetooth, and Atlantic sharpnose sharks are found throughout all areas. Although bull sharks can be found over a variety of habitats, the areas of highest abundance are those adjacent to freshwater inflow.

Obtaining information regarding trophic relationships and feeding habits of sharks, also critical to understanding essential fish habitat, is another goal of the GULFSPAN program. A quantitative examination of feeding ecology from different areas can assist in understanding how juvenile sharks use nursery habitats, and which habitats are more valuable as nursery areas than others.

Mote Marine Laboratory's CSR program is focusing on identifying and understanding shark nursery areas of the U.S. Gulf of Mexico and southeast Atlantic coasts. Through tagging studies, this program aims to characterize these nursery areas, obtain estimates of juvenile shark relative abundance, distribution, and growth rates, and reveal the movement patterns of these sharks. As of fall 2004, the CSR has collected data on 20,732 sharks of 16 species that utilize these coastal waters as pupping and nursery areas. More than half of the captured sharks (12,241) comprise neonate, young-of-the-year (YOY) or older juvenile sharks. The studies found that most pupping activity in the region occurs in the late spring and early summer, and the neonate and YOY animals inhabit the primary nurseries throughout the summer and into the fall. Typically, declining water temperatures in the fall are associated with the southward movement of sharks from these natal waters to warmer and in some cases offshore, winter nurseries. Tag returns of Year-1 sharks have demonstrated travel distances to winter nursery areas of at least 500 km (311 mi). Tag return data have further demonstrated annual cycles of philopatric behavior whereby juveniles of both large and small coastal species migrate back to their natal nurseries in spring and summer (Hueter and Tyminski, in review).

In the 1999 HMS FMP, the smallest size class of sharks was described as "neonates and early juveniles." This definition has been modified to include primarily neonates and only small young-of-the-year sharks in order to better define and identify nursery areas. The total length cutoff for this size class is determined as the maximum embryo size in term females plus 10%. This criteria was used because it helps to eliminate some of the small one-year-old sharks that fall within the young-of the-year size range, making it easier to identify primary nursery areas (where pupping occurs and young-of-the-year are present). These criteria can also be more easily applied to other species given the lack of published data on growth rates for many species, especially during the first year. This modification should also better represent the habitat shift between primary nursery areas and secondary nursery areas (occupied by age 1+ sharks), although many species do overlap habitat use between these two size classes.

The middle size class designated in the 1999 HMS FMP, "late juveniles and subadults," has been renamed "juveniles". This size class includes all immature sharks from young juveniles to older or late juveniles. Some overlap between the "neonate and early juveniles" and the "adult" EFH areas may occur, depending on the species, due to the return to primary nursery areas by many juveniles, age 1+, and the developing conformity to adult migration patterns by late juveniles. As in the 1999 HMS FMP, the largest size class, "adults," still consists of mature sharks based on the size at first maturity for females of the species. Changes to the size range of the adult size class for some species have been made based on new information on the size at first maturity for females of those particular species.

As a result of technical reviewer comments of the 2006 Consolidated Highly Migratory Species FMP, several changes to EFH boundaries may be considered in the future. These include, but are not limited to, potential modification of EFH boundaries for basking, hammerhead, white, bull, Caribbean reef, lemon, spinner, tiger, Atlantic sharpnose, blacknose, longfin mako, shortfin mako, oceanic whitetip, and thresher sharks (J. Castro and J. Carlson, pers. comm.). In summary, based on the preliminary examination of new information acquired since the original EFH identifications in 1999, and on comments from technical reviewers, modifications to some of the existing EFH descriptions and boundaries may be warranted. Any proposed modifications to existing boundaries, as well as consideration of any new HAPC areas, would be addressed by the NOAA Fisheries Service's Highly Migratory Species Division in a subsequent document to the 2006 Consolidated HMS FMP.

7.3 Essential Fish Habitat and Environmental Protection Policy

In recognizing that managed species are dependent on the quantity and quality of their essential habitats, it is the policy of the SAFMC to protect, restore, and develop habitats upon which species fisheries depend; to increase the extent of their distribution and abundance; and to improve their productive capacity for the benefit of present and future generations. For purposes of this policy, "habitat" is defined as the physical, chemical, and biological parameters that are necessary for continued productivity of the species that is being managed. The objectives of the SAFMC policy will be accomplished through the recommendation of no net loss or significant environmental degradation of existing habitat. A long-term objective is to support and promote a net-gain of fisheries habitat through the restoration and rehabilitation of the productive capacity of habitats that have been degraded, and the creation and development of productive habitats where increased fishery production is probable. The SAFMC will pursue these goals at state, Federal, and local levels. The Council shall assume an aggressive role in the protection and enhancement of habitats important to species, and shall actively enter Federal, decision-making processes where proposed actions may otherwise compromise the productivity of fishery resources of concern to the Council.

7.4 Essential Fish Habitat Policies and Policy Statements

7.4.1 Policy Statements of Essential Fish Habitat Types

7.4.1.1 Policy for the Protection and Enhancement of Marine Submerged Aquatic Vegetation (SAV) Habitat

The South Atlantic Fishery Management Council (Council) and the Habitat and Environmental Protection Advisory Panel has considered the issue of the decline of Marine Submerged Aquatic Vegetation SAV (or seagrass) habitat in Florida and North Carolina as it relates to Council habitat policy. Subsequently, the Council's Habitat Committee requested that the Habitat Advisory Panel develop the following policy statement to support Council efforts to protect and enhance habitat for managed species.

Description and Function

In the South Atlantic region, SAV is found primarily in the states of Florida and North Carolina where environmental conditions are ideal for the propagation of seagrasses. The distribution of SAV habitat is indicative of its importance to economically important fisheries: in North Carolina, total SAV coverage is estimated to be 200,000 acres; in Florida, the total SAV coverage is estimated to be 2.9 million acres. SAV serves several valuable ecological functions in the marine systems where it occurs. Food and shelter afforded by SAV result in a complex and dynamic system that provides a primary nursery habitat for various organisms that is important both to the overall system ecology as well as to commercial and recreationally important fisheries. SAV habitat is valuable both ecologically as well as economically; as feeding, breeding, and nursery ground for numerous estuarine species, SAV provides for rich ecosystem diversity. Further, a number of fish and shellfish species, around which is built several vigorous commercial and recreational fisheries, rely on SAV habitat for a least a portion of their life cycles. For more detailed discussion, please see Appendix 1

Status

SAV habitat is currently threatened by the cumulative effects of overpopulation and consequent commercial development and recreation in the coastal zone. The major anthropogenic threats to SAV habitat include:

1. mechanical damage due to:
    a. propeller damage from boats,
    b. bottom-disturbing fish harvesting techniques,
    c. dredging and filling;

2. biological degradation due to:
    a. water quality deterioration by modification of temperature, salinity, and light attenuation regimes;
    b. addition of organic and inorganic chemicals.

SAV habitat in both Florida and North Carolina has experienced declines from both natural and anthropogenic causes. However, conservation measures taken by state and federal agencies have produced positive results. The NOAA Fisheries Service has produced maps of SAV habitat in the Albemarle-Pamlico Sound region of North Carolina to help stem the loss of this critical habitat. The threats to this habitat and the potential for successful conservation measures highlight the need to address the decline of SAV. Therefore, the Council recommends immediate and direct action be taken to stem the loss of this essential habitat. For more detailed discussion, please see Appendix 2.

Management

Conservation of existing SAV habitat is critical to the maintenance of the living resources that depend on these systems. A number of federal and state laws and regulations apply to modifications, either direct or indirect, to SAV habitat. However, to date the state and federal regulatory process has accomplished little to slow the decline of SAV habitat. Furthermore, mitigative measures to restore or enhance impacted SAV have met with little success. These habitats cannot be readily restored; the Council is not aware of any seagrass restoration project that has ever prevented a net loss of SAV habitat. It has been difficult to implement effective resource management initiatives to preserve existing seagrass habitat resources due to the lack of adequate documentation and specific cause/effect relationships. (for more detailed discussion, please see Appendix 3).

Because restoration/enhancement efforts have not met with success, the Council considers it imperative to take a directed and purposeful action to protect remaining SAV habitat. The Council strongly recommends that a comprehensive strategy to address the disturbing decline in SAV habitat in the South Atlantic region. Furthermore, as a stepping stone to such a long-term protection strategy, the Council recommends that a reliable status and trend survey be adopted to verify the scale of local declines of SAV.

The Council will address the decline of SAV, and consider establishing specific plans for revitalizing the SAV resources of the South Atlantic region. This may be achieved by the following integrated triad of efforts:

Planning

- The Council promotes regional planning which treats SAV as an integral part of an ecological system.
- The Council supports comprehensive planning initiatives as well as interagency coordination and planning on SAV matters.
- The Council recommends that the Habitat Advisory Panel members actively seek to involve the Council in the review of projects which will impact, either directly or indirectly, SAV habitat resources.

Monitoring and Research

Periodic surveys of SAV in the region are required to determine the progress toward the goal of a net resource gain.

The Council supports efforts to:

- standardize mapping protocols,
- develop a Geographic Information System databases for essential habitat including seagrass, and
- research and document causes and effects of SAV decline including the cumulative impacts of shoreline development.

Education and Enforcement

- The Council supports education programs designed to heighten the public's awareness of the importance of SAV. An informed public will provide a firm foundation of support for protection and restoration efforts.
- Existing regulations and enforcement need to be reviewed for their effectiveness.
- Coordination with state resource and regulatory agencies should be supported to assure that existing regulations are being enforced.

SAFMC SAV Policy Statement- Appendix 1

Description and function

Worldwide, Submerged Aquatic Vegetation (SAV) constitutes one of the most conspicuous and common shallow-water habitat types. These angiosperms have successfully colonized standing and flowing fresh, brackish, and marine waters in all climatic zones, and most are rooted in the sediment. Marine SAV beds occur in the low intertidal and subtidal zones and may exhibit a wide range of habitat forms, from extensive collections of isolated patches to unbroken continuous beds. The bed is defined by the presence of either aboveground vegetation, its associated root and rhizome system (with living meristem), or the presence of a seed bank in the sediments, as well as the sediment upon which the plant grows or in which the seed back resides. In the case of patch beds, the unvegetated sediment among the patches is considered seagrass habitat as well.

There are seven species of seagrass in Florida's shallow coastal areas: turtle grass (*Thalassia testudium*); manatee grass (*Syringodium filiforme*); shoal grass (*Halodule wrightii*); star grass (*Halophila engelmanni*); paddle grass (*Halophila decipiens*); and Johnson's seagrass (*Halophila johnsonii*) (Distribution maps in Appendix 4 SAFMC, 1998a). Recently, *H. johnsonii* has been proposed for listing by the NOAA Fisheries Service as an endangered plant species. Areas of seagrass concentration along Florida's east coast are Mosquito Lagoon, Banana River, Indian River Lagoon, Lake Worth and Biscayne Bay. Florida Bay, located between the Florida Keys and the mainland, also has an abundance of seagrasses, but is currently experiencing an unprecedented decline in SAV distribution.

The three dominant species found in North Carolina are shoalgrass (*Halodule wrightii*), eelgrass (*Zostera marina*), and widgeongrass (*Ruppia maritima*). Shoalgrass, a subtropical species has its northernmost distribution at Oregon Inlet, North Carolina. Eelgrass, a temperate species, has its southernmost distribution in North Carolina. Areas of seagrass concentration in North Carolina are southern and eastern Pamlico Sound, Core Sound, Back Sound, Bogue Sound and the numerous small southern sounds located behind the beaches in Onslow, Pender, Brunswick, and New Hanover Counties (See distribution maps in Appendix 4 SAFMC, 1998).

Seagrasses serve several valuable ecological functions in the marine estuarine systems where they occur. Food and shelter afforded by the SAV result in a complex and dynamic system that provides a primary nursery habitat for various organisms that are important both ecologically and to commercial and recreational fisheries. Organic matter produced by these seagrasses is transferred to secondary consumers through three pathways: herbivores that consume living plant matter; detritivores that exploit dead matter; and microorganisms that use seagrass-derived particulate and dissolved organic compounds. The living leaves of these submerged plants also provide a substrate for the attachment of detritus and epiphytic organisms, including bacteria, fungi, meiofauna, micro- and macroalgae, macroinvertebrates. Within the seagrass system, phytoplankton also are present in the water column, and macroalgae and microalgae are associated with the sediment. No less important is the protection afforded by the variety of living spaces in the tangled leaf canopy of the grass bed itself. In addition to biological benefits, the

SAVs also cycle nutrients and heavy metals in the water and sediments, and dissipate wave energy (which reduces shoreline erosion and sediment resuspension).

There are several types of association fish may have with the SAVs. Resident species typically breed and carry out much of their life history within the meadow (e.g., gobiids and syngnathids). Seasonal residents typically breed elsewhere, but predictably utilize the SAV during a portion of their life cycle, most often as a juvenile nursery ground (e.g., sparids and lutjanids). Transient species can be categorized as those that feed or otherwise utilize the SAV only for a portion of their daily activity, but in a systematic or predictable manner (e.g., haemulids).

In Florida many economically important species utilize SAV beds as nursery and/or spawning habitat. Among these are spotted seatrout (*Cynoscion nebulosus*), grunts (Haemulids), snook (*Centropomus* sp.), bonefish (*Albula vulpes*), tarpon (*Megalops atlanticus*) and several species of snapper (Lutjanids) and grouper (Serranids). Densities of invertebrate organisms are many times greater in seagrass beds than in bare sand habitat. Penaeid shrimp, spiny lobster (*Panulirus argus*), and bay scallops (*Argopecten irradians*) are also dependent on seagrass beds.

In North Carolina, 40 species of fish and invertebrates have been captured on seagrass beds. Larval and juvenile fish and shellfish including gray trout (*Cynoscion regalis*), red drum (*Sciaenops ocellatus*), spotted seatrout (*Cynoscion nebulosus*), mullet (*Mugil cephalus*), spot (*Leiostomus xanthurus*), pinfish (*Orthopristis chrysoptera*), gag (*Mycteroperca microlepis*), white grunt (*Haemulon plumieri*), silver perch (*Bairdiella chrysoura*), summer flounder (*Paralichthys dentatus*), southern flounder (*P. lethostigma*), blue crabs (*Callinectes sapidus*), hard shell clams (*Mercenaria mercenaria*), and bay scallops (*Argopecten irradians*) utilize the SAV beds as nursery areas. They are the sole nursery grounds for bay scallops in North Carolina. SAV meadows are also frequented by adult spot, spotted seatrout, bluefish (*Pomatomus saltatrix*), menhaden (*Brevoortia tyrannus*), summer and southern flounder, pink and brown shrimp, hard shell clams, and blue crabs. Offshore reef fishes including black sea bass (*Centropristis striata*), gag (*Mycteroperca microlepis*), gray snapper (*Lutjanus griseus*), lane snapper (*Lutjanus synagris*), mutton snapper (*Lutjanus annalis*), and spottail pinfish (*Diplodus holbrooki*). Ospreys, egrets, herons, gulls and terns feed on fauna in SAV beds, while swans, geese, and ducks feed directly on the grass itself. Green sea turtles (*Chelonia mydas*) also utilize seagrass beds, and juveniles may feed directly on the seagrasses.

SAFMC SAV Policy Statement- Appendix 2

Status

The SAV habitat represents a valuable natural resource which is now threatened by overpopulation in coastal areas. The major anthropogenic activities that impact seagrass habitats are: 1) dredging and filling, 2) certain fish harvesting techniques and recreational vehicles, 3) degradation of water quality by modification of normal temperature, salinity, and light regimes, and 4) addition of organic and inorganic chemicals. Although not caused by man, disease (“wasting disease” of eelgrass) has historically been a factor.

Direct causes such as dredging and filling, impacts of bottom disturbing fishing gear, and impacts of propellers and boat wakes are easily observed, and can be controlled by wise management of our seagrass resources (See Appendix 3 below). Indirect losses are more subtle and difficult to assess. These losses center around changes in light availability to the plants by changes in turbidity and water color. Other indirect causes of seagrass loss may be ascribed to changing hydrology which may in turn affect salinity levels and circulation. Reduction in flushing can cause an increase in salinity and the ambient temperature of a water body, stressing the plants. Increase in flushing can mean decreased salinity and increased turbidity and near-bottom mechanical stresses which damage or uproot plants.

Increased turbidity and decreasing water transparency are most often recognized as the cause of decreased seagrass growth and altered distribution of the habitats. Turbidity may result from upland runoff, either as suspended sediment or dissolved nutrients. Reduced transparency due to color is affected by freshwater discharge. The introduction of additional nutrients from terrigenous sources often leads to plankton blooms and increased epiphytization of the plants, further reducing light to the plants. Groundwater enriched by septic systems also may infiltrate the sediments, water column, and near-shore seagrass beds with the same effect. Lowered dissolved oxygen is detrimental to invertebrate and vertebrate grazers. Loss of these grazers results in overgrowth by epiphytes.

Large areas of Florida where seagrasses were abundant have now lost these beds from both natural and man-induced causes (this is not well documented on a large scale except in the case of Tampa Bay). One of these depleted areas is Lake Worth in Palm Beach County. Here, dredge and fill activities, sewage disposal and stormwater runoff have almost eliminated this resource. North Biscayne Bay lost most of its seagrasses from urbanization. The Indian River Lagoon has lost many seagrass beds from stormwater runoff has caused a decrease in water transparency and reduced light penetration. Many seagrass beds in Florida have been scarred from boat propellers disrupting the physical integrity of the beds. Vessel registrations, both commercial and recreational, have tripled from 1970-71 (235, 293) to 1992-93 (715,516). More people engaged in marine activities having an effect on the limited resources of fisheries and benthic communities, Florida’s assessment of dredging/propeller scar damage indicates that Dade, Lee, Monroe, and Pinellas Counties have the most heavily damaged seagrass beds. Now Florida Bay, which is rather remote from human population concentrations, is experiencing a die-off of seagrasses, the cause of which has not yet been isolated. Cascading effects of die-offs cause a release of nutrients resulting in algal blooms which, in turn, adversely affect other seagrass areas, and appear to be preventing recolonization and natural succession in the bay. It appears that Monroe County’s commercial fish and shellfish resources, with a dockside landing value of $50 million per year, is in serious jeopardy.

In North Carolina, total SAV coverage is estimated at 200,000 acres. Compared to the state’s brackish water SAV community, the marine SAVs appear relatively stable. The drought and increased water clarity during the summer of 1986 apparently caused an increase in SAV abundance in southeastern Pamlico Sound and a concomitant increase in bay scallop densities. Evidence is emerging, however, that characteristics of "wasting disease" are showing up in some of the eelgrass populations in southern Core Sound, Back Sound, and Bogue Sound. The number of permits requested for development activities that potentially impact SAV populations is increasing. The combined impacts of a number of small, seemingly isolated activities are cumulative and can lead to the collapse of large seagrass biosystems. Also increasing is evidence of the secondary removal of seagrasses. Clam-kicking (the harvest of hard clams utilizing powerful propeller wash to dislodge the clams from the sediment) is contentious issue within the state of North Carolina. The scientific community is convinced that mechanical harvesting of clams damages SAV communities. The scallop fishery also could be harmed by harvest-related damage to eelgrass meadows.

SAFMC SAV Policy Statement- Appendix 3

Management

Conservation of existing SAV habitat is critical to the maintenance of the living resources that depend on these systems. A number of federal and state laws require permits for modification and/or development in SAV. These include Section 10 of the Rivers and Harbors Act (1899), Section 404 of the Clean Water Act (1977), and the states' coastal area management programs. Section 404 prohibits deposition of dredged or fill material in waters of the United States without a permit from the U.S. Army Corps of Engineers. The Fish and Wildlife Coordination Act gives federal and state resource agencies the authority to review and comment on permits, while the National Environmental Policy Act requires the development and review of Environmental Impact Statements. The Magnuson-Stevens Fisheries Conservation and Management Act has been amended to require that each fishery management plan include a habitat section. The Council's habitat subcommittee may comment on permit requests submitted to the Corps of Engineers when the proposed activity relates to habitat essential to managed species. State and federal regulatory processes have accomplished little to slow the decline of SAV habitat. Many of the impacts cannot be easily controlled by the regulations as enforced. For example, water quality standards are written so as to allow a specified deviation from background concentration, in this manner standards allow a certain amount of degradation. An example of this is Florida's class III water transparency standard, which defines the compensation depth to be where 1% of the incident light remains. The compensation depth for seagrass is in excess of 10% and for some species is between 15 and 20%. The standard allows a deviation of 10% in the compensation depth which translates into 0.9% incident light or an order of magnitude less than what the plants require. Mitigative measures to restore or enhance impacted areas have met with little success. SAV habitats cannot be readily restored; in fact, the Council is not aware of any seagrass restoration project that has ever avoided a net loss of seagrass habitat. It has been difficult to implement effective resource management initiatives to preserve seagrass habitat due to the lack of documentation on specific cause/effect relationships. Even though studies have identified certain cause/effect relationships in the destruction of these areas, lack of long-term, ecosystem-scale studies precludes an accurate scientific evaluation of the long-term deterioration of seagrasses. Some of the approaches to controlling propeller scar damage to seagrass beds include: education, improved channel marking restricted access zones, (complete closure to combustion engines, pole or troll areas), and improved enforcement. The Council sees the need for monitoring of seagrass restoration and mitigation not only to determine success from plant standpoint but also for recovery of faunal populations and functional attributes of the essential habitat type. The Council also encourages long-term trend analysis monitoring of distribution and abundance using appropriate protocols and Geographic Information System approaches.

SAFMC SAV Policy Statement- Appendix 4
(SAV Distribution Maps in SAFMC 1995 and Revised in Appendix C of the Habitat Plan)

7.4.2 Policy Statements on Non-fishing Activities Affecting Habitat

7.4.2.1 Policies for the Protection and Restoration of EFH from Beach Dredging and Filling and Large-Scale Coastal Engineering

Policy Context

This document establishes the policies of the South Atlantic Fishery Management Council (SAFMC) regarding protection of the essential fish habitats (EFH) and habitat areas of particular concern (EFH-HAPCs) impacted by beach dredge and fill activities, and related large-scale coastal engineering projects. The policies are designed to be consistent with the overall habitat protection policies of the SAFMC as formulated and adopted in the Habitat Plan (SAFMC, 1998a) and the Comprehensive EFH Amendment (SAFMC, 1998b).

The findings presented below assess the threats to EFH potentially posed by activities related to the large-scale dredging and disposal of sediments in the coastal ocean and adjacent habitats, and the processes whereby those resources are placed at risk. The policies established in this document are designed to avoid, minimize and offset damage caused by these activities, in accordance with the general habitat policies of the SAFMC as mandated by law.

EFH At Risk from Beach Dredge and Fill Activities
The SAFMC finds:

1. In general, the array of large-scale and long-term beach dredging projects and related disposal activities currently being considered for the United States southeast together constitute a real and significant threat to EFH under the jurisdiction of the SAFMC.

2. The cumulative effects of these projects have not been adequately assessed, including impacts on public trust marine and estuarine resources, use of public trust beaches, public access, state and federally protected species, state critical habitat, SAFMC-designated EFH and EFH-HAPCs.

3. Individual beach dredge and fill projects and related large-scale coastal engineering activities rarely provide adequate impact assessments or consideration of potential damage to fishery resources under state and federal management. Historically, emphasis has been placed on the logistics of dredging and economics, with environmental considerations dominated by compliance with the Endangered Species Act for sea turtles, piping plovers and other listed organisms. There has been little or no consideration of hundreds of other species affected, many with direct fishery value.

4. Opportunities to avoid or minimize impacts of beach dredge and fill activities on fishery resources, and offsets for unavoidable impacts have rarely been proposed or implemented. Monitoring is rarely adequate to develop statistically appropriate impact evaluations.

5. Large-scale beach dredge and fill activities have the potential to impact a variety of habitats across the shelf, including:

    a. waters and benthic habitats near the dredging sites
    b. waters between dredging and filling sites
    c. waters and benthic habitats in or near the fill sites, and
    d. waters and benthic habitats potentially affected as sediments move subsequent to deposition in fill areas.

6. Certain nearshore habitats are particularly important to the long-term viability of commercial and recreational fisheries under SAFMC management, and potentially threatened by large-scale, long-term or frequent disturbance by dredging and filling:

    a. the swash and surf zones and beach-associated bars
    b. underwater soft-sediment topographic features
    c. onshore and offshore coral reefs, hardbottom and worm reefs
    d. inlets

7. Large sections of South Atlantic waters potentially affected by these projects, both individually and collectively, have been identified as EFH or EFH-HAPC by the SAFMC, as well as the Mid-Atlantic Fishery Management Council (MAFMC) in the case of North Carolina. Potentially Affected species and their EFH under federal management include (SAFMC, 1998b):

    a. summer flounder (various nearshore waters, including the surf zone and inlets; certain offshore waters)
    b. bluefish (various nearshore waters, including the surf zone and inlets)
    c. red drum (ocean high-salinity surf zones and unconsolidated bottoms nearshore waters)

d. many snapper and grouper species (live hardbottom from shore to 600 feet, and – for estuarine-dependent species [e.g., gag grouper and gray snapper] – unconsolidated bottoms and live hardbottoms to the 100 foot contour).
e. black sea bass (various nearshore waters, including unconsolidated bottom and live hardbottom to 100 feet, and hardbottoms to 600 feet)
f. penaeid shrimp (offshore habitats used for spawning and growth to maturity, and waters connecting to inshore nursery areas, including the surf zone and inlets)
g. coastal migratory pelagics [e.g., king mackerel, Spanish mackerel] (sandy shoals of capes and bars, barrier island ocean-side waters from the surf zone to the shelf break inshore of the Gulf Stream; all coastal inlets)
h. corals of various types (hard substrates and muddy, silt bottoms from the subtidal to the shelf break)
i. areas identified as EFH for Highly Migratory Species (HMS) managed by the Secretary of Commerce (e.g., sharks: inlets and nearshore waters, including pupping and nursery grounds)

In addition, hundreds of species of crustaceans, mollusks, and annelids that are not directly managed, but form the critical prey base for most managed species, are killed or directly affected by large dredge and fill projects.

8. Beach dredge and fill projects also potentially threaten important habitats for anadromous species under federal, interstate and state management (in particular, inlets and offshore overwintering grounds), as well as essential overwintering grounds and other critical habitats for weakfish and other species managed by the Atlantic States Marine Fisheries Commission (ASMFC) and the states. The SAFMC also identified essential habitats of anadromous and catadromous species in the region (inlets and nearshore waters).

9. Many of the habitats potentially affected by these projects have been identified as EFH-HAPCs by the SAFMC. The specific fishery management plan is provided in parentheses:

    a. all nearshore hardbottom areas (SAFMC, snapper grouper).
    b. all coastal inlets (SAFMC, penaeid shrimps, red drum, and snapper grouper).
    c. near-shore spawning sites (SAFMC, penaeid shrimps, and red drum).
    d. benthic *Sargassum* (SAFMC, snapper grouper).
    e. from shore to the ends of the sandy shoals of Cape Lookout, Cape Fear, and Cape Hatteras, North Carolina; Hurl Rocks, South Carolina; *Phragmatopoma* (worm reefs) reefs off the central coast of Florida and nearshore hardbottom south of Cape Canaveral (SAFMC, coastal migratory pelagics).
    f. Atlantic coast estuaries with high numbers of Spanish mackerel and cobia from ELMR, to include Bogue Sound, New River, North Carolina; Broad River, South Carolina (SAFMC, coastal migratory pelagics).
    g. Florida Bay, Biscayne Bay, Card Sound, and coral hardbottom habitat from Jupiter Inlet through the Dry Tortugas, Florida (SAFMC, Spiny Lobster)

h. Hurl Rocks (South Carolina), The *Phragmatopoma* (worm reefs) off central east coast of Florida, nearshore (0-4 meters; 0-12 feet) hardbottom off the east coast of Florida from Cape Canaveral to Broward County; offshore (5-30 meters; 15-90 feet) hardbottom off the east coast of Florida from Palm Beach County to Fowey Rocks; Biscayne Bay, Florida; Biscayne National Park, Florida; and the Florida Keys National Marine Sanctuary (SAFMC, Coral, Coral Reefs and Live Hardbottom Habitat).
i. EFH-HAPCs designated for HMS species (e.g., sharks) in the South Atlantic region (NOAA Fisheries Service, Highly Migratory Species).

10. Habitats likely to be affected by beach dredge and fill projects include many recognized in state-level fishery management plans. Examples of these habitats include Critical Habitat Areas established by the North Carolina Marine Fisheries Commission, either in FMPs or in Coastal Habitat Protection Plans (CHAs).

11. Recent work by scientists in east Florida has documented important habitat values for nearshore, hardbottom habitats often buried by beach dredging projects, is used by over 500 species of fishes and invertebrates, including juveniles of many reef fishes. Equivalent scientific work is just beginning in other South Atlantic states, but life histories suggest that similar habitat use patterns will be found.

Threats to Marine and Estuarine Resources from Beach Dredge and Fill Activities and Related Large Coastal Engineering Projects

The SAFMC finds that beach dredge and fill activities and related large-scale coastal engineering projects (including inlet alteration projects) and disposal of material for navigational maintenance, threaten or potentially threaten EFH through the following mechanisms:

1. Direct mortality and displacement of organisms at and near sediment dredging sites
2. Direct mortality and displacement of organisms at initial sediment fill sites
3. Elevated turbidity and deposition of fine sediments down-current from dredging sites
4. Alteration of seafloor topography and associated current and waves patterns and magnitudes at dredging areas
5. Alteration of seafloor sediment size-frequency distributions at dredging sites, with secondary effects on benthos at those sites
6. Elevated turbidity in and near initial fill sites, especially in the surf zone, and deposition of fine sediment down-current from initial fill sites (ASMFC, 2002)
7. Alteration of nearshore topography and current and wave patterns and magnitudes associated with fill
8. Movement of deposited sediment away from initial fill sites, especially onto hardbottoms
9. Alteration of large-scale sediment budgets, sediment movement patterns and feeding and other ecological relationships, including the potential for cascading disturbance effects
10. Alteration of large-scale movement patterns of water, with secondary effects on water quality and biota

11. Alteration of movement patterns and successful inlet passage for larvae, post-larvae, juveniles and adults of marine and estuarine organisms
12. Alteration of long-term shoreline migration patterns (inducing further ecological cascades with consequences that are difficult to predict)
13. Exacerbation of transport and/or biological uptake of toxicants and other pollutants released at either dredge or fill sites

In addition, the interactions between cumulative and direct (sub-lethal) effects among the above factors certainly triggers non-linear impacts that are completely unstudied.
SAFMC Policies for Beach Dredge and Fill Projects and Related Large Coastal Engineering Projects

The SAFMC establishes the following general policies related to large-scale beach dredge and fill and related projects, to clarify and augment the general policies already adopted in the Habitat Plan and Comprehensive Habitat Amendment (SAFMC 1998a; SAFMC 1998b):

1. Projects should avoid, minimize and where possible offset damage to EFH and EFH-HAPCs.

2. Projects requiring expanded EFH consultation should provide detailed analyses of possible impacts to each type of EFH, with careful and detailed analyses of possible impacts to EFH-HAPCs and state CHAs, including short and long-term, and population and ecosystem scale effects. Agencies with oversight authority should require expanded EFH consultation.

3. Projects requiring expanded EFH consultation should provide a full range of alternatives, along with assessments of the relative impacts of each on each type of EFH, HAPC and CHAs.

4. Projects should avoid impacts on EFH, HAPCs and CHAs that are shown to be avoidable through the alternatives analysis, and minimize impacts that are not.

5. Projects should include assessments of potential unavoidable damage to EFH and other marine resources, using conservative assumptions.

6. Projects should be conditioned on the avoidance of avoidable impacts, and should include compensatory mitigation for all reasonably predictable impacts to EFH, taking into account uncertainty about these effects. Mitigation should be local, up-front and in-kind, and should be adequately monitored, wherever possible.

7. Projects should include baseline and project-related monitoring adequate to document pre-project conditions and impacts of the projects on EFH.

8. All assessments should be based upon the best available science, and be appropriately conservative so follow and precautionary principles as developed for various federal and state policies.

9. All assessments should take into account the cumulative impacts associated with other beach dredge and fill projects in the region, and other large-scale coastal engineering projects that are geographically and ecologically related.

7.4.2.2 Policy Statement Concerning Dredging and Dredge Material Disposal Activities

Ocean Dredged Material Disposal Sites (ODMDS) and SAFMC Policies

The shortage of adequate upland disposal sites for dredged materials has forced dredging operations to look offshore for sites where dredged materials may be disposed. These Ocean Dredged Material Disposal Sites (ODMDSs) have been designated by the U.S. Environmental Protection Agency (EPA) and the U.S. Army Corps of Engineers (COE) as suitable sites for disposal of dredged materials associated with berthing and navigation channel maintenance activities. The South Atlantic Fishery Management Council (SAFMC; the Council) is moving to establish its presence in regulating disposal activities at these ODMDSs. Pursuant to the Magnuson-Stevens Fishery Conservation and Management Act (the Magnuson-Stevens Act), the regional fishery management Councils are charged with management of living marine resources and their habitat within the 200 mile Exclusive Economic Zone (EEZ) of the United States. Insofar as dredging and disposal activities at the various ODMDSs can impact fishery resources or essential habitat under Council jurisdiction, the following policies address the Council's role in the designation, operation, maintenance, and enforcement of activities in the ODMDSs:

The Council acknowledges that living marine resources under its jurisdiction and their essential habitat may be impacted by the designation, operation, and maintenance of ODMDSs in the South Atlantic. The Council may review the activities of EPA, COE, the state Ports Authorities, private dredging contractors, and any other entity engaged in activities which impact, directly or indirectly, living marine resources within the EEZ. The Council may review plans and offer comments on the designation, maintenance, and enforcement of disposal activities at the ODMDSs.

ODMDSs should be designated or redesignated so as to avoid the loss of live or hard bottom habitat and minimize impacts to all living marine resources.

Notwithstanding the fluid nature of the marine environment, all impacts from the disposal activities should be contained within the designated perimeter of the ODMDSs.
The final designation of ODMDSs should be contingent upon the development of suitable management plans and a demonstrated ability to implement and enforce that plan. The Council encourages EPA to press for the implementation of such management plans for all designated ODMDSs.

All activities within the ODMDSs are required to be consistent with the approved management plan for the site.

The Council's Habitat and Environmental Protection Advisory Panel when requested by the Council will review such management plans and forward comment to the Council. The Council may review the plans and recommendations received from the advisory sub-panel and comment to the appropriate agency. All federal agencies and entities receiving a comment or recommendation from the Council will provide a detailed written response to the Council regarding the matter pursuant to 16 U.S.C. 1852 (i). All other agencies and entities receiving a comment or recommendation from the Council should provide a detailed written response to the Council regarding the matter, such as is required for federal agencies pursuant to 16 U.S.C. 1852 (i).

ODMDSs management plans should indicate appropriate users of the site. These plans should specify those entities/ agencies which may use the ODMDSs, such as port authorities, the U.S. Navy, the Corps of Engineers, etc. Other potential users of the ODMDSs should be acknowledged and the feasibility of their using the ODMDSs site should be assessed in the management plan.

Feasibility studies of dredge disposal options should acknowledge and incorporate ODMDSs in the larger analysis of dredge disposal sites within an entire basin or project. For example, Corps of Engineers analyses of existing and potential dredge disposal sites for harbor maintenance projects should incorporate the ODMDSs as part of the overall analysis of dredge disposal sites.

The Council recognizes that EPA and other relevant agencies are involved in managing and/or regulating the disposal of all dredged material. The Council recognizes that disposal activities regulated under the Ocean Dumping Act and dredging/filling carried out under the Clean Water Act have similar impacts to living marine resources and their habitats. Therefore, the Council urges these agencies apply the same strict policies to disposal activities at the ODMDSs. These policies apply to activities including, but not limited to, the disposal of contaminated sediments and the disposal of large volumes of fine-grained sediments. The Council will encourage strict enforcement of these policies for disposal activities in the EEZ. Insofar as these activities are relevant to disposal activities in the EEZ, the Council will offer comments on the further development of policies regarding the disposal/ deposition of dredged materials.

The Ocean Dumping Act requires that contaminated materials not be placed in an approved ODMDS. Therefore, the Council encourages relevant agencies to address the problem of disposal of contaminated materials. Although the Ocean Dumping Act does not specifically address inshore disposal activities, the Council encourages EPA and other relevant agencies to evaluate sites for the suitability of disposal and containment of contaminated dredged material. The Council further encourages those agencies to draft management plans for the disposal of contaminated dredge materials. A consideration for total removal from the basin should also be considered should the material be contaminated to a level that it would have to be relocated away from the coastal zone.

Offshore and Nearshore Underwater Berm Creation
The use of underwater berms in the South Atlantic region has recently been proposed as a disposal technique that may aid in managing sand budgets on inlet and beachfront areas. Two types of berms have been proposed to date, one involving the creation of a long offshore berm, the second involving the placement of underwater berms along beachfronts bordering an inlet. These berms would theoretically reduce wave energy reaching the beaches and/or resupply sand to the system.

The Council recognizes offshore berm construction as a disposal activity. As such, all policies regarding disposal of dredged materials shall apply to offshore berm construction. Research should be conducted to quantify larval fish and crustacean transport and use of the inlets prior to any consideration of placement of underwater berms. Until the impacts of berm creation in inlet areas on larval fish and crustacean transport are determined, the Council recommends that disposal activities should be confined to approved ODMDSs. Further, new offshore and near shore underwater berm creation activities should be reviewed under the most rigorous criteria, on a case-by-case basis.

Maintenance Dredging and Sand Mining for Beach Renourishment
The Council recognizes that construction and maintenance dredging of the seaward portions of entrance channels and dredging borrow areas for beach re-nourishment occur in the EEZ. These activities should be done in an appropriate manner in accordance with the policies adopted by the Council.

The Council acknowledges that endangered and threatened species mortalities have occurred as a result of dredging operations. Considering the stringent regulations placed on commercial fisherman, dredging or disposal activities should not be designed or conducted so as to adversely impact rare, threatened or endangered species. NOAA Fisheries Service's Protected Resources Division should work with state and federal agencies to modify proposals to minimize potential impacts on threatened and endangered sea turtles and marine mammals.

The Council has and will continue to coordinate with Minerals Management Service (MMS) in their activities involving exploration, identification and dredging/mining of sand resources for beach renourishment. This will be accomplished through membership on state task forces or directly with MMS. The Council recommends that live bottom/hard bottom habitat and historic fishing grounds be identified for areas in the South Atlantic region to provide for the location and protection of these areas while facilitating the identification of sand sources for beach renourishment projects.

Open Water Disposal
The SAFMC is opposed to the open water disposal of dredged material into aquatic systems which may adversely impact habitat that fisheries under Council jurisdiction are dependent upon. The Council urges state and federal agencies, when reviewing permits considering open water disposal, to identify the direct and indirect impacts such projects could have on fisheries habitat.

The SAFMC concludes that the conversion of one naturally functioning aquatic system at the expense of creating another (marsh creation through open water disposal) must be justified given best available information.

7.4.2.3 Policies for the Protection and Restoration of EFH from Energy Exploration, Development, Transportation and Hydropower Re-Licensing

Policy Context

This document establishes the policies of the South Atlantic Fishery Management Council (SAFMC) regarding protection of Essential Fish Habitat (EFH) and Essential Fish Habitat - Habitat Areas of Particular Concern (EFH-HAPCs) from threats associated with energy exploration, development, transportation and hydropower licensing. The policies are designed to be consistent with the overall habitat protection policies of the SAFMC as formulated and adopted in the Habitat Plan (SAFMC 1998a), the Comprehensive EFH Amendment (SAFMC 1998b) and the various Fishery Management Plans (FMPs) of the Council.

The findings presented below assess the threats to EFH potentially posed by activities related to energy development and hydropower licensing in offshore and coastal waters, riverine systems, and adjacent wetland habitats, and the processes whereby those resources are placed at risk. The policies established in this document are designed to avoid, minimize, and offset damage caused by these activities, in accordance with the general habitat policies of the SAFMC as mandated by law. To address any future energy projects in the South Atlantic region, the SAFMC reserves the right to revise this policy when more information becomes available.

EFH at Risk from Energy Exploration, Development Transportation and Hydropower Licensing Activities

The SAFMC finds:

1. That oil or gas drilling for exploration or development on or closely associated with EFH including – but not limited to – coral, coral reefs, and live/hardbottom habitat at all depths in the Exclusive Economic Zone (EEZ), EFH-HAPCs, or other special biological resources essential to commercial and recreational fisheries under SAFMC jurisdiction, be prohibited.

2. That all facilities associated with oil and gas exploration, development, and transportation be designed to avoid impacts on coastal ecosystems and sand sharing systems.

3. That adequate spill containment and cleanup equipment be maintained for all development and transportation facilities and, that the equipment be available on-site or located so as to be on-site within the landing time trajectory. An environmental bond should be required to assure that adequate resources will be available for

unanticipated environmental impacts, spill response, clean-up and environmental impact assessment.

4. That exploration and development activities should be scheduled to avoid migratory patterns, breeding and nesting seasons of endangered and threatened species, including – but not limited to – northern right whales in coastal waters off the southeastern United States.

5. That the Environmental Impact Statement (EIS) for any Lease Sale address impacts from activities specifically related to natural gas production, safety precautions required in the event of the discovery of "sour gas" or hydrogen sulfide reserves and the potential for transport of hydrocarbons to nearshore and inshore estuarine habitats resulting from the cross-shelf transport by Gulf Stream spin-off eddies. The EIS should also address the development of contingency plans to be implemented if problems arise due to oceanographic conditions or bottom topography, the need for and availability of onshore support facilities in coastal areas, and an analysis of existing facilities and community services in light of existing major coastal developments.

6. That EISs prepared for liquefied natural gas (LNG) pipeline projects or other energy-related projects must fully describe direct and cumulative impacts to EFH, including deepwater coral communities. Impact evaluations should include quantitative assessments for each habitat based on recent scientific studies pertinent to that habitat, and the best available information.

7. That construction and operation of open-loop (flow-through) LNG processing facilities be prohibited in areas that support EFH.

8. That hydropower project licenses issued by the Federal Energy Regulatory Commission include specific terms and conditions to ensure that the amount and timing of river flows mimic natural conditions to the extent possible for protection of migratory diadromous fish species and their spawning habitats. In addition, the best available technologies that allow for safe, timely, and effective upstream and downstream fish passage should be integrated into the project design as specified in prescriptions issued by NOAA Fisheries Service.

9. That projects requiring expanded EFH consultation provide a full range of alternatives, along with assessments of the relative impacts of each on each type of EFH, EFH-HAPC and state-designated Critical Habitat Areas (CHAs).

10. That energy development activities have the potential to cause impacts to a variety of habitats across the shelf and to nearshore, estuarine, and riverine systems and wetlands, including:

a) waters and benthic habitats in or near drilling and disposal sites, including those potentially affected by sediment movement and by physical disturbance associated with drilling activities and site development;
b) waters and benthic habitats in or near LNG processing facilities or other energy development or transportation sites,
c) exposed hardbottom (e.g., reefs and live bottom) in shallow and deep waters,
d) coastal wetlands and
e) riverine systems and associated wetlands.

11. That certain offshore, nearshore and riverine habitats are particularly important to the long-term viability of commercial and recreational fisheries under SAFMC management, and potentially threatened by oil and gas and other energy exploration, development, transportation, and hydropower licensing activities:

a) coral, coral reef and live/hardbottom habitat, including deepwater coral communities,
b) marine and estuarine waters,
c) estuarine wetlands, including mangroves and marshes,
d) submersed aquatic vegetation,
e) waters that support diadromous fishes, and their spawning habitats
f) waters hydrologically and ecologically connected to waters that support EFH.

12. That siting and design of onshore receiving, holding, and transport facilities could have impacts on wetlands and endangered species' habitats if they are not properly located.

13. Sections of South Atlantic waters potentially affected by these projects, both individually and collectively, have been identified as EFH or EFH-HAPC by the SAFMC. Potentially affected species and their EFH under federal management include (SAFMC, 1998b):

a) summer flounder (various nearshore waters, including the surf zone and inlets; certain offshore waters),
b) bluefish (various nearshore waters, including the surf zone and inlets),
c) red drum (ocean high-salinity surf zones and unconsolidated bottoms in the nearshore),
d) many snapper and grouper species (live hardbottom from shore to 600 feet, and – for estuarine-dependent species (e.g., gag grouper and gray snapper) – unconsolidated bottoms and live hardbottoms to the 100 foot contour),
e) black sea bass (various nearshore waters, including unconsolidated bottom and live hardbottom to 100 feet, and hardbottoms to 600 feet),
f) penaeid shrimp (offshore habitats used for spawning and growth to maturity, and waters connecting to inshore nursery areas, including the surf zone and inlets), How about including estuarine emergent wetlands and deepwater habitats??

g) coastal migratory pelagics (e.g., king mackerel, Spanish mackerel) (sandy shoals of capes and bars, barrier island ocean-side waters from the surf zone to the shelf break inshore of the Gulf Stream; all coastal inlets),
h) corals of various types and associated organisms (on hard substrates in shallow, mid-shelf, and deepwater),
i) muddy, silt bottoms from the subtidal to the shelf break, deepwater corals and associated communities),
j) areas identified as EFH for Highly Migratory Species managed by the Secretary of Commerce (e.g., sharks: inlets and nearshore waters, including pupping and nursery grounds), and
k) riverine areas that support diadromous fishes, including important prey species such as shad, herring and other alosines in addition to shortnose and Atlantic sturgeon.

14. Many of the habitats potentially affected by these activities have been identified as EFH-HAPCs by the SAFMC. Each habitat, type of activity posing a potential threat and FMP is provided as follows:

a) all nearshore hardbottom areas – exploration, transportation and development (SAFMC snapper grouper);
b) all coastal inlets – transportation and development (SAFMC penaeid shrimp, red drum, and snapper grouper);
c) nearshore spawning sites – transportation and development (SAFMC penaeid shrimps and red drum);
d) benthic Sargassum – exploration, transportation and development (SAFMC snapper grouper);
e) from shore to the ends of the sandy shoals of Cape Lookout, Cape Fear, and Cape Hatteras, North Carolina; Hurl Rocks, South Carolina; and *Phragmatopoma* (worm reefs) reefs off the central coast of Florida and near shore hardbottom south of Cape Canaveral – transportation and development (SAFMC coastal migratory pelagics);
f) Atlantic coast estuaries with high numbers of Spanish mackerel and cobia from ELMR, to include Bogue Sound, New River, North Carolina; Broad River, South Carolina – transportation and development (SAFMC coastal migratory pelagics);
g) Florida Bay, Biscayne Bay, Card Sound, and coral hardbottom habitat from Jupiter Inlet through the Dry Tortugas, Florida – exploration, transportation and development (SAFMC spiny lobster);
h) Hurl Rocks (South Carolina); The *Phragmatopoma* (worm reefs) off central east coast of Florida; nearshore (0-4 meters; 0-12 feet) hardbottom off the east coast of Florida from Cape Canaveral to Broward County; offshore (5-30 meters; 15-90 feet) hardbottom off the east coast of Florida from Palm Beach County to Fowey Rocks; Biscayne Bay, Florida; Biscayne National Park, Florida; and the Florida Keys National Marine Sanctuary – transportation and development (SAFMC Coral, Coral Reefs and Live Hardbottom Habitat); and

i) EFH-HAPCs designated for HMS species (e.g., sharks) in the South Atlantic region – exploration, transportation and development (NOAA Fisheries Service Highly Migratory Species).

15. Habitats likely to be affected by oil and gas exploration, development and transportation, and hydropower re-licensing activities include many recognised in state level fishery management plans. Examples of these habitats include Critical Habitat Areas (CHAs) established by the North Carolina Marine Fisheries Commission, either in FMPs or in Coastal Habitat Protection Plans.

16. Scientists in east Florida have documented exceptionally important habitat values for nearshore hardbottom used by over 500 species of fishes and invertebrates, including juveniles of many reef fishes. Equivalent scientific work is just beginning in other South Atlantic states, but life histories suggest that similar habitat use patterns will be found.

17. Proposed Deepwater Coral HAPCs and the pelagic and benthic species including their early life stages are potentially affected by oil and gas exploration, development and transportation, LNG development and alternative energy development including ocean current and wave energy facilities.

Threats to Marine and Estuarine Resources from Energy Exploration, Development, Transportation and Hydropower Licensing Activities (Revised Draft March 2008)

The SAFMC finds that energy exploration, development, transportation and hydropower licensing activities threaten or potentially threaten EFH through the following mechanisms:

1. Direct mortality and displacement of organisms at and near drilling, dredging, and/or trenching sites,

2. Deposition of fine sediments (sedimentation) and drilling muds down-current from drilling, dredging, trenching, and/or backfilling sites,

3. Chronic elevated turbidity in and near drilling, dredging, trenching, and/or backfilling sites,

4. Direct mortality of larvae, post-larvae, juveniles and adults of marine and estuarine organisms occurring from water intake, spills from pipelines, or from vessels in transit near or close to inlet areas,

5. Alteration of long-term shoreline migration patterns (with complex, often indeterminable, ecological consequences),

6. Burial of sensitive coral resources and associated habitat resulting from "frac-outs" associated with horizontal directional drilling,

7. Permanent conversion of soft bottom habitat to artificial hardbottom habitat through installing a hard linear structure (i.e., a pipe covered in articulated concrete mats),

8. Impacts to benthic resources from placement and shifting of pipelines and cables, and from other types of direct mechanical damage,

9. Alterations in amount and timing of riverflow and significant blockage or reduction in area of critical spawning habitat resulting from damming or diverting rivers, and

10. Alteration of community diversity, composition, food webs and energy flow due to addition of structure.

In addition, the interactions between cumulative and direct (lethal and sub-lethal) effects among the above-listed can affect the magnitude of the overall impacts. Such interactions may result in a scale of effect that is multiplicative rather than additive. Those effects are at present nearly completely unstudied.

Potential Impacts of Offshore Ocean Current Energy Installations on Benthic Resources (USDOI, MMS 2007a):

Construction

- Bottom disturbances from installation of foundations or anchoring systems and anchoring of construction and maintenance vessels
- Sediment disturbance and suspension during installation of foundations or anchoring systems
- Sound during pile driving or drilling
- Habitat loss from foundations and units attached to the seafloor to gather the power and feed to the transmission cable to shore
- Habitat disturbance during cable laying
- Introduction of hard substrates
- Habitat disturbance resulting from scour

Operation

- Operational sound and vibration
- Introduction of contaminants from use of antifouling coatings and cleaning of marine fouling

- Introduction of different communities from fouling growth on monopiles and scour protection around the foundation or anchoring systems

Potential Impacts to Fishery Resources from Ocean Current Installations:

Construction activities

- Habitat disturbance or loss from foundations, moorings, anchors, and cable laying
- Sound associated with pile driving and drilling

Operations activities

- Introduction of artificial hard substrates
- Scour impacts on benthic habitats
- EMF effects on sensitive species
- Collisions with moving parts
- Changes in water flow and pressures

Potential Impacts to Fishery Resources from Wave Installations:

- anchored on hard bottom, a more sensitive habitat than soft sediments, and could affect essential fish habitat and Habitat Areas of Particular Concern

- transmission cable cannot be buried in hard bottom areas, creating concerns for those species that have EMF sensitivities

- antifouling agents (e.g., Tri-butyl tin) have toxic effects on many marine and estuarine organisms, and specifically different life stages of fishes

- some of the devices that use overtopping as part of their process might entrain fish, primarily embryos and larvae, that live at the surface of the ocean

SAFMC Policies for Energy Exploration, Development, Transportation and Hydropower Licensing Activities

The SAFMC establishes the following general policies related to energy exploration, development, transportation, and hydropower licensing activities and related projects, to clarify and augment the general policies already adopted in the Habitat Plan and Comprehensive Habitat Amendment (SAFMC 1998a; SAFMC 1998b):

1. Projects should avoid, minimize, and – where possible – offset damage to EFH and EFH-HAPCs. This should be accomplished, in part, by integrating the best available and least impactive technologies into the construction design.

2. Agencies with oversight authority should require expanded EFH consultation for projects with the potential to significantly damage EFH. Projects requiring expanded EFH consultation should include detailed analyses for a full range of alternatives of possible impacts to each type of EFH, each EFH-HAPC and each CHA, including short and long-term effects and cumulative impacts at local, population and ecosystem scales. These analyses should utilize resource-protective assumptions and the best available science.

3. Projects should utilize the alternative that minimizes total impact EFH, EFH-HAPCs, and CHAs.

4. Projects should include detailed assessments of potentially unavoidable damage to EFH and other marine resources associated with the preferred or selected alternative and cumulative impacts, using conservative assumptions and the best available science.

5. Compensatory mitigation should not be considered until avoidance and minimization measures have been duly demonstrated. Compensatory mitigation should be required to offset losses to EFH, including losses associated with temporary impacts, and should take into account uncertainty and the risk of the chosen mitigation measures inadequately offsetting the impacts. Mitigation should be local, "up-front," and "in-kind," and include long-term monitoring to assess and ensure the efficacy of the mitigation program selected.

6. Projects should include pre-project, project-related, and post-project monitoring adequate to document pre-project conditions and the initial, long-term and cumulative impacts of the project on EFH.

7. All EFH assessments should be based upon the best available science, be conservative, and follow precautionary principles as developed for various Federal and State policies.

8. All EFH assessments should document the cumulative impacts associated with all natural and anthropogenic stressors on EFH, including other energy exploration, development, transportation, and re-licensing projects that are geographically and ecologically related.

9. Projects should comply with existing standards and requirements regulating domestic and international transportation of energy products including regulated waste disposal and emissions which are intended to minimize negative impacts on and preserve the quality of the marine environment.

10. Open-loop LNG processing facilities should be avoided in favor of closed-loop systems. Water intake associated with closed-loop should be minimized and the

effects to fishery resources should be determined through baseline studies and project monitoring.

11. The original licensing or re-licensing of hydropower projects should provide for adequate and ecologically based instream flows, and safe, timely, and effective upstream and downstream fish passage.

12. Third party environmental inspectors should be required on all projects to provide for independent monitoring and permit compliance.

13. Resource sensitivity training modules should be developed specific to each project, construction procedures and habitat types found within the project impact area. This training should be provided to all contractors and sub-contractors that are anticipated to work in or adjacent to areas that support sensitive habitats.

The SAFMC recommends the following specific concerns and issues be addressed by the Federal Energy Regulatory Commission, Minerals Management Service, and/or the U.S. Army Corps of Engineers prior to approval of any license, application, or permit.

A. The following requirements should apply to any permit to drill any exploratory well or wells in any Lease Sale with the potential to affect EFH in the SAFMC's jurisdiction. These concerns and issues should also be included in a new EIS for any future Outer Continental Shelf (OCS) Leasing Plan:

1. Identification of the on-site fisheries resources, including both pelagic and benthic communities, that inhabit, spawn, or migrate through the lease sites with special focus on those specific lease blocks where industry has expressed specific interest in the pre-lease phases of the leasing process. Particular attention should be given to critical life history stages (i.e., eggs and larvae) that are most sensitive to oil spills and seismic exploration.

2. Identification of on-site or potentially affected state or federally-listed species (e.g., endangered, threatened, special concern, etc.), marine mammals, pelagic birds, diadromous fishes, and all species regulated under federal fishery management plans.

3. Determination of impacts of all exploratory and development activities on the fisheries resources prior to MMS approval of any applications for permits to drill in the Exploratory Unit area, including effects of seismic survey signals on fish behavior, eggs and larvae.

4. Identification of commercial and recreational fishing activities in the vicinity of the lease or Exploratory Unit area, their season of occurrence and intensity, and any impacts whether temporary or permanent on the potential to continue those activities associated with the project or activity.

5. Determination of the physical and chemical oceanographic and meteorological characteristics of the area through field studies by MMS or the applicant, including on-site direction and velocity of currents and tides, sea states, temperature, salinity, water quality, wind storms frequencies, and intensities and icing conditions. Such studies must be required prior to approval of any exploration plan submitted in order to have adequate information upon which to base decisions related to site-specific proposed activities. Studies should include detailed characterization of seasonal surface currents and likely spill trajectories.

6. Description of required monitoring activities to be used to evaluate environmental conditions, and assess the impacts of exploration activities in the lease area or the Exploratory Unit.

7. Identification of the quantity, composition, and method of disposal of solid and liquid wastes and pollutants likely to be generated by offshore, onshore, and transportation operations associated with oil and gas exploration development and transportation.

8. Development of an oil spill contingency plan which includes oil spill trajectory analyses specific to the area of operations, dispersant-use plan including a summary of toxicity data for each dispersant, identification of response equipment and strategies, establishment of procedures for early detection and timely notification of an oil spill, and "chain-of-command" and notification procedures inclusive of all local, state and federal agencies and agency personnel to be notified when an oil spill is discovered, as well as defined and specific actions to be taken after discovery of an oil spill.

9. Mapping of environmentally sensitive areas (e.g., spawning aggregations of snappers and groupers); coral resources and other significant benthic habitats (e.g., tilefish mudflats) along the edge of the continental shelf (including the upper slope); calico scallop, royal red shrimp, and other productive benthic fishing grounds; other special biological resources; and northern right whale calving grounds and migratory routes, and subsequent deletion from inclusion in the respective lease block(s).

10. Planning for oil and gas product transport should be done to determine methods of transport, pipeline corridors, and onshore facilities.

11. The applicant, or MMS, must provide an analysis of biological community dynamics, and pathways and flows of energy, to ascertain accumulation of toxins and impacts on biological communities.

12. Due to the critical nature of canyons and steep relief to important fisheries (e.g., billfishes, swordfish and tunas) an evaluation of shelf-edge and down-slope dynamics, and a resource assessment to determine transport and fate of contaminants should be required.

13. Discussion of the potential adverse impacts upon fisheries resources of the discharges of all drill cuttings and all drilling muds that may be approved for use in the lease area or the Exploration Unit, as well as discharges associated with production activities (i.e., produced waters). This should include: physical and chemical effects upon pelagic and benthic species and communities, including spawning behavior, effects on eggs and larval stages; effects upon sight-feeding species of fish; and analysis of methods and assumptions underlying the model used to predict the dispersion of discharged muds and cuttings from exploration activities.

14. Discussion of secondary impacts affecting fishery resources associated with onshore oil and gas related development such as storage and processing facilities, dredging and dredged material disposal, roads and rail lines, fuel and electrical transmission line routes, waste disposal, and others.

B. The following requirements should apply to any permit or license to construct LNG gas pipelines and related facilities with the potential to affect EFH in the SAFMC's jurisdiction:

1. The least damaging construction method for traversing reef tracts and deepwater corals should be integrated into the project design.

2. Hydrotest chemicals that may be harmful to fish and wildlife resources shall not be discharged into waters of the United States.

3. Geotechnical studies shall be completed to ensure that the geology of the area is appropriate for the construction method and that geological risks are appropriately mitigated.

4. All work vessels associated with construction that traverses any reef system should be equipped with standard navigation aids, safety lighting and communication equipment. A vessel monitoring system with global positioning system will be employed to continuously monitor all vessel movements and locations in real time.

5. Any anchor placement should completely avoid corals and be diver verified. In addition, measures to avoid anchor sweep should be developed and implemented.

6. Appropriate exclusion zones should be designated around sensitive marine habitats.

7. Pre- and post-project monitoring should be completed in addition to monitoring during construction. The pre-project monitoring should establish pre-project conditions; project monitoring should examine if unanticipated impacts are occurring and if corrective actions are needed; and post-project (immediate and

long-term) monitoring should document impacts to resources resulting from the project, and any recovery from those impacts.

8. All feasible avoidance and minimization measures must be used to protect deepwater coral communities. Those measures must be fully described in detail prior to authorization of any permit or license.

9. A contingency plan should be required to address catastrophic blowouts or more chronic material losses from LNG facilities, including trajectory and other impact analyses and remediation measures and responsibilities.

10. Periodic long-term monitoring of pipelines and nearby deepwater resources should be conducted to evaluate the environmental effects of these installations on deepwater marine communities.

11. Appropriate mitigation should be developed in concert with the NOAA Fisheries Service Habitat Conservation Division to offset unavoidable impacts.

C. The requirement listed below should apply to any relevant permit or license to construct windfarms or hydroturbine energy producing facilities with the potential to affect EFH in the SAFMC jurisdiction. To date, such projects are conceptual, yet reasonably foreseeable as future proposed actions. Given the existing information, it is reasonable to conclude that such projects may have an impact on EFH. However, at this time sufficient information is not available to make general project-type recommendations.

1. Submarine cables should be placed in a manner that avoids impacts to EFH; use of existing conduits is preferred over creating new conduits. The best available technologies should be used to install such cables to avoid and minimize temporary and long-term impacts to EFH. If placed on the seabed, cables should be anchored and/or stabilized, and stability analyses should be conducted to ensure that the cable can withstand a 100-year storm event in appropriate water depths.

2. Many of the areas designated as EFH are important to protected resources (e.g., endangered and threatened species and marine mammals) in the region. Direct and indirect impacts may result from noise, electromagnetic fields, vessel traffic, pollutants/water quality issues, alteration of the benthos and habitat degradation or habitat exclusion. The degree of impact can depend on the species, the type of turbine, the method of installation, site characteristics and the layout and size of the facility. Therefore, any EIS prepared for the construction, operation or decommissioning of a wind energy generating facility should include maps of species' ranges, migratory pathways, and use of habitat as part of an evaluation of direct and cumulative impacts to protected resources.

Alternative Energy Environmental Information Needs (USDOI, MMS 2007a):

1. Finer-grained data on the distribution and life history for key species in each regional ecosystem; environmental assessments for specific projects need more detailed data on benthic habitats and multiyear studies of seasonal abundance and distribution of key species of each resource.

2. Development of better field data collection methods for baseline studies and Post-construction monitoring surveys to improve the confidence of impact detection; study of highly mobile species in offshore areas is particularly difficult, requiring new approaches and technologies.

3. Focused laboratory studies to determine thresholds for potential effects resulting from exposure to the types and levels of sound and electromagnetic fields likely to be generated by different types of alternative energy devices in full-scale installations.

4. Development of protocols for field studies on potential effects from exposure to sound, electromagnetic fields, and obstructions on the behavior and survival of key species of each resource of concern.

5. Development of guidelines to set acceptable limits of direct, indirect, and cumulative impacts resulting from the installation and operation of offshore alternative energy projects; guidelines are needed for all types of potential impacts such as changes to the hydrodynamic climate, erosion of adjacent shorelines, habitat loss and alteration, avoidance and attraction behavior, mortality, aesthetics, and lost use.

D. The following requirements should apply to the initial licensing or re-licensing of hydropower plants on rivers draining to waters under SAFMC jurisdiction:

1. The construction of adequate fish passage facilities (ladders, lifts, bypasses and screens) should be provided to ensure safe, timely and effective passage of fish to and from vital upstream spawning and maturation habitats.
2. Adequate, ecologically based instream flows approximating natural conditions should be provided to protect, enhance, or restore important riverine spawning and maturation habitats affected or potentially affected by hydropower projects.

SAFMC Policy and Position on Previous Oil and Gas Exploration Proposals

The SAFMC urged the Secretary of Commerce to uphold the 1988 coastal zone inconsistency determination of the State of Florida for the respective plans of exploration filed with MMS by Mobil Exploration and Producing North America, Inc. for Lease OCS-G6520 (Pulley Ridge Block 799) and by Union Oil Company of California for Lease OCS-G6491/6492 (Pulley Ridge Blocks 629 & 630). Both plans of exploration involved lease blocks lying within the lease area comprising the offshore area encompassed by Part 2 of Lease Sale 116, and south of 26° North latitude. The Council's objection to the proposed exploration activities was based on the potential degradation or loss of extensive live bottom and other habitat essential to fisheries under Council jurisdiction.

The SAFMC also supported North Carolina's determination that the plans of exploration filed with MMS by Mobil Exploration and Producing North America, Inc. for Lease OCS Manteo Unit are not consistent with North Carolina's Coastal Zone Management program.

The Council has expressed concern to the Outer Continental Shelf Leasing and Development Task Force about the proposed area and recommended that no further exploration or production activity be allowed in the areas subject to Presidential Task Force Review (the section of Sale 116 south of 26° N latitude).

The following section addresses the recommendations, concerns and issues expressed by the South Atlantic Council (Source: Memorandum to Regional Director, U.S. Fish and Wildlife Service, Atlanta, Georgia from Regional Director, Gulf of Mexico OCS Region dated October 27, 1995):

"The MMS, North Carolina, and Mobil entered into an innovative Memorandum of Understanding on July 12, 1990, in which the MMS agreed to prepare an Environmental Report (ER) on proposed drilling offshore North Carolina. The scope of the ER prepared by the MMS was more comprehensive than an EIS would be. The normal scoping process used in preparation of a NEPA-type document would not only 'identify significant environmental issues deserving of study' but also 'de-emphasize insignificant issues, narrowing the scope' (40 CFR 1500.4) by scoping out issues not ripe for decisions.

Of particular interest to North Carolina are not the transient effects of exploration, but rather the downstream and potentially broader, long-term effects of production and development. The potential effects associated with production and development would normally be "scoped out" of the (EIS-type) document and would be the subject of extensive NEPA analysis only after the exploration phase proves successful, and the submittal of a full-scale production and development program has been received for review and analysis. The ER addressed three alternatives: the proposed Mobil plan to drill a single exploratory well, the no-action alternative and the alternative that the MMS approve the Mobil plan with specific restrictions (monitoring programs and restrictions on discharges). The ER also analyzes possible future activities, such as development and production, and the long-term environmental and socioeconomic effects associated with such activities. The MMS assured North Carolina that all of the State's comments and concerns would be addressed in the Final ER (USDOI 1990).

The MMS also funded a Literature Synthesis study (USDOI MMS 1993a) and a Physical Oceanography study (USDOI MMS 1994), both recommended by the Physical

Oceanography Panel and the Environmental Sciences Review Panel (ESRP). Mobil also submitted a draft report to the MMS titled *Characterization of Currents at Manteo Block 467 off Cape Hatteras, North Carolina*. The MMS also had a Cooperative Agreement with the Virginia Institute of Marine Science to fund a study titled *Seafloor Survey in the Vicinity of the Manteo Prospect Offshore North Carolina* (USDOI MMS 1993b). The MMS had a Cooperative Agreement with East Carolina University to conduct a study titled *Coastal North Carolina Socioeconomic Study* (USDOI MMS 1993c). The above-mentioned studies were responsive to the ESRP's recommendations as well as those of the SAFMC and the State of North Carolina."

Minerals Management Service, Technical Communication Services
MS 4530 381 Elden Street
Herndon, VA 22070-4897 (703) 787-1080

In addition, by letter dated November 21, 2003, the SAFMC provided the following recommendations on the AES Ocean Express LNG pipeline project:

- The deepwater touch down route should be pre-inspected by ROV and the pipeline right of way shall be clear of all deepwater resources;
- Adjust deepwater touchdown position to maintain an appropriate buffer from any such deepwater resources;
- Require deepwater resources, other EFH and the deepwater touchdown position be mapped by ROV to confirm the resource position in relation to the installed pipeline;
- Conduct pre-installation video surveys to select the route that maximizes avoidance of these deepwater coral and live bottom habitats; and
- Monitor pipelines and nearby deepwater resources after installation to evaluate the environmental effects of these installations on deepwater marine communities.

7.4.2.4 Policies for the Protection and Restoration of EFH from Alterations to Riverine, Estuarine and Nearshore Flows

Policy Context

This document establishes the policies of the South Atlantic Fishery Management Council (SAFMC) regarding protection of the essential fish habitats (EFH) and habitat areas of particular concern (EFH-HAPCs) associated with alterations of riverine, estuarine and nearshore flows. Such hydrologic alterations occur through activities such as flood control reservoir and hydropower operations, water supply and irrigation withdrawals, deepening of navigation al channels and inlets, and other modifications to the normative hydrograph. The policies are designed to be consistent with the overall habitat protection policies of the SAFMC as formulated and adopted in the Habitat Plan (October 1998) and the Comprehensive EFH Amendment (October 1998).

The findings presented below assess the threats to EFH potentially posed by activities related to the alteration of flows in southeast rivers, estuaries and nearshore ocean habitats, and the processes whereby those resources are placed at risk. The policies established in this document are designed to avoid, minimize and offset damage caused by these activities, in accordance with the general habitat policies of the SAFMC as mandated by law.

EFH at Risk from Flow-Altering Activities

The SAFMC finds:

1. In general, the array of existing and proposed flow-altering projects being considered for the southeastern United States for states with river systems that drain into the South Atlantic Fishery Management Council area of jurisdiction together constitutes a real and significant threat to EFH under the jurisdiction of the SAFMC.

2. The cumulative effects of these projects have not been adequately assessed, including impacts on public trust marine and estuarine resources (especially diadromous species), use of public trust waters, public access, state and federally protected species, state critical habitat, SAFMC-designated EFH and EFH-HAPCs.

3. Individual proposals resulting in hydrologic alterations rarely provide adequate assessments or consideration of potential damage to fishery resources under state and federal management. Historically, emphasis has been placed on the need for human water supply, hydropower generation, agricultural irrigation, flood control and other human uses. Environmental considerations have been dominated by compliance with limitations imparted by the Endangered Species Act for shortnose sturgeon, and/or through provisions of Section 18 of the Federal Power Act, as administered by the Federal Energy Regulatory Commission, which applies to the provision of passage for anadromous species, as well as the provisions of the Fish and Wildlife Act.

4. Opportunities to avoid and minimize impacts of hydrologic alterations on fishery resources, and offsets for unavoidable impacts have rarely been proposed or implemented.

5. Hydrologic alterations have caused impacts to a variety of habitats including:
    a. waters, wetlands and benthic habitats near the discharge and withdrawal points, especially where such waters are used for spawning by anadromous species;
    b. waters, wetlands and benthic habitats in the area downstream of discharge or withdrawal points;
    c. waters wetlands and benthic habitats in receiving estuaries of southeast rivers; and
    d. waters and benthic habitats of nearshore ocean habitats receiving estuarine discharge.

6. Certain riverine, estuarine and nearshore habitats are particularly important to the long-term viability of commercial and recreational fisheries under SAFMC management, and threatened by large-scale, long-term or frequent hydrologic alterations:
    a. freshwater riverine reaches and/or wetlands used for anadromous spawning;
    b. downstream freshwater, brackish and mid-salinity portions of rivers and estuaries serving as nursery areas for anadromous and estuarine-dependant species; and
    c. nearshore oceanic habitats off estuary mouths.

7. Large sections of South Atlantic waters potentially affected by these projects, both individually and collectively, have been identified as EFH or EFH-HAPC by the SAFMC, as well as the Mid-Atlantic Fishery Management Council (MAFMC) in the case of North Carolina. Potentially affected species and their EFH under federal management include (SAFMC 1998) include:
    a. summer flounder (various nearshore waters, including the surf zone and inlets; certain offshore waters).
    b. bluefish (various nearshore waters, including the surf zone and inlets)
    c. red drum (ocean high-salinity surf zones and unconsolidated bottoms in the nearshore).
    d. many snapper and grouper species (live hard bottom from shore to 600 feet, and – for estuarine-dependent species [e.g., gag grouper and gray snapper] – unconsolidated bottoms and live hard bottoms to the 100 foot contour).
    e. black sea bass (various nearshore waters, including unconsolidated bottom and live hard bottom to 100 feet, and hard bottoms to 600 feet).
    f. penaeid shrimp (offshore habitats used for spawning and growth to maturity, and waters connecting to inshore nursery areas, including the surf zone and inlets).
    g. coastal migratory pelagics (e.g., king mackerel, Spanish mackerel) (sandy shoals of capes and bars, barrier island ocean-side waters from the surf zone to the shelf break inshore of the Gulf Stream; all coastal inlets).
    h. corals of various types (hard substrates and muddy, silt bottoms from the subtidal to the shelf break).

i. areas identified as EFH for Highly Migratory managed by the Secretary of Commerce (e.g., sharks / inlets and nearshore waters, including pupping and nursery grounds).

8. Projects which entail hydrologic alterations also threaten important fish habitats for anadromous species under federal, interstate and state management (in particular, riverine spawning habitats, riverine and estuarine habitats, including state designated areas such as Primary and Secondary Nursery Areas of North Carolina), as well as essential overwintering grounds in nearshore and offshore waters. All diadromous species are under management by the Atlantic States Marine Fisheries Commission and the states. The SAFMC also identified essential habitats of anadromous and catadromous species in the region (inlets and nearshore waters).

9. Numerous habitats that have been by these projects causing hydrologic alterations have been identified as EFH-HAPCs by the SAFMC. The specific fishery management plan is provided in parentheses:
   a. all nearshore hard bottom areas (SAFMC, snapper-grouper).
   b. all coastal inlets (SAFMC, penaeid shrimps, red drum, and snapper-grouper).
   c. nearshore spawning sites (SAFMC, penaeid shrimps, and red drum).
   d. benthic *Sargassum* (SAFMC, snapper-grouper).
   e. from shore to the ends of the sandy shoals of Cape Lookout, Cape Fear, and Cape Hatteras, North Carolina; Hurl Rocks, South Carolina; *Phragmatopoma* (worm reefs) reefs off the central coast of Florida and near-shore hard-bottom south of Cape Canaveral (SAFMC, coastal migratory pelagics).
   f. Atlantic coast estuaries with high numbers of Spanish mackerel and Cobia from ELMR, to include Bogue Sound, New River, North Carolina; Broad River, South Carolina (SAFMC, coastal migratory pelagics).
   g. Florida Bay, Biscayne Bay, Card Sound, and coral hard bottom habitat from Jupiter Inlet through the Dry Tortugas, Florida (SAFMC, Spiny Lobster)
   h. Hurl Rocks (South Carolina), The Phragmatopoma (worm reefs) off central east coast of Florida, nearshore (0-4 meters; 0-12 feet) hard bottom off the east coast of Florida from Cape Canaveral top Broward County); offshore (5-30 meters; 15-90 feet) hard bottom off the east coast of Florida from Palm Beach County to Fowey Rocks; Biscayne Bay, Florida; Biscayne National Park, Florida; and the Florida Keys National Marine Sanctuary (SAFMC, Coral, Coral Reefs and Live hard Bottom Habitat).
   i. EFH-HAPCs designated for HMS species (e.g., sharks) in the South Atlantic region (NOAA Fisheries Service, Highly Migratory Species).

10. Habitats likely to be affected by projects which alter hydrologic regimes include many recognized in state level fishery management plans. Examples of these habitats include Critical Habitat Areas established by the North Carolina Marine Fisheries Commission, either in FMPs or in Coastal Habitat Protection Plans.

Threats to Marine and Estuarine Resources from Hydrologically-Altering Activities

The SAFMC finds that activities which alter normative hydrologic regimes of rivers, estuaries, inlets and nearshore oceanic habitats threaten or potentially threaten EFH through the following mechanisms:

1. Direct mortality of organisms at withdrawal points through hydrologic regimes

In addition, the interactions between cumulative and direct (sub-lethal) effects among the above factors certainly trigger non-linear impacts that are completely unstudied.

SAFMC Policies for Flow-altering Projects

The SAFMC establishes the following general policies related projects resulting in hydrologic alterations, to clarify and augment the general policies already adopted in the Habitat Plan and Comprehensive Habitat Amendment (SAFMC 1998a; SAFMC 1998b):

1. Projects should avoid, minimize and where possible offset damage to EFH and EFH-HAPCs.
2. Projects requiring expanded EFH consultation should provide detailed analyses of possible impacts to each type of EFH, with careful and detailed analyses of possible impacts to EFH-HAPCs and state Critical Habitat Areas (CHAs), including short and long term, and population and ecosystem scale effects. Agencies with oversight authority should require expanded EFH consultation.
3. Projects requiring expanded EFH consultation should provide a full range of alternatives, along with assessments of the relative impacts of each on each type of EFH, HAPC and CHAs.
4. Projects should avoid impacts on EFH, HAPCs and CHAs that are shown to be avoidable through the alternatives analysis, and minimize impacts that are not.
5. Projects should include assessments of potential unavoidable damage to EFH and other marine resources, using conservative assumptions.
6. Projects should be conditioned on the avoidance of avoidable impacts, and should include compensatory mitigation for all reasonably predictable impacts to EFH, taking into account uncertainty about these effects. Mitigation should be local, up-front and in-kind, and should be adequately monitored, wherever possible.
7. Projects should include baseline and project-related monitoring adequate to document pre-project conditions and impacts of the projects on EFH.
8. All assessments should be based upon the best available science, and be appropriately conservative so follow and precautionary principles as developed for various federal and state policies.
9. All assessments should take into account the cumulative impacts associated with other projects in the same southeast watershed.

7.4.2.5 Policies for the Protection and Restoration of EFH from Marine Aquaculture

Policy Context

This document establishes the policies of the South Atlantic Fishery Management Council (SAFMC) regarding protection of Essential Fish Habitat (EFH) and Essential Fish Habitat - Habitat Areas of Particular Concern (EFH-HAPCs) from potential impacts associated with marine aquaculture. The policies are designed to be consistent with the overall habitat protection policies of the SAFMC as formulated in the Habitat Plan (SAFMC 1998a) and adopted in the Comprehensive EFH Amendment (SAFMC 1998b) and the various Fishery Management Plans (FMPs) of the Council.

The findings presented below assess potential impacts, negative and positive to EFH and EFH-HAPCs posed by activities related to marine aquaculture in offshore and coastal waters, riverine systems and adjacent wetland habitats, and the processes which could place those resources at risk. The policies and recommendations established in this document are designed to avoid, minimize, and offset potential impacts from these activities, in accordance with the general habitat policies of the SAFMC as mandated by law. To address any future marine aquaculture projects in the South Atlantic region, or as legislation is developed to provide additional guidelines, the SAFMC will revise this policy when more information becomes available.

The recommendations presented here should be applied to aquaculture facilities in reasonable proximity to EFH and EFH-HAPCs, however managed. Current laws, regulations and policies differ for offshore aquaculture, and for aquaculture activities in nearshore and inshore waters managed by the various states. As the federal FMPs in the region are amended to address offshore aquaculture as "fishing" activities, then these recommendations should be factored into those FMPs. Where aquaculture remains outside federal FMP-based management, then EFH protection mechanisms for "non-fishing" activities should be used to protect EFH, wherever possible.

EFH Potentially At Risk from Marine Aquaculture Activities

The SAFMC finds that:

EFH Potentially At Risk from Marine Aquaculture Activities

The SAFMC finds that:

1. Properly sited, designed and managed marine aquaculture operations can have beneficial economic and environmental outcomes. However, marine aquaculture activities or associated support facilities can have the potential to cause adverse impacts to a variety of habitats across the shelf and to nearshore systems including:

    a) waters and benthic habitats in or near marine aquaculture sites,

b) exposed hardbottom (e.g., reefs and live bottom) in shallow and deep waters,
c) submerged aquatic vegetation beds,
d) shellfish beds,
e) spawning and nursery areas,
f) coastal wetlands, and
g) riverine systems and associated wetlands.

2. Certain offshore, nearshore and riverine habitats are particularly important to the long-term viability of commercial and recreational fisheries under SAFMC management, and are potentially threatened by marine offshore aquaculture activities, including:

   a) coral, coral reef and live/hardbottom habitat, including deepwater coral communities;
   b) marine and estuarine waters;
   c) estuarine wetlands, including mangroves and marshes;
   d) submerged aquatic vegetation;
   e) waters that support diadromous fishes, and their spawning and nursery habitats; and
   f) waters hydrologically and ecologically connected to waters that support EFH.

3. Construction and operation of poorly sited and/or designed aquaculture support facilities could adversely impact wetlands, other EFH and protected species' habitats.

4. Sections of South Atlantic waters potentially affected by these projects, both individually and collectively, have been identified as EFH or EFH-HAPC by the SAFMC. Potentially affected species and their EFH under federal management include (SAFMC, 1998b):

   a) summer flounder (various nearshore waters; certain offshore waters);
   b) bluefish (various nearshore waters);
   c) red drum (unconsolidated bottoms in the nearshore);
   d) many snapper and grouper species (live hardbottom from shore to 600 feet, and – for estuarine-dependent species (e.g., gag grouper and gray snapper) – unconsolidated bottoms and live hardbottoms to the 100 foot contour);
   e) black sea bass (various nearshore waters, including unconsolidated bottom and live/hardbottom to 100 feet, and hardbottoms to 600 feet);
   f) penaeid shrimp (offshore habitats used for spawning and growth to maturity, and waters connecting to inshore nursery areas);
   g) coastal migratory pelagics (e.g., king mackerel, Spanish mackerel) (sandy shoals of capes and bars, barrier island ocean-side waters from the surf zone to the shelf break inshore of the Gulf Stream);

h) corals of various types and associated organisms (on hard substrates in shallow, midshelf, and deep water);
i) muddy, silt bottoms from the subtidal to the shelf break, deepwater corals and associated communities; and
j) areas identified as EFH for Highly Migratory Species managed by the Secretary of Commerce (e.g., sharks: inlets and nearshore waters, including pupping and nursery grounds).

5. Many of the habitats potentially affected by these activities have been identified as EFH-HAPCs by the SAFMC. Each habitat and FMP is provided as follows:

a) all hardbottom areas (SAFMC snapper grouper);
b) nearshore spawning and nursery sites (SAFMC penaeid shrimps and red drum);
c) benthic Sargassum (SAFMC snapper grouper);
d) from shore to the ends of the sandy shoals of Cape Lookout, Cape Fear, and Cape Hatteras, North Carolina; Hurl Rocks, South Carolina; and Phragmatopoma (worm reefs) reefs off the central coast of Florida and near shore hardbottom south of Cape Canaveral (SAFMC coastal migratory pelagics);
e) Hurl Rocks (South Carolina); the Phragmatopoma (worm reefs) off central east coast of Florida; nearshore (0-4 meters; 0-12 feet) hardbottom off the east coast of Florida from Cape Canaveral to Broward County; offshore (5-30 meters; 15-90 feet) hardbottom off the east coast of Florida from Palm Beach County to Fowey Rocks; Biscayne Bay, Florida; Biscayne National Park, Florida; and the Florida Keys National Marine Sanctuary (SAFMC Coral, Coral Reefs and Live Hardbottom Habitat);
f) EFH-HAPCs designated for HMS species (e.g., sharks) in the South Atlantic region (NOAA Fisheries Service Highly Migratory Species);
g) Oculina Bank HAPC and proposed deepwater coral HAPCs (SAFMC Coral, Coral Reefs and Live Hardbottom Habitat); and
h) HAPCs for diadromous species adopted by the Atlantic States Marine Fisheries Commission (ASMFC).

6. Habitats likely to be affected by marine aquaculture activities include many recognized in state-level fishery management plans and interstate fishery management plans of the ASMFC. Examples of these habitats include state-designated Critical Habitat Areas (CHAs) or Strategic Habitat Areas (SHAs) established by the North Carolina Marine Fisheries Commission, either in FMPs or in Coastal Habitat Protection Plans. Many state-managed and interstate-managed species serve as key prey for SAFMC-managed species.

7. Scientists have documented exceptionally important habitat values for East coast Florida nearshore hardbottom used by over 500 species of fishes and invertebrates, including juveniles of many reef fishes. Equivalent scientific work

is just beginning in other South Atlantic states, but life histories suggest that similar habitat use patterns will be found.

Threats to EFH from Marine Aquaculture Activities

Aquaculture-related development without adequate safeguards may threaten wild stocks and the habitats that support them. The future of some aquaculture sectors is inextricably intertwined with fisheries and the health of marine ecosystems. Some coastal forms of aquaculture are known to degrade marine ecosystems, and may result in a net loss of fish. Finfish netpens in offshore waters may pose risks similar to netpens in inshore waters, where several potential environmental issues have been documented (summarized in Naylor et al. 2000; and Nash, ed. 2005).

Experimental or small-scale commercial fish farms are unlikely to have major environmental effects. However, if marine aquaculture booms, and becomes a major means of food production, the potential impacts on marine ecosystems and wild fisheries – and the communities that depend upon them – could be significant. An analysis of the potential cumulative impacts of aquaculture development in the southeast region is essential prior to any large-scale expansion, onshore or offshore.

<u>The SAFMC finds the following to constitute potential threats to EFH:</u>

1) Escapement: Ecological damage caused by escaped organisms has been documented, including the introduction of non-native species, and reduced fitness of wild stocks as a result of interbreeding with escapees of the same species. The likelihood of escapes from farms may be high, if cages are sited in storm-prone areas, either offshore on nearshore.

Moreover, species potentially targeted for offshore or nearshore production may spawn in netpens. Ocean fish cages are incapable of containing fish eggs. The impacts of fertilized egg releases on the health of wild fisheries could be significant if farmed fish are genetically less well adapted to the ocean environment, as a result of selective breeding, genetic engineering, or simply because animals being farmed were taken from a geographic area with different ecological conditions

2) Spread of pathogens and use of antibiotics and other drugs: Concentration of large numbers of animals in a small area can facilitate outbreaks of disease and parasites, potentially jeopardizing wild stocks. Disease and parasite outbreaks can also lead producers to administer antibiotics and other drugs, usually via feed. Drugs can end up in marine ecosystems where they can select for resistant bacteria, sometimes in species targeted by fisheries (Ervik et al. 1994). Note that the U.S. Food and Drug Administration regulates the use of drugs in aquaculture and there are only a very few drugs approved for controlled and limited use.

3) Water pollution: Concentrated animal production operations use substantial amounts of feeds. Even very efficient operations may lose a portion of the nutrients in feeds through uneaten food and through oxygen-demanding wastes, which are transmitted to surrounding waters.

Nitrogen is the nutrient primarily responsible for eutrophication in marine waters in the U.S. southeast, resulting in algal blooms and deoxygenation. In inshore waters, both nitrogen and phosphorus are nutrients of concern.

Nutrient impacts can be considerable in oligotrophic oceanic systems at levels significantly below those used as benchmarks for pollution in inshore and estuarine waters. The importance of the surface microlayer to larval ecology and its vulnerability to perturbations from airborne or locally-sourced excess nutrients cannot be overstated. Standards and criteria for nutrient-related water quality impacts on these oceanic ecological functions do not yet exist, and compliance with state-based water quality standards and national water quality criteria for nutrients may not prevent loading-based impacts.

Fish farms may cluster geographically near infrastructure such as processing plants and transportation, like terrestrial hog farms, concentrating potential impacts. However, widely-spaced marine farms sited in areas with strong currents and strong mixing would have less localized impact.

Finally, other feed additives, including metals and persistent organic pollutants, may contribute to longer-term bioaccumulation.

SAFMC Policies for Marine Aquaculture Projects

The SAFMC establishes the following general policies related to marine aquaculture projects, to clarify and augment the general policies already adopted in the Habitat Plan and Comprehensive Habitat Amendment (SAFMC 1998a; SAFMC 1998b):

1. The Council strongly supports thorough public review and effective regulation of marine aquaculture activities in the South Atlantic EEZ. South Atlantic fisheries are exceptionally dependent upon healthy habitat already under attack from many sources.

2. Permits should be for at least a ten-year duration with annual reporting requirements (activity reports) and a five-year comprehensive operational review with the option for revocation at any time in the event there is no prolonged activity or there are documented adverse impacts to marine resources. Given the changes underway in coastal ecosystems in response to storm events, rising seas and introduced species, such a review cycle is essential.

3. Environmental review and performance expectation are paramount. This is a new and totally optional class of private uses being imposed on already at-risk ecosystems where unacceptable ecological cascades could occur. The Council is

committed to ensuring that marine aquaculture activities are held to the same level of EFH conservation protections as are other non-fishing[*] activities.

4. The Council approves of use of therapeutic agents and feed additives that have been approved by the FDA specifically for use in offshore open-water or net pen aquaculture.

5. The use of genetically modified and non-native species should be prohibited.

6. Given the critical nature of proper siting, the applicant should provide all needed information to evaluate in full the suitability of potential sites. If sufficient information is not provided in the application review time allotted by existing processes, the permit should be denied or held in abeyance until required information is available.

7. Monitoring plans should be developed by the applicant/permit holder and approved by NOAA Fisheries Service with input from the Council. Monitoring plans should be reviewed, approved, and funded prior to implementation.

8. Permitees must have adequate resources legally committed to ensure proper decommissioning of obsolete or storm-damaged facilities.

9. The issuing agency should have clear authority to repeal or condition permits in order to prevent environmental damage and exercise its authority to repeal permits if it becomes evident that environmental damage is occurring or if permit conditions are not met.

[*] The reference to non-fishing activities is meant to clarify that the Council's role is to comment on aquaculture activities similar to process the Council uses for non-fishing activities. The MSA currently defines aquaculture as a fishing activity. However, the proposed Aquaculture Bill would remove aquaculture as a fishing activity. The Council applies the same EFH standards to both fishing and non-fishing impacts.

7.4.3 Activity-based Policies

(Source: the Habitat Plan SAFMC, 1998a)

7.4.3.1 Docks and Piers

Docks and piers, whether built over or floating on the water, are generally acceptable methods of gaining access to deep water. General considerations include:

1. Docks and piers should be constructed so that waterflow restriction and blockage of sunlight on wetland surfaces is avoided or minimized;

2. Docks and piers should be of adequate length to reach navigational depths without increasing dredging needs; and

3. Docks and piers should be designed and located to avoid areas that support submerged aquatic vegetation, shellfish beds and harvest areas, and other fragile and productive habitats.

7.4.3.2 Boat Ramps

1. Sites should be located along shorelines that do not support wetland vegetation and where adjacent waters have adequate navigational depths. Acceptable sites may include existing marinas; bridge approaches and causeways (with highway agency approval) where construction access channels exist; and natural and previously created deep water habitats;

2. Preferably, sites should be restricted to areas that do not require dredging to gain access to navigable waters. When located in the vicinity of seagrass beds, adequate navigation channels must exist and should be clearly marked. Boat ramps should not be located in areas where boats will encroach on sensitive and productive habitats;

3. Ramps should not be located in areas where encroachment into wetlands is likely to occur. Sites should contain adequate upland area for parking and for boat launching/removal; and

4. Adequate waste collection facilities should be required at public facilities.

7.4.3.3 Marinas

All marinas adversely affect aquatic habitats to some degree. These effects can be minimized through proper location and design. In addition to applicable recommendations for boat ramps, bulkheads, and seawalls, the following apply:

1. Marinas should be located in areas where suitable physical conditions exist. For example, potential sites should be located close to navigable waters and in locations where marina-related activities would not affect living marine resource forage, cover, harvest, and/or nursery habitats. Attention also should be given to sediment deposition rates and maintenance dredging requirements;

2. Marinas should be located at least 1,000 feet from shellfish harvest areas, unless state regulations or other considerations specify differently;

3. Dry-stack storage is generally preferable to wet mooring of boats. Open dockage extending into deep water is generally preferable to basin excavation;

4. Mooring basins should be sited in uplands rather than wetlands, and they should be designed so that water quality degradation does not occur. This may require consideration of basin flushing characteristics and incorporation of other design features such as surface and waste water collection and treatment facilities;

5. Turning basins and navigation channels should not create sumps and other slack-water areas that could degrade water quality nor should they be located in areas where circulation is poor. Depths generally should not exceed those of adjoining waters and, where practicable, they should provide for light penetration that is capable of sustaining benthic plant life. Dissolved oxygen levels in channels and basins should be adequate for fish and macroinvertebrate survival;

6. Consideration should be given to aligning access channels and configuring marinas to take full advantage of circulation from prevailing summer winds;

7. Permanent dredged material disposal sites (for use in initial and maintenance dredging) that do not impact wetland areas should be identified and acquired. Suitable disposal alternatives include placing dredged material on uplands, and using dredged material to create/restore wetlands. Projects that lack permanent disposal sites should not be authorized if maintenance dredging is needed and disposal sites/options are not available;

8. Catchment basins for collecting and storing surface runoff should be included as components of the site development plan. Marine railways or upland repair facilities should be equipped with hazardous material containment facilities so that biocides such as marine paints, oil and grease, solvents, and related materials are not directly or indirectly discharged into coastal waters and wetlands;

9. Consideration should be given to parking and other support facilities when it appears that available uplands are not adequate to support such needs and wetland encroachment is anticipated;

10. Marinas with fueling facilities should be designed to include practical measures for reducing oil and gas spillage into the aquatic environment. Spill control plans may be needed when marina facilities are to be located in the vicinity of large, emergent wetland areas, shellfish harvest sites, and other fragile/productive aquatic sites; and

11. Facilities for collection of trash and potential marine debris should be required. Where vessels with marine toilets will be moored, pump out facilities and notices regarding prohibition of sewage and other discharges should be provided.

7.4.3.4 Bulkheads and Seawalls

Bulkheads are used to protect adjacent shorelines from wave and current action and to enhance water access. Applications for bulkheads usually specify construction in open water followed by placing fill material behind the structure. Bulkheads may adversely impact wetlands through direct filling; through isolation; and through exacerbation of wave scour. Adverse impacts may be reduced by applying the following criteria:

1. Except in cases of recent and rapid erosion, structures should be aligned at or shoreward of the normal high waterline. Structures should be constructed so that reflective wave energy does not scour or otherwise adversely affect adjacent EFH or wetlands. For example, in areas that support fringing wetlands consideration should be given to the use of breakwaters (with regular openings -- see item 3 below) or placement of riprap at the toe of the bulkhead or along the waterward edge of eroding wetlands;

2. Where possible, sloping (3:1) riprap, gabions, or vegetation should be used rather than vertical seawalls; and

3. Shoreline protection devices that are located in areas having fringe wetlands should have openings that allow for fish ingress and egress and water circulation. Recommended spacing for structure openings is no less than one linear foot per five linear feet of structure.

7.4.3.5 Cables, Pipelines, and Transmission Lines

Wetland excavation is sometimes required for installing submerged cables, pipelines, and transmission lines. Construction also may require temporary or permanent wetlands filling. The following recommendations apply:

1. Wetland crossings should be aligned along the least environmentally damaging route. Submerged aquatic vegetation, shellfish beds, coral reefs, etc., must be avoided;

2. Construction of permanent access channels should be avoided since they disrupt natural drainage patterns and destroy wetlands through direct excavation, filling, and bank erosion. The push-ditch method, in which the trench is immediately backfilled, reduces the impact duration;

3. Excavated wetlands should be backfilled with either the same material as removed or a comparable material that is capable of supporting suitable replacement wetlands. Original marsh elevations should be restored and, where practicable, excavated vegetation should be stockpiled, kept viable, and returned to the excavated site. After backfilling, erosion protection measures should be implemented where needed to prevent fish habitat degradation and loss;

4. Excavated materials should be stored on uplands. If storage in wetlands cannot be avoided, discontinuous stock-piles should be used to allow continuation of sheet flow. Where practicable, stockpiled materials should be stored on construction cloth rather than bare marsh surfaces. Topsoil and organic surface material such as root mats should be stockpiled separately and returned to the surface of the restored site;

5. In open-water areas, excavated materials should be deposited in discontinuous piles to preclude significant blockage of water movement. Back-filling is recommended if the excavated material would alter circulation patterns or interfere with fishing;

6. Use of existing rights-of-way should be recommended when use of these areas would lessen overall wetland encroachment and disturbance; and

7. Directional drilling, a technique that allows horizontal, sub-surface, placement of pipelines should be used in situations where normal trenching and backfill would cause unacceptable levels of habitat loss or alteration.

7.4.3.6 Transportation

State and federal highway agencies generally have the capability of conducting advanced planning with road, causeway, and bridge construction. To the extent possible, NOAA Fisheries Service Branch Office and USFWS personnel should participate in early planning efforts. Since highway projects are generally considered to be in the public interest and frequently require wetland crossings, identification of mitigation needs, and development of suitable mitigation plans should be undertaken early in the planning process. The following criteria should be considered:

1. Transportation corridors/facilities should avoid wetlands. Where wetland crossings cannot be avoided, bridging should be used rather than filling, and the least environmentally damaging route, preferably along existing rights-of-way and road beds, should be followed;

2. Disrupting or reducing fish and invertebrate migration routes should be avoided. In areas that support or could support anadromous fish migrations, low, narrow, and/or dark passageways such as culverts and small bridges should not be utilized unless aligned and designed so that elimination of or significant reductions in fish migrations do not occur;

3. Structures should be designed to prevent shoaling and alteration of natural water circulation. Suitable erosion control and vegetation restoration should be implemented at wetland crossings; and

4. Transportation facilities should be designed to accommodate other public utilities, thus avoiding the need for additional wetland alteration. An example would be using bridges to support transmission lines and pipelines.

7.4.3.7 Navigation Channels and Boat Access Canals

Construction and maintenance of navigation channels and boat access canals may cause severe environmental harm. In addition to direct habitat losses associated with wetland and deepwater excavation and filling, these activities may significantly modify salinity and water circulation patterns. These changes could greatly modify the distribution and abundance of living marine resources. The following criteria should be followed:

1. Where possible, dredging should be minimized through the use of natural and existing channels;

2. Alignments should avoid sensitive habitats such as shellfish beds, finfish and invertebrate nurseries, submerged aquatic vegetation, and emergent wetlands;

3. Permanent dredged material disposal sites should be located in non-wetland areas. Where long-term maintenance excavation is anticipated, disposal sites should be acquired and maintained for the entire project life;

4. Boat access canals should be designed to ensure adequate flushing and should be uniform in depth or made progressively deeper in the direction of receiving waters. Where possible, they should be aligned to take advantage of wind and lunar tides;

5. Construction techniques that minimize turbidity and dispersal of dredged materials into sensitive wetland areas (e.g., submerged grasses and shellfish beds) are encouraged. Work should be scheduled to avoid periods of high biological activity such as fish and invertebrate migration and spawning;

6. Care should be taken to avoid adverse alteration of tidal circulation patterns, salinity regimes, or other factors that influence local ecological and environmental conditions;

7. Channels and access canals should not be constructed in areas known to have high sediment contaminant levels. If construction must occur in these areas, consideration should be given to the use of silt curtains or other techniques needed to contain suspended contaminants; and

8. Use of sidecast dredges should be confined to areas such as inlets and open water areas where benthic communities are limited and hopper or pipeline dredging is not possible.

7.4.3.8 Disposal of Dredged Material

Previous and on-going disposal of dredged material is a major contributor to wetland losses in marine and estuarine ecosystems. Recognizing that most navigation channels and access canals require periodic maintenance dredging, it is important that long-range plans be developed and that they provide for mitigation of unavoidable adverse environmental impacts. Implementing the following criteria would minimize adverse impacts associated with most dredged material disposal activities:

1. Dredged material should be viewed as a potentially reusable resource and beneficial uses of these materials should be encouraged. Materials that are suitable for beach replenishment, construction, or other useful purposes should be placed in accessible non-wetland disposal areas;

2. Disposal sites that are located in unprotected coastal areas and adjacent to wetlands are especially susceptible to wind and water erosion. These forces can carry substantial quantities of dredged material into aquatic habitats. If located near wetlands, disposal site surfaces should be stabilized using vegetation or other means to eliminate possible erosion or encroachment onto adjacent wetlands;

3. Dredged material should be placed in contained upland sites or approved open-water locations where adverse impacts to living marine resources are minimal. When placed in open water, dredged material should be used to enhance marine fishery resources. For example, materials could be used to renourish eroding wetlands or to fill previous borrow sites;

4. The capacity of existing disposal areas should be used to the fullest extent possible. This may necessitate increasing the elevation of embankments to augment the holding capacity of the site and applying techniques that render dredged material suitable for export or for use in reestablishing wetland vegetation;

5. Where possible, outfalls should be positioned so that they discharge into the dredged area or other sites that lack biological/ecological significance. When evaluating potential upland disposal sites, the possibility of saltwater intrusion into ground water and surrounding freshwater habitats should be assessed by the construction/regulatory agencies. Groundwater contamination could necessitate

redesign of disposal practices, with subsequent harm to living marine resources; and

6. Toxic and highly organic materials should be disposed in impervious containment basins located on upland. Effluent should be monitored to ensure compliance with state and federal water quality criteria and measures should be incorporated to ensure that surface runoff and leachate from dredged material disposal sites do not enter aquatic ecosystems.

7.4.3.9 Impoundments and Other Water-Level Controls

1. Wetland impoundments:

Thousands of wetland acres are impounded each year in the southeast for purposes such as waterfowl habitat creation, aquaculture, agriculture, flood control, hurricane protection, mosquito control, and control of marsh subsidence and erosion. Projects range in size from minor, such as repair of existing embankments, to large-scale marsh management projects where constructing dikes and water- control structures may affect thousands of wetland acres.

Proposals to impound or control marsh water levels should contain water management plans with sufficient detail to determine the accessibility of impounded areas to marine organisms and the degree to which detrital and nutrient export into adjacent estuarine areas will be affected. Significant adverse impacts can be avoided or minimized with implementation of the following recommendations:

a. Proposals to impound or reimpound previously unimpounded wetlands are unacceptable unless designed to accommodate (1) normal access and wetland use by marine fish and invertebrates and (2) continuation of other biological interaction, such as nutrient exchange, and other similarly important physical and chemical interactions; and

b. Proposals to repair or replace water control structures will be assessed on a case-by-case basis.

2. Watershed Impoundments:

Water-development agencies sometimes propose impounding rivers, bayous, and tributaries for such purposes as flood control or creation of industrial, municipal, and agricultural water supplies. Activities of this type are usually unacceptable because associated alteration of the quality, quantity, and timing of freshwater flow into estuaries may cause large-scale adverse modification or elimination of estuarine and marine habitats. Such actions also may block fish and invertebrate migrations.

7.4.3.10 Drainage Canals and Ditches

Drainage canals may be important components of upland development. Their potential to shunt polluted runoff and fresh water directly into tidal waters requires intermediate connection to retention ponds or wetlands. This allows natural filtration and assimilation of pollutants and dampening of freshwater surges prior to discharge into tidal waters. Recommendations include:

1. Drainage canals that dewater or cause other adverse wetland impacts are unacceptable and should not be built;

2. Drainage canals and ditches from upland development generally should not extend or discharge directly into wetlands;

3. Constructing upland retention ponds and other water management features such as sheet-flow diffusers is encouraged. A retention pond or other pollution elimination/assimilation structure should be required if the effluent contains or may contain materials that are toxic to marsh vegetation or other aquatic life,

4. Excavated materials resulting from canal and retention pond construction should be placed on upland or used to restore wetlands;

5. Proposed drainage plans should be in accordance with comprehensive flood plain management plan(s) and applicants should be encouraged to consult with the EPA and appropriate state agencies to ensure that federal and state water quality standards are met;

6. Locating mosquito control ditches in wetlands should be discouraged. If built, they should be designed so that they do not drain coastal wetlands. They also should be designed to avoid water stagnation, and they should provide access for aquatic organisms that feed on mosquito larvae; and

7. Use of innovative techniques such as rotary ditching, spray dispersal of dredged materials, and open-water marsh management should be encouraged where appropriate.

7.4.3.11 Oil and Gas Exploration and Production

Exploration and production of oil and gas resources in wetlands usually have adverse impacts since excavation and filling are generally required to accommodate access and production needs. In open marine waters, dredging and filling is usually not necessary, but special stipulations are required to minimize adverse impacts to living marine resources. In addition to the above recommendations for navigation channels, access canals, and pipeline installation, the following apply:

1. In coastal wetlands:
    a. Activities should avoid wetland use to the extent practicable. Alternatively, the use of uplands, existing drilling sites and roads, canals, and naturally deep waters should be encouraged. When wetland use is unavoidable, work in unvegetated and disturbed wetlands is generally preferable to work in high quality and undisturbed wetlands;

b. Temporary roadbeds (preferably plank roads) generally should be used instead of canals for access to well sites;

c. Water crossings should be bridged or culverted to prevent alteration of natural drainage patterns;

d. Culverts or similar structures should be installed and maintained at sufficient intervals (never more than 500-feet apart) to prevent blockage of surface drainage or tidal flow;

e. Petroleum products, drilling muds, drill cuttings, produced water, and other toxic substances should not be placed in wetlands;

f. If the well is productive, the drill pad and levees should be reduced to the minimum size necessary to conduct production activities; and

g. Defunct wells and associated equipment should be removed and the area restored to the extent practicable. Upon abandonment of wells in coastal wetlands, the well site, various pits, levees, roads, and work areas should be restored to preproject conditions by restoring natural elevations and planting indigenous vegetation whenever practicable. Abandoned well access canals should generally be plugged at their origin (mouths) to minimize bank erosion and saltwater intrusion, and spoil banks should be graded back into borrow areas or breached at regular intervals to establish hydrological connections.

2. In open estuarine waters:
   a. Activities in estuarine waters should be conducted as follows:

   b. Existing navigable waters already having sufficient width and depth for access to mineral extraction sites should be used to the extent practicable;

   c. Petroleum products, drilling muds, drill cuttings, produced water, and other toxic substances should not be placed in wetlands; and

   d. Defunct equipment and structures should be removed.

3. On the continental shelf:
   a. Activities should be conducted so that petroleum-based substances such as drilling mud, oil residues, produced waters, or other toxic substances are not released into the water or onto the sea floor. The following measures may be recommended with exploration and production activities located close to hard banks and banks containing reef building coral:

b. Drill cuttings should be shunted through a conduit and discharged near the sea floor, or transported ashore or to less sensitive, NOAA Fisheries Service-approved offshore locations. Usually, shunting is effective only when the discharge point is deeper than the site that is to be protected;

c. Drilling and production structures, including pipelines, generally should not be located within one mile of the base of a live reef;

d. All pipelines placed in waters less than 300 feet-deep should be buried to a minimum of three feet beneath the sea floor, where possible. Where this is not possible and in deeper waters where user-conflicts are likely, pipelines should be marked by lighted buoys and/or lighted ranges on platforms to reduce the risk of damage to fishing gear and the pipelines. Pipeline alignments should be located along routes that minimize damage to marine and estuarine habitat. Buried pipelines should be examined periodically for maintenance of adequate earthen cover.

7.4.3.12 Other Mineral Mining/Extraction

1. Proposals for mining mineral resources (sand, gravel, shell, phosphate, etc.) from or within 1,500 feet of exposed shell reefs and vegetated wetlands, and within 1,500 feet of shorelines are unacceptable except when the material is to be used for oyster cultch; and

2. All other proposals will be considered on a case-by-case basis.

7.4.3.13 Sewage Treatment and Disposal

Urbanization and high density development of coastal areas has resulted in a substantial increase in proposals to construct sewage treatment and discharge facilities in coastal wetlands. Since many of these facilities utilize gravity flow systems for movement of waste water and materials, wetlands and other low-lying areas are often targeted as sites for placement of pipelines and treatment facilities. Since pipelines and treatment facilities are not water dependent with regard to positioning, it is not essential that they be placed in wetlands or other fragile coastal habitats. The guidance provided in the Section on "Cables, Pipelines, and Transmission Lines," also applies to sewage collector and discharge pipelines. The following guidance should be considered with other aspects of sewage treatment and discharge:

1. Discharges should be treated to the maximum extent practicable, including implementation of up-to-date methodologies for reducing discharges of biocides (e.g., chlorine) and other toxic substances;

2. Use of land treatment and upland disposal/storage techniques should be implemented where possible. Use of vegetated wetlands as natural filters and pollutant assimilators for large scale discharges should be limited to those

instances where other less damaging alternatives are not available and the overall environmental and ecological suitability of such an action has been demonstrated;

3. Discharging into open ocean waters is generally preferable to discharging into estuarine waters since discharging into estuarine waters is more likely to result in living marine resources contamination and nutrient overloading. Discharge points in coastal waters should be located well away from shellfish beds, seagrass beds, coral reefs, and other similar fragile and productive habitats. Proposals to locate outfalls in coastal waters must be accompanied by hydrographic studies that demonstrate year round dispersal characteristics and provide proof that effluents will not reach or affect fragile and productive habitats.

7.4.3.14 Steam-Electric Plants and Other Facilities Requiring Water for Cooling or Heating

Facilities that require substantial intake and discharge of water, especially heated and chemically-treated discharge water, are generally not suited for construction and operation in estuarine and near-shore marine environments. Major adverse impacts may be caused by impingement of organisms on intake screens; entrainment of organisms in heat-exchange systems or discharge plumes; and through the discharge of toxic materials in discharge waters. Protected Species Branch personnel should be notified of such projects early in the planning process since the operation of steam-electric plants often affects endangered species such as shortnose sturgeon and West Indian manatee. Projects that must be sited in the coastal zone and utilize estuarine and marine waters are subject to the following recommendations:

1. Facilities that rely on surface waters for cooling should not be located in areas such as estuaries, inlets, or small coastal embayments where fishery organisms are concentrated. Discharge points should be located in areas that have low concentrations of living marine resources, or they should incorporate cooling towers that employ sufficient safeguards to ensure against release of blow-down pollutants into the aquatic environment;

2. Intakes should be designed to minimize impingement. Velocity caps that produce horizontal intake/discharge currents should be employed and intake velocities across the intake screen should not exceed 0.5 feet per second;

3. Discharge temperatures (both heated and cooled effluent) should not exceed the thermal tolerance of the majority of the plant and animal species in the receiving body of water;

4. The use of construction materials that may release toxic substances into receiving waters should be minimized. The use of biocides (e.g., chlorine) to prevent fouling should be avoided where possible and least damaging antifouling alternatives should be implemented; and

5. Intake screen mesh should be sized to avoid entrainment of most larval and post-larval marine fishery organisms. Acceptable mesh size is generally in the range of 0.5 mm and rarely exceeds 1.0 mm in estuarine waters or waters that support anadromous fish eggs and larvae.

7.4.3.15 Mariculture/Aquaculture

The culture of estuarine and marine species in coastal areas can reduce or degrade habitats used by native stocks of commercially and recreationally important fisheries. The following criteria should be employed to reduce or eliminate adverse impacts:

1. Facilities should be located on upland. Tidally influenced wetlands should not be enclosed or impounded for mariculture purposes. This includes hatchery and grow-out operations;

2. Water intakes should be designed to avoid entrainment and impingement of native fauna;

3. Water discharge should be treated to avoid contamination of the receiving water, and should be located only in areas having good mixing characteristics;

4. Where cage mariculture operations are undertaken, water depths and circulation patterns should be investigated and should be adequate to preclude the buildup of waste products, excess feed, and chemical agents; and

5. Mariculture sites should be stocked with hatchery-reared organisms only. Non-native species should be certified to be disease free, and project design features that minimize escape or accidental release of cultured species should be required. The rearing of ecologically undesirable species is unacceptable since escape and accidental release of these species is virtually assured.

7.4.3.16 Mitigation

Sections 7.4.3.1 – 7.4.3.15 provide specific guidance for avoiding and reducing adverse impacts to fishery resources and their habitats. Compensatory mitigation is considered in cases where a resource is not unique and irreplaceable and only after a project has been demonstrated to be water-dependent, has no feasible alternative, is clearly in the public interest, and all significant impacts are found to be unavoidable. In all cases, mitigation shall comply with the definition of mitigation that is provided at 40 CFR 1508.20 of the Council on Environmental Quality Recommendations. Those recommendations define mitigation as a sequential process whereby impacts are avoided, minimized, rectified, reduced over time, or are offset through compensation.

Despite increasing use of mitigation to offset wetland and other losses, there are situations (e.g., projects affecting seagrass) where the affected habitats are of such enormous value that the anticipated adverse impacts cannot be offset. In instances involving such unique and irreplaceable resources, mitigation is not acceptable. There is also disagreement over the functional equivalency of created and natural wetlands and it should not be assumed they are equivalent in habitat value.

As a general rule, mitigation that restores previously existing habitats is more desirable and likely to succeed than that which seeks to create new habitat. The numerous impacted wetlands that exist in the southeast provide substantial opportunity for wetlands restoration. Restoration may be relatively simple, such as restoring tidal flows to an impounded wetland area, or more complex such as restoring dredged cuts and disposal areas. Restoration of destroyed emergent and, to a lesser degree, submerged vegetation is a feasible and recognized option when implemented with the services of experienced restoration personnel.

The creation of new wetland habitat involves conversion of uplands or, in some situations, submerged bottom to vegetated wetlands or another desirable habitat such as oyster reef. Generation of wetland habitat should not involve converting one valuable wetland type to another. For example, building emergent wetlands in shallow water is unacceptable unless it can be demonstrated that the site is insignificant with regard to habitat or water quality function(s) or it previously supported wetland vegetation and restoration is desirable in terms of the ecology of the overall hydrological unit (e.g., estuary). Regardless of which option is used (restoration or creation), a ratio of at least two acres of mitigation for each acre of habitat destroyed should be recommended. Four basic considerations involved in the planning for habitat generation are type of habitat to be created, and its location, size, and configuration. Each of these considerations must be applied to the specific ecological setting and in accordance with the following recommendations:

1. Habitat type - As a general rule the created habitat should be vegetatively, functionally, and ecologically comparable to that which is being replaced. For example, a smooth cordgrass marsh should be created if a smooth cordgrass marsh is eliminated. The principal exception would be those cases where a different habitat is shown to be more desirable based on overall ecological considerations.

2. Location - Except in the case of overriding ecological considerations, the new site should be located as near as possible to the site that would be eliminated. In any event, the new site should be in the same estuarine system as the habitat that is being replaced. The replacement wetland should consider physical implications such as shoaling and existing circulation and drainage patterns.

   NOAA Fisheries Service and USFWS consider the overall ecological and environmental implications of its recommendations, including upland impacts. Mitigation that may alleviate impacts to aquatic environments, but cause significant adverse impacts to important upland habitats should be carefully evaluated.

3. Size - The habitat to be restored or created should be at least twice the (areal) size of that which would be destroyed. This requirement is designed to offset differences in productivity and habitat functions that may exist between established project site wetlands and newly developed replacement wetlands. This size difference is also designed to address the possibility that the overall, long-term functional and ecological value of replacement habitats may be less than those of the impacted wetlands at the worksite.

4. Configuration - The configuration of replacement habitats is determined by the ecological setting and physical factors such as existing drainage and circulation patterns. Consideration should be given to maximizing edge habitat and to the needs of desirable biota that may inhabit the site.

   Interest in the use of "mitigation banks" or created/restored wetlands that are intended for use in offsetting anticipated future wetland losses is increasing nationwide. Because of the complexity of developing and administering mitigation banks, guidance concerning their creation is beyond the scope of this document. NOAA Fisheries Service Southeast Region Habitat Conservation Division Branch Office personnel that are participating in such efforts should consult early with other NOAA Fisheries Service office personnel that have undertaken or are involved in such efforts since reliance on existing mitigation banking agreements may be beneficial. Habitat Conservation Division Branch Office personnel also should notify other participating agencies that signatory authority for mitigation bank agreements rests with the Regional Director. In all cases, consideration of mitigation banks should be guided by the principle that no net-loss of wetlands would be incurred.

7.5 Interagency and Interstate Policies

7.5.1 Joint Agency Habitat Statement

The SAFMC has endorsed a "Joint Statement to Conserve Marine, Estuarine, and Riverine Habitat" to promote interagency coordination in the preservation, restoration, and enhancement of fishery habitat. This statement as adopted by state, Federal, and regional bodies concerned over fishery habitat, is presented in Appendix VII of The Fishery Management Plan for Shrimp (SAFMC 1993a).

7.5.2 Atlantic States Marine Fisheries' Commission Seagrass Policy and Implementation Plan

The Atlantic States Marine Fisheries Commission seagrass policy (June 1997) is available at http://www.asmfc.org/publications/habitat/savpolicy.pdf
The Policy is based on a collection of review papers that investigated the ecological value of SAV, its importance to Commission managed species, human impacts to SAV, and its regulation by state agencies. The SAV Policy establishes recommendations for protection and conservation of SAV by emphasizing assessment of SAV resources, protection of existing SAV, SAV restoration, public education, and scientific research.

As directed in the SAV Policy, the Commission developed a document titled *Evaluate Fishing Gear Impacts to Submerged Aquatic Vegetation and Determining Mitigation Strategies* (July 2000). This document is available at http://www.asmfc.org/.

7.6 Federal Habitat Protection Laws, Programs and Policies

(Source: SAFMC Habitat Plan 1998).

The Clean Water Act (CWA) 33 U.S.C. s/s 121 et seq. (1977)

The Clean Water Act is a 1977 amendment to the Federal Water Pollution Control Act of 1972, which set the basic structure for regulating discharges of pollutants to waters of the United States. This law gave EPA the authority to set effluent standards on an industry-by-industry basis (technology-based) and continued the requirements to set water quality standards for all contaminants in surface waters. The CWA makes it unlawful for any person to discharge any pollutant from a point source into navigable waters unless a permit (NPDES) is obtained under the Act. The 1977 amendments focused on toxic pollutants. In 1987, the CWA was reauthorized and again focused on toxic substances, authorized citizen suit provisions, and funded sewage treatment plants (POTWs) under the Construction Grants Program. The CWA provides for the delegation by EPA of many permitting, administrative, and enforcement aspects of the law to state governments. In states with the authority to implement CWA programs, EPA still retains oversight responsibilities.

The Comprehensive Environmental Response, Compensation and Liability Act (CERCLA or Superfund) 42 U.S.C. s/s 9601 et seq. (1980)

CERCLA (pronounced SERK-la) provides a federal "Superfund" to clean up uncontrolled or abandoned hazardous waste sites as well as accidents, spills, and other emergency releases of pollutants and contaminants into the environment. Through the Act, EPA was given power to seek out those parties responsible for any release and assure their cooperation in the cleanup. EPA cleans up orphan sites when potentially responsible parties (PRPs) cannot be identified or located, or when they fail to act. Through various enforcement tools, EPA obtains private party cleanup through orders, consent decrees, and other small party settlements. EPA also recovers costs from financially viable individuals and companies once a response action has been completed. EPA is authorized to implement the Act in all 50 states and U.S. territories. Superfund site identification, monitoring, and response activities in states are coordinated through the state environmental protection or waste management agencies.

The Emergency Planning and Community Right-to-know Act (EPCRA) 42 U.S.C. 11011 et seq. (1986)

Also known as Title III of SARA, EPCRA was enacted by Congress as the national legislation on community safety. This law was designed to help local communities protect public health, safety, and the environment from chemical hazards. To implement EPCRA, Congress required each state to appoint a State Emergency Response Commission (SERC). The SERCs were required to divide their states into Emergency

Planning Districts and to name a Local Emergency Planning Committee (LEPC) for each district. Broad representation by fire fighters, health officials, government and media representatives, community groups, industrial facilities, and emergency managers ensures that all necessary elements of the planning process are represented.

The Endangered Species Act 7 U.S.C. 136; 16 U.S.C. 460 et seq. (1973)
The Endangered Species Act provides a program for the conservation of threatened and endangered plants and animals and the habitats in which they are found. The U.S. Fish and Wildlife Service (FWS) of the Department of Interior maintains the list of 632 endangered species (326 are plants) and 190 threatened species (78 are plants). Species include birds, insects, fish, reptiles, mammals, crustaceans, flowers, grasses, and trees. Anyone can petition FWS to include a species on this list or to prevent some activity, such as logging, mining, or dam building. The law prohibits any action, administrative or real, that results in a "taking" of a listed species, or adversely affects habitat. Likewise, import, export, interstate, and foreign commerce of listed species are all prohibited. EPA's decision to register a pesticide is based in part on the risk of adverse effects on endangered species as well as environmental fate (how a pesticide will affect habitat). Under FIFRA (see below), EPA can issue emergency suspensions of certain pesticides to cancel or restrict their use if an endangered species will be adversely affected. Under a new program, EPA, FWS, and USDA are distributing hundreds of county bulletins which include habitat maps, pesticide use limitations, and other actions required to protect listed species. In addition, we are enforcing regulations under various treaties, including the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). The U.S. and 70 other nations have established procedures to regulate the import and export of imperiled species and their habitat. The Fish and Wildlife Service works with U.S. Customs agents to stop the illegal trade of species, including the Black Rhino, African elephants, tropical birds and fish, orchids, and various corals.

The Federal Insecticide, Fungicide and Rodenticide act (FIFRA) 7 U.S.C. s/s 135 et seq. (1972)
The primary focus of FIFRA was to provide federal control of pesticide distribution, sale, and use. EPA was given authority under FIFRA not only to study the consequences of pesticide usage but also to require users (farmers, utility companies, and others) to register when purchasing pesticides. Through later amendments to the law, users also must take exams for certification as applicators of pesticides. All pesticides used in the U.S. must be registered (licensed) by EPA. Registration assures that pesticides will be properly labeled and that, if used in accordance with specifications, will not cause unreasonable harm to the environment.

The (Federal) Freedom of Information Act (FOIA) U.S.C. s/s 552 (1966)
The Freedom of Information Act provides specifically that "any person" can make requests for government information. Citizens who make requests are not required to identify themselves or explain why they want the information they have requested. The position of Congress in passing FOIA was that the workings of government are "for and by the people" and that the benefits of government information should be made available to everyone. All branches of the federal government must adhere to the provisions of

FOIA with certain restrictions for work in progress (early drafts), enforcement confidential information, classified documents, and national security information.

The National Environmental Policy Act (NEPA) 42 U.S.C. s/s 4321 et seq. (1969)
The National Environmental Policy Act was one of the first laws ever written that establishes the broad national framework for protecting our environment. NEPA's basic policy is to assure that all branches of government give proper consideration to the environment prior to undertaking any major federal action which significantly affects the environment. NEPA requirements are invoked when airports, buildings, military complexes, highways, parkland purchases, and other such federal activities are proposed. Environmental Assessments (EAs) and Environmental Impact Statements (EISs), which are assessments of the likelihood of impacts from alternative courses of action, are required from all federal agencies and are the most visible NEPA requirements.

The Occupational Safety and Health Act 29 U.S.C. 61 et seq. (1970)
Congress passed the Occupational and Safety Health Act to ensure worker and workplace safety. Their goal was to make sure employers provide their workers a place of employment free from recognized hazards to safety and health, such as exposure to toxic chemicals, excessive noise levels, mechanical dangers, heat or cold stress, or unsanitary conditions. In order to establish standards for workplace health and safety, the Act also created the National Institute for Occupational Safety and Health (NIOSH) as the research institution for the Occupational Safety and Health Administration (OSHA). OSHA is a division of the U.S. Department of Labor which over-sees the administration of the Act and enforces federal standards in all 50 states.

The Pollution Prevention Act 42 U.S.C. 13101 and 13102, s/s 6602 et seq. (1990)
The Pollution Prevention Act focused industry, government, and public attention on reducing the amount of pollution produced through cost-effective changes in production, operation, and raw materials use. Opportunities for source reduction are often not realized because existing regulations, and the industrial resources required for compliance, focus on treatment and disposal. Source reduction is fundamentally different and more desirable than waste management or pollution control. Pollution prevention also includes other practices that increase efficiency in the use of energy, water, or other natural resources, and protect our resource base through conservation. Practices include recycling, source reduction, and sustainable agriculture.

The Resource Conservation and Recovery Act (RCRA) 42 U.S.C. s/s 321 et seq. (1976)
RCRA gave EPA the authority to control hazardous waste from "cradle-to-grave." This includes the generation, transportation, treatment, storage, and disposal of hazardous waste. RCRA also set forth a framework for the management of non-hazardous solid wastes. The 1986 amendments to RCRA enabled EPA to address environmental problems that could result from underground tanks storing petroleum and other hazardous substances. RCRA focuses only on active and future facilities and does not address abandoned or historical sites (see CERCLA).

The 1984 Federal Hazardous and Solid Waste Amendments (HSWA) to RCRA required phasing out land disposal of hazardous waste. Some of the other mandates of this strict law include increased enforcement authority for EPA, more stringent hazardous waste management standards, and a comprehensive underground storage tank program.

The Safe Drinking Water Act (SDWA) 43 U.S.C. s/s 300f et seq. (1974)
The Safe Drinking Water Act was established to protect the quality of drinking water in the U.S. This law focuses on all waters actually or potentially designated for drinking use, whether from above ground or underground sources. The Act authorized EPA to establish safe standards of purity and required all owners or operators of public water systems to comply with primary (health-related) standards. State governments, which assume this power from EPA, also encourage attainment of secondary standards (nuisance-related).

The Superfund Amendments and Reauthorization Act (SARA) 42 U.S.C. 9601 et seq. (1986)
The Superfund Amendments and Reauthorization Act of 1986 reauthorized CERCLA to continue cleanup activities around the country. Several site-specific amendments, definitions, clarifications, and technical requirements were added to the legislation, including additional enforcement authorities. Title III of SARA also authorized the Emergency Planning and Community Right-to-Know Act (EPCRA).

The Toxic Substances Control Act (TSCA) 15 U.S.C. s/s 2601 et seq. (1976)
The Toxic Substances Control Act of 1976 was enacted by Congress to test, regulate, and screen all chemicals produced or imported into the U.S. Many thousands of chemicals and their compounds are developed each year with unknown toxic or dangerous characteristics. To prevent tragic consequences, TSCA requires that any chemical that reaches the consumer market place be tested for possible toxic effects prior to commercial manufacture. Any existing chemical that poses health and environmental hazards is tracked and reported under TSCA. Procedures also are authorized for corrective action under TSCA in cases of cleanup of toxic materials contamination. TSCA supplements other federal statutes, including the Clean Air Act and the Toxic Release Inventory under EPCRA.

7.7 State Habitat Protection Programs

7.7.1 North Carolina

The Coastal Area Management Act was passed in 1974 to protect North Carolina’s fragile coastal resources through planning and management at the state and local level. The Department of Environment, Health and Natural Resources administers the program. Policy direction is provided by the Coastal Resources Commission, a group of citizens appointed by the Governor. The Division of Coastal Management (DCM), under authority from the Coastal Resources Commission (CRC), is responsible for implementing the North Carolina Coastal Management Program for the protection, preservation, orderly development and management of the state's twenty coastal counties. DCM is part of the Department of Environment, Health and Natural Resources. Activities of DCM include: permitting and enforcing regulations in areas of environmental concern; reviewing consistency of government and larger private activities in the coastal zone for compliance with the Coastal Area Management Act; planning for the ocean resources in North Carolina's jurisdictional waters; providing for effective disposal of boat sewage; identifying high priority watersheds; developing strategies for managing secondary and cumulative impacts; Transferring technology and information to local governments; identifying wetlands in the coastal area; assessing the relative significance of wetlands on the landscape; and identifying and prioritizing wetland restoration sites.

7.7.2 South Carolina

The Office of Ocean and Coastal Resource Management implements the Coastal Management Act. The Office has authority to formulate and implement a comprehensive coastal management program and direct control through a permit program that oversees activities in critical areas that include coastal waters, tidelands, beaches, and primary ocean-front sand dunes. Indirect management authority of coastal resources is granted to the Office in counties containing one or more of the critical areas. In issuing permits, the Coastal Management Act requires that the Office consider the effects of proposed alterations on the production of fish, shrimp, oysters, crab, or any marine life, wildlife, or other natural resources.

7.7.3 Georgia

On April 22, 1997, Governor Miller signed the Georgia Coastal Management Act into law which established the Department of Natural Resources Coastal Resource Division as the authority to create the program, receive and dispense funds, and to coordinate with federal and state agencies regarding Coastal Management issues. On January 26, 1998 the Georgia Coastal Management Program received official approval. This approval marked the end of a six year combined effort by state and local government in partnership with private citizens to develop an integrated, networked program. The program uses existing State laws to manage Georgia's critical coastal resources. With the approval of the Georgia Coastal Management Program comes over $1 million in federal funds annually. Most of the funds are allocated to local communities and organizations through the "Coastal Incentive Grant" program. Incentive grants are presented to local governments and universities to address critical local issues in coastal Georgia such as water management, local government planning and small scale construction projects.

7.7.4 Florida

The Florida Legislature adopted the Florida Coastal Management Act in 1978. This act authorized the development of a coastal management program and its submittal to the appropriate federal agency. In 1981, the Florida Coastal Management Program (FCMP) was approved by the Secretary of the United States Department of Commerce. Florida’s goal in creating the FCMP was not to create a new agency or new statutes concerned with coastal issues, but instead to use existing agencies and laws to address Florida’s coastal needs. Florida's rules and laws adequately protected the coast, but were not always effectively implemented because of breakdowns in communication between agencies and administrative shortcomings. The FCMP was created to bridge these gaps and to open the lines of communication among the agencies so that their actions could be coordinated. The FCMP, as it exists today, is a network of ten state agencies and five water management districts using 23 statutes to protect Florida's coastal interests. The agencies most directly involved in issues that affect Essential Fish Habitat are listed below.

The Department of Community Affairs (DCA) is the lead agency for the FCMP, serving as coordinator of coastal issues and as the liaison between the state agencies and the federal government. DCA also houses the State Clearinghouse and serves as the state's land planning agency and emergency management agency.

The Department of Environmental Protection (DEP), formed by the merger of the former Department of Environmental Regulation and the former Department of Natural Resources, serves as the state's chief environmental regulatory agency and the manager and steward of many of its natural resources. Among the natural resources over which the DEP has jurisdiction are submerged lands within state estuarine and marine waters. The Department of Health regulates on-site sewage disposal. The Marine Fisheries Commission exercises jurisdiction over saltwater fisheries and marine mammals. The five water management districts, organized along watershed lines, act in partnership with DEP in regulating activities in wetlands and waters of the state and the use of water resources.

8.0 Fisheries Management Evaluation and Recommendations

8.1 Area Management in the South Atlantic Region

8.1.1 South Atlantic Fishery Management Council

8.1.1.1 SMZs

Since 1983, the Council has allowed the designation of SMZs as an incentive to create artificial reefs and fish attraction devices to increase the numbers of fish in an area and/or create fishing opportunities that would not otherwise exist.

Designation of an area as a SMZ allows for gear restrictions in the area to prevent overexploitation. Many of these areas have been established through cooperation with fishing organizations and local governments and serve as a means to promote localized conservation and positive fishing experiences. A total of 51 SMZs have been designated off South Carolina, Georgia and Florida.

8.1.1.2 MPAs

(Source: Historical Overview of the South Atlantic Fishery Management Council's Marine Protected Areas Related Activities: 1990-2006)

The timeline below summarizes the Council's activities pertaining to the designation of Marine Protected Areas in the South Atlantic region from 1990 through 2006. This timeline highlights the transparency of the process that the Council undertook. For more information, including minutes from meetings and background documentation, please go to www.safmc.net.

1990 - The potential for using marine reserves within the snapper grouper fishery first originated with the Council's Snapper Grouper Plan Development Team (PDT). This technical group prepared a report (April 1990) entitled "The Potential of Marine Fishery Reserves for Reef Fish Management in the U.S. South Atlantic." The Plan Development Team offered this approach because they believed it was the only viable option for maintaining optimum size, age, and genetic structure of slow growing, long-lived species over the long-term. The Council received an extensive briefing on marine reserves at the February 1990 Council meeting. This provided an opportunity for the Council to discuss marine reserves as a concept and to hear about experiences with marine reserves in other parts of the world.

1992 - Marine reserves were initially considered as a possible option in early discussions on Amendment 4 to the Snapper Grouper Fishery Management Plan, however the Council determined the reserve concept should be addressed separately and scheduled scoping meetings in each of the states. During 1992 the Council held scoping meetings. Scoping meetings are less formal than public hearings and occur prior to the Council taking any position on a management issue. When the Council is considering the need for management, scoping meetings provide an opportunity for members of the public to make suggestions BEFORE the Council has made any decisions.

1993 - During the 1992 scoping process support for and against the concept surfaced. The Council reviewed the scoping information at the January 1993 meeting and decided to (1) recommend to National Marine Fisheries Service that they convene a Scientific Review Panel to review the concept of Marine Reserves and (2) drop consideration of the marine reserve concept at that time.

1994 - The previously designated Oculina Bank Habitat Area of Particular Concern (HAPC) off Ft. Pierce in eastern-central Florida was declared the Experimental Oculina Research Reserve (EORR). This area, measuring 4 x 23 nautical miles with depths between 30 and 75 fathoms, was closed to bottom fishing for a period of 10 years to allow for scientific studies in a closed area. The 10 year "sunset" was specified to ensure establishment of a proper research and evaluation program. In 1995, the closure was extended to include all anchoring within the boundaries of the experimental closed area. The area was closed to bottom fishing to enhance stock stability and increase recruitment by providing an area where deep water species (snowy grouper, golden tilefish, speckled hind and Warsaw, misty and yellowedge groupers) can grow and reproduce without being subjected to fishing mortality. Virtually any level of fishing mortality results in a large reduction in numbers of males and an altered size, age, and genetic structure. This effect is magnified when fishing in areas where these groupers gather for spawning.

Such spawning aggregations have been observed in the Oculina Habitat Area of Particular Concern.

1995 - A scientific review of the 1990 Snapper Grouper Plan Development Team report was completed by the Scientific Review Panel as requested by the Council. The panel consisted of international experts with different experience in fishery science, marine reserves, ecology, fish genetics, sociology, and economics.

The Scientific Review Panel concluded that properly designed marine reserves in combination with other management measures can be an effective management tool for reef fish resources in the U.S. South Atlantic region subject to the following conditions: (a) biological, ecological, social, and economic objectives of the reserves are clearly specified; (b) the relative biological, ecological, and economic impacts of reserves in the context of other fishery management measures have been estimated for various constituents; and (c) the development of marine reserve proposals proceed with the involvement of all constituencies and stakeholders.

Also the scientific review panel concluded that recognizing the alarming declines in stocks of key fishery species, the panel would urge that reserve options be considered immediately as part of a comprehensive fisheries management plan to prevent irreversible loss to species and fisheries.

1997 - In further developing Snapper Grouper Amendment 8 (and later Amendment 9), the Council realized that severe impacts would be felt by fishermen if necessary percentage reductions in catches of overfished species were imposed to achieve the mandated fishery management goals. Marine reserves once again surfaced as a potential alternative to fisheries closures.

Also in 1997 the Council accepted portions of the final Management Plan for the Florida Keys National Marine Sanctuary that designated one larger reserve that extended into the Council's jurisdiction and 12 small "preservation areas" that also function as marine reserves. These areas are being evaluated and will be reexamined at a five year review.

1998 - After deciding to reconsider the possibilities of marine reserves, the Council proceeded to take steps to initiate a fact-finding process using the Marine Reserves Committee and the Advisory Panel.

1999 - In May,, the Marine Reserves Advisory Panel unanimously passed a motion confirming that the Panel believes there is potential in using marine reserves as a fishery management tool.

2000 - The Council then laid out a deliberative process by which they would determine if marine protected areas were a tool that they should use to manage fisheries in the South Atlantic. This process included a series of informal meetings that Council members and staff attended in the spring of 2000. Any organizations that requested to could have a Council member and/or staff member come and talk with them about the potential use of marine protected areas. It was the Council's intent to begin a dialogue with stakeholders on ways to solve the overfishing problems in the South Atlantic Snapper Grouper Fishery and to ask the public if they thought marine protected areas may be one answer to a complex problem.

The stakeholders voiced many different opinions on the use of marine protected areas. There was an equal amount of support and opposition for no-take marine protected areas, but many variations were offered from all sides. Many groups were in support of protecting known spawning areas from fishing, and creating artificial habitats and prohibiting fishing in these areas. The responses the Council heard from the more formal scoping meetings they held later in the spring of 2000 were similar.

In September 2000, after reviewing comments received from the informal meetings and scoping meetings, the Council voted to move forward with the use of marine protected areas.

2001 through 2003 - In the Spring of 2001 the Council held a final round of nine scoping meetings. The public was provided charts that showed known hardbottom areas off the South Atlantic coast and was asked to use their experience and knowledge of snapper grouper species (specifically deepwater snapper grouper species) to suggest areas the Council may want to consider designating as marine reserves. As a part of this scoping process, the Marine Reserves Advisory Panel was asked to also suggest areas. As a result of this process over 40 sites were suggested and originally considered as potential marine reserves.

At their February 2001 meeting, the Council's Marine Reserves Committee discussed the difficulty managers and stakeholders were facing given that many different agencies were looking at marine reserves, marine sanctuaries, marine protected areas, etc. The different nomenclature associated with this management tool made things very confusing to the public and managers alike. The Committee determined that the term "marine reserves" was coming to imply an area that allowed no fishing. This was contrary to the Council's definition and intent. In order to be more consistent with national definitions the Council adopted the term Marine Protected Areas (MPAs).

During 2001 and into 2002 the Council, with help from its advisors, began working to determine which sites would best meet the Council's management objective to protect deepwater snapper grouper species. In August of 2001 the Council held an unprecedented "Mega-AP" meeting of the Habitat, Coral, Snapper Grouper, MPA, Law Enforcement, and Wreckfish Advisory Panels (APs). The APs were asked to help the Council select sites that would be the most beneficial for overfished, deepwater snapper grouper species using their various and vast knowledge, understanding that the Council's intent was to look at sites that protect more inshore snapper grouper species further down the line (that is, in the future).

Later in 2001 the Snapper Grouper Assessment Group, the Scientific and Statistical Committee, and the Snapper Grouper AP met with the Council's Snapper Grouper

Committee to provide additional input on possible MPA sites. Based on input from the SSC, APs, and the Snapper Grouper Committee, the Council instructed staff to develop an options paper for Snapper Grouper Amendment 14 with an initial level of analysis of sites the Council felt met the criteria of protecting overfished, deepwater snapper grouper species.

2004 - The sites that met the criteria of protecting overfished, deepwater snapper grouper species were included in the Informational Public Hearing Document and taken out to public hearings in early 2004. At those public hearings social and economic data were collected to help staff refine sites and analyze the impacts of the proposed sites. The information gathered at the Informational Public Hearings was useful in helping staff begin to assess the social and economic impacts of each individual site. It became clear that the location of a few of the sites may need to be tweaked in order to achieve the Council's goals and lessen social and economic impacts.

2005 - At their September 19-23 Council meeting in Charleston, South Carolina the Council voted to include MPAs as an approach to manage deepwater snapper grouper species in Snapper Grouper Amendment 13B. Of the nine sites originally proposed to be considered, only eight were to be included in Amendment 13B. The site not carried forward was a proposed artificial reef MPA two miles off the North Carolina coast. The Council felt that this site did not meet the criteria of protecting deepwater snapper grouper species.

At the December 5-9 Council meeting in Carolina Beach, North Carolina the Council voted to move consideration of MPAs into a separate Snapper Grouper Amendment 14 to address deepwater Type II MPAs.

2006 - At the March 2nd Council meeting in Jekyll Island, Georgia the Council reviewed a draft of Snapper Grouper Amendment 14 and approved motions to: (a) add a monitoring plan to the research needs section and (b) add alternatives to look at Vessel Monitoring Systems (VMS) for snapper grouper vessels with a snapper grouper permit and bottom longline gear onboard.

At their June 12-17, 2006 Council Meeting in Miami, Florida the Council approved Snapper Grouper Amendment 14 for public hearing. Council may want to consider designating as marine reserves. As a part of this scoping process, the Marine Reserves Advisory Panel was asked to also suggest areas. As a result of this process over 40 sites were suggested and originally considered as potential marine reserves.

2008 - On September 2, 2008 Snapper Grouper Amendment 14 was approved establishing deepwater MPAs in the South Atlantic region.

8.1.2 National Marine Sanctuaries

The National Marine Sanctuary Program (NMSP) is responsible for identifying, designating, and managing ocean and Great Lake areas of special national significance as national marine sanctuaries. Sanctuaries are managed to protect and conserve their resources and to allow uses that are compatible with resource protection. Management of sanctuaries is composed of a number of components:

- authorizing legislation (National Marine Sanctuaries Act - NMSA);
- regulations;
- management plans;
- management effectiveness programs;
- permitting;
- conservation policy; and
- strategic planning.

Legislation

The NMSA authorizes the existence of the NMSP, describes the purposes and policies of the NMSP, and provides authorization for appropriations. The NMSA is reauthorized every four to five years, allowing for updating and adaptation as necessary. While the NMSA provides the basis for everything else that follows, the NMSP must also develop regulations, management plans, policies, and operational procedures.

Regulations

Regulations represent the detailed implementation of the NMSA in the protection and conservation of sanctuary resources. Upon designation of a sanctuary or during a management plan review, site-specific regulations are issued that restrict a narrow range of activities, because an activity has already been found to be incompatible with the primary mandate of resource protection or is a proactive step necessary for the protection of a specific resource. The NMSP can also revise existing regulations or issue new regulations after the designation of a site. This may occur after a sanctuary has been in operation for several years and either a new activity is identified that did not exist prior to the sanctuary's designation, or new information about an existing activity reveals it is incompatible with resource protection or is resulting in user conflict. Under certain circumstances, the NMSP can also issue emergency regulations. Although the NMSP would generally seek non-regulatory means to address an issue, circumstances may warrant the issuance of a new regulation.

Management Plans

Management plans are site-specific documents that the NMSP uses to manage individual sanctuaries. Management plans:

- summarize existing programs and regulations;
- guide preparation of annual operating plans;
- articulate visions, goals, objectives, and priorities;
- guide management decision making;
- guide future project planning;

- ensure public involvement in management processes; and
- contribute to the attainment of system goals and objectives.

The NMSP has begun a comprehensive process that will lead to the review and possible revision of management plans at all 13 Sanctuaries. Reviews of management plans have been undertaken because:

- most existing management plans are 10 years old or older and evolving issues may not be adequately addressed;
- most existing management plans do not incorporate state-of-the-art concepts and practices associated with management of marine protected areas; and
- the NMSA has a statutory requirement that management plans should be reviewed on a periodic basis.

Management Effectiveness

Assessing management effectiveness (the achievement of a planned effort or action) is a critical element of the management of sanctuaries, and is done both internally by the NMSP and by external sources. It is part of routine sanctuary management efforts in order to foster a feedback loop that encourages an internal approach to problem solving and improved performance.

Internal Performance Evaluation

The NMSP has developed a suite of "program performance measures" to measure progress on several representative functions of the program dictated by the mandate of the National Marine Sanctuaries Act. Each sanctuary undergoing management plan review also develops site-specific performance measures that measure progress toward the goals and objectives of the individual sanctuary.

Performance evaluation contributes to the overall management process by:

- fostering the development of clear, concise problem statements and measurable outcomes;
- providing a tool that allows managers to comprehensively evaluate their sites in both the short and long term;
- allowing site staff to make decisions based on more accurate and relevant information;
- promoting accountability;
- supporting sanctuary efforts with an informed resource-allocation process; and
- motivating staff with clear policies and a focused direction.

Program performance measures are reported on and reviewed annually. The result of that effort is used in the internal resource-allocating process as a means to inform NMSP leadership on performance-based priorities.

External Evaluations on Management Effectiveness

Every few years, the NMSP commissions an external evaluation by an independent organization in order to obtain fresh insights, and to assess and support programmatic improvements in the broad operation of the NMSP. External evaluations work to help assess, adjust, and guide the NMSP. Five independent, external evaluations have been conducted on the NMSP since passage of the NMSA in 1972: the General Accounting Office in 1981, an External Review Team in 1993, the National Research Council (NRC) in 1997, and the National Academy of Public Administration in 2000 and 2006.

In 2004, the NMSP also completed the Program Assessment Rating Tool (PART), a government-wide performance evaluation process implemented by the Office of Management and Budget (OMB). The PART's primary function is to determine whether federal programs are meeting the mandated requirements identified for them in their enabling legislation and if mechanisms are in place to track their progress in doing so (namely, performance measures). The NMSP was "PARTed" with the Marine Protected Area Center (MPAC) under the rubric "NOAA Protected Areas Program." The NMSP will be "PARTed" again in the near future, following OMB's schedule for reviewing all federal agencies.

Permits
The NMSP has the authority to issue permits to allow some types of activities that are otherwise prohibited by sanctuary regulations, but which generally present a public benefit by furthering the management and protection of sanctuary resources. Permits usually include conditions that are designed to minimize or eliminate impacts to sanctuary resources. Permit conditions may also be included to minimize user conflict.

Conservation Policy
The NMSP conducts policy planning to provide a framework for the development of policies at both the national (system-wide) and individual sanctuary level. While this proactive approach to resource management is best, in reality most policies are developed in response to something that has already become a problem. The simple scale of some issues may seem prohibitive (e.g., invasive species), while in other cases the newness of an issue makes response difficult since little information may be available about its impacts (e.g., alternative energy). Policies are often used not only to address issues by themselves, but they also provide guidance in the use of other management tools, such as marine zoning, permits, and regulations. Sites should, for complex issues or those with broad national implications, work within the guidelines of national policies that have been or are being developed.

Strategic Planning
Since 2004, the National Marine Sanctuary Program has invested a great deal of staff time and effort in developing and implementing a comprehensive and efficient program planning, execution, and reporting system. This system is coordinated by the Senior Policy Advisor for Strategic Planning and Program Integration and the NMSP Strategic Planning Team (SPT), which has representatives from all HQ units, regions, and cross cutting programs across the NMSP. Although originally established to institutionalize the annual operating plan process and the structure and operations that support it, the

overall purpose of the SPT now is to facilitate the NMSP strategic planning process and provide information on areas of subject matter expertise, while thinking about innovative ways to better integrate operations of the NMSP. Specifically, the SPT focused in three areas:

1) NMSP planning and operations -- refining the NMSP AOP process, schedule and components

2) Agency-level budget and administrative requirements – integrating NMSP activities and requirements within the Coastal and Marine Resource Program (CMRP), Ecosystem Goal Team, and other NOAA matrix/goal teams.

3) Emerging opportunities – responding to high priority activities or issues that must be addressed due to high visibility or public expectations.

8.1.2.1 Gray's Reef

Gray's Reef National Marine Sanctuary (GRNMS) started reviewing its existing management plan in 1999. As part of the process, the Sanctuary Advisory Council was formed in August 1999. By 2001, the council consisted of 11 members representing education, research, sport diving, sport fishing, conservation, and selected government agencies. Since then, additional members have been added to the council representing charter/commercial fishing and two governmental seats.

Once in place, the advisory council and sanctuary staff considered the original list of GRNMS goals and objectives from the 1983 plan, and modified them to be consistent with the most recent reauthorization of the National Marine Sanctuaries Act (2000), as well as contemporary issues.

The management plan review process also relied on active public participation. In addition to producing a revised plan, the process brought together diverse stakeholder interests and expertise to shape and support new program directions that address current priority resource issues and conservation objectives.

Eight public scoping meetings were held at which sanctuary users, members of the public and agencies identified issues and problems they said they thought GRNMS might be able to address. Approximately 2,000 people made comments on the draft plan. They expressed concerns and provided recommendations in person and via fax, telephone and email. The comments were incorporated into a summary report which was presented to the advisory council and distributed to all participants, the media, and other interested parties. Seven additional, separate public meetings were held to review the draft plan. The final GRNMS management plan is available at
http://graysreef.noaa.gov/management.html

8.1.2.2 Florida Keys

The Florida Keys National Marine Sanctuary (FKNMS) was designated in accordance with the National Marine Sanctuaries Act (NMSA). Regulatory and enforcement powers of National Marine Sanctuaries are specified in the Act. The National Oceanic and Atmospheric Administration (NOAA) has been assigned responsibility for managing the nation's National Marine Sanctuaries and has developed regulations uniquely suited to protect the resources at each sanctuary. The primary regulations governing management of the FKNMS are described in the United States Code of Federal Regulations, Title 15, Part 922.

Ecological Reserves (ER's): Western Sambo and Tortugas. In addition to Sanctuary-wide regulations, special regulations have been set in place in these areas in order to protect resources.

Sanctuary Preservation Areas (SPA). There are 18 small SPAs that protect popular shallow coral reefs. In addition to Sanctuary-wide regulations, special regulations have been set in place in these areas in order to protect resources. Activities that will be prohibited in the Sanctuary Preservation Areas include spearfishing, shell collecting, tropical fish collecting, fishing and other activities that result in the harvest of marine life by divers, snorkelers, and fishermen. In addition, direct physical impact to corals in these areas is restricted.

Wildlife Management Areas (WMA). There are 27 WMA's. The majority of these areas (20) fall under the jurisdiction of the U.S. Fish and Wildlife Service (USFWS) and Sanctuary regulations have been established to complement the existing USFWS management plan. Public access restrictions in these areas include idle speed only/no wake, no access buffer, no motor, and limited closures.

Existing Management Areas (EMA). Sanctuary regulations have been established to complement those in existing management areas, including Looe Key and Key Largo Management Areas as well as the Great White Heron and Key West National Wildlife Refuges, and all the State Parks and Aquatic Preserves.

Special Use Areas. There are four areas designated: Conch Reef, Tennessee Reef, Looe Key (patch reef), and Eastern Sambo Reef. These are all designated as research-only areas. No person may enter these areas except as specifically authorized by a valid permit.

The FKNMS Management Plan is available at
http://floridakeys.noaa.gov/regs/welcome.html

8.1.2.3 Monitor

Management of the Monitor National Marine Sanctuary is composed of a number of components including authorizing legislation, regulations, management plans and permitting. Management plans are site-specific documents that the NMSP uses to manage individual sanctuaries. Sanctuaries are managed to protect and conserve their resources and to allow uses that are compatible with resource protection. The public management plan review process will begin for the Monitor NMS in 2008.

8.1.3 Minerals Management Service

8.1.3.1 OCS Leasing

(from MMS website: http://www.mms.gov/5-year/2007-2012main.htm#Proposed_Program)
The OCS Lands Act requires the Department of the Interior (DOI) to prepare a 5-year program that specifies the size, timing and location of areas to be assessed for Federal offshore natural gas and oil leasing. It is the role of DOI to ensure that the U.S. government receives fair market value for acreage made available for leasing and that any oil and gas activities conserve resources, operate safely, and take maximum steps to protect the environment.

OCS oil and gas lease sales are held on an area-wide basis with annual sales in the Central and Western Gulf of Mexico with less frequent sales held in the Eastern Gulf of Mexico and offshore Alaska. The program operates along all the coasts of the United States - with oil and gas production occurring on the Gulf of Mexico, Pacific and Alaska OCS. The MMS is also responsible for other mineral production offshore, which currently includes using sand and gravel for coastal restoration projects.

The following planning areas are still subject to a 1998 Presidential withdrawal from leasing through June 30, 2012, under the authority of Section 12 of the OCS Lands Act (43 USC 1341). All but North Aleutian Basin, Alaska, are also subject to annual Congressional moratoria, some from as early as Fiscal Year (FY) 1982:

- Washington-Oregon
- Northern, Central and Southern California
- Eastern Gulf of Mexico, except for the portion located off Alabama and more than 100 miles off Florida that was proposed, but not offered, for Lease Sale181 in 2001
- South, Mid and North Atlantic

In addition, in 1998 President Clinton withdrew indefinitely all National Marine Sanctuaries.

The first Congressional moratorium was enacted in FY 1982, prohibiting leasing off the Central and Northern California coast. In 1984, Southern California, the North Atlantic, and part of the Eastern Gulf Of Mexico, basically south of the 26 degree N latitude, were subject to moratoria. In FY 1990, the North Aleutian Basin, Alaska, and the Mid-Atlantic became moratoria areas. Washington/Oregon and the Florida Panhandle area of the Easter Gulf of Mexico were added to the moratoria list in FY 1991. The South

Atlantic was added in 1992. These areas have been continued to be subject to annual congressional moratoria, with the exception of the North Aleutian Basin, Alaska, which has not been included since FY 2004.

8.1.4 Environmental Protection Agency

8.1.4.1 ODMDSs

In 1972, Congress enacted the Marine Protection, Research, and Sanctuaries Act (MPRSA) to prohibit the dumping of material into the ocean that would unreasonably degrade or endanger human health or the marine environment. The MPRSA, also known as the Ocean Dumping Act, implements the requirements of the London Convention, which is the international treaty governing ocean dumping.

Virtually all material dumped in the oceans off the United States today is dredged material. Other materials that are currently ocean-disposed include fish wastes, human remains, and vessels. Certain materials, such as high-level radioactive waste, medical waste, sewage sludge, and industrial waste, may not be dumped in the ocean.

Ocean dumping cannot occur unless a permit is issued under the MPRSA. In the case of dredged material, the decision to issue a permit is made by the U.S. Army Corps of Engineers (COE), using the Environmental Protection Agency's (EPA) environmental criteria and subject to EPA's concurrence. For all other materials, EPA is the permitting agency. EPA is also responsible for designating recommended ocean dumping sites for all types of materials (http://www.epa.gov/Region4/water/oceans/).

Site Selection of ODMDS's

Twenty-one commercial ports and four military ports are located within EPA Region 4. Millions of cubic yards of sediments are dredged from these ports each year, much of which is disposed in the ocean off the southeastern United States. Regulation of dredged material disposal within ocean waters in the southeast is a shared responsibility of EPA Region 4 and the COE South Atlantic Division. Under the MPRSA, the COE is the permitting authority for the proposed disposal of dredged material. Permits for ocean disposal of dredged material are subject to EPA review and concurrence. EPA is also responsible for designating and managing ocean disposal sites for dredged material.

Most of the dredged material disposed in the ocean is disposed at ocean dumping sites specifically designated by EPA for dredged material disposal under section 102 of the Marine Protection, Research, and Sanctuaries Act (MPRSA). EPA designated sites are to be used for ocean disposal to the extent feasible.

All ocean dumping sites (Figure 1) are required to have a site management and monitoring plan (SMMP). Appropriate management of ocean dumping sites is aimed at assuring that disposal activities will not unreasonably degrade or endanger human health, welfare, the marine environment or economic potentialities.

Management of ocean dredged material disposal sites involves:

1. Regulating the times, the quantity, and the physical/chemical characteristics of dredged material that is dumped at the site;
2. establishing disposal controls, conditions, and requirements to avoid and minimize potential impacts to the marine environment; and
3. monitoring the site environs to verify that unanticipated or significant adverse effects are not occurring from past or continued use of the disposal site and that permit terms are met.

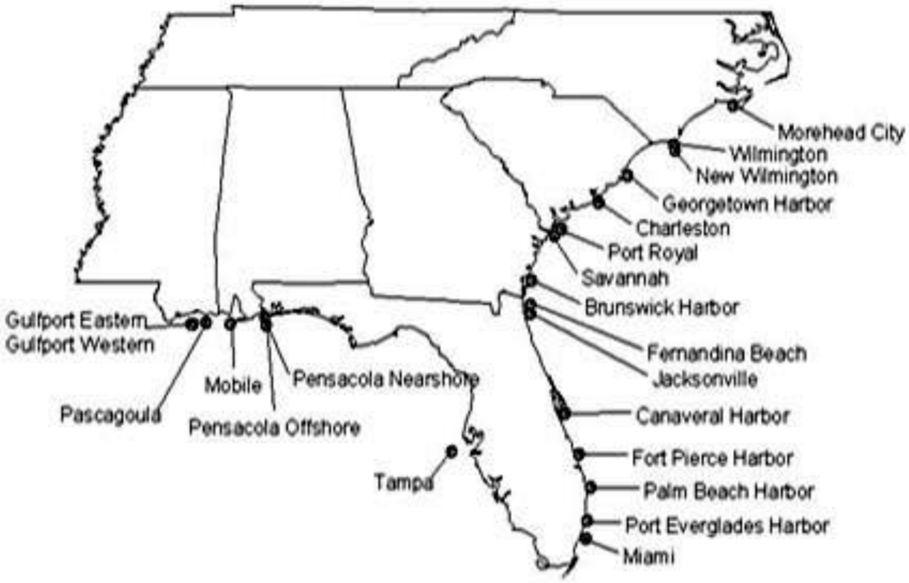

Figure 8.1-1. Disposal sites in the Southeast
(http://www.epa.gov/Region4/water/oceans/sites.html).

Permitting Procedures
Marine Protection, Research and Sanctuaries Act (MPRSA) Section 103 permits for the ocean dumping of dredged materials are issued by the Corps of Engineers (COE) subject to EPA approval. The COE District office is responsible for coordination of all federal actions, including EPA concurrences, pertaining to MPRSA Section 103 applications. All applications should be coordinated with EPA Region 4. Applicants are encouraged to arrange for a pre-application conference with the District and EPA in order to fully understand the process and requirements for obtaining the permit. EPA will not approve the permit unless the proposed dredged material has been shown to meet the ocean dumping criteria. Data requirements for ensuring this compliance can be extensive and the permitting process typically takes from 6 to 18 months (http://www.epa.gov/Region4/water/oceans/).

The permit process is outlined below and consists of 10 main steps:
Pre-application Consultation: Includes discussion of alternatives and the information required for use in evaluating the proposed dredged material.

Evaluation of Dredged Material Proposed for Ocean Disposal: Includes development, approval and implementation of a sampling and analysis plan and an assessment of compliance with the ocean dumping criteria.

Permit Application: Title 33 Code of Federal Regulations Part 325.1 (33 CFR 325.1) describes the requirements of the permit application. In addition, the application should include:

a. An evaluation of dredged material disposal alternatives including an examination of potential beneficial uses of the proposed dredged material.
b. Written documentation of the site dredging history and a general survey of other prior or current dredging activities at or near the site.
c. References to existing or prior MPRSA Section 103 permits.

Review of Application for Completeness: Additional information is requested if the application is incomplete.

Issuance of Public Notice by District: Public Notices must include all of the information required in 33 CFR 325.3(a)

EPA Review: EPA has 45 days with an optional additional 45 day extension to review the information and to determine compliance with the ocean dumping criteria. If additional information is needed, EPA has 30 days to request that information.

District Engineer Completes Evaluation: The COE addresses comments and holds a public meeting if needed.

Public Interest Review: The COE considers all comments and incorporate them into the administrative record of the application.

Permit Issued: A decision to issue or deny a permit is discussed in either a Statement of Findings or Record of Decision and the permit is issued.

Permit Public Notice: A list of permit decisions is published.

Evaluation of dredged material for ocean disposal under the MPRSA relies largely on biological (bioassay) tests. The ocean testing manual, commonly referred to as the Green Book, provides national guidance for determining the suitability of dredged material for ocean disposal. Regional guidance is provided in the EPA Region 4 - U.S. Army Corps of Engineers South Atlantic Division Regional Implementation Manual PDF (RIM) (http://www.epa.gov/Region4/water/oceans/).

The Green Book sets out a framework containing the procedures approved by EPA and the Corps for evaluating the dredged material. The framework provides that the intensity of evaluation increases with the risk of contaminants and/or absence of existing information. If an evaluation in one level (tier) is not adequate to determine the material's suitability for ocean disposal, the evaluation proceeds to the next tier(s), and the protocols of the next tier(s) must be followed (Appendix K, SAFMC 1998a).

The following is a general summary of the testing and evaluation procedures included in each tier:

Tier I - Evaluation of Existing Information
Tier I specifies when and how existing information, such as results from previous tests on the material, can be used to evaluate the material. If the existing information is inadequate, the evaluation must go to the next tier(s).

Tier II - Conservative Screening Tools
Tier II specifies when and how sediment chemistry can be used in evaluating material by using worst case water column modeling and Theoretical Bioaccumulation Potential (TBP) calculations for the dredged material. (Because there is no model for evaluating toxicity, all sediments entering Tier II must also be tested for toxicity in Tier III.) The 1991 manual includes updated scientific models for evaluating compliance with water quality criteria issued by EPA to help protect marine species. The dumping must meet the applicable water quality criteria. The 1991 manual includes use of TBP, which is a scientifically valid approach for evaluating the potential bioaccumulation of certain specific, non-ionic compounds (such as PCBs and dioxin). There is no counterpart model available for metals or polar compounds so if their presence is a concern, actual bioaccumulation testing in Tier III is still necessary.

Tier III - Laboratory Bioassays
Tier III specifies approved testing procedures for toxicity and bioaccumulation. The acute toxicity tests employ 10 day exposures. The 1991 manual stresses the use of amphipods, which are sensitive bottom-dwelling organisms, and describes standardized test methods that were not available when the 1977 manual was developed. The bioaccumulation tests employ 28 day exposures if contaminants with the potential to bioaccumulate are present in the material. The 1977 manual specified 10 day exposures for all compounds. Use of 28 day exposures to assess bioaccumulation of contaminants was found to be more appropriate.

Tier IV - Advanced Biological Evaluations
Tier IV consists of laboratory and field tests and other evaluations to reduce specific uncertainties about the potential impacts of proposed projects. Tests conducted under this tier are not considered routine in the regulatory program, and can require significant time and expense.

The Green Book includes evaluation methods which can be tailored to the material and location. This is intended to ensure that material is adequately evaluated to make a scientifically sound decision regarding the potential environmental impacts of the proposed ocean dumping, without requiring unnecessary or inappropriate tests in any given case.

Corps Districts and EPA Regional offices work together to develop Regional Implementation Manuals providing supplemental site-specific refinements to the national guidance, such as: identifying the contaminants of concern for the harbors within the region; and identifying the specific species of organisms to be tested (from the list of organisms in the national manual). Testing procedures used to evaluate ocean dumping must be approved by EPA and the Corps. No permit is issued unless the agencies have enough information to determine that the ocean dumping will not cause significant harmful effects. (Appendix K, SAFMC 1998a)

8.1.4.2 National Estuary Program

As part of the 1987 amendments to the Clean Water Act, Section 320 National Estuary Program (NEP) promotes comprehensive planning efforts to help protect nationally significant estuaries in the United States that are deemed to be threatened by pollution, development, or overuse. Since the inception of the program, 28 estuaries have been nominated by their respective state Governors and officially designated as NEP estuaries (National Estuary Program Coastal Condition Report, Executive Summary, June 2007). As one of the U.S. EPA most successful watershed programs, the NEP demonstrates the effectiveness of a stakeholder-driven, collaborative process to address water quality problems and to target habitat restoration. Individual NEPs are required to monitor the effectiveness of their management activities to address estuary-specific priority actions. The Clean Water Act also requires that EPA report periodically on the condition of the nation's estuarine waters. Coastal states provide EPA with valuable information about the condition of their estuarine resources; however, because the individual states, the NEPs, and their partners use different approaches for data collection and the evaluation of estuarine condition, it has been difficult to compare this information among states, NEPs, or on a regional or national basis (National Estuary Program Coastal Condition Report, Executive Summary, June 2007).

The purpose of the NEP is to identify, restore, and protect the nationally significant estuaries of the United States. The southeast coast is home to two NEP estuaries: the Albemarle-Pamlico Estuarine Complex and the Indian River Lagoon (National Estuary Program Coastal Condition Report, Chapter 4: Southeast National Estuary Program Coastal Condition, June 2007).

Albemarle-Pamlico National Estuary Program (APNEP)

The Albemarle-Pamlico Estuarine Complex drains approximately 30,000 mi^2 of watershed and comprises the largest lagoonal estuarine system in the United States. This NEP has a 23,000-mi^2 study area that extends south from Prince George County, VA, to Carteret County, NC, and includes 7 sounds (Albemarle, Bogue, Core, Croatan, Currituck, Pamlico, and Roanoke) (APNEP, 2006) (National Estuary Program Coastal

Condition Report, Chapter 4: Southeast National Estuary Program Coastal Condition, Albemarle-Pamlico National Estuary Program, June 2007).

The Albemarle-Pamlico Estuarine Complex NEP study area contains large tracts of forested and undeveloped land, including 11 National Wildlife Refuges (e.g., Great Dismal Swamp, Back Bay, Mackay Island, Currituck, Roanoke River, Alligator River, Pocosin Lakes, Pea Island, Mattamuskeet, Swan Quarter, and Cedar Islands). The Complex's watershed also contains the Cape Lookout and Cape Hatteras National Seashores; the Croatan National Forest; and many state-owned parks, forests, and research reserves (Martin et al. 1996). In addition, several U.S. Department of Defense (DoD) lands are located in this watershed.

Freshwater inputs to this system are provided by five major rivers — the Pasquotank, Chowan, and Roanoke rivers that flow into Albemarle Sound and the Tar-Pamlico and Neuse rivers that flow into Pamlico Sound. This region features a variety of habitat types, including significant pocosins (southeastern shrub bogs), pine savannahs, hardwood swamp forests, bald cypress swamps, salt marshes, brackish marshes, freshwater marshes, and beds of submerged aquatic vegetation (SAV) (Martin et al. 1996). On the eastern side of the Albemarle-Pamlico Estuarine Complex, a chain of islands forms a barrier with the Atlantic Ocean. The Complex is uniquely characterized by random wind-driven tides, which result in less predictable variations in water circulation and salinity patterns (Focazio 2006a). Economically, this estuarine system represents the southeast region's key resource base for commercial fishing, tourism, recreation, and resort development. Economic benefits are also derived from the use of the area's natural resources for mining, forestry, and agriculture (APNEP 2006).

The Albemarle-Pamlico National Estuary Program (APNEP) was among the first NEPs established by EPA in 1987. Its overall condition is good to fair based on the four indices of estuarine condition used by the NCA (National Coastal Assessment). The water quality index for the Complex is rated good, the sediment quality and fish tissue contaminants indices are rated good to fair, and the benthic index is rated fair. However, factors such as chlorophyll a, dissolved oxygen, and sediment quality may signal declining health, especially in some tributary river areas.

The APNEP continues to work toward fulfilling its goals and has already seen some major accomplishments, including the following:

- Restoration of more than 1,100 miles of anadromous fish habitat through the removal of three dams.
- Enhancement of interagency and interstate coordination through creation of the APNEP.
- Organizational restructuring to promote region-wide interstate citizen involvement through collaboration and coordination.
- Development of bycatch reduction gear (e.g., sea turtle exclusion devices) and practices to reduce fisheries impacts.

- Restoration of two miles of riparian habitat along the Roanoke River through livestock fencing and riverbank-stabilization practices (APNEP 2006).

Indian River Lagoon National Estuary Program

The Indian River Lagoon is located along Florida's east coast and stretches 156 miles from Volusia County to Palm Beach County, FL. This area comprises one of the most diverse estuaries in North America and one of Florida's most popular fishing destinations, with more than 1 million anglers visiting the Lagoon area each year (U.S. EPA 2000c). The Lagoon and its surrounding watershed include a wide variety of habitats that support a diverse assemblage of plants and animals (SJRWMD 2004). These habitats range from xeric scrub through pine flatwoods, tropical and temperate hardwood hammocks, salt marshes, mangrove swamps, and other intertidal communities such as seagrass meadows and other SAV communities (Hill 2002) (National Estuary Program Coastal Condition Report, Chapter 4: Southeast National Estuary Program Coastal Condition, Indian River Lagoon National Estuary Program, June 2007).

This region's broad diversity of habitats support more than 4,300 different species, including 700 saltwater and freshwater fish species and 310 bird species (SJRWMD 2004). Thirty-six of the species found in this region are classified as threatened or endangered, including the southeastern beach mouse, Atlantic saltmarsh snake, bald eagle, and Florida scrub jay (SJRWMD 2004; U.S. EPA 2006d). In addition, an estimated one-third of Florida's endangered West Indian manatees live in the Indian River Lagoon.

Commercially, the estuary is one of the most important waterways in Florida and is a productive nursery ground for an estimated $300 million in annual commercial fishing revenues, including $100 million from inshore species. The Indian River Lagoon accounts for 50% of Florida's total East Coast fisheries landings (SJRWMD 1994). Also, tourism and recreation contribute $540 million to the local economy, and the influx of tourists and part-time residents to the area is considerable (SJRWMD 2002).

In 1987, the Florida Legislature passed the Surface Water Improvement and Management (SWIM) Act, which designated the Indian River Lagoon as a priority water body in need of restoration and special protection (Florida Statutes, Chapter 373.451–373.4595). Created in 1990, the Indian River Lagoon NEP (IRLNEP) fosters active participation by other federal agencies, notably the FWS, NASA, and USACE. It also manages a local government cost-share program that assists counties and municipalities with planning and implementing pollution-abatement projects, typically small-scale efforts with an emphasis on stormwater treatment. For instance, both the St. John's River Water Management District (SJRWMD) and South Florida Water Management District (SFWMD) focus on projects designed to improve water and sediment quality, restore or enhance the seagrass community in the Lagoon, or rehabilitate wetlands, recovering many of the natural functions of these areas.

The overall condition of the Indian River Lagoon is rated good based on three of four indices of estuarine condition used by the NCA. The water quality, sediment quality, and benthic indices were each rated good for the Indian River Lagoon, and data was unavailable to calculate the fish tissue contaminants index for this estuary.

The greatest tangible improvement to date in the Indian River Lagoon is the hydrologic reconnection of more than 23,000 acres of impounded wetlands since 1989 under the SWIM Act (in addition to nearly 5,000 acres reconnected through other programs). These impoundment reconnections restore many natural functions provided by salt marshes and mangrove wetlands (Steward et al. 2003).

There is also a noticeable increase in public awareness of the Lagoon's problems and its ecology, as well as an understanding of the projects that are underway to benefit the Lagoon's recovery and management. Much has been accomplished, but the IRLNEP recognizes that more work remains to be done to reach restoration targets established for seagrass and coastal wetlands. Preventative safeguards, vigilance, and education are needed to ensure that achievements in addressing problems in the Indian River Lagoon are maintained and that progress continues in protecting and restoring the water quality and natural resources of the Lagoon (Steward et al. 2003).

There is also progress taking place within the Indian River Lagoon watershed. More than 56,000 acres of wetlands and uplands have been acquired for various purposes (such as water quality remediation projects and habitat preservation). The various agencies and local governments with jurisdiction over the Indian River Lagoon basin have made advancements in ending discharges of treated wastewater, removing harmful muck deposits, and making incremental improvements in stormwater management throughout the basin.

In recent years, the IRLNEP has tackled some of the most important and controversial issues to address pollution in the Indian River Lagoon basin including addressing the impact of septic tanks on water quality, promoting the acquisition of environmentally sensitive lands, promoting the development of regional stormwater management plans, and participating in the development of local management plans for threatened and endangered species.

Some of the ongoing goals of the IRLNEP include:

- Attaining and maintaining water and sediment of sufficient quality to support a healthy, macrophyte-based estuarine Lagoon ecosystem.
- Attaining and maintaining a functioning macrophyte-based ecosystem that supports endangered and threatened species, fisheries, and wildlife.
- Improving the understanding and management of impacts of invasive and exotic species and the emerging challenges to aquatic animal health.
- Achieving heightened public awareness and coordinated interagency management of the Indian River Lagoon ecosystem (Steward et al. 2003).

Based on data collected by the NCA, the overall condition of the Indian River Lagoon is rated good. In general, the IRLNEP considers seagrass coverage in the Indian River Lagoon to be a key indicator of trends in environmental condition. Areas with good seagrass coverage are located adjacent to fairly undeveloped watersheds or close to inlets, whereas areas of extensive SAV loss and sparse seagrass are adjacent to highly developed watersheds or shoreline areas. The areas with poorest water quality are Cocoa to Melbourne/Palm Bay, the southern Banana River, and the Vero Beach, Fort Pierce, and St. Lucie River areas. Areas of the Indian River Lagoon adjacent to larger tributaries and major drainages systems experience elevated levels of nutrients and total suspended solids.

(All cited references found in National Estuary Program Coastal Condition Report, Appendix & Back Cover, June 2007)

8.1.6 National Estuarine Research Reserves

(Information from the NERR web pages http://www.nerrs.noaa.gov/welcome.html)
The National Estuarine Research Reserves System is a network of 27 areas representing different biogeographic regions of the United States that are protected for long-term research, water-quality monitoring, education and coastal stewardship. Established by the Coastal Zone Management Act of 1972, as amended, the reserve system is a partnership program between the National Oceanic and Atmospheric Administration and the coastal states. NOAA provides funding, national guidance and technical assistance. Each reserve is managed on daily basis by a lead state agency or university, with input from local partners.

North Carolina
In North Carolina the reserve is comprised of 10,000 acres in four sites located near Corolla (Currituck Banks), Beaufort (Rachel Carson) and Wilmington (Masonboro Island and Zeke's Island).

The North Carolina National Estuarine Research Reserve encourages researchers from universities and government laboratories to use the four sites for short or long-term investigations that will promote better understanding and management of estuaries. Data from monitoring stations, an annotated bibliography of work done on each site, species lists and GIS maps are offered to participating investigators. Projects have been completed on such diverse topics as estuarine eutrophication, productivity of benthic microalgae, use of dredge material to renourish salt marshes and effects of feral horses on salt marsh productivity.

The Graduate Fellows Program of the National Estuarine Research Reserve System fosters graduate student use of the reserves for their research projects. Fellows then contribute to other current reserve programs.

The research office initiates and conducts research into the dynamics of estuaries. Two ongoing projects are: 1) a Habitat Assessment Tool that can gather water quality data for a large body of water by the use of a towed instrument and 2) the National Telemetry Project that will provide real-time weather and water quality data accessibility throughout the National Estuarine Research Reserve System.

South Carolina

The North Inlet-Winyah Bay reserve encompasses 12,327 acres located in Georgetown County, SC. The reserve features the salt marshes and ocean dominated tidal creeks of the North Inlet Estuary plus the brackish waters and marshes of the adjacent Winyah Bay Estuary. North Inlet is a relatively pristine system in which water and habitat quality are much higher than those in Winyah Bay. As the estuary with the third largest watershed on the east coast, Winyah Bay has been greatly influenced by agriculture, industry and other human activities. More than 90% of North Inlet's watershed is in its natural forested state

The reserve is home to many threatened and endangered species, including sea turtles, sturgeons, least terns and wood storks.

Reserve resources range from tidal and transitional marshes to oyster reefs, beaches, and inter-tidal flats and from coastal island forests to open waterways.

More than 90 research and environmental monitoring projects involving more than 70 scientists are currently underway within the reserve. Long-term ecological data collections initiated more than 20 years ago continue to provide insights into patterns and mechanisms of both natural and human-related change in the estuaries. University based researchers use the System-wide Monitoring Program data to support field and laboratory studies, which range from the molecular to ecosystems level.

The Ashepoo-Combahee-Edisto (ACE) Basin reserve comprises134,710 acres located in Colleton, Charleston, Beaufort and Hampton counties. The ACE Basin is one of the largest undeveloped estuaries on the East Coast. The Ashepoo, Combahee and Edisto rivers, meander past cypress swamps, historic plantation homes, old rice fields and abundant tidal marshes to meet at South Carolina’s biologically rich St. Helena Sound.

The ACE Basin National Estuarine Research Reserve protects the natural beauty, abundant wildlife and unique cultural heritage of the area. In addition, the reserve preserves habitat for many endangered or threatened species, such as shortnose sturgeon, wood storks, loggerhead sea turtles and bald eagles.

Research conducted at the ACE Basin Reserve enhances the protection of these commercial and recreational uses by monitoring water quality, providing information on the abundance and types of important plant and animal species, and evaluating the overall health of the ACE Basin ecosystem.

Through a variety of educational programs, the reserve provides timely information to coastal decision makers, lawmakers, teachers, students and the general public. The reserve sponsors a summer lecture series, develops curriculum materials for teachers, offers a touch tank program for children and conducts educational cruises where students and teachers learn about estuaries and their values to marine life.

Georgia

The Sapelo Island National Estuarine Research Reserve, comprising 6,110 acres, is a coastal plain estuary, protected on its seaward side by a Pleistocene barrier island.

Sapelo Island is the fourth largest Georgia barrier island and one of the most pristine. The reserve is made up of salt marshes, maritime forests and beach dune areas. Not only is the island rich in natural history, but also in human history dating back 4,000 years.

The Sapelo Island Reserve habitats include a sand-sharing system comprised of shoreface, foreshore, backshore and dune components; an extensive band of salt marsh (comprising two-thirds of the reserve) and some 2,300 acres of upland forest, dominated by stands of oak hardwoods and pines.

Florida

The Guana Tolomato Matanzas National Estuarine Research Reserve encompasses approximately 55,000 acres of salt marsh and mangrove tidal wetlands, oyster bars, estuarine lagoons, upland habitat and offshore seas in northeast Florida. It contains the northern most extent of mangrove habitat on the east coast of the United States.

The coastal waters of the GTM Reserve are important calving grounds for the endangered Right Whales. Manatees, wood storks, roseate spoonbills, bald eagles and peregrine falcons also find refuge in the reserve.

The reserve is geographically separated into a northern section where the Tolomato and Guana rivers mix with the waters of the Atlantic Ocean, and a southern section along the Matanzas River, extending from Moses Creek south of Pellicer Creek. The unique Matanzas Inlet is one of the last natural, unaltered inlets on Florida's Atlantic coast.

The GTM estuary is rich with scenic beauty and economic value as it produces or supports the vast majority of the commercially and recreationally valuable fish and shellfish found in the region. The submerged lands, marshes, islands and conservation lands provide important habitat for a diversity of plants and animals, including the migrating birds stopping along the Atlantic Coastal Flyway.

Data generated from the research programs are used to assess the health of the ecosystem and guide future research efforts.

Visiting scientists utilize on-site field station for systems and baseline studies of the plant and animal communities of the reserve.

Long-term ecological monitoring efforts of the GTM Reserve include water quality monitoring (physical, chemical and biological), and meteorological and tidal conditions.

Geographic Information System (GIS) data and remote sensing are used to analyze natural resources within the reserve and human use of the coastal area.

Special Report No. 88
of the

Atlantic States Marine Fisheries Commission

Working towards healthy, self-sustaining populations for all Atlantic coast fish species or successful restoration well in progress by the year 2015

Prioritized Research Needs in Support of Interjurisdictional Fisheries Management

2008

Atlantic States Marine Fisheries Commission
Prioritized Research Needs
in Support of Interjurisdictional Fisheries Management

Prepared by Melissa Paine
Scientific Committee Coordinator

with assistance of the
Management and Science Committee

A report of the Atlantic States Marine Fisheries Commission pursuant to U.S. Department of Commerce, National Oceanic and Atmospheric Administration Award Nos. NA07 FGO 024 and NA03NMF4740078.

Acknowledgments

The Atlantic States Marine Fisheries Commission (Commission) would like to thank all state, federal and university representatives who contributed to the completion of this document. Identification and prioritization of research needs was provided by members of various Commission committees, including species stock assessment subcommittees, technical committees, advisory committees, plan development and review teams, and management boards. Input was also provided by the Commission's Habitat Committee, Committee on Economics and Social Sciences, and Management and Science Committee. The research needs topics listed in this publication are consistent with those developed by the National Marine Fisheries Service Northeast Fisheries Science Center for organization and classification of Stock Assessment Workshop/Stock Assessment Review Committee (SAW/SARC) research recommendations.

The Commission extends its appreciation to the members of the Management and Science Committee for providing oversight to the effort to identify and prioritize Commission research needs.

Table of Contents

Introduction

Research needs listed in this document were identified from Atlantic States Marine Fisheries Commission (Commission) fishery management plans and amendments, annual plan reviews, special reports conducted by the Commission on species technical and stock assessment issues, Stock Assessment Workshop (SAW) documents conducted by the National Marine Fisheries Service (1996 - 1999), and Commission external peer reviews. This publication is an update of Special Report #62 Prioritized Research Needs in Support of Inter-jurisdictional Fisheries Management published by the Commission in January 1997. Updates are periodically published via the Commission's website at www.asmfc.org.

Research needs were prioritized by Commission stock assessment subcommittees and technical committees under the purview of the Plan Development/Review Teams. Additional input to priorities is provided periodically by Advisory Committees, Management Boards, the Habitat Committee, the Committee on Economics and Social Sciences, and the Management and Science Committee. The prioritized research needs in this document should not supplant any prioritization conducted by Commission technical committees or management boards on an annual basis, or in any way hinder the management process.

It is the intent of the Commission to periodically update this document as research needs are either met or as new research needs are identified. Research needs that have been met since previous publication of this document have been moved to a separate section for each species and appropriate references have been included. The overall purpose of this document is to encourage state, federal and university research programs to develop projects to meet the research needs of Commission-managed species and thereby improve the overall management of these fisheries. It also hoped that state, federal and non-profit organizations will utilize this document in prioritization of research projects for future funding programs.

American Eel

High Priority

- A coastwide fishery-independent sampling program for yellow and silver American eels should be formulated using standardized and statistically robust methodologies.
- Regular periodic stock assessments and establishment of sustainable reference points for eel are required to develop a sustainable harvest rate in addition to determining whether the population is stable, decreasing, or increasing.
- A stock assessment committee should identify the best stock assessment methods for American eel.[1]
- Research the effects of swim bladder parasite *Anguillacolla crassus* on the American eel's growth and maturation, migration to the Sargasso Sea, and the spawning potential.
- Investigate, develop, and improve technologies for American eel passage upstream and downstream at various barriers for each life stage. In particular, investigate low-cost alternatives to traditional fishway designs for passage of eel.
- Investigate: fecundity, length, and weight relationships for females throughout their range; growth rates for males and females throughout their range; age and maturity data

Medium Priority

- Evaluate the impact, both upstream and downstream, of barriers to eel movement with respect to population and distribution effects. Determine relative contribution of historic loss of habitat to potential eel population and reproductive capacity.
- Investigate survival and mortality rates of different life stages (leptocephalus, glass eel, yellow eel, and silver eel) to assist in the assessment of annual recruitment. Continuing and initiating new tagging programs with individual states could aid such research.
- Tagging Programs: A number of issues could be addressed with a properly designed tagging program. These include:
    - Local and regional movement and migration patterns
    - Natural, fishing, and/or discard mortality; survival
    - Growth
    - Validation of aging method(s)
    - Abundance
    - Reporting rates
    - Tag shedding or tag attrition rate

  A tagging study to examine local and regional movement has been completed by a graduate student at Delaware State University and other studies on local movements and abundance are currently being conducted by other Delaware graduate students.

---

[1] Comment/question: The SAC included a table of stock assessment methods and minimum data requirements for each in Table 1 of the 2006 stock assessment report. Surplus production models had the least data requirements. However, there were convergence problems when ASPIC models were run with five relative abundance indices. Recently the SASC used the SLYME model to assess the impact of maximum size limits. Is SLYME a surplus production model? If so, perhaps the SASC and the TC could review the data needs and sensitivity analysis for SLYME and identify the most critical data needs. For example the model was very sensitive to the assumed value for proportion of future males. It would also be useful to know if data are required for every state (e.g. fecundity) and if long-term or short-term information is needed (biological sampling of a fishery in one year might be possible, but biological sampling every year might not be). A single SLYME model was developed, but perhaps regional version would be more appropriate?

- Research contaminant effects on eel and the effects of bioaccumulation with respect to impacts on survival and growth (by age) and effect on maturation and reproductive success.
- Investigate: predator-prey relationships; behavior and movement of eel during their freshwater residency; oceanic-behavior, movement, and spawning location of adult mature eel; and all information on the leptocephalus stage of eel.
- Assess characteristics and distribution of eel habitat and value of habitat with respect to growth and sex determination.
- Identify location and triggering mechanism for metamorphosis to mature adult, silver eel life stage, with specific emphasis on the size and age of the onset of maturity, by sex. A maturity schedule (proportion mature by size or age) would be extremely useful in combination with migration rates.

Low Priority

- Perform economics studies to determine the value of the fishery and the impact of regulatory management.
- Review the historic participation level of subsistence fishers in wildlife management planning and relevant issues brought forth with respect to those subsistence fishers involved with American eel.
- Examine the mechanisms for exit from the Sargasso Sea and transport across the continental shelf.
- Research mechanisms of recognition of the spawning area by silver eel, mate location in the Sargasso Sea, spawning behavior, and gonadal development in maturation.
- Examine age at entry of glass eel into estuaries and fresh waters.
- Examine migratory routes and guidance mechanisms for silver eel in the ocean.
- Investigate the degree of dependence on the American eel resource by subsistence harvesters (e.g., Native American Tribes, Asian and European ethnic groups).
- Examine the mode of nutrition for leptocephalus in the ocean.
- Provide analysis of food habits of glass eel while at sea.

Research Needs Identified As Being Met

Accurately document the commercial eel fishery so that our understanding of participation in the fishery and the amount of directed effort could be known. ***Trip-level reporting of catch and effort became mandatory in 2007.***

Evaluate the use of American eel as a water quality indicator.

Investigate practical and cost-effective methods of re-establishing American eel in underutilized habitat.

American Lobster

High Priority

- *Age and Growth*

All assessments of lobster stock status have been based on analyses of length data. Age is assumed by applying per-molt growth increments and molt frequencies to the length data. Based on these analyses, the American lobster has been treated as an extremely long-lived animal, reaching a reproductive maximum at a relatively old age. These assumptions are justified, but are based on no actual age data. Applying aging techniques developed in England and Australia for lobster and other crustaceans would greatly improve our understanding of how many year-classes support the current trap fishery, how length relates to age, and how variable the age structure is over stock area and time.

- *Ecosystem-based Management*

NOAA's 2004 Strategic Plan for Fisheries Research recommends the inclusion of ecosystem and environmental information in all stock assessments. Further examination of lobster mortality not related to the fishery would provide a better understanding of factors limiting productivity and longevity. Topics should include: predator/prey interactions and community structure, climatic shifts in ocean currents and temperature, and toxic substances causing chronic stress or disease.

- *Fishery-Dependent Information*

Accurate and comparable landings are the principal data needed to assess the impact of fishing on lobster populations. The quality of current landings data is not consistent spatially or temporally. Standardized mandatory reporting of landings data resource-wide would improve the assessment. Aligning stock management areas with area designations for landings is necessary. Enhanced sea sampling and port sampling to create a more complete record of biological characteristics of the catch and harvest would also improve the usefulness of these data. This is especially needed in offshore waters.

- *Investigation of Historical Levels of Stock Production*

It has been pointed out that one limitation of the proposed reference points is the period covered by the assessment. Investigations of past levels of stock size and size structure could provide additional insight in to setting reference points that relate to the full range of stock productivity.

- *Investigation of Trans-boundary Assessments*

Investigate conducting joint US and Canadian assessments.

Lower Priority

- *Model Development*

Size based models should be examined to determine their ability to match length frequencies and other biological characteristics observed in local lobster populations. Additionally, the utility of using yield and spawning biomass per recruit and surplus production models should be evaluated through simulation as a basis for developing alternative reference points.

Research Needs Identified as Having Been Met

Fishery-Independent Information

There is a need to develop consistent techniques that monitor distribution and abundance of lobster independent of the fishery. Current methods (e.g. trawls) are limited in area (gear conflicts) and habitat sampled (unable to access complex bottom). Additional methodologies should be investigated that cover a wide range of sizes and habitats. These could include ventless traps, dive/ROV, and settlement surveys.

American Shad/River Herring

High Priority

- Determine the impact of directed fisheries on American shad and river herring stocks and reduce F.
- Determine American shad and river herring bycatch within state and ocean waters.[2]
- Determine predation by fish, mammals and birds on American shad and river herring.
- Verify Juvenile indices of alosa species.
- Verify tag-based estimates of American shad.
- Mandate FMPs for rivers with active restoration plans for American shad or river herring.
- Continue to assess current aging techniques for American shad and river herring, using known age fish, scales, otoliths, and spawning marks.
- Validate the different values of M for shad stocks through verification of shad aging techniques and repeat spawning information and develop methods for calculating M.
- Determine which stocks are impacted by coastal intercept fisheries (including bycatch fisheries) and evaluate the fishing mortality on those stocks. Methods to be considered to differentiate among stocks could include otolith micro-chemistry, oxytetracycline otolith marking, tagging or DNA/RNA methods.
- Develop an integrated coastal remote telemetry system or network that would allow tagged fish to be tracked throughout their coastal migration and into the estuarine and riverine environments.
- Identify ways to improve fish passage efficiency including hydroacoustics to repel alosines or pheromones or other chemical substances to attract them. Test commercially available acoustic equipment at existing fish passage facility to determine effectiveness. Develop methods to isolate/manufacture pheromones or other alosine attractants.
- Refine techniques for tank spawning of American shad. Evaluate the use of hormone implants vs. natural spawning. Secure adequate eggs for culture programs using native broodstock, when possible.
- Conduct population assessments on river herring - particularly needed in the south.
- Evaluate effectiveness of fishways for American shad and river herring. Compare features of effective fishways and in-effective fishways and develop guidelines for fishway design.
- Conduct basic research on American shad behavior as it relates to fishways to assist in development of design parameters.
- Quantify fishing mortality (in-river, ocean bycatch, bait fisheries) for major river stocks.

Medium Priority

- Determine and update biological benchmarks used in assessment modeling (fecundity at age, mean weight at age for both sexes, partial recruitment vector/maturity schedules) for American shad and river herring stocks in a variety of coastal river systems, including both semelparous and iteroparous stocks.
- Develop effective culture and marking techniques for river herring.
- Develop and implement techniques to determine shad and herring population targets for tributaries.
- Characterize passage-associated mortality, migration delay, and sub-lethal effects on American shad at hydroelectric dams.
- Conduct studies of river herring egg and larval survival and development.

[2] ASMFC American Shad Stock Assessment, 2007

- Identify directed harvest and bycatch losses of American shad in ocean and bay waters of Atlantic Maritime Canada.
- Spatially delineate between mixed stock and Delaware stock areas within the Delaware system.

Low Priority

- Characterize tributary habitat quality and quantity for Alosa reintroductions and fish passage development.
- Evaluate and ultimately validate large-scale hydroacoustic methods to quantify American shad escapement (spawning run numbers) in major river systems. Identify how shad respond (attract/repelled) by various hydroacoustic signals.
- Identify and quantify potential American shad spawning and rearing habitat not presently utilized and conduct an analysis of the cost of recovery.
- Conduct studies on energetics of feeding and spawning migrations of shad on the Atlantic coast.
- Encourage university research on hickory shad.
- Conduct studies of shad egg and larval survival and development.
- Conduct and evaluate historical characterization of socio-economic development (potential pollutant sources and habitat modification) of selected shad rivers along the east coast.
- Review studies dealing with the effects of acid deposition on anadromous alosids.

Research Needs Identified as Being Met

Develop comprehensive angler use and harvest survey techniques for use by Atlantic states to assess recreational fisheries for American shad. ***To be accomplished through MRIP.***

Determine the stock/recruitment relationships for American shad and river herring stocks

1

Atlantic Croaker

High Priority

- Studies of croaker growth rates and age structure need to be conducted throughout the species range.
- Age-length keys that are representative of all gear types in the fishery should be developed.
- Fishery dependent and independent size, age and sex specific relative abundance estimates should be developed to monitor long term changes in croaker abundance.
- Improve catch and effort statistics from the commercial and recreational fisheries, along with size and age structure of the catch.
- Examine reproductive biology of croaker with emphasis on developing maturity schedules and estimates of fecundity.
- Determine migratory patterns and mixing rates through cooperative, multi-jurisdictional tagging studies.
- Conduct stock identification research on croaker.

Medium Priority

- Cooperative coastwide croaker juvenile indices should be developed and validated to clarify stock status.
- Evaluate hook and release mortality under varying environmental factors and fishery practices.
- The effects of mandated bycatch reduction devices (BRD's) on croaker catch should be evaluated and compiled.
- In trawl fisheries or other fisheries that historically take significant numbers of croaker, states should monitor and report on the extent of unutilized bycatch and fishing mortality on fish less than age-1. Incorporate bycatch estimates into croaker assessment models.
- The optimum utilization (economic and biological) of a long term fluctuating population such as croaker should be evaluated.
- Continue monitoring of juvenile croaker populations in major nursery areas.
- Cooperatively develop a yield per recruit analysis to establish a minimum size that maximizes YPR.
- Determine the onshore vs. offshore components of the croaker fishery.
- Identify essential habitat requirements.

Low Priority

- Determine species interactions and predator/prey relationships for croaker (prey) and other more highly valued fisheries (predators).
- Determine the impacts of any dredging activity (i.e. for beach re-nourishment) on all life history stages of croaker.

Research Needs Identified as Being Met

Criteria should be cooperatively developed for aging croaker otoliths. ***To be met at October 2008 aging workshop.***

Atlantic Menhaden

High Priority

- Monitor landings, size, age, gear, effort and harvest area in the reduction and bait fisheries, and determine age composition by area. Continue biostatistical sampling of bait samples in purse seine fisheries for Virginia and New Jersey to improve stock assessment.
- Develop and test methods for estimating size of recruiting year-classes of juveniles using fishery-independent survey techniques.
- Re-evaluate menhaden natural mortality, by age and response to changing predator population sizes.
- Develop and improve fishery independent estimates of adult abundance at age on a coast-wide scale to replace or augment the existing pound net index.

Medium Priority

- Determine how loss/degradation of critical estuarine and nearshore habitat affects growth, survival and abundance of juvenile and adult menhaden abundance.
- Study the coast wide ecological role of menhaden (predator/prey relationships, nutrient enrichment, oxygen depletion, etc.) in major Atlantic coast embayments and estuaries.
- The feasibility of estimating yearclass strength using biologically stratified sampling design should be evaluated. The efforts could be supported by process studies linking plankton production to abundance of young menhaden (need resources).
- Monte Carlo simulations should be conducted to evaluate precision of current assessment models.
- Alternative measures of effort, including spotter pilot logbooks, trip length, or other variables, should be evaluated. Spotter pilot logbooks should be evaluated for spotter plane search time, GPS coordinates, and estimates of school sizes observed by pilots.
- Evaluate effects of selected environmental factors on growth, survival and abundance of juvenile and adult menhaden, particularly in Chesapeake Bay and other coastal nursery areas.
- Determine the effects of fish diseases (such as ulcerative mycosis and toxic dinoflagellates) on the menhaden stock.
- Update fecundity and maturity schedules.
- Update estuary-specific productivity estimates used to weight the juvenile abundance indices.

Low Priority

- Growth back-calculation studies should be pursued to investigate historical trends in growth rate. The NMFS has an extensive database on scale growth increments which should be utilized for this purpose.
- Determine the effects of regulations on the fishery, the participants and the stock.
- Monitor fish kills along the Atlantic coast and use the NMFS Beaufort Laboratory as a repository for these reports.
- Develop bycatch studies of menhaden by other fisheries. DISCARDS
- Periodically monitor the economic structure and sociological characteristics of the menhaden reduction industry.

Notes:
MSVPA model provides new insight on menhaden natural mortality, by age and response to changing predator population sizes.

Ongoing research in Chesapeake Bay to evaluate effects of selected environmental factors on growth, survival and abundance of juvenile and adult menhaden

Ongoing research is being conducted to develop and test methods for estimating size of recruiting year-classes of juveniles using fishery-independent survey techniques.

Ongoing research is being conducted to determine the effects of fish diseases (such as ulcerative mycosis and toxic dinoflagellates) on the menhaden stock.

Research Needs Identified as Being Met

Evaluate use of coastal power plant impingement data as a possible means to estimate young-of-the-year menhaden abundance.

Atlantic Sea Herring

High Priority

- Continue to utilize the inshore and offshore hydroacoustic and trawl surveys to provide an independent means of estimating stock sizes. Collaborative work between NMFS, DFO, state agencies, and the herring industry on acoustic surveys for herring should continue to be encouraged.
- Continue resource-monitoring activities, especially larval surveys to evaluate distribution and abundance of herring larvae, and to indicate the relative importance of individual spawning areas and stocks and the degree of spawning stock recovery on Georges Bank and Nantucket Shoals.
- Continue tagging and morphometric studies to explore uncertainties in stock structure and the impacts of harvest mortality on different components of the stock. Although tagging studies may be problematic for assessing survivorship for a species like herring, they may be helpful in identifying the stock components and the proportion of these components taken in the fishery on a seasonal basis.
- Investigate bycatch/discards in the directed herring fishery through both at-sea and portside sampling.
- Continue commercial catch sampling of Atlantic herring fishery according to ACCSP protocols.
- Continue to organize annual U.S.-Canada workshops to coordinate stock assessment activities and optimize cooperation in management approaches between the two countries.
- Synthesize predator/prey information and conduct investigations to address information gaps; investigate the role of herring in the Northwest Atlantic ecosystem and the importance of herring as a forage species for other commercial fish stocks; assess the importance of herring as forage relative to other forage species in the region. Re-evaluate Atlantic herring natural mortality by age and the response to changing predator population sizes through an ecosystem based assessment.

Medium Priority

- Develop new approaches to estimating recruitment (i.e. juvenile abundance) from fishery-independent data.
- Conduct a retrospective analysis of herring larval and assessment data to determine the role larval data plays in anticipating stock collapse and as a tuning index in the age-structured assessment.
- Develop socio-economic analyses appropriate to the determination of optimum yield.
- Develop a strategy for assessing individual spawning components to better manage heavily exploited portion(s) of the stock complex, particularly the Gulf of Maine inshore spawning component.

Low Priority

- Possible effects of density-dependence (e.g. reduced growth rates at high population size) on parameter estimates used in assessments should be examined.
- Investigate the natural mortality rate assumed for all ages, the use of catch-per-unit-effort tuning indices, and the use of NEFSC fall bottom trawl survey tuning indices in the analytical assessment of herring.
- Develop economic analyses necessary to evaluate the costs and benefits associated with different segments of the industry.

Maine DMR proposed Research Needs:

Investigate/evaluate the current herring spawning closure design in terms of areas covered, closure periods, catch at age within (before fishing prohibition in 2007) and outside of spawning areas to determine minimal spawning regulations.

Research Needs Identified as Being Met

Evaluate the merit of acoustic surveys and other techniques to achieve sub stock complex monitoring.

Atlantic Striped Bass

STOCK ASSESSMENT AND POPULATION DYNAMICS

High Priority

- Develop method to integrate VPA and tagging models to produce a single estimate of F and stock status (ongoing, G. Nelson)
- Develop a spatial and temporal catch at age model incorporating tag-based movement information
- Examine reporting rates by commercial and recreational fishermen using high reward tags (ongoing, J. Hoenig)
- Develop methods for combining tag results from programs releasing fish from different areas on different dates.
- Examine potential biases associated with the number of tagged individuals, such as gear-specific mortality (associated with trawls, pound nets, gill nets, and electrofishing), tag-induced mortality, and tag loss.

Medium Priority

- Improve methods for determining population sex ratio for use in estimates of spawning stock biomass and biological reference points.
- Evaluate the overfishing definition relative to uncertainty in biological parameters.
- Develop studies to provide information on gear-specific discard morality rates and to determine the magnitude of bycatch mortality (ongoing, G. Nelson).
- Develop refined and cost-efficient fisheries-independent coastal population index for striped bass stocks.
- Examine methods to estimate annual variation in natural mortality (ongoing, Striped Bass Tagging Subcommittee).
- Examine causes of different tag-based survival estimates among programs estimating similar segments of the population.
- Evaluate truncated matrices and covariate-based tagging models.
- Develop reliable estimates of poaching loss from striped bass fisheries.
- Develop maturity ogive applicable to coastal migratory stock.
- Improve estimates of striped bass harvest removals in coastal areas during wave 1 and in inland waters of all jurisdictions year-round.

Low Priority

- Develop simulation models to look at the implications of overfishing definitions relative to development of a striped bass population that will provide “quality” fishing. Quality fishing must first be defined.
- Examine issues with time saturated tagging models for the = 18 inch length group.

RESEARCH AND DATA NEEDS

High Priority

- Continue in-depth analysis of migrations, stock compositions, etc. using mark-recapture data (ongoing, e.g., Cooperative Winter Tagging Cruise 20 Year Report, W. Laney)
- Continue evaluation of striped bass dietary needs and relation to health condition.

Medium Priority

- Continue to conduct research to determine limiting factors affecting recruitment and possible density implications.
- Evaluate the percentage of fishermen using circle hooks.
- Conduct study to calculate the emigration rates from producer areas now that population levels are high and conduct multi-year study to determine inter-annual variation in emigration rates.

Low Priority
- Determine inherent viability of eggs and larvae.
- Conduct additional research to determine the pathogenicity of the IPN virus isolated from striped bass to other warm water marine species, such as flounder, menhaden, shad, and largemouth bass

Atlantic Sturgeon

High Priority

- Characterize size, condition, and relative abundance of Atlantic sturgeon by gear and season taken as bycatch in various fisheries.
- Develop methods to determine sex and maturity of captured sturgeon. [3]
- Develop sperm cryo-preservation techniques and refine to assure availability of male gametes. Refine induced spawning procedures.
- Evaluate aging techniques for Atlantic sturgeon with known age fish. Emphasis should be placed on verifying current methodology based on fin rays. Determine length, fecundity, and maturity at age for North, Mid and South Atlantic stocks.
- Conduct basic cultural experiments to provide information on: a) efficacy of alternative spawning techniques, b) egg incubation and fry production techniques, c) holding and rearing densities, d) prophylactic treatments, e) nutritional requirements and feeding techniques, and f) optimal environmental rearing conditions and systems.
- Establish stocking goals and success criteria prior to development of stock enhancement or recovery programs. *Partially done*.
- Conduct research to identify suitable fish sizes, and time of year for stocking cultured fish
- Conduct and monitor pilot-scale-stocking programs before conducting large-scale efforts over broad geographic areas.
- Establish tolerance of different life stages to important contaminants and levels of such environmental factors such as DO, pH, and temperature.
- Utilize pilot-scale stocking trials to evaluate available habitat, survival and distribution in potential restoration target tributaries
- Conduct assessments of population abundance and age structure in various river systems. Particular emphasis should be placed in documenting occurrence of age 0-1 juveniles and spawning adults as indicators of natural reproduction.

Medium Priority

- Obtain baseline data on habitat condition and quantity in important sturgeon rivers. Data should address both spawning and nursery habitat.
- Evaluate the exposure and effect of endocrine disrupting chemicals.
- Assess loss to ship/boat strikes.

Low Priority

- Determine the extent to which Atlantic sturgeon are genetically differentiable among rivers.
- Research should be conducted to determine the susceptibility of Atlantic sturgeon to sturgeon adenovirus and white sturgeon iridovirus. Methods should be developed to isolate the sturgeon Adenovirus and an Atlantic sturgeon cell line should be established for infection trials.
- Encourage shortnose sturgeon researchers to include Atlantic sturgeon research in their projects.
- Identify rates of tag loss and tag reporting.
- Evaluate existing sea sampling data to characterize at-sea migratory behavior. *Partially done.*

---

[3] Partially done. Laparoscopic techniques have been developed to visually inspect gonads (Dr. Rob Bakal, USFWS, Aquatic Animal Health Coordinator, National Fish Hatchery System). The focus should be directed to blood chemistry analysis of compounds such as vitellogenin or sex steroids.

- Research should be conducted to identify the major pathogens of Atlantic sturgeon and a cell line for this species should be developed.
- Conduct a cost benefit analysis of various stocking protocols.
- Conduct further analyses to assess the sensitivity of F50 to model inputs.

Research Needs Identified As Being Met

Develop and implement long-term marking/tagging procedures to provide information on individual tagged Atlantic sturgeon for up to 20 years. ***PIT tags.***

Standardize collection procedures and develop suitable long-term repository for biological tissues for use in genetic and other studies.

Develop the capability to capture wild broodstock and develop adequate holding and transport techniques for large broodstock.

Establish a tag recovery clearinghouse and database for consolidation and evaluation of tagging and tag return information including associated biological, geographic, and hydrographic data. ***Uncertainty whether this includes acoustic tag information.***

Black Sea Bass

High Priority

- Sampling should be increased for commercial landing in black sea bass fisheries, specifically the fish pot fisheries in the Mid-Atlantic.
- Sampling should be increased in the recreational fisheries.
- Age sampling should be increased across all components of the fishery.
- Sampling should be done to characterize discards.
- Develop fishery independent surveys and expand existing surveys to capture all sizes and age classes in order to develop independent catch-at-age and CPUE.
- Investigate the effect of sex transition rates, sex ratio and differential natural mortality by sex on the calculation of spawning stock biomass per recruit and eggs per recruit.
- Investigate the impact of the removal of large males from the population has on reproduction.
- Studies on sex-specific mortality rates and growth are needed.
- Increase sea sampling to verify information from commercial logbooks to provide better estimates of discards.
- Consideration should be given to a pot survey for an index of abundance

Medium Priority

- Explore alternative assessment models, including non-age based alternatives.
- Further delineate essential fish habitat (EFH), particularly in nursery areas. Further investigate possible gear impacts on EFH.
- Identify transport mechanisms or behavior that move early juvenile black sea bass into estuaries.
- Evaluate habitat use by overwintering yearling, young-of-the-year, and adult black sea bass.
- Evaluate food habits of black sea bass larvae and overwintering adults.

Low Priority

- Develop mariculture techniques.
- A study determining the value of artificial reefs for increased production of black sea bass would be valuable in estimating potential yield.

***Notes*:**
Black sea bass are currently scheduled to take part in a data poor workshop to be scheduled for November-December 2008. The workshop participants will be looking for innovative ways to conduct stock assessments on species with little data.

Research Needs Identified as Being Met

A tagging program should be initiated through state fisheries agencies to estimate mortality independent of traditional methods. *Tagging study complete with peer reviewed results to be published in 2008, G. Shepherd, NMFS.*

Bluefish

High Priority

- Evaluate amount and length frequency of discards from the commercial and recreational fisheries.
- Initiate fisheries-dependent and independent sampling of offshore populations of bluefish during the winter months.
- Test the sensitivity of the bluefish assessment to assumptions concerning age-varying M, level of age-0 discard, and selection patterns.
- Measures of CPUE under different assumptions of effective effort should be evaluated to allow evaluation of sensitivity of results.
- Evaluate fishery-independent surveys to determine if the state surveys can be combined or coordinated to yield broader temporal and spatial representation of the stock.[1]
- Collect size and age composition of the fisheries by gear type and statistical area.[2]
- Target commercial and recreational landings for biological data collection when possible.[3]

Medium Priority

- Age any archived age data for bluefish and use the data to supplement North Carolina age keys.
- Increase intensity of biological sampling of the NER commercial and coastwide recreational fisheries.
- Conduct research on oceanographic influences on bluefish recruitment, including information on migratory pathways of larval bluefish.
- Increase sampling frequencies when bluefish are encountered, especially when medium size fish are encountered.
- Conduct studies on the interactive effects of pH, contaminants, and other environmental variables on survival of bluefish.
- Initiate research on species interactions and predator-prey relationships.
- Study tag mortality and retention rates for American Littoral Society dorsal loop and other tags used for bluefish.

Low Priority

- Continue work on catch and release mortality.
- Initiate a coastal surf-zone seine study to provide more complete indices of juvenile abundance.
- Investigate the long term, synergistic effects of combinations of environmental variables on various biological and sociological parameters such as reproductive capability, genetic changes, and suitability for human consumption.
- Explore alternative methods for assessing bluefish, such as length-based and modified DeLury models.

---

[1] SARC-41. 2005. 41st Chair's Report from the Northeast Regional Stock Assessment Workshop (SAW-41) Stock Assessment Review Committee (SARC) Meeting, Northeast Fisheries Science Center, National Marine Fisheries Service, Woods Hole, Massachusetts, June 6-9, 2005.

[2] Perhaps this should continue and remain a priority (e.g., Robillard et al. (2008) have data on 36 fish in 2003 from the southernmost extent of range predominantly from the recreational fishery; analogously, Robillard et al. (2008) report that data from NC were primarily from commercial gillnet fishers in 2002 and 2003).

[3] Same comment as footnote 2.

Research Needs Identified as Being Met

- Complete a scale-otolith age comparison study.
  Robillard, E., et al. 2008. Age-validation and growth of bluefish (*Pomatomus saltatrix*) along the East Coast of the United States. Fish. Res.doi:10.1016/j.fishres.2008.07.012
- Conduct research to determine the timing of sexual maturity and fecundity of bluefish.
  Robillard, E. et al. Reproductive biology of bluefish (Pomatomus saltatrix) along the East Coast of the United States. Fish. Res. 90 (2008) 198-208.

Coastal Sharks

High Priority

- Continue to acquire better species-specific landings information on number of species, by weight, from dealers should be sought.
- Initiation or expansion of dockside sampling for sharks.
- Conduct species-specific assessments for all shark species, with a priority for smooth dogfish.
- Re-evaluate finetooth life history in the Atlantic Ocean in order to validate fecundity and reproductive periodicity.
- Determine bonnethead life history in Atlantic Ocean, spanning the range of the stock.
- Re-evaluate blacknose life history in Atlantic Ocean, spanning the range of the stock. Expand research efforts directed towards tagging of individuals in south Florida and Texas/Mexico border to get better data discerning potential stock mixing.
- Identify Essential Fish Habitat and nursery areas for shark species found along the Atlantic Coast of the U.S.

Medium Priority

- Develop empirically based estimates of natural mortality.
- Additional life history studies for all species of the shark complex should be carried out to allow for additional species specific assessments.
- Additional length sampling and age composition collection to improve information for developing selectivities.
- The Atlantic menhaden fishery data should be examined to determine shark bycatch estimates, if available.
- Additional life history research into sandbar sharks to supplement or replace the available data from the mid 1990's
- Coordinate a biological study for Atlantic sharpnose so that samples are made *at least* monthly, and within each month samples would be made consistently at distinct geographic locations. For example, sampling locations would be defined in the northern Gulf, west coast of Florida, the Florida Keys (where temperature is expected to be fairly constant over all seasons), and also several locations in the South Atlantic, including the east coast of Florida, Georgia, South Carolina, and North Carolina. This same sampling design could be applied to all small coastal sharks.
- Dockside sampling information would be helpful to verify landings information such as species composition.
- Population level genetic studies are needed that could lend support to arguments for stock discriminations using new loci and/or methodology that has increased levels of sensitivity.
- Develop a fishery-independent porbeagle shark survey to provide additional size composition and catch rate data to calculate index of abundance.

Low Priority

- Biological data should be collected on the illegal Mexican Shark catch confiscated in U.S. waters, including species, sex, and length.
- Gear-related information, including effort and gear used for each species should be collected on the interdicted Mexican vessels.
- One central electronic database for biological and gear data should be created to keep information regarding the confiscated sharks and vessels.

- Scientists should help the Coast Guard create the database and teach the agents how to identify the species and gear information.
- Determine reproduction biology for finetooth in the Gulf of Mexico.

Note: Work with NMFS on all priorities to ensure no duplication of efforts.

Horseshoe Crab

High Priority

- Investigate factors (habitat, harvest, sampling methods, etc) that might be causing the large discrepancies between DE and NJ in egg survey numbers.
- Expand or implement fishery-independent surveys to encompass the full range of horseshoe crabs along the coast including inland waters.
- Estimate juvenile age/size-specific survivorship for year 0 to adult.
- Estimate size-specific fecundity of Delaware Bay females.
- Estimate catchability for gear used in benthic trawl surveys and determine effect of size, sex, substrate, topography, timing, and temperature.
- Model relationship between egg availability and spawning biomass/abundance.
- Assess horseshoe crab prey availability and determine whether horseshoe crab population growth will be/is limited by prey availability.
- Determine stock composition of Virginia, Maryland, and New York landings.
- Conduct risk assessment for the effect of oil spill (timing, location, and amount) on horseshoe crab and shorebird populations and determine best practices to reduce risk.

Medium Priority

- Further evaluate life table information including sex ratio and population age structure.
- Evaluate the impacts of beach nourishment projects on horseshoe crab populations.
- Estimate the proportion of sub-tidal spawning and determine if this affects spawning success (i.e. egg survivability).
- Identify coastal populations through tagging studies (mark-recapture) and genetics work.
- Ground truth sub-sampling method used in DE Bay spawning survey for calibration to the “population” scale.
- Improve measures to characterize landings and bycatch in the commercial fisheries by life stage.
- Investigate analysis of tagging data to provide mortality rates and population abundance in addition to migration and movements.
- Characterize essential horseshoe crab habitat, other than spawning habitat, in different regions.
- Characterize abundance and size structure of juveniles coastwide as indicators of recruitment to adulthood.
- Investigate supplemental bait and alternative trap designs to reduce the commercial fisheries need for horseshoe crabs.
- Estimate mortality from the entire biomedical collection process, from capture to post-return.

Low Priority

- Evaluate the effect of mosquito control chemicals on horseshoe crab populations.
- Estimate fishing discard numbers and associated mortality rates.
- Evaluate the importance of horseshoe crabs to other marine resources such as sea turtles.

- Continue to conduct additional stock assessments and determine harvest mortality rates (F). Use these data to develop a more reliable sustainable harvest rate.

Notes:
Several priority research needs are currently being addressed through the following surveys:

Delaware Bay spawning beach survey:

a) Determine sampling frame or list of beaches in the Bay with a nonzero probability of being sampled in a given year.
b) Determine how many beaches need to be surveyed on how many days to meet survey objectives.
c) Determine whether subsampling effort (no. of quadrats per beach) was adequate.
d) Consider a survey design that includes both fixed and random beaches.

Delaware Bay egg count survey:

a) Set primary objective of egg count surveys to be shorebird food availability and focus on density of eggs at the surface (< 5cm).
b) Determine survey frequency (i.e., survey eggs annually, every 3 years, every 5 years, or other?).
c) Determine where, along the beach profile, eggs should be sampled.
d) Determine sample size for sampling eggs on a beach.
e) Determine the relationship between spawning activity and density of eggs at the surface (<5cm). Is there a threshold of spawning activity below which eggs remain buried and unavailable to shorebirds?

Offshore benthic survey:

a) Design comparative surveys or experiments to determine gear efficiencies.

Research Needs Identified as Being Met

- Evaluate the effectiveness of currently used benthic sampling gear for stock assessment (Qualitative evaluation completed through 2006 peer review)
- Determine beach fidelity by horseshoe crabs to determine habitat use.
- Develop a young-of-year or age 1 recruitment index from the Delaware 16-foot trawl survey.
- Conduct economic studies to determine the value of the commercial fishery and the impact of regulatory management. Such economic studies should also include an assessment of economic impacts on other fisheries as they relate to horseshoe crabs.

Northern Shrimp

High Priority

- Continue to examine values of natural mortality, M. Revisit older work that established M=0.25 (Rinaldo, Clark). Estimate M from year-sex-stage-class ratio data from surveys. Examine predation data and other environmental factors. Investigate possible annual variation in M. Benefits: better understanding of ecological role; more accurate model estimates of F and B. Resources required: several person-months for data analysis.
- Examine several survey issues: recalculate fall survey indices for shrimp, eliminating the nighttime tows; verify that summer survey tow bottom tending times have been consistent; investigate survey design for optimal number and stratification of tows; explore ways to quantify age 1 and younger shrimp. Benefits: more accurate survey indices for model estimates of F and B; earlier estimates of future recruitment. Resources required: several person-months for data analysis, and further research into collecting small shrimp, possibly development of a trap survey.
- Explore the stock-recruitment relationship and the impact of environmental factors on recruitment. Consider impacts of climate change. Benefits: better understanding of natural population fluctuations; better modeling of population dynamics. Resources required: many person-months for data analysis.
- Better characterize shrimp discards in the shrimp and other small-mesh (i.e., herring and whiting) fisheries. Benefits: more accurate estimate of shrimp removals for modeling. Resources required: more at-sea sampling; several person-months for analysis of existing VTR and sea-sampling databases.
- Evaluate the stock recruitment relationship for northern shrimp.
- Evaluate natural mortality, including relative impacts of predation and disease and variation at age and over time.
- Evaluate larval growth and survival in response to environmental conditions.
- Further research to refine annual estimates of consumption by predators could be useful in several ways. Consumption estimates could lead to annual estimates of *M* that would be more realistic than assuming constant *M*, for use in models that include *M* explicitly. Alternatively, consumption estimates could be used in production models as annual removals similar to fishery removals.
- Power analysis of estimates of mean weight from port sampling should be investigated to optimize sample design.
- Improve separator and excluder devices to reduce bycatch and discard of non-targeted species. Explore gear modifications, such as larger mesh, to minimize shrimp bycatch in finfish trawl fisheries.[1]
- Characterize demographics of the fishing fleet by area and season; perform comparative analysis of fishing practices between areas.
- Develop an understanding of product flow and utilization through the marketplace; identify performance indicators for various sectors of the shrimp industry.
- Efforts to quantify the magnitude of bycatch by species, area, and season should be continued and the steps necessary to limit negative impacts taken.

---

[1] Some work has been done by Schick and He.

- Explore new markets for Gulf of Maine shrimp.[1]
- Develop a framework to aid evaluation of the impact of limited entry proposals on the Maine fishing industry.[2]
- Broad-based and detailed socioeconomic description and analysis of the structure, operations, markets, revenues and expenditures of the northern shrimp fishery itself and in relation to other commercial fisheries in northern New England.
- Ground-truthing for all of the data gathered via Federal and State databases. Contradictions and inaccuracies abound, so face-to-face interviews with a randomized sample of participants in all sectors of the fishery are needed.
- Determine the relative power relationships between the harvesting and processing sector and the larger markets for shrimp and shrimp products. Identify significant variables driving market prices and how their dynamic interactions result in the observed intraannual and inter-annual fluctuations in market price for northern shrimp.
- Study the effects of large-scale climatic events (like the North Atlantic Oscillation) on the cold water refuges for shrimp in the Gulf of Maine.

Medium Priority

- Recover/convert older port sampling data to useable database. Benefit: Data will be available for future queries re fishing locations, catch rates, size distributions, sex stage and timing of egg hatch, other shrimp species, etc. Resources required: several person-months for data entry, uploads, and proofing.
- Evaluate appropriate biological reference points and define sustainable harvest levels. The potential for improving estimates of mortality, abundance, and biomass from historical fishery and survey data from the 1960s should be investigated for further guidance on appropriate biological reference points.
- Target and threshold reference points for northern shrimp are set equal to one another at F = 0.22/yr. Using a buffer of zero between target and threshold reduces the relevance of reference points to management. Specifically, the distinction between desirable exploitation rates and those that indicate overfishing is blurred. The SARC recommends dialogue with managers and industry on this matter, as well as research to illustrate whether separating threshold from target would allow more stable or robust management techniques. When a common agreement exists about the function of each reference point, assessment scientists can calculate values to best serve each function
- Research on annual variation of size at age could increase precision of the assessment.
- The possibility of using a more detailed assessment model, such as the CASA model used for Atlantic sea scallop, should be studied. Use of a model with a more detailed treatment of northern shrimp population dynamics could increase accuracy and precision of assessment results.
- Evaluate maturation, fecundity and lifetime spawning potential.
- Evaluate growth, including frequency of molting and variation in growth rates as a function of environmental factors and population density.
- Evaluate distribution of larval, juvenile, and adult shrimp. Evaluate migration and local movements.[3]

[1] Maine Fishermen's Forum panel discussions, 2006 and 2007
[2] Maine Coastal Fishery Research Priorites, 2001, online at http://www.maine.gov/dmr/research/table_of_contents.htm, and Maine Fishermen's Forum panel discussion, 2007
[3] Some migration work has been done by Schick et al. 2006 NEC

- Estimates of fecundity at length should be updated, and the potential for annual variability should be explored.
- Investigate changes in transition and maturation as a function of stock size and temperature.[1]
- Evaluate competition and predator-prey relationships between species.
- Continue sea-sampling efforts.
- Evaluate vulnerability of shrimp to various fishing gear.
- Exploration of any spatial, depth, or temperature influences on survey catchability could contribute to better standardization of the survey abundance index.
- Environmental effects could likewise be examined through development of a surplus-production model that includes effects of environmental variation on per-capita production or carrying capacity.
- The CSA model as used here requires a parameter that is the ratio of catchabilities for the two age or size classes. Sensitivity analysis on the values used would contribute to a better understanding of model stability. A thorough evaluation of possible methods for better estimating this parameter could reduce uncertainty in the assessment.
- Develop a time series of standardized effort to corroborate patterns of estimated F.
- Methods for age determination from length and ontogenetic stage information should be continued to develop the possibility of using age-based assessment methods.
- Expand the time series of stock and recruitment data using catchability estimates from the production model.
- Modify sea sampling protocol to characterize discards of shrimp in the shrimp trawl fishery and the small-mesh whiting fishery.
- Perform cost-benefit analyses to evaluate management measures.
- Develop a bioeconomic model to study the interactions between four variables: movements of shrimp, catchability of shrimp, days fished, and market price.
- Develop an economic-management model to determine (1) the most profitable times to fish, (2) how harvest timing effects markets, and (3) how the market effects the timing of harvesting.
- Study specific habitat requirements for all life history stages.
- Evaluate effects of habitat loss/degradation on northern shrimp.
- Develop habitat maps for all life history stages.
- Identify migration routes of immature males offshore, and ovigerous females inshore.
- Determine the short and long-term effects of mobile fishing gear on shrimp habitat.[2]

Low Priority

- Increased sampling of commercial catches, ensuring good allocation of samples among ports and months, could provide better estimates of size composition.[3]

***Notes**:*

In 2008, the greatest problems facing the Gulf of Maine shrimp industry were not a lack of research on stock dynamics, assessment methods, or management practices; they were high fuel prices and poor shrimp prices. Government research efforts should target energy policy and the development of markets, as well as good fishery management.

---

[1] Some work has been done by Wieland 2004, 2005

[2] Short term effects have been studied by A. Simpson and L. Watling, 2006.

[3] It would be useful to first analyze the existing sampling protocol, to determine whether more or less sampling is necessary, and whether existing sampling is representative.

Sea sampling effort to date has probably identified adequately the catch and bycatch in the shrimp fishery in the Gulf of Maine under current gear and season constraints. Until changes are made in gear and season, sea sampling may remain minimal. Research to improve on excluder devices to reduce bycatch is still a reasonable investment in that bycatch of small whiting and small flatfish is still a problem. Bycatch by species, area and season has been adequately quantified as long as the fishing season and gear remain generally the same. Limiting negative impacts is still a fairly important area of research focus.

Dunham and Muller at the University of Maine conducted an economic study of the shrimp fishery including the characterization of demographics of the fishing fleet by area and season in 1976. This study should be updated.

Some recent work has been done on the relative distribution of shrimp and juvenile groundfish along the Maine coast. Little is known of the distribution and/or life history of the juvenile stage of *P. borealis*, therefore the age structure of the population is less certain.

Migration of *P. borealis* is known to occur to a greater extent in the Gulf of Maine than anywhere else in the world. Several aspects of this migration remain an enigma.

Red Drum

High Priority

- Support fishery-independent sampling of sub-adult and adult red drum in each state from Virginia to Florida. The purpose of this survey would be to: 1) verify escapement to the spawning population, 2) provide an index of recruitment to age 1, and 3) provide an estimate of the biomass of adult red drum.
- Continue tagging studies to determine stock identity, inshore/offshore migration patterns and mortality estimation.
- Determine the survival rate of red drum following regulatory and voluntary discard from commercial and recreational gear, including recreational net fisheries. Evaluate effects of water temperature and depth of capture.
- Quantify relationships between red drum production and habitat.

Medium Priority

- Develop a more reliable estimate of natural and fishing mortality through directed sampling of the adult population.
- Identify spawning areas of red drum in each state from Virginia to Florida so these areas may be protected from degradation and/or destruction. Determine qualities of those areas (bottom type, depth, temperature, salinity, etc.). Determine the impacts of dredging and beach re-nourishment on red drum spawning and early life history stages.
- Improve catch/effort estimates and biological sampling from recreational and commercial fisheries for red drum, including increased efforts to intercept night-time fisheries for red drum by the NMFS MRFSS. Characterize magnitude of commercial and recreational discards.
- States with significant fisheries should be encouraged to collect socio-economic data on red drum fisheries through add-ons to the MRFSS or by other means so as to determine the economic value of the Atlantic coast recreational red drum fishery.
- Investigate and evaluate new stock assessment techniques as alternatives to age-structured models. Conduct yield modeling on red drum.
- Fully evaluate the efficacy of using cultured red drum to restore native stocks along the Atlantic coast, including cost-benefit analyses.
- Identify the effects of water quality degradation on the survival of red drum eggs, post-larvae, larvae, and juveniles.
- Refine maturity schedules on a geographic basis, determine relationships between annual egg production over a range of sizes, ages and across latitude.
- Determine methods for restoring red drum habitat and/or improving existing environmental conditions that adversely affect red drum production.

Low Priority

- Determine habitat preferences, environmental conditions, growth rates, and food habits of larval and juvenile red drum throughout the species range along the Atlantic coast. Assess the effects of environmental factors on stock density.
- Investigate the concept of estuarine reserves to increase the escapement rate of red drum along the Atlantic coast.
- Document and characterize schooling behavior for Atlantic coast red drum.

Scup

- Continue to support and fund both the RI commercial fish trap survey and the Fishery Independent Scup Survey of Hard Bottom Areas in Southern New England Waters. It is recommended that the fishery independent survey be expanded to include waters further west and that scales should be collected for aging.

- Increased and more representative sea and port sampling of the various fisheries in which scup are landed and discarded is needed to adequately characterize the length composition of both landings and discards. The current level of sampling, particularly of the discards, seriously impedes the development of analytic assessment and forecasts of catch and stock biomass for this stock. A pilot study to develop a sampling program to estimate discards should be implemented. Expanded age sampling of scup from commercial and recreational catches is required, with special emphasis on the acquisition of large specimens. *Improved sampling intensity for landings, increase in funding for observer program since 2004, this has improved discard sampling intensity in the directed and bycatch fisheries for scup, but* ***still need to increase observer coverage for winter I offshore directed scup fishery and bycatch squid fishery****.*

- Commercial discard mortality had previously been assumed to be 100% for all gear types. The committee recommends that studies be conducted to better characterize the mortality of scup in different gear types to more accurately assess discard mortality.

- Additional information on compliance with regulations (e.g. length limits) and hooking mortality is needed to interpret recreational discard data.

- Explore alternative biomass indices for development of biomass proxies for reference point determination based on multiple survey indices.

- Evaluate the current biomass reference point and consider alternative proxy reference points such as B_{MAX} (the relative biomass associated with F_{MAX}).

- Continue exploration of relative biomass and relative exploitation calculations based on CPUE data from the recreational private boat fishery. *Use a different CPUE measure than what is in the trawl survey, Paul will do it.*

- Surveys should be evaluated to test the assumption of equal catchability at age in projections (i.e. through forward projection methods).

- In the absence of reliable estimates of the catch, consideration should be given to simple forward projection models that rely on trends from the survey indices in the absence of catch information. 35th SAW Consensus Summary 141 Done, Done in AIM resulted in no improvement over VPA because inconstancy between fishery dependent and independent data.

- Design an optimal sampling plan that would be considered for implementation by the fishery observer sampling, recreational, and commercial port sampling program. Formal sampling design has been implemented in the at sea observer program (SBRM), Redesign of MRFSS (MRIP), For all sampling these programs are designed for multi-species and are designed for optimal sampling of all species and not a single species.

- Explore alternative decision support methodologies for updating TALs directly from relative trends in abundance without relying on direct estimates of F. *Explored but no alternatives have been acceptable.*

- Age backlog of samples. (NMFS, MA)

- Conduct an aging comparison/workshop to (1) compare ototliths and scales (2) compare state age length keys.

- Biological studies to investigate factors affecting annual availability of scup to research surveys and maturity schedules.

- Explore other approaches for analyzing survey data, including bootstrap resampling methods to generate approximate confidence intervals around the survey index point estimates. *Needs to be done, low priority*

Research Needs Identified as Being Met or in Progress

- The SARC discussed some of the reasons why the research recommendations from previous SARCs had not been adequately addressed. There is currently no mechanism for accountability, resulting in other research needs taking priority. It was suggested that summaries of research recommendations be forwarded to the NRCC for review and comment, followed by a feasibility analysis. At that point a list of priorities and perhaps assignments for research could be made. The SARC recommends that a working group be developed to assess what group would be best suited to address each research need. *This is now a TOR that must be responded to in each assessment.*
- Investigate the statistical properties of the three commercial discard estimation approaches presented for consideration in future analyses. *In progress.*
- Quantify the percentage of commercial fishery trips that had discards, but no landings, and evaluate how such trips contribute to the total commercial fishery discard estimate. *In progress*

Spanish Mackerel

High Priority

- Biological data collection should be increased and should include all states where Spanish mackerel are landed.
- Evaluation of weight and especially length at age of Spanish mackerel, including updated conversion equations (e.g., gutted to whole weight) and sampling of age-0 fish.
- Development of fishery-independent methods to monitor stock size of Atlantic Spanish mackerel (consider aerial surveys used in south Florida waters).
- Improved information on discard rates and discard mortality, including 5-10% observer coverage of commercial fisheries.
- Simulations on CPUE trends should be explored and impacts on VPA and assessment results determined.
- Determine the bycatch of Spanish mackerel in the directed shrimp fishery in Atlantic
- Coastal waters.
- Conduct an aging workshop to develop approved methods and reporting standards, include lab exchanges of structures
- More timely reporting of mid-Atlantic catches for quota monitoring.
- Provide better estimates of recruitment, natural mortality rates, fishing mortality rates, and standing stock. Specific information should include an estimate of total amount caught and distribution of catch by area, season, and type of gear.
- Develop methodology for predicting year class strength and determination of the relationship between larval abundance and subsequent year class strength.
- Commission and member states should support and provide the identified data & input needed to improve the SAFMC's SEDAR process.

Medium Priority

- Yield per recruit analyses should be conducted relative to alternative selective fishing patterns.
- Evaluate potential bias of the lack of appropriate stratification of the data used to generate age-length keys for Atlantic and Gulf Spanish mackerel.
- Evaluate CPUE indices related to standardization methods and management history, with emphasis on greater temporal and spatial resolution in estimates of CPUE.
- Evaluate whether catchability varies with abundance or environmental conditions
- Determine normal Spanish mackerel migration routes and changes therein, as well as the climatic or other factors responsible for changes in the environmental and habitat conditions, which may affect the habitat and availability of stocks.
- Determine the relationship, if any, between migration of prey species (i.e., engraulids, clupeids, carangids), and migration patterns of the Spanish mackerel stock.

Low Priority

- Complete research on the application of assessment and management models relative to dynamic species such as Spanish mackerel.
- Delineation of spawning areas and areas of larval abundance through temporal and spatial sampling.
- Consideration of MRFSS add-ons or other mechanisms for collection of socioeconomic data for recreational and commercial fisheries.
- The full implementation of ecosystem-based management and the implementation of monitoring /research efforts needed to support ecosystem-based management needs should be conducted.

Spiny Dogfish

High Priority

- Determine coastwide discard mortality rate for fixed and mobile gear fisheries that catch dogfish as bycatch.
- Characterize and quantify bycatch of spiny dogfish in other fisheries.
- Monitor the level of effort and harvest in other fisheries as a result of no directed fishery for spiny dogfish.
- Increase observer trips to document the level of incidental capture of spiny dogfish during the spawning stock rebuilding period.
- Continue work on the change-in-ratio estimators for mortality rates and suggest several options for analyses
- Standardize age determination along the entire East coast. Conduct an aging workshop for spiny dogfish, encouraging participation by NEFSC, NCDMF, Canada DFO, and other interested agencies, academia and other international investigators with and interest in dogfish aging (US and Canada Pacific Coast, ICES).
- Quantify effort directed on spiny dogfish in waters outside of the U.S.
- Conduct a coastwide tagging study to explore stock structure, migration, and mixing rates.

Medium Priority

- Increase the biological sampling of dogfish in the commercial fishery and on research trawl surveys.
- Identify how spiny dogfish abundance and movement affect other organisms.
- Monitor the changes to the foreign export markets for spiny dogfish, and evaluate the potential to recover lost markets or expand existing ones.

Low Priority

- Further analyses of the commercial fishery is also warranted, especially with respect to the effects of gear types, mesh sizes, and market acceptability on the mean size of landed dogfish.
- Continue to analyze the effects of environmental conditions on survey catch rates.
- Update on a regular basis the characterization of fishing communities involved in the spiny dogfish fishery, including the processing and harvesting sectors, based upon Hall-Arber et al. (2001) and McCay and Cieri (2000).
- Characterize the value and demand for spiny dogfish in the biomedical industry on a state-by-state basis.
- Characterize the spiny dogfish processing sector

Research Needs Identified as Being Met

- **Genetic analysis of spiny dogfish to determine if more than one unit stock exist along the Northwest Atlantic. *Canadian researchers are working on this but not published yet.***
- **Update maturation and fecundity estimates by length class.**
- **Recover and encode information on the sex composition prior to 1980 from the survey database.**

- **Quantify effort directed on spiny dogfish in waters outside of the U.S.** ***Canada should have numbers available on this soon.***

Spot

High Priority

- In trawl fisheries or other fisheries that take significant numbers of spot, states should monitor and report on the extent of unutilized bycatch and fishing mortality on fish less than age-1. Incorporate bycatch estimates into spot assessment models.
- The effects of mandated bycatch reduction devices (BRD's) on spot catch should be evaluated in those states with significant commercial harvests.
- Fishery dependent and independent size and sex specific relative abundance estimates should be developed.
- Cooperative coastwide spot juvenile indices should be developed to clarify stock status.
- Monitor long term changes in spot abundance, growth rates, and age structure.
- Continue monitoring of juvenile spot populations in major nursery areas.
- Improve spot catch and effort statistics from the commercial and recreational fisheries, along with size and age structure of the catch, in order to develop production models.
- Criteria should be cooperatively developed for aging spot otoliths and scales, and an age validation study should be conducted.

Medium Priority

- A yield per recruit analysis should be cooperatively developed.
- Develop stock identification methods.
- Determine migratory patterns through tagging studies.
- Determine the onshore vs. offshore components of the spot fishery.

Spotted Seatrout

High Priority

- Stock assessments should be conducted to determine the status of stocks relative to the plan objective of maintaining a spawning potential of at least 20%.
- Initiate fishery independent surveys of spotted seatrout.
- Emphasis should be placed on collecting the necessary biological data to be able to conduct stock assessments and to assist in drafting fishery management plans.
- Age structure analyses by sex should be utilized in stock assessments.
- Collect data on the size or age of spotted seatrout released alive by anglers and the size and age of commercial discards.
- Continue work to examine the stock structure of spotted seatrout on a regional basis, with particular emphasis on advanced tagging techniques.
- Expand the NMFS recreational fishery survey to assure adequate data collection for catch and effort data, increased intercepts, and state add-ons of social and economic data needs.

Medium Priority

- Collection of commercial and recreational landings data should be continued and expanded.
- Identify essential habitat requirements.
- Evaluate effects of environmental factors on stock density.
- Work should be continued to examine the stock structure of spotted seatrout on a regional basis, with particular emphasis on molecular techniques.
- Collection of social and economic aspects of the spotted seatrout fishery should be initiated.
- Improve precision of effort reporting through commercial trip ticket programs.

***Notes*:**

Florida Department of Environmental Protection developed a spotted seatrout stock assessment in January 1995 that addressed by sex yield modeling, spawning potential ratios, use of fishery independent monitoring to tune virtual population models.

Commercial effort is collected through Florida's Marine Fisheries Information System (Trip Tickets).

Trip level landings data is collected through North Carolina's Trip Ticket Program.

The North Carolina Division of Marine Fisheries is currently reviewing an assessment of spotted seatrout as part of the state's first FMP for the species, due for completion in late 2008.   A statistical catch-at-age model was used to determine the status of the NC spotted seatrout population.

Summer Flounder

High Priority

- Develop a program to annually sample the length and age frequency of summer flounder discards from the recreational fishery.
- Collect and evaluate information on the reporting accuracy of recreational discards estimates in the recreational fishery.
- The SDWG noted that more comprehensive collection of otoliths, for all components of the catch-at-age matrix, needs to be collected on a continuing basis for fish larger than 60 cm (~7 years). The collection of otoliths and the proportion at sex for all of the catch components could provide a better indicator of stock productivity.
- The SDWG recommends that a reference collection of summer flounder scales and otoliths be developed to facilitate future quality control of summer flounder production aging. In addition, a comparison study between scales and otoliths as aging structures for summer flounder should be completed.
- The SDWG noted that the observed change in the sex ratio in NEFSC survey samples may result in the SSB estimates not translating as directly to egg production since there are more males proportionally in those older age-categories. Collecting information on overall fecundity for the stock, both egg condition and production may be a better indicator of stock productivity.
- Investigate trends in sex ratios and mean lengths and weights of summer flounder in state agency and federal surveys catches.
- Examine mesh selectivity patterns for a range of commonly used mesh sizes greater than the currently mandated sizes (5.5 Diamond/6 inch square)
- Continue fishery independent surveys and expand existing surveys to capture all sizes and age classes in order to develop independent catch-at-age and CPUE.
- Continue to collect and analyze age/length samples and catch/effort data from the commercial and recreational fisheries throughout the range of summer flounder.

Medium Priority

- Use NEFSC fishery observer age-length keys for 1994 and later years (as they become available) to supplement NEFSC survey data in aging the commercial fishery discard.
- Consider use of management strategy evaluation techniques to address the implications of harvest policies that incorporate consideration of retrospective patterns (see ICES Journal of Marine Science issue of May 2007).
- Undertake research to determine hooking mortality on summer flounder by circle, kahle, and regular "J" hooks and make the results of work already completed available to the Management Board.
- Conduct a detailed socio-economic study of the summer flounder fisheries.
- Research directed at evaluating the mesh exemption program should be continued, with increased sample sizes to allow reliable statistical testing of results.
- Develop stock identification methods via meristics, morphometrics, biochemical research and tagging; particularly off Virginia and North Carolina.
- Develop fish excluder devices to reduce bycatch of immature flatfish in fisheries that target species other than flounder.
- Collect data to determine the sex ratio for all of the catch components

Low Priority

- Consider treating scallop-closed areas as separate strata in calculations of summer flounder discards in the commercial fisheries.
- Conduct the basic research necessary to develop land and pen culture techniques.
- Evaluate effects of dissolved oxygen and water current requirements for adult summer flounder and summer flounder eggs.
- Evaluate the relationship between recruitment of summer flounder to nursery areas and Ekman transport or prevailing directions of water flow.
- Examine the sensitivity of the summer flounder assessment to the various unit stock hypotheses and evaluate spatial aspects of the stock to facilitate sex and spatially-explicit modeling of summer flounder.
- Conduct further research to examine the predator-prey interactions of summer flounder and other species, including food habitat studies, to better understand the influence of these other factors on the summer flounder population.
- Examine male female ratio at age-0 and potential factors (eg. environmental) that may influence determination of that ratio.
- Evaluate potential changes in fishery selectivity relative to the spawning potential of the stock; analysis should consider the potential influence of the recreational and commercial fisheries.
- Determine the appropriate level for the steepness of the S-R relationship and investigate how that influences the biological reference points.

Tautog

High Priority

- Establish standardized state-by-state long-term fisheries independent surveys to monitor tautog abundance and length-frequency distributions, and to develop young-of-the-year indices.
- Initiate biological sampling of the commercial catch for each gear type over the entire range of the stock (Including weight, lengths, age, sex, and discards).
- Increase collection of effort data for determining commercial and recreational CPUE.
- Increase MRFSS sampling levels to improve recreational catch estimates by state and mode. Current sampling levels are high during times of the year when more abundant and popular species are abundant in catches, but much lower than in early spring/late fall when tautog catches are more likely.

Medium Priority

- Define larval diets and prey availability requirements. This information can be used as determinants of recruitment success and habitat function status. Information can also be used to support aquaculture ventures with this species.
- Define local and regional movement patterns and site fidelity in the southern part of the species range. This information may provide insights into questions of aggregation vs. recruitment to artificial reef locations. More clarification is required on what the southern part of the range is and to clarify the need for local and regional assessment.
- Define the role of prey type and availability in local juvenile/adult population dynamics over the species range. This information can explain differences in local abundance, movements, growth, fecundity, etc. Conduct studies in areas where the availability of primary prey, such as blue mussels or crabs, is dependent on annual recruitment, the effect of prey recruitment variability as a factor in tautog movements (to find better prey fields), mortality (greater predation exposure when leaving shelter to forage open bottom), and relationship between reef prey availability/quality on tautog condition/fecundity.
- Define the status (condition and extent) of optimum or suitable juvenile habitats and trends in specific areas important to the species. It is critical to protect these habitats or to stimulate restoration or enhancement, if required.
- Define the specific spawning and pre-spawning aggregating areas and wintering areas of juveniles and adults used by all major local populations, as well as the migration routes used by tautog to get to and from spawning and wintering areas and the criteria or times of use. This information is required to protect these areas from damage and overuse or excessive exploitation.
- Define the susceptibility of juveniles to coastal/anthropogenic contamination and resulting effects. This information can explain differences in local abundance, movements, growth, fecundity, and serve to support continued or increased regulation of the inputs of these contaminants and to assess potential damage. Since oil spills seem to be a too frequent coastal impact problem where juvenile tautog live, it may be helpful to conduct specific studies on effects of various fuel oils and typical exposure concentrations, at various seasonal temperatures and salinities. Studies should also be conducted to evaluate the effect of common piling treatment leachates and common antifouling paints on young of the year tautog. The synergistic effects of leaked fuel, bilge water, treated pilings, and antifouling paints on tautog health should also be studied.

Low Priority

- Define the source of offshore eggs and larvae (in situ or washed out coastal spawning).
- Confirm that tautog, like cunner, hibernate in the winter, and in what areas and temperature thresholds, for how long, and are there special habitat requirements during these times that should be protected or conserved from damage or disturbance. This information will aid in understanding behavior variability and harvest availability.

Research Needs Identified as Being Met

Ongoing effort to explore possible regional and local genetic differences (stock differentiation) and relate these to recruitment, growth, exploitation rates, and habitat differences. These differences can help support appropriate region-specific management strategies.

Ongoing effort to determine pot and trap escape vent dimensions needed to release tautog over a range of sizes.

Sample hard parts for annual aging from the catches of recreational and commercial fisheries and fishery independent surveys throughout the range of the stock. *Being conducted by all participating states.*

Weakfish

High Priority

- Collect catch and effort data including size and age composition of the catch, determine stock mortality throughout the range, and define gear characteristics. In particular, increase length-frequency sampling, particularly in fisheries from Maryland and further north.
- Derive estimates of discard mortality rates and the magnitude of discards for all commercial gear types from both directed and non-directed fisheries. In particular, quantify trawl bycatch, refine estimates of mortality for below minimum size fish, and focus on factors such as distance from shore and geographical differences.
- Conduct an age validation study.
- Identify stocks and determine coastal movements and the extent of stock mixing, including characterization of stocks in over-wintering grounds (e.g., tagging).
- Conduct spatial and temporal analysis of the fishery independent survey data. The analysis should assess the impact of the variability of the surveys in regards to gear, time of year and geographic coverage on their (survey) use as stock indicators.
- Analyze the spawner recruit relationship and examine the relationships between parental stock size and environmental factors on year-class strength.
- Develop latitudinal/seasonal/gear specific age length keys for the Atlantic coast. Increase sample sizes to consider gear specific keys.

Medium Priority

- The impact of aging errors and other statistical uncertainties in the catch-at-age matrix on virtual population analysis (VPA) should be included. Retrospective analyses are needed on all VPA approaches investigated.
- Biological studies should be conducted to better understand migratory aspects and how this relates to observed trends in weight at age. Test for individual growth differences and their geospatial pattern, as well as the geospatial pattern of the catch rate surveys.
- Define reproductive biology of weakfish, including size at sexual maturity, maturity schedules, fecundity, and spawning periodicity. Continue research on female spawning patterns: what is the seasonal and geographical extent of "batch" spawning; do females exhibit spawning site fidelity?[1]
- Compile existing data on larval and juvenile distribution from existing databases in order to obtain preliminary indications of spawning and nursery habitat location and extent.
- Conduct hydrophonic studies to delineate weakfish spawning habitat locations and environmental preferences (temperature, depth, substrate, etc.) and enable quantification of spawning habitat.
- Continue studies on mesh-size selectivity; up-to-date (1995) information is available only for North Carolina's gill net fishery. Mesh-size selectivity studies for trawl fisheries are particularly sparse.
- Assemble socio-demographic-economic data as it becomes available from ACCSP.

---

[1] This is important information, but care must be taken in analysis. For instance, if a fish is captured in a net and used for fecundity, are there mechanical POFs present that would compromise assessments? Regarding maturity schedules, here is a prime example of how the NMFS survey, and NEAMAP survey, can be helpful. Right now NEFSC is cataloguing photos and histo samples of species to verify gross assessments of maturity (otos are taken for age). Consideration for this sampling should be given during the new NEAMAP survey. Most important, maturity assessments must be consistent among institutions.

- Continue studies on recreational hook-and-release mortality rates, including factors such as depth, warmer water temperatures, and fish size in the analysis. Studies are needed in deep and warm water conditions. Further consideration of release mortality in both the recreational and commercial fisheries is needed, and methods investigated to improve survival among released fish.

Low Priority

- Define restrictions necessary for implementation of projects in spawning and over-wintering areas and develop policies on limiting development projects seasonally or spatially.
- Document the impact of power plants and other water intakes on larval, post larval and juvenile weakfish mortality in spawning and nursery areas, and calculate the resultant impact to adult stock size.
- Develop a coastwide tagging database.
- Determine the onshore versus offshore components of the weakfish fishery.

Research Needs Identified as Having Being Met

Update the scale – otolith comparison for weakfish.

Winter Flounder

Coastwide

High Priority

- Expand sea sampling for estimation of commercial discards.
- Increase the intensity of commercial fishery discard length sampling.
- Focus research on quantifying mortality associated with habitat loss and alteration, contamination by toxics and power plant entrainment and impingement. Examine the implications of these anthropogenic mortalities on estimation of yield per recruit, if feasible.
- Provide reliable estimates of anthropogenic mortality from sources other than fishing. Both mortality sources should then be incorporated into fisheries yield/recruit models to simultaneously evaluate these dual mortality factors.

Lower Priority

- Conduct studies of flounder populations in impacted areas to fully quantify physiological adaptation to habitat alteration, and interactive effects, on an individual and population level.
- Evaluate the maturity at age of fish sampled in the NEFSC fall and winter surveys, as well as other inshore surveys (i.e., MEDMR, MADMF, NEAMAP, etc.).
- Develop mortality estimates from the American Littoral Society tagging data, if feasible.

Southern New England - Mid-Atlantic Stock Complex

High Priority

- Maintain or increase sampling levels and collect age information from MRFSS samples.
- Conduct studies to delineate all major substocks in terms of geographic spawning area and seasonal offshore movements (e.g. exposure to fishing pressure).
- Examine the sources of differences between NEFSC, MA, and CT survey maturity (validity of evidence for younger size/age at 50% maturity in NEFSC data). Compare NEFSC inshore versus offshore strata for differences in maturity. Compare confidence intervals for maturity ogives. Calculate annual ogives and investigate for progression of maturity changes over time. Examine maturity data from NEFSC strata on Nantucket Shoals and near George=s Bank separately from more inshore areas. Consider methods for combining maturity data from different survey programs. *Note that this work is in progress.*
- Conduct periodic maturity staging workshops involving state and NEFSC trawl survey staff.
- Examine the implications of anthropogenic mortalities caused by pollution and power plant entrainment in estimation of yield per recruit, if feasible.

Medium Priority

- Examine egg and larvae distribution and abundance to determine yield per recruit to predict future biomass development for the fishery.
- Understand distribution of winter flounder during each life stage by conducting tagging methods; in which majority of research focuses on juvenile to adult life stages, which would be useful for estimating yield per recruit and helpful to find answers as to why recruitment is at a vulnerable state.
- Examine winter flounder distribution, abundance, and productivity based on oceanographic and climatic warming temperatures and how that impacts biomass for the fishery in SNE/MA waters.

Low Priority

- Examine predator-prey relationships due to increased populations of cormorants seals, and striped bass (examine stomach contents of predators to get a better idea on the quantification of predation on winter flounder by these predators).
- Quantify adult female to male ratios to determine the possibility of populations decline due to a skewed gender ratio.

Gulf of Maine Stock

<u>High Priority</u>

- Process archived age samples from surveys and commercial landings, and develop analytical age based assessment.[1]
- Improve sampling for biological data (particularly hard parts for ageing) of commercial landings of winter flounder.
- Expand sea sampling in order to validate commercial discard estimates from Vessel Trip Reports (logbooks).
- Update or conduct regional maturity studies. This may require a maturity workshop to ensure the use of standardized criteria among regional studies.
- Develop a geographically more comprehensive data set to calculate maturity at age, reflecting any differential availability of mature fish to inshore and offshore surveys. Re-examine the maturity ogive to incorporate any recent research results. (see below also)
- Incorporate the results from the MEDMR research trawl survey (begun in 2000) into the assessment as they become available.
- Further examine the stock boundaries to determine if Bay of Fundy winter flounder should be included in the Gulf of Maine stock complex.
- Examine growth variations within the Gulf of Maine, using results from the Gulf of Maine Biological Sampling Survey (1993-94).[2]

<u>Medium Priority</u>

- Maintain or increase sampling levels and collect age information from MRFSS samples.
- Evaluate size-selectivity performance of survey gear compared to typical commercial gear, and implications for estimation of commercial discards from research survey length frequency information.
- Evaluate the feasibility of virtual population analysis based only on ages fully recruited to landings (i.e. no discards).

<u>Low Priority</u>

- Evaluate effects of smoothed length-frequency distributions on the relationship between survey and commercial catches at length.
- Estimate/evaluate effects of catch-and-release components of recreational fishery on discard at age.

[1] MEDMR has archived WF otoliths since 2002.
[2] Biological data on WF has been collected on the MEDMR trawl survey from 2000-2008, we need to use this data as well.

FUTURE HABITAT RESEARCH INFORMATION NEEDS FOR DIADROMOUS SPECIES

Group I. Research Needs for All Commission-Managed Diadromous Species

Dams and Other Obstructions

Fish Passage

1) Evaluate performance of conventional fishways, fish lifts, and eel ladders, and determine features common to effective passage structures and those common to ineffective passage structures.
2) Conduct basic research into diadromous fish migratory behavior as it relates to depth, current velocity, turbulence, entrained air, light, structures, and other relevant factors.
3) Use information from (1) and (2) to conduct computer fluid dynamics (CFD) modeling to develop more effective fishway designs.
4) Research technologies (barriers, guidance systems, etc.) for directing emigrating fish to preferred passage routes at dams.
5) Identify low-cost alternatives to traditional fishway designs.
6) Develop effective downstream passage strategies to reduce mortality.

Other Dam Issues

1) Document the impact of power plants and other water intakes on larval, postlarval, and juvenile mortality in anadromous fish spawning areas, and calculate the resultant impacts to adult population sizes.
2) Evaluate the upstream and downstream impacts of barriers on diadromous species, including population and distribution effects.

Water Quality and Contamination

1) Determine effects of change in temperature and pH for all life stages of all diadromous species. Use this information to model impacts of climate change on species.
2) Develop studies to document which contaminants have an impact on the various life stages of each diadromous species; also note the life stages that are affected, and at what concentrations.
3) Determine unknown optima and tolerance ranges for depth, temperature, salinity, dissolved oxygen, pH, substrate, current velocity, and suspended solids.

Habitat Protection and Restoration

1) Use multi-scale approaches (including GIS) to assess indicators of suitable habitat, using watershed and stream-reach metrics if possible (it should be noted, that where site-specific data is lacking, it may not be appropriate to assess at this scale).
2) Use multi-scale approaches for restoring diadromous fish habitat, including vegetated buffer zones along streams and wetlands, and implementing measures to enhance acid-neutralizing capacity.
3) Conduct studies on the effects of land use change on diadromous species population size, density, distribution, health, and sustainability.

4) Examine how deviation from the natural flow regime impacts all diadromous species. This work should focus on key parameters such as rate of change (increase and decrease), seasonal peak flow, and seasonal base flow, so that the results can be more easily integrated into a year-round flow management recommendation by state officials.
5) Investigate consequences to diadromous stocks from wetland alterations.

Other

1) Determine survival and mortality rates for all life stages of all diadromous species.
2) Investigate predator-prey relationships for all life stages of all diadromous species.
3) Determine the effects of channel dredging, shoreline filling, and overboard spoil disposal in the Atlantic coast on diadromous species.
4) Define restrictions necessary for implementation of energy projects in diadromous species habitat areas, and develop policies on limiting development projects seasonally or spatially.

Group II. Alosine-Specific Research Needs

Water Quality and Contamination

1) Review studies dealing with the effects of acid deposition on anadromous alosines.
2) Determine if intermittent episodes of pH depressions and aluminum elevations (caused by acid rain) affect any life stage in freshwater that might lead to reduced reproductive success of alosines, especially in poorly buffered river systems.
3) Determine if chlorinated sewage effluents are slowing the recovery of depressed shad stocks.

Habitat Protection and Restoration

1) Conduct research on habitat requirements for all life stages of hickory shad.

Migration

1) Determine factors that regulate and potentially limit downstream migration, seawater tolerance, and early ocean survival of juvenile alosines.
2) Conduct research on hickory shad migratory behavior.

Other

1) Focus research on within-species variation in genetic, reproductive, morphological, and ecological characteristics, given the wide geographic range and variation at the intraspecific level that occurs in alosines.
2) Research predation rates and impacts on alosines.
3) Evaluate the effect of bycatch on alosines.
4) Ascertain how abundance and distribution of potential prey affect growth and mortality of early life stages of alosines.

Group III. American Eel-Specific Research Needs

Dams and Other Obstructions

Fish Passage

1) Research the behavior of American eel approaching hydropower dams to determine searching behavior and preferred routes of approach to confirm best siting options for upstream passage.
2) Investigate, develop, and improve technologies for American eel passage upstream and downstream at various barriers for each life stage.
3) Investigate how river flow, lunar phase, water temperature, and behavior near artificial lighting impact the behavior of American eel, and influence the amount of time that the eels spend at a dam.
4) Research the behavior of silver eels at downstream passages; determine specific behavior of eels migrating downstream, and research how they negotiate and pass hydropower facilities.

Water Quality and Contamination

1) Determine the effects of contaminant bioaccumulation on American eel, including impacts on survival and growth (by age), maturation, and reproductive success.
2) Research the ability of contaminated eels to carry out successful breeding.
3) Examine the environmental conditions required for the hatching success of American eel.

Habitat Protection and Restoration

1) Establish characteristics and distribution of American eel habitat (using conventional methods as well as GIS), and the value of that habitat with respect to growth and sex determination.
2) Determine the effects of loss of historic habitat to potential American eel population and reproductive capacity.
3) Investigate the impact of seaweed harvesting on American eel.
4) Research the changes in ocean climate and environmental quality that might influence larval and adult eel migration, spawning, recruitment, and survival, including oceanic heat transport and interactions with the atmosphere and greenhouse gas warming.
5) Determine the importance of coastal lakes and reservoirs to American eel populations.

Migration

Silver-phase

1) Identify migratory routes and guidance mechanisms of silver eels migrating to the ocean.
2) Determine mechanisms for the recognition of the spawning area by silver eels, mate location in the Sargasso Sea, spawning behavior, and gonadal development in maturation.

3) Identify verify specific American eel spawning locations in the Sargasso Sea.
4) Research the factors that cause American eel to initiate downstream migration and affect their patterns of movement.

Leptocephalus

1) Identify the precise mechanisms of larval transport for American eel.
2) Examine the mechanisms for leptocephalus exit from the Sargasso Sea and transport across the continental shelf.
3) Determine mechanisms of recruitment of leptocephali and glass eels to coastal areas.

Glass Eel

1) Investigate the impact of stream velocity/discharge and stream morphology on upstream migration of glass eel and elvers.

Yellow-phase

1) Research behaviors and movements of American eel during their freshwater residency.

Parasitism

1) Evaluate the occurrence and impact of the nematode parasite, *Anguillicola crassus*, on all life stages.

Feeding

1) Examine the mode of nutrition for leptocephali in the ocean.
2) Examine food habits for glass eels at sea.

Other

1) Research all aspects of the leptocephalus life history stage.

<u>Group IV. Atlantic Sturgeon-Specific Research Needs</u>

Dams and Other Obstructions

Fish Passage

1) Fish passage requirements and appropriate structures for Atlantic sturgeon are largely unknown. Research all fish passage requirements for Atlantic sturgeon.

Bycatch

1) Determine levels of bycatch and compare to F_{50} target levels for individual Atlantic sturgeon populations.
2) Characterize Atlantic sturgeon bycatch in various fisheries by gear and season; include data on fish size, health condition at capture, and number of fish captured.
3) Develop markers that permit identification of bycatch of Atlantic sturgeon by population origin.

Population Status

1) Conduct assessments of population abundance and age structure in various river systems, with particular emphasis on documenting occurrence of age 0-12 juveniles and spawning adult Atlantic sturgeon as indicators of natural reproduction.
2) Continue to determine the extent to which Atlantic sturgeon are genetically differentiable among rivers, and interpret biological significance of findings.
3) Conduct further analyses to assess the sensitivity of F_{50} to model inputs for northern and southern stocks of Atlantic sturgeon.

Culture and Stock Enhancement

1) Further develop techniques for capture, transport, and long-term holding of wild Atlantic sturgeon brood stock.
2) Refine maturation-induced spawning procedures, and sperm cryo-preservation techniques for Atlantic sturgeon to assure availability of male gametes.
3) Continue basic cultural experiments at all life stages of Atlantic sturgeon to provide information on:
    a. Efficacy of alternative spawning techniques
    b. Egg incubation and fry production techniques
    c. Holding and rearing densities
    d. Prophylactic treatments
    e. Nutritional requirements and feeding techniques, and
    f. Optimal environmental rearing conditions and systems.
4) Identify suitable stocking protocols for hatchery-reared Atlantic sturgeon (e.g., individual size, time of year, site, and marking technique).
5) Conduct and monitor pilot-scale Atlantic sturgeon stocking programs before conducting large-scale efforts that encompass a broad geographic area.
6) Establish Atlantic sturgeon stocking goals and success criteria prior to development of large-scale stock enhancement or recovery programs.

Tagging and Tissues

1) Standardize collection procedures, and develop a suitable long-term repository for Atlantic sturgeon biological tissues for use in genetic and other studies.
2) Establish coordinated tagging programs to delineate migratory patterns and stock composition, giving priority to marking juveniles in important sturgeon rivers before they migrate to the ocean.
3) Maintain database for tagged Atlantic sturgeon.
4) Identify rates of tag loss and tag reporting for Atlantic sturgeon.
5) Analyze existing sea sampling data to characterize at-sea migratory behavior. Use electronic tagging to model coastal migrations of juvenile and adult Atlantic sturgeon.

Maturity and Aging

1) Develop methods to determine sex and maturity of captured Atlantic sturgeon.
2) Evaluate aging techniques for Atlantic sturgeon with known-age fish, with emphasis on verifying current methodology based on fin rays.

3) Determine length, fecundity, and maturity at age for all Atlantic sturgeon stocks.
4) Develop a protocol for ageing validation in Atlantic sturgeon.

Group V. Striped Bass-Specific Research Needs

To be identified shortly.

ASMFC Critical Research Needs in Support of Interjurisdictional Fisheries Management

2009

American Eel

- Formulate a coastwide fishery-independent sampling program for yellow and silver American eels using standardized and statistically robust methodologies.
- Investigate: fecundity, length, and weight relationships for females throughout their range; growth rates for males and females throughout their range; age and maturity data.
- Investigate, develop, and improve technologies for American eel passage upstream and downstream at various barriers for each life stage. In particular, investigate low-cost alternatives to traditional fishway designs for passage of eel.

American Lobster

- Develop reliable sex-specific estimates of molt frequency and molt increment for each stock.
    - Address problems associated with the growth matrix through aging studies or use of the extensive Canadian tag database for obtaining better estimates of growth and molt frequency. Apply the biochemical assessment of lipofuscin content to help estimate growth.
- Develop a reliable recruitment index, based on the ventless trap catches, larval/settlement indices, etc. A standardized coast-wide fishery-independent survey that is designed to target American lobster, such as the ventless trap survey, is critical for this.
- Increase biological sampling (either port or sea-sampling), especially in offshore areas of the Gulf of Maine, Georges Bank, and the Southern New England Canyons.

American Shad/River Herring

- Determine American shad and river herring bycatch within state and ocean waters.
- Determine which stocks are impacted by coastal intercept fisheries (including bycatch fisheries) and evaluate the fishing mortality on those stocks. Methods to be considered to differentiate among stocks could include otolith micro-chemistry, oxytetracycline otolith marking, tagging or DNA/RNA methods.
- Conduct population assessments on river herring, including biosampling - particularly needed in the south.
- Continue to assess current aging techniques for American shad and river herring, using known age fish, scales, otoliths, and spawning marks.
- Determine predation by fish, mammals and birds on American shad and river herring.

Atlantic Croaker

- Develop fishery-dependent and independent size, age and sex specific relative abundance estimates to monitor long term changes in croaker abundance.
- Improve catch and effort statistics from the commercial and recreational fisheries, along with size and age structure of the catch.
- Conduct stock identification research on croaker via otoliths microchemistry, tagging, or genetics.

Atlantic Menhaden

- Develop and improve fishery-independent estimates of adult abundance at age on a coast-wide scale to replace or augment the existing pound net index. Aerial survey has been discussed, perhaps in cooperation with the menhaden industry using spotter pilots.
- Develop and test methods for estimating size of recruiting year-classes of juveniles using fishery-independent survey techniques. State seine indices are used for juvenile abundance indices, but there is a need to update information on stream productivity for combining across state surveys for a coastwide index.

Atlantic Sea Herring

- Synthesize predator/prey information and conduct investigations to address information gaps; investigate the role of herring in the Northwest Atlantic ecosystem and the importance of herring as a forage species for other commercial fish stocks; assess the importance of herring as forage relative to other forage species in the region.
    - Re-evaluate Atlantic herring natural mortality by age and the response to changing predator population sizes through an ecosystem based assessment.
- Investigate bycatch/discards in the directed herring fishery through both at-sea and portside sampling.
- Continue tagging and morphometric studies to explore uncertainties in stock structure and the impacts of harvest mortality on different components of the stock. Although tagging studies may be problematic for assessing survivorship for a species like herring, they may be helpful in identifying the stock components and the proportion of these components taken in the fishery on a seasonal basis.

Atlantic Striped Bass

- Develop a spatial, temporal and sex specific catch-at-age model incorporating tag-based movement information.
- Compare scale and otolith ages and develop methodology to incorporate otolith ages into the assessment.
- Continue in-depth analysis of migrations, stock compositions, etc. using mark-recapture data (ongoing, e.g., Cooperative Winter Tagging Cruise 20 Year Report, W. Laney).
- Examine potential biases associated with the number of tagged individuals, such as gear-specific mortality (associated with trawls, pound nets, gill nets, and electrofishing), tag-induced mortality, and tag loss.

Atlantic Sturgeon

- Establish current spawning stock status in historic spawning rivers, and evaluate habitat use, or suitability.
    - Conduct assessments of population abundance and age structure in various river systems. Particular emphasis should be placed in documenting occurrence of age 0-1 juveniles and spawning adults as indicators of natural reproduction.
- Characterize size, condition, and relative abundance of Atlantic sturgeon by gear and season taken as bycatch in various fisheries.
- Establish stocking goals and success criteria prior to development of stock enhancement or recovery programs.

Black Sea Bass

- Develop fishery-independent surveys and expand existing surveys to capture all sizes and age classes in order to develop independent catch-at-age and CPUE. Expansion could include improvements or augmentation of existing trawl surveys and/or addition of a pot type survey to acquire older ages.
- Increase sea sampling to verify information from commercial logbooks to provide better estimates of discards. Should be part of a comprehensive fisheries dependent sampling program for both the recreational and commercial fisheries.
- Increase age sampling across all components of the fishery. Could be done through a comprehensive multispecies market and recreational catch sampling program.

Bluefish

- Collect size and age composition of the fisheries by gear type and statistical area.
- Initiate fishery-dependent and independent sampling of offshore populations of bluefish during the winter months.
- Evaluate amount and length frequency of discards from the commercial and recreational fisheries.

Coastal Sharks

- Continue to acquire better species-specific landings information on number of species, including smooth dogfish, by weight, from dealers.
- Conduct smooth dogfish assessment.
- Better identify and quantify the use of Essential Fish Habitat and nursery areas for shark species found along the Atlantic Coast of the U.S. Continue and expand long term shark monitoring programs to assess population status, and trends in demographic parameters.
- Identify and evaluate the effects of shark bycatch in other fisheries. Initiate or expand species identification of bycatch in shrimp trawls to allow for better bycatch estimates particularly of blacknose sharks and other shark species.

Horseshoe Crab

- Model relationship between egg availability and spawning biomass/abundance.
- Expand or implement fishery-independent surveys to encompass the full range of horseshoe crabs along the coast including inland waters.
- Assess horseshoe crab prey availability and determine whether horseshoe crab population growth will be/is limited by prey availability.

Northern Shrimp

- Refine annual estimates of consumption by predators. Consumption estimates could lead to annual estimates of *M* that would be more realistic than assuming constant *M*, for use in models that include *M* explicitly. Alternatively, consumption estimates could be used in production models as annual removals similar to fishery removals.
    - o Continue NEFSC bottom trawl survey finfish stomach sampling. Initiate a similar program for the ME/NH and MA surveys. Improve predator/prey spatial and temporal overlaps from available data.
- Better characterize shrimp discards in the shrimp and other small-mesh (i.e., herring and whiting) fisheries. Resources required: more at-sea sampling; several person-months for analysis of existing VTR and sea-sampling databases.
- Explore the stock-recruitment relationship and the impact of environmental factors on larval and juvenile abundance, growth, and survival.
    - o Extend the range of environmental variables and datasets used previously. Integrate the biological and environmental data sets and conduct multivariate analyses of effects of the environmental variables.

Red Drum

- Support fishery-independent sampling of sub-adult and adult red drum in each state from Virginia to Florida. The purpose of this survey would be to: 1) verify escapement to the spawning population, 2) provide an index of recruitment to age-1, and 3) provide an estimate of the biomass of adult red drum.
- Continue tagging studies to determine stock identity, inshore/offshore migration patterns and mortality estimation.

Scup

- Maintain the current level of sampling, particularly of the discards, to adequately characterize the length composition of both landings and discards, to ensure reliability of the analytic assessment and forecasts of catch and stock biomass for this stock.
  - Expanded age sampling of scup from commercial and recreational catches is required, with special emphasis on the acquisition of large specimens. Need to increase observer coverage for winter I offshore directed scup fishery and bycatch squid fishery.
- Continue to support and fund both the Rhode Island commercial fish trap survey and the Fishery Independent Scup Survey of Hard Bottom Areas in Southern New England Waters. Expand the fishery independent survey to include waters farther west and collect scales for aging.

Spanish Mackerel

- Evaluate weight- and especially length-at-age, including updated conversion equations (e.g., gutted to whole weight) and sampling of age-0 fish.
- Improved information on discard rates and discard mortality, including 5-10 % observer coverage of commercial fisheries.
- Increase biological sampling, especially hard parts for aging, from all states where Spanish mackerel are landed.
- Determine the bycatch of Spanish mackerel in the directed shrimp fishery in Atlantic Coastal waters.
- Develop fishery-independent methods to monitor stock size of Atlantic Spanish mackerel (consider aerial surveys used in south Florida waters).

Spiny Dogfish

- Characterize and quantify bycatch of spiny dogfish in other fisheries.
- Determine coastwide discard mortality rate for fixed and mobile gear fisheries that catch dogfish as bycatch.
- Conduct a coastwide tagging study to explore stock structure, migration, and mixing rates.
- Standardize age determination along the entire East coast. Conduct an aging workshop for spiny dogfish, encouraging participation by NEFSC, NCDMF, Canada DFO, and other interested agencies, academia and other international investigators with an interest in dogfish aging (US and Canada Pacific Coast, ICES).

Spot

- Improve spot catch and effort statistics from the commercial and recreational fisheries, along with size and age structure of the catch, in order to develop production models.
- Develop fishery-dependent and independent size- and sex-specific relative abundance estimates.
- Develop cooperative coastwide spot juvenile indices to clarify stock status.
- Monitor and report on the extent of unutilized bycatch and fishing mortality on fish less than age-1in trawl fisheries or other fisheries that take significant numbers of spot. Incorporate bycatch estimates into spot assessment models.
- Monitor long term changes in spot abundance, growth rates, and age structure.

Spotted Seatrout

- Initiate fishery-independent surveys of spotted seatrout, especially for juvenile abundance indices. Begin with a review of existing data and programs. States should conduct routine fishery-independent surveys using entanglement gear to generate annual indices of abundance for use in regional stock assessments.
- Collect the necessary biological data to be able to conduct stock assessments and to assist in drafting fishery management plans.

Summer Flounder

- Develop a program to annually sample the length- and age-frequency of summer flounder discards from the recreational fishery.
    - Expand MRIP for-hire survey to collect scale samples; expand to collect samples from other modes, or utilize existing volunteer angler surveys. Ideally, this would be part of a long term comprehensive fishery-dependent sampling program.
- Continue to collect and analyze age/length samples and catch/effort data from the commercial and recreational fisheries throughout the range of summer flounder. Increase the number of length samples taken by MRIP.
- Collect otoliths more comprehensively, for all components of the catch-at-age matrix, on a continuing basis for fish larger than 60 cm (~7 years). Collecting information on overall fecundity for the stock, both egg condition and production may be a better indicator of stock productivity.
- Continue fishery-independent surveys and expand existing surveys to capture all sizes and age classes in order to develop fishery-independent catch-at-age and CPUE.

Tautog

- Establish standardized state-by-state long-term fishery-independent surveys to monitor tautog abundance and length-frequency distributions, and to develop young-of-the-year indices.
- Increase MRIP sampling levels to improve recreational catch estimates by state and mode. Current sampling levels are high during times of the year when more abundant and popular species are abundant in catches, but much lower than in early spring/late fall when tautog catches are more likely.
- Initiate biological sampling of the commercial catch for each gear type over the entire range of the stock (including weight, lengths, age, sex, and discards).

Weakfish

- Conduct spatial and temporal analysis of the fishery-independent survey data. The analysis should assess the impact of the variability of the surveys in regards to gear, time of year and geographic coverage on the use of the surveys as stock indicators.
- Analyze the spawner-recruit relationship and examine the relationships between parental stock size and environmental factors on year-class strength.
  - Analyze the characteristics of the process error variability (noise) in the recruitment dynamics.
- Identify stocks and determine coastal movements and the extent of stock mixing, including characterization of stocks in over-wintering grounds (e.g., tagging).
  - Develop an operational model(s) that incorporates catch uncertainty, to improve on limitations of the currently used VPA model.

Winter Flounder

- Expand sea sampling for estimation of commercial discards.

FISHERY ECOSYSTEM PLAN OF THE SOUTH ATLANTIC REGION

VOLUME V: SOUTH ATLANTIC RESEARCH PROGRAMS AND DATA NEEDS

April 2009

South Atlantic Fishery Management Council

THIS IS A PUBLICATION OF THE SOUTH ATLANTIC FISHERY MANAGEMENT COUNCIL PURSUANT TO National Oceanic and Atmospheric Administration Award No. FNA05NMF4410004

ABBREVIATIONS AND ACRONYMS

ABC	Acceptable Biological Catch
ACCSP	Atlantic Coastal Cooperative Statistics Program
APA	Administrative Procedures Act
AUV	Autonomous Underwater Vehicle
B	A measure of stock biomass either in weight or other appropriate unit
B_{MSY}	The stock biomass expected to exist under equilibrium conditions when fishing at F_{MSY}
B_{OY}	The stock biomass expected to exist under equilibrium conditions when fishing at F_{OY}
B_{CURR}	The current stock biomass
CEA	Cumulative Effects Analysis
CEQ	Council on Environmental Quality
CFMC	Caribbean Fishery Management Council
CPUE	Catch per unit effort
CRP	Cooperative Research Program
CZMA	Coastal Zone Management Act
DEIS	Draft Environmental Impact Statement
EA	Environmental Assessment
EBM	Ecosystem-Based Management
EEZ	Exclusive Economic Zone
EFH	Essential Fish Habitat
EFH-HAPC	Essential Fish Habitat - Habitat Area of Particular Concern
EIS	Environmental Impact Statement
EPAP	Ecosystem Principles Advisory Panel
ESA	Endangered Species Act of 1973
F	A measure of the instantaneous rate of fishing mortality
$F_{30\%SPR}$	Fishing mortality that will produce a static SPR = 30%.
$F_{45\%SPR}$	Fishing mortality that will produce a static SPR = 45%.
F_{CURR}	The current instantaneous rate of fishing mortality
FMP	Fishery management plan
F_{MSY}	The rate of fishing mortality expected to achieve MSY under equilibrium conditions and a corresponding biomass of B_{MSY}
F_{OY}	The rate of fishing mortality expected to achieve OY under equilibrium conditions and a corresponding biomass of B_{OY}
FEIS	Final Environmental Impact Statement
FMU	Fishery Management Unit
FONSI	Finding Of No Significant Impact
GOOS	Global Ocean Observing System
GFMC	Gulf of Mexico Fishery Management Council
IFQ	Individual fishing quota
IMS	Internet Mapping Server
IOOS	Integrated Ocean Observing System
M	Natural mortality rate

MARMAP	Marine Resources Monitoring Assessment and Prediction Program
MARFIN	Marine Fisheries Initiative
MBTA	Migratory Bird Treaty Act
MFMT	Maximum Fishing Mortality Threshold
MMPA	Marine Mammal Protection Act of 1973
MRFSS	Marine Recreational Fisheries Statistics Survey
MSA	Magnuson-Stevens Act
MSST	Minimum Stock Size Threshold
MSY	Maximum Sustainable Yield
NEPA	National Environmental Policy Act of 1969
NMFS	National Marine Fisheries Service
NMSA	National Marine Sanctuary Act
NOAA	National Oceanic and Atmospheric Administration
NRC	National Research Council
OY	Optimum Yield
POC	Pew Oceans Commission
R	Recruitment
RFA	Regulatory Flexibility Act
RIR	Regulatory Impact Review
SAFE	Stock Assessment and Fishery Evaluation Report
SAFMC	South Atlantic Fishery Management Council
SEDAR	Southeast Data, Assessment, and Review
SEFSC	Southeast Fisheries Science Center
SERO	Southeast Regional Office
SDDP	Supplementary Discard Data Program
SFA	Sustainable Fisheries Act
SIA	Social Impact Assessment
SSC	Scientific and Statistical Committee
TAC	Total allowable catch
T_{MIN}	The length of time in which a stock could rebuild to B_{MSY} in the absence of fishing mortality
USCG	U.S. Coast Guard
USCOP	U.S. Commission on Ocean Policy
VMS	Vessel Monitoring System

Table of Contents

LIST OF FIGURES

9.0 Data and Research Necessary to Support Ecosystem Management

9.1 Research Needs and Research and Monitoring Plans

The 2006 reauthorization of the Magnuson-Stevens Act includes the following language pertaining to research and monitoring needs for regional fishery management councils:

(c) COUNCIL FUNCTIONS.—Section 302(h) (16 U.S.C. 1852(h)) is amended—
''(6) develop annual catch limits for each of its managed fisheries that may not exceed the fishing level recommendations of its scientific and statistical committee or the peer review process established under subsection (g); and''.

(d) SCIENTIFIC RESEARCH PRIORITIES.—Section 302(h) (16 U.S.C. 1852(h)), as amended by subsection (c), is further amended—
(1) by striking ''(g); and'' in paragraph (6) and inserting ''(g);''; (2) by redesignating paragraph (7), as redesignated by subsection (c)(2), as paragraph (8); (2) by inserting after paragraph (6) the following: ''(7) develop, in conjunction with the scientific and statistical committee, multi-year research priorities for fisheries, fisheries interactions, habitats, and other areas of research that are necessary for management purposes, that shall—
''(A) establish priorities for 5-year periods;
''(B) be updated as necessary; and
''(C) be submitted to the Secretary and the regional science centers of the National Marine Fisheries Service for their consideration in developing research priorities and budgets for the region of the Council; and''.

SEC. 318. COOPERATIVE RESEARCH AND MANAGEMENT PROGRAM.
''(a) IN GENERAL.—The Secretary of Commerce, in consultation with the Councils, shall establish a cooperative research and management program to address needs identified under this Act and under any other marine resource laws enforced by the Secretary. The program shall be implemented on a regional basis and shall be developed and conducted through partnerships among Federal, State, and Tribal managers and scientists (including interstate fishery commissions), fishing industry participants (including use of commercial charter or recreational vessels for gathering data), and educational institutions.
''(b) ELIGIBLE PROJECTS.—The Secretary shall make funds available under the program for the support of projects to address critical needs identified by the Councils in consultation with the Secretary. The program shall promote and encourage efforts to utilize sources of data maintained by other Federal agencies, State agencies, or academia for use in such projects.
''(c) FUNDING.—In making funds available the Secretary shall award funding on a competitive basis and based on regional fishery management needs, select programs that form part of a coherent program of research focused on solving priority issues identified by the Councils, and shall give priority to the following projects:

‘‘(1) Projects to collect data to improve, supplement, or enhance stock assessments, including the use of fishing vessels or acoustic or other marine technology.
‘‘(2) Projects to assess the amount and type of bycatch or post-release mortality occurring in a fishery.
‘‘(3) Conservation engineering projects designed to reduce
bycatch, including avoidance of post-release mortality, reduction of bycatch in high seas fisheries, and transfer of such fishing technologies to other nations.
‘‘(4) Projects for the identification of habitat areas of particular concern and for habitat conservation.
‘‘(5) Projects designed to collect and compile economic and social data.
‘‘(d) EXPERIMENTAL PERMITTING PROCESS.—Not later than 180 days after the date of enactment of the Magnuson-Stevens Fishery Conservation and Management Reauthorization Act of 2006, the Secretary, in consultation with the Councils, shall promulgate regulations that create an expedited, uniform, and regionally-based process to promote issuance, where practicable, of experimental fishing permits.
‘‘(e) GUIDELINES.—The Secretary, in consultation with the Councils, shall establish guidelines to ensure that participation in a research project funded under this section does not result in loss of a participant’s catch history or unexpended days-at-sea as part of a limited entry system.
‘‘(f) EXEMPTED PROJECTS.—The procedures of this section shall not apply to research funded by quota set-asides in a fishery.’’.
ADDITION TO SEC 303(A) (FMP contents)
(a)(10)‘‘(15) establish a mechanism for specifying annual catch limits in the plan (including a multiyear plan), implementing regulations, or annual specifications, at a level such that overfishing does not occur in the fishery, including measures to ensure accountability.’’.
(b) EFFECTIVE DATES; APPLICATION TO CERTAIN SPECIES.—The amendment made by subsection (a)(10)—
(1) shall, unless otherwise provided for under an international agreement in which the United States participates, take effect—
(A) in fishing year 2010 for fisheries determined by the Secretary to be subject to overfishing; and
(B) in fishing year 2011 for all other fisheries; and
(2) shall not apply to a fishery for species that have a life cycle of approximately 1 year unless the Secretary has determined the fishery is subject to overfishing of that species; and
(3) shall not limit or otherwise affect the requirements of section 301(a)(1) or 304(e) of the Magnuson-Stevens Fishery
Conservation and Management Act (16 U.S.C. 1851(a)(1) or 1854(e), respectively).

9.1.1 South Atlantic Research and Monitoring Priorities 2008

Introduction

The 2006 reauthorization of the Magnuson-Stevens Fishery Conservation and Management Act (MSFCMA) directs the Federal Regional Fishery Management Councils to develop a prioritized research plan for submission to the Secretary of Commerce. The following research and monitoring needs were developed by the South Atlantic Council in fulfillment of that requirement.

The goals of the South Atlantic Research and Monitoring Plan are:

1) to improve the quality and quantity of information available for stock assessment and management program development and evaluation; and

2) to encourage a proactive approach to fisheries monitoring and research with priorities based on management needs and intentions.

These goals can be fulfilled by achieving the following objectives:

- Obtain complete fisheries statistics (landings, effort, discards) for all managed resources.
- Obtain adequate landings characterization information (biological sampling of landings & discard, effort details) for priority species.
- Develop representative fishery-dependent abundance measures for priority species.
- Provide reliable and up-to-date species biology and life history information (reproduction, growth, habits, ecosystem role) for all managed resources.
- Obtain adequate economic and social characterization information for all fisheries.
- Obtain fishery and catch data necessary for the Council to monitor and evaluate its management programs.
- Document and quantify habitat usage and availability for all Southeast habitats.
- Develop robust yet documented and validated analytical models appropriate for South Atlantic resources, management requirements, and data availability.

The proposed research and monitoring plan is documented in the following sections in order of decreasing priority and is summarized as follows:

1) Collect basic data for all managed fisheries.
2) Collect biological and survey information for priority species to support qualitative stock assessments.
3) Collect specific information to support evaluation and refinement of SAFMC management programs and actions.
4) Collect basic social and economic information to support management impact evaluations.
5) Collect general habitat information to support habitat protection efforts.
6) Collect ecosystem information to support ecosystem management.

SAFMC Prioritized Research Recommendations for the first 5 years (2008-2012)

The South Atlantic Council recommends that the first priority is obtaining accurate fishery level information with increased spatial resolution for landings, discards, and effective effort. Research and monitoring programs must accommodate the multi-species nature of many South Atlantic fisheries.

To address the challenge of multi-species fisheries, the basic unit to sample proposed here is a fishery rather than a species. To address the many managed species of the SAFMC, individual species are separated into two groups: those requiring 'basic' data elements and those requiring 'detailed' data elements. Initial classification into these two groups is based on the SEDAR assessment schedule, indicator species identified by the Council, those species included in NOAA Fisheries' Fish Stock Status Indicators listing in the Report to Congress, and recommendations of the SAFMC Science and Statistics Committee.

1. Collect basic data elements by fishery

The following information applies for all fisheries listed:

- All catch and bycatch reporting to species level
- Per tow/set/site/deployment information for for-hire and commercial fisheries collected through an electronic logbook linked to GPS
- License i.d. information available for all participants/vessels linked to trip and set reports
- Global participant frame provided through licensing of all participants
- Location elements include latitude, longitude, depth, and duration of effort

1. Shrimp Trawl Fishery
   Per tow: duration, location, trawl details, catch estimate, discard estimate
   Per trip: landings by species, trip costs, price paid per lb, # crew
   Supplement: 5% observer coverage for discard, 20% coverage for detailed social & economic reporting.

2. Trap Fisheries (e.g., sea bass, golden crab, spiny lobster)
   Per trap/string: duration, location, trap details, catch estimate, discard count
   Per trip: landings by species, trip costs, price paid per lb, # crew
   Supplement: 2% observer coverage for discard, 10 % video discard coverage, 20% coverage for detailed social & economic reporting.

3. Dive or Spear Fisheries
   Per dive: duration, location, gear details, # divers, catch estimate
   Per trip: landings by species, trip costs, price paid per lb, # crew
   Supplements: 20% coverage for detailed social & economic reporting.

4. Handline Fisheries
   Per set/site: duration, location, gear details, catch estimate, discard count
   Per trip: landings by species, trip costs, price paid per lb, # crew
   Supplement: 5% observer coverage for discard, 10% video discard coverage, 20% coverage for detailed social & economic reporting.

5. Deepwater Longline Fishery
   Per set/deployment: duration, location, gear details, catch estimate, discard count
   Per trip: landings by species, trip costs, price paid per lb, # crew
   Supplement: 5% observer coverage for discard, 10% video discard coverage, 20% coverage for detailed social & economic reporting.

6. Pelagic Longline Fishery
   Per set/deployment: soak, location, gear details, catch estimate, discard count
   Per trip: landings by species, trip costs, price paid per lb, # crew
   Supplement: 5% observer coverage for discard, 10% video discard coverage, 20% coverage for detailed social & economic reporting.

7. Bottom Longline
   Per set/deployment: soak, location, gear details, catch estimate, discard count
   Per trip: landings by species, duration, trip costs, price paid per lb, # crew,
   Supplement: 5% observer coverage for discard, 10% video discard coverage, 20% coverage for detailed social & economic reporting.

8. Private Recreational
   Per trip: mode, location, gear details, duration, landings by species, discard by species, expenditures,
   Per Year: # trips by mode, location
   Supplement: Voluntary logbook for discard characteristics (e.g., size and reason for discarding), 20% coverage for detailed social & economic reporting.

9. Headboat Recreational
   Per set/site: location, duration, catch & discard estimate by species
   Per Trip: # anglers, # lines, duration, landings by species
   Supplement: 5% observer coverage for discard characteristics. Voluntary logbook for discard (size), 20% coverage for detailed social & economic reporting of owner/operators. 20% coverage for social & economic evaluations of participants.

10. Party/Charter Recreational Fishery
   Per trip: mode, location, gear details, duration, catch & discard by species
   Supplement: 5% observer coverage for discard characteristics. Voluntary logbook for discard (size), 20% coverage for detailed social & economic reporting of owner/operators. 20% coverage for social & economic evaluations of participants.

<u>2. Collect biological and survey information for priority species to support quantitative stock assessments.</u>

Detailed, species-specific information is required for species that support the bulk of fishery landings to enable high resolution assessment models (i.e., age structured models) and directed management. This information should be collected for individual species, with sampling effort allocated across time, space, and the fisheries listed above as appropriate to ensure useful and statistically valid data.

Additional Data Elements for Primary Species:

- Representative sampling by season, fishery, and area of length, age, sex, and weight for landed & discarded fish.
- Fishery-dependent CPUE, based on increased effort resolution collected through the basic elements (1)
- Survey-based fishery-independent CPUE
- Life history research: rates of growth, mortality, maturity, fecundity
- Movement, migration, and stock structure evaluations

Additional Data Elements for Secondary species:

- Fishery-dependent CPUE, based on increased effort resolution collected through the basic elements (1)
- Survey-based fishery-independent CPUE
- Life history details: rates of growth, mortality, maturity, fecundity
- Movements, migration, and stock structure evaluations

SAFMC Proposed Primary Data Collection Species:

Vermillion snapper	Yellowtail snapper
Red snapper	Gray triggerfish
Snowy grouper	Mutton snapper
Tilefish	Red porgy
Red grouper	Wreckfish
Black sea bass	King mackerel
Gag grouper	Spanish mackerel
Greater amberjack	Dolphin
White grunt	Spiny lobster

SAFMC Secondary Data Collection Species

Scamp	Yellowedge grouper
Black grouper	Goliath grouper
Blueline tilefish	Little tunny
Cobia	Wahoo
Speckled hind	Hogfish
Warsaw grouper	

3. Collect specific information to support evaluation and refinement of SAFMC management programs and actions.

The Council has implemented some management actions that cannot be adequately evaluated with the information in the previous sections alone. This section also includes recommendations that affect collection and dissemination of the information desired above.

1. Full implementation of ACCSP in the South Atlantic.

2. Resolve confidentiality issues that prohibit reporting of and access to basic catch statistics by species, state, and year.
3. Eliminate duplicative programs such as paper logbooks, which duplicate information provided in state trip ticket programs.
4. Restructure the FSSI stocks for the South Atlantic Council to include only those stocks listed in Section VI-2 above as target species.
5. Provide annual SAFE reports and 'Trends' reports for each FMP summarizing the data elements contained in Sections III.1 and III.2.
6. Resolve ongoing issues with recreational data collection; ensure that recreational statistics can be reported according to Council boundaries.
7. Reduce data dissemination delays by continuing to develop and implement automated and web-based data entry programs that can accommodate the set level information described above.
8. Monitor fish population abundance inside protected areas (Oculina Closed Area, MPAs).
9. Determine stock status for severely restricted species (Warsaw grouper, speckled hind and Goliath grouper) to enable the Council to evaluate its management program.
10. Develop education programs for all participants that stress the importance of accurate and timely reporting of fisheries data and improve species i.d. for self-reported data.
11. Collect information on enforcement activities and develop statistics to enable the Council to objectively evaluate enforcement.

<u>4. Improve Social and Economic Evaluations</u>

Fishery and species specific monitoring information necessary for social and economic information is addressed in the previous sections. Recommendations that cross multiple fisheries or that represent research needs are listed here.

1. Determine recreational value.
2. Develop improved bio-economic models.
3. Develop models to test between different management scenarios.
4. Develop methods to integrate socio-economic information with the management process.
5. Evaluate the impacts of imported fisheries products.

<u>5. Improve Habitat Evaluation and Documentation</u>

Extensive habitat research and monitoring recommendations are detailed in various Council FMPs. The items listed here cross multiple FMPs and help support the Council's place-based management approaches for South Atlantic fisheries. These are research needs that should only need occasional updating once initially addressed.

1. Develop maps of and quantify available habitat and seasonal usage by target species.
2. Develop maps describing habitat types in proposed HAPCs.

3. Develop maps describing available habitat in proposed MPAs.

6. Improve Ecosystem-level information

The Council's Fishery Ecosystem Plan (FEP) will address many ecosystem level research and monitoring needs in detail. The primary short-term need is to implement robust monitoring programs to start building the long-term time series of information that is needed to evaluate ecosystem-level issues. These are both monitoring needs that need to be conducted annually.

1. Initiate a comprehensive survey of South Atlantic living marine resources.
2. Develop long-term monitoring of diet, productivity, and species interactions as required for ecosystem-level modeling.

Long Term Research Needs

The items listed above address the most critical needs in the South Atlantic and are considered to represent the minimum information required for adequate management. There are other needs that are less pressing and are therefore considered long-term. The same list of general issues is repeated for consistency.

1. Basic Data Elements, Long Term Improvements

1. Evaluate the convenience, quality, and utility of set-level logbook reporting and supplemental data collection programs; refine data elements, sampling intensity, collection programs, and methods as needed.
2. Develop a process to enable changes to historic data sources that will enable resolution of errors, address misidentification of species, and allow elimination of 'unclassified' categories.

2. Improving Detailed Information for Primary Species

1. Evaluate data collected by fishery and from comprehensive surveys to ensure the appropriate species receive intensified sampling.
2. Develop a long-term plan for regularly evaluating life history characteristics of target species.
3. Develop robust QA/QC programs for age determination.
4. Evaluate sampling intensity and modify sampling targets as necessary.

3. Improving Evaluation of Specific Management Actions

1. Develop a long-term plan for regularly evaluating life history characteristics for all species included in Council FMPs.
2. Support monitoring and research programs necessary to develop and evaluate limited access programs.
3. Develop a long-term plan for regularly evaluating trends and indicators of stock status for secondary species and all other managed species to enable management to adapt to fisheries changes as necessary.

9.1.2 SAFMC Fishery Management Plans

9.1.2.1 Shrimp

1. Research to relate the fishery independent SFA parameters with stock health in specific geographic locations.
2. Determine the possible impacts on indigenous shrimp species of inadvertent introductions of exotic shrimp species and diseases from mariculture operations, and develop methods and protocol to prevent such introductions.
3. Assess the potential utility of releasing maricultured white shrimp into the environment to supplement natural reproduction, especially following cold kills.
4. Assess the potential of controlled closures and other measures to enhance the production and economics of the South Atlantic shrimp fishery.
5. Determine the effects of beach renourishment projects on subsequent shrimp production.
6. Evaluate the impacts of habitat and water quality alteration on shrimp growth, survival and productivity.
7. Investigate the costs, benefits and utility of limited entry programs in the shrimp fishery of the South Atlantic.
8. Determine the impact of shrimp trawl bycatch on the habitat and all non-target species of fish and invertebrates (i.e., expand the congressionally mandated study to include impacts on habitat and all incidental species, not just the impact on other "fishery resources").
9. Determine the relationship between absolute number of adults (or adult biomass) and subsequent recruitment to allow development of a threshold level of population size to serve as a trigger to request a closure of the EEZ.
10. Determine the biological, economic and sociological status of the rock shrimp fishery.
11. Research ways to better monitor the shrimp fishery effects on listed species.

Additional research requirements pertaining to the economic and social aspects of the shrimp fishery:

1. Demographic information may include but is not necessarily limited to: population; age; gender; ethnic/race; education; language; marital status; children (age & gender); residence; household size; household income (fishing/non-fishing); occupational skills; and association with vessels and firms (role & status).
2. Social structure information may include but is not necessarily limited to: historical participation; description of work patterns; kinship unit, size and structure; organization and affiliation; patterns of communication and cooperation; competition and conflict; spousal and household processes; and communication and integration.
3. Cultural information (from the perspective of the respondent) may include but is not necessarily limited to: occupational motivation and satisfaction; attitudes and perceptions concerning management; constituent views of their personal future of fishing; psycho-social well-being; and cultural traditions related to fishing (identity and meaning).
4. Fishing community information might include but is not necessarily limited to: identifying communities; dependence upon fishery resources (this includes recreational use); identifying businesses related to that dependence; and determining the number of employees within these businesses and their status.

9.1.1.2 Snapper Grouper Complex

Oculina Experimental Closed Area Research and Monitoring Plan

In April 2004, regulations were implemented through Amendment 13A to the South Atlantic Snapper Grouper Fishery Management Plan that extended the fishing restrictions for the designated 92-square mile Oculina Experimental Closed Area for an indefinite period. The amendment was developed by the South Atlantic Fishery Management Council to address the 10-year sunset provision for the closure of the area to snapper/grouper fishing. Located off the coast of Ft. Pierce, Florida, the area is part of the larger Oculina Habitat Area of Particular Concern (HAPC) designed to protect the *Oculina* coral found there. In addition to extending the closure, the amendment requires that the size and configuration of the Experimental Closed Area be reviewed within three years of the implementation date of Amendment 13A and that a 10-year re-evaluation be conducted for the area. The Council also stipulated that an Evaluation Plan be developed to address needed monitoring and research, outreach, and enforcement efforts within one year of implementation of the Amendment.

Research and Assessment Needs below are listed in priority order as indicated in the Evaluation Plan. For more detailed information, please refer to that document.

1. What and where are the major habitat types in the Oculina Experimental Closed Area, the Oculina Bank Habitat Area of Particular Concern and adjacent hardbottom areas? (short-term, 3 years)

Objective 1: Complete high definition bathymetric mapping 1) within the Oculina Experimental Closed Area; 2) coral areas adjacent to the Habitat Area of Particular Concern; 3) in Habitat Area of Particular Concern within coral zone 50-100 m; 4) soft bottom habitat east of the coral zone within the Habitat Area of Particular Concern and 5) suspected and known hard coral areas north and south of the Habitat Area of Particular Concern, specifically from Cape Canaveral to the north and from St. Lucie mound and Jupiter Inlet to the south.

Objective 2: Complete habitat characterization 1) within the Oculina Experimental Closed Area; 2) coral areas adjacent to the Habitat Area of Particular Concern; 3) in Habitat Area of Particular Concern within coral zone 50-100 m; 4) soft bottom habitat east of the coral zone within the Habitat Area of Particular Concern and 5) suspected and known hard coral areas north and south of the Habitat Area of Particular Concern, specifically from Cape Canaveral to the north and from St. Lucie mound and Jupiter Inlet to the south.

2. Will *Oculina* thicket habitat recover throughout the Oculina Experimental Closed Area without human intervention? What time frame will be needed for significant recovery? Will it be necessary to introduce artificial substrate to serve as an initial settlement surface? (short-term, 3 years)

Objective 1: Identify coral/fish recruitment pathways and compare settlement, growth, and survival rates on artificial substrate relative to settlement, growth, and survival rates on nearby unconsolidated coral rubble.

Objective 2: Model biophysical, chemical, and physiological characters. Previous studies have shown the benthic environment of the *Oculina* reefs to be very dynamic and widely fluctuating due to upwelling events and meandering of the Florida Current.

3. What are the magnitude and causes of changes in habitat structure and functionality over time? (short-term, 3 years)
Objective 1: Determine causes and timing of coral death.
Objective 2: Origin and functional characterization of rubble zone.

4. What are the key trophodynamic functional groups? (short-term, 5 years)
Objective 1: Identify food web structure and dynamics.

5. Determine and monitor the effect of the Oculina Experimental Closed Area on fish distribution and status? (long-term, 10 years)
Objective 1: Assess spawning aggregations of fishery species.
Objective 2: Track fish movement.
Objective 3: Identify Oculina Experimental Closed Area fish population demographics.

6. What is the effect of management measures in the Oculina Experimental Closed Area on the status of fishery stocks? (long-term, 10 years)
Objective 1: Characterize (including distribution and abundance patterns, size and age distribution, spawning aggregation presence, sex ratios, etc) major fishery species within the Oculina Experimental Closed Area compared to reference sites.
Objective 2: Characterize fish communities, inside and out, including habitat utilization patterns, trophic interactions, ontogenetic changes, predator-prey relationships, etc.
Objective 3: Examine connectivity to the broader seascape (larval sources and sinks, spill-over effects).
Objective 4: Determine pre-closure distribution of dominant harvested species in and outside the reserve areas, in order to provide historical context for subsequent assessments. Review landings; spillover effects (i.e., identify benthic and juvenile pathways, upwelling events, spill-over between deep and shallow reefs).
Objective 5: Determine age distribution, nursery grounds, migratory patterns, and mortality rates for dominant harvested fish stocks.

4. What are the stressors affecting the Oculina Experimental Closed Area? (long-term, 10 years)
Objective 1: Identify natural and anthropogenic stressors (i.e., disease, gear impacts, poaching, enforcement).
Objective 2: Determine the frequency and severity of sedimentation induced by benthic storms.
Objective 3: Identify physiological tolerances of the coral to environmental stressors

6. Develop index of physical and chemical parameters that characterize a healthy Oculina coral ecosystem. (long-term, 10 years)
Objective 1: Develop index for coral health (including structural damage, recruitment, genetics, physiology, life history).

Objective 2: Develop index of community health for entire biota including coral (biodiversity, richness, biocomplexity).
Objective 3: Determine indicator species that are intimately tied with *Oculina* (invertebrates or vertebrates).
Objective 4: What is the age of the coral substrate, and geological formations (last 15,000 years) (death rates)? Also look at associated mollusks and other biota and their changes.
Objective 5: Examine association of paleo-data (age) with past climate and oceanographic conditions.
Objective 6: Are there other paleo-data from elsewhere in the world that will give perspective on *Oculina* growth (ice cores, deep-water sediment cores)?
3. What is the population structure of corals? (long-term, 10 years)
Objective 1: Research population genetics of *Oculina varicosa.*
Objective 2: Identify cross-shelf relationships between shallow and deep *Oculina varicosa* populations.
Objective 3: Conduct biogeographic studies.

4. How do oceanographic conditions and episodic events affect production, coral condition, reproduction and growth? (long-term, 10 years)
Objective 1: Quantify the extent, intensity and frequency of episodic events (upwelling, storms, etc).
Objective 2: Assess the impact of episodic events (upwelling, storms, etc).
Objective 3: Optimize design of restoration efforts.
Objective 4: Characterize impacts from anthropogenic sources of pollution (nutrients/sedimentation).

7. Conduct research on coral feeding ecology (long-term, 10 years)
Objective 1: Define feeding dynamics.

9.1.2.3 Coral, Coral Reefs and Live/Hard Bottom Habitat

Deepwater Coral Research and Monitoring Plan

In developing a Deepwater Coral Research and Monitoring Plan, the Council is responding to recent amendments to the Magnuson-Stevens Act and NOAA's determination that an agency strategy is needed to effectively and efficiently address deepwater coral ecosystems issues. The primary goal of this Research and Monitoring Plan is to support conservation and management of deepwater coral ecosystems in the South Atlantic region while addressing NOAA's strategy to balance long-term uses of the marine ecosystem with maintenance of biodiversity. The Plan will also assist in meeting the new mandates of the Magnuson-Stevens Act.

This plan incorporates recommendations and needs developed through the Deep-Sea Corals Collaboration meeting held in Tampa, Florida in 2002 and the Deep Sea Corals workshop report (McDonough and Puglise 2003). This will allow the Council to build on the expertise and insight of the international deepwater coral research community. To focus the needs to the South Atlantic region, the Council has engaged regional experts to serve as the primary contributors of this Research and Monitoring Plan.

This Research and Monitoring Plan responds directly to mandates included in the 2006 reauthorization of the Magnuson-Stevens Act:

‘‘SEC. 408. DEEP SEA CORAL RESEARCH AND TECHNOLOGY PROGRAM.
‘‘(a) IN GENERAL.—The Secretary, in consultation with appropriate regional fishery management councils and in coordination with other federal agencies and educational institutions, shall, subject to the availability of appropriations, establish a program—

‘‘(1) to identify existing research on, and known locations of, deep sea corals and submit such information to the appropriate Councils;
‘‘(2) to locate and map locations of deep sea corals and submit such information to the Councils;
‘‘(3) to monitor activity in locations where deep sea corals are known or likely to occur, based on best scientific information available, including through underwater or remote sensing technologies and submit such information to the appropriate Councils;

‘‘(4) to conduct research, including cooperative research with fishing industry participants, on deep sea corals and related species, and on survey methods;
‘‘(5) to develop technologies or methods designed to assist fishing industry participants in reducing interactions between fishing gear and deep sea corals; and
‘‘(6) to prioritize program activities in areas where deep sea corals are known to occur, and in areas where scientific modeling or other methods predict deep sea corals are likely to be present.
‘‘(b) REPORTING.—Beginning 1 year after the date of enactment of the Magnuson-Stevens Fishery Conservation and Management Reauthorization Act of 2006, the Secretary, in consultation with the Councils, shall submit biennial reports to Congress and the public on steps taken by the Secretary to identify, monitor, and protect deep sea coral areas, including summaries of the results of mapping, research, and data collection performed under the program.’’

The president signed the reauthorized Magnuson-Stevens Act on January 12, 2007. Therefore, the first report is due to Congress on or before January 12, 2008. It is the Council’s intent to review the report at the December 2008 Council meeting. Table 1 presents a timeline for items contained in this Plan based solely on the South Atlantic Council’s priorities.

For purposes of this plan, Deepwater Coral Ecosystems (DWCE) are defined as:
Deepwater coral, coral reefs, and live/hard bottom habitat in waters extending from 200 m to the seaward boundary of the EEZ.

Goal
To protect deepwater corals by:
A. Refining existing (proposed) and designating new deepwater Coral HAPCs.
B. Increasing our understanding of DWCEs’ ecological role and function in the South Atlantic region to guide future management actions.

Phase I: Map and describe known and expected deepwater coral ecosystems in the South Atlantic region.

Phase II: Determine the ecological role of deepwater coral ecosystems in the South Atlantic region, especially the role of deepwater coral habitats as Essential Fish Habitat, and expand the understanding of structure-forming species' biology and ecology.

PHASE I: MAP AND DESCRIBE KNOWN AND EXPECTED DEEPWATER CORAL ECOSYSTEMS IN THE SOUTH ATLANTIC REGION

Justification/Background

Deepwater coral ecosystems (DWCEs) are herein defined as deepwater coral, coral reefs, and live/hard bottom habitat in waters extending from 200 m to the seaward boundary of the EEZ. Azooxanthellate cnidarians include branching stony corals (Scleractinia), gorgonians and soft corals (Octocorallia), black corals (Antipatharia) and lace corals (Stylasteridae). These DWCEs therefore include the constructional habitats generated chiefly by colonial scleractinians as well as the non-constructional "gardens" dominated chiefly by other anthozoans and sponges. DWCEs are common within the Exclusive Economic Zone (EEZ) off the southeastern U.S. and include a variety of high-relief, hard-bottom habitats at numerous sites from the Blake Plateau off North Carolina, southward through the Straits of Florida to the eastern Gulf of Mexico. Despite a series of exploratory expeditions during the last decade, only a few DWCEs in this region have been mapped in any detail, observed directly or have had their benthic and fish assemblages examined. The limited number of direct observations via submersible or Remotely Operated Vehicle (ROV) indicate that they provide hard substrates and habitat for a relatively unknown but biologically rich and diverse community of associated fishes and invertebrates, including commercial species such as wreckfish (*Polyprion americanus*), Warsaw grouper (*Epinephelus nigritus*), deepwater snappers and golden crab (*Chaceon fenneri*).

Two potential threats—fossil fuel development and bottom fishing—create a time-sensitive need to map and characterize these habitats. A moratorium on oil/gas exploration in Florida waters has long prevented impact from fossil fuel extraction; however, recent U.S. legislation directed at expanding energy production in the Gulf of Mexico, coupled with exploration by Cuba in waters adjacent to the Florida Keys, has expanded this threat. Liquefied natural gas re-gassification facilities and several proposed natural gas pipelines and offshore facilities could also directly impact local DWCEs. With respect to fishing, DWCEs worldwide have been seriously impacted by bottom trawls (Fosså et al. 2002, Freiwald et al. 2004). In Florida waters, unprotected portions of the Oculina Bank off the central east coast (75-100 m depth) have been severely affected both by overfishing and bottom trawling (Koenig et al. 2000, 2005; Reed et al. 2005b, Reed et al. in review).

Increasing our understanding of the distribution and composition of these assemblages; the physical, trophic and biochemical interactions of their components; and the environmental forcing factors that control distribution and composition across regional to local scales will enable effective ecosystem management. Such information will also provide the requisite baseline for examining ecosystem response to potential stressors and for investigating all aspects of component organism biology, including population dynamics, physiology, genetics and biopharmacology.

<u>Objective 1: Map the distribution of DWCEs in the Southeastern U.S. EEZ.</u>

1A. Determine the extent of known DWCEs in the South Atlantic region.

DWCEs occur along the southeastern coast of the United States from North Carolina to the southwestern Gulf of Mexico. Areas where DWCEs have been identified include: 1) North Carolina *Lophelia* mounds—three mound systems represent the northernmost DWCEs in the South Atlantic Bight; 2) Stetson Reefs—hundreds of pinnacles up to 152 m tall at depths of 640 to 900 m on the eastern Blake Plateau off South Carolina; 3) Savannah Lithoherms—numerous lithoherms at depths of 490 to 550 m with up to 60 m vertical relief; 4) East Florida *Lophelia* Reefs—hundreds of 15-152m tall coral bioherms and lithoherms at depths of 600 to 870 m along the shelf margin from southern Georgia to the Straits of Florida; 5-6) Miami and Pourtalès Terraces—relict phosphoritic limestone bank-margin hardgrounds and escarpments extending from Boca Raton to Key West at depths of 200 to 600 m; and 7) Southwest Florida Lithoherms—dozens of 15m tall *Lophelia* lithoherms at 500 m in the eastern Gulf of Mexico (Reed et al. 2004, 2005a, 2006). Only a small percentage of these sites has been investigated beyond fathometer transects; each new exploratory expedition discovers new sites. Many more coral sites are likely, and the full extent of topographic features on the Blake Plateau remains unknown. Similarly, the distribution of possible DWCEs along the southern margin of the Florida peninsula south of Miami and along the Florida shelf margin in the Gulf of Mexico are largely uninvestigated.

Increasingly sophisticated mapping technology, such as ship- and Autonomous Underwater Vehicle (AUV)-mounted multibeam sonar systems with backscatter data, side-scan sonar systems, and sub-bottom seismic profilers can be used to provide detailed bottom imagery with resolution from one-three meters. A simple light-weight digital camera system can also be lowered during fathometer or AUV transects of topographic features to provide first-order ground-truthing (i.e., to determine presence/absence of corals) (see Grasmueck et al. 2006, in review). Geographic Information Systems (GIS) can be used to integrate mapping data with other geo-spatial information (e.g., fishing pressure, management areas, biological, geological, physicochemical observations, geophysical structure, hydrodynamics) to generate detailed and precise maps and datasets and foundation for robust system analyses, predictions, and management protocols. Only a small portion of this region has been mapped using ship based multibeam sonar (S. W. Ross et al. 2006, unpubl. data); maps from the North Carolina coral mounds and a portion of the Stetson Banks revealed numerous new features, suggesting that the coral habitat is much more extensive than previously thought. Only a few days of multibeam mapping (Ross et al. 2006 cruise) provided more bottom type data than had been accumulated in 6 years of previous cruises.

<u>TASK 1</u>: Inventory existing literature and data with a focus on expanding work within existing (proposed) Coral Habitats of Particular Concern (CHAPCs) by:

a. Completing the Southeastern United States Deep Sea Corals (SEADESC) Initiative (Partyka et al. in press) and integrating data into Council IMS, and

b. Completing and integrating data sources identified by deepwater portion of the Southeast Area Monitoring and Assessment Program (SEAMAP) -- Recovery, Interpretation, Integration and Distribution of Bottom Habitat Information for the South Atlantic Bight, 200-2000m.

<u>TASK 2</u>: Rank areas to be mapped within proposed CHAPCs and potential DWCEs outside CHAPCs by:

a. Identifying data gaps based on above inventory,
b. Obtaining SAFMC input to rank priority areas for investigation, and
c. Conducting an ad hoc workshop to rank gaps based on proposed CHAPCs as well as outlying areas.

TASK 3: Conduct acoustic seabed mapping, and ground-truth with visual surveys within proposed CHAPCs and priority areas outside CHAPCs . Begin with low-resolution over wide areas followed by high-resolution mapping of targeted area (e.g., multibeam echo sounder, sidescan sonar) and ground-truthing (e.g., ROVs, AUVs, towed cameras, cores, samples) based on SAFMC recommendations.

1B. Map human activities that may impact DWCEs.

As noted in the Justification/Background section above, fossil fuel development and bottom fishing represent the primary potential near-term threats to local DWCEs. The continuing depletion of coastal fisheries may expand fishing efforts into deeper habitats in search of valuable commercial species such as royal red shrimp (*Hymenopenaeus robustus*), other shrimps and crabs, wreckfish, and other fish species (some not yet exploited). One of these, the Warsaw grouper, is a candidate for designation as a threatened or endangered species.

TASK 1: Obtain Vessel Monitoring System (VMS) access and produce maps showing fishing effort by location.

TASK 2: Assess fishing pressure in and outside CHAPCs through analysis of fisheries-dependent (e.g., NMFS landings) and fisheries-independent data. Produce maps showing fishing effort by location.

TASK 3: Map non-fishing activities that may affect DWCE resources (e.g., dredging, cables, outfalls, run-off, shipping routes and energy development and exploration activities).

1C. Assess condition of DWCEs in the South Atlantic.

Assessing the health and status of deepwater corals in the southeastern U.S. is difficult because there is a general lack of criteria on what constitutes good or bad conditions in these systems and a lack of historical data for comparisons. Dead corals are abundant at almost all locations, but whether this is normal or not, is unclear. Whether reefs are declining, stable, or building cannot be judged without additional studies. It seems clear that fairly strong currents coupled with bottom temperatures below 12º C are needed and monitoring these conditions may be good starting points. There is concern that changing ocean pH may negatively impact deepwater corals (Guinotte et al. 2006), and this should also be considered in monitoring or impact assessment.

Live coral coverage is generally low on the majority of deepwater *Lophelia* reefs in this region (1-10%); however, cover varies from nearly 100% living coral on portions of some reefs to extensive areas of 100% dead coral rubble on others (Reed et al. 2005b, 2006, in review; Grasmueck et al. in review). The deepwater *Oculina* reefs off eastern Florida have been designated a habitat area of particular concern (HAPC) for the protection of the coral habitat since 1984 (Reed 2002b, Reed et al. 2005b). A portion also has been designated a marine protected area (MPA) for management of the snapper grouper complex. Even so, extensive areas of the *Oculina* reefs have been severely impacted by both legal and illegal bottom trawling since 1984 (Koenig et al. 2005, Reed et al. 2005b, in review). Some areas in the northern section of the MPA that were documented as thriving reefs by photo transects in the 1970s had been found to be reduced to 100% rubble during submersible dives in 2001 (Reed et al. in review). However, some of the reefs in the southern portion that had been protected since 1984 are still thriving. So far we have no evidence that commercial bottom trawling has occurred on the *Lophelia* reefs in this region of the western Atlantic, and so it is still speculative as to whether the cause of the high percentage of dead coral could be due to natural senescence of the reefs, paleoclimatic factors, coral pathogens, or other unknown factors.

TASK 1: Identify and quantify natural and anthropogenic stressors (e.g., disease, gear impacts, energy development and exploration, nutrients, sedimentation, ocean disposal of dredge spoil, sewage sludge, paleoclimatic changes, temperature).
TASK 2: Conduct biological and environmental monitoring of indicator species at different scales.

a. Identify potential indicator species for deepwater corals and associated species, and
b. Identify monitoring programs for those species.

TASK 3: Monitor impacts of episodic events (e.g., changing currents, temperatures, pH, sediment dynamics, food dynamics).

Objective 2: Describe the physiographic environment of DWCEs.

2A. Describe abiotic features (i.e., hydrographic, chemical) of DWCEs.

The waters and seafloor of the continental margin of the southeastern U.S. have been investigated for over a century and a half, beginning with work by the U.S. Coast Survey and U.S. Navy (e.g., Agassiz 1888). The Gulf Stream, a principal oceanographic feature of the region, is among the most thoroughly studied of marine systems, and the physiography and underlying geology of much of the region are well documented. However, apart from instantaneous localized observations made during submersible or ROV operations -- and broad-scale datasets and models of geologic structure, hydrography and physicochemical parameters -- little if any information exists about how abiotic factors directly affect and control local DWCEs. No time-series data of the environmental factors (e.g., bottom currents, turbidity, upwelling, temperature, dissolved oxygen or sedimentation rates) have been collected on DWCEs that would contribute to understanding DWCE distribution, growth, and the composition and dynamics of associated assemblages. However, annual records of hundreds to thousands of years that are relevant to abiotic conditions in these habitats may be contained in several species of deepwater corals (see Williams et al. in press; Druffel et al. 1995; Holmes et al. unpubl. data). This research should be continued. Although much work has been done on the southeastern U.S. margin, relatively little is known about basic parameters compared to the mid-Atlantic and north Atlantic costs of the U.S. There is a need to conduct physical and chemical monitoring at multiple spatial (individual mound to regional) and temporal (tidal to decadal) scales, including identification of episodic oceanographic events (e.g., intrusions, upwelling) and physical disturbances (e.g., turbidity plumes, storms).

TASK 1: Inventory existing deepwater (seafloor) data sources in the South Atlantic region (e.g., Ocean Observing System, OOS).
TASK 2: Identify required data sets and observing technologies (e.g., OOS, benthic landers).

TASK 3: Establish and carry out a deepwater monitoring plan for CHAPCs in partnership with the Southeast Coastal Ocean Observing Regional Association (SECOORA), starting with a pilot observing station at a fairly well-described DWCE.

2B. Investigate the internal structure of DWCEs, particularly in relation to overlying hydrodynamic and physicochemical conditions, and changing climate over time.

TASK 1: Conduct sub-bottom acoustic profiling survey over various DWCE habitats.
TASK 2: Based on profile surveys, target specific DWCE types for follow-up coring from surface to base mounds.

Objective 3: Describe and inventory biota of DWCEs.

The dominant biogenic architectural components of local DWCEs are the azooxanthellate, colonial scleractinian corals *Lophelia pertusa* and *Enallopsammia profunda*, with *Madrepora oculata* and *Solenosmilia variabilis* occurring as isolated colonies (Reed 2002a, b). Both constructional DWCEs and non-biogenic hard substrates (e.g., Miami and Pourtalès Terraces) provide habitat for a wide diversity of sessile macrofauna including solitary Scleractinia, gorgonians and soft corals (Octocorallia), black corals (Antipatharia), hydrozoan corals (Stylasteridae) and sponges (Demospongiae and Hexactinellida), which in turn provide habitat and living space for a relatively unknown but biologically rich and diverse community of associated organisms, including fishes, anemones, zoanthids, crustaceans, mollusks, echinoderms, polychaete and sipunculan worms, and foraminiferans (Ross and Nizinski in press).

Qualitative studies of the DWCEs off the southeastern U.S. identified 142 taxa of invertebrates and 58 species of fish directly associated with these coral habitats (Reed et al. 2006). The deepwater fauna of the east Florida margin includes at least 53 species of Scleractinia (Cairns and Chapman 2001), ~15 stylasterids (Cairns 1986) and dozens of octocorals. The deep Gulf of Mexico fauna includes 84 Scleractinia (Cairns and Chapman 2001; Cairns in prep.), 5 stylasterids, and 115 octocorals (Cairns in prep.). Because Florida, and the Straits of Florida in particular, represents an important biogeographic boundary where different deepwater faunas meet to generate the greatest known species richness in the western (and perhaps entire) Atlantic Ocean (Carpenter 2002), it is expected that the complex three-dimensional habitats of local DWCEs will include important biodiversity "hotspots." However, current taxonomic information is scattered in the primary specialist literature. The fish fauna of the region (at least 98 species identified on and around deepwater coral habitat) was reviewed by Ross and Quattrini (in press and in review), but only preliminary notes of other fauna from scattered locations exist. This region may harbor a number of new species associated with deepwater corals, some described (e.g., McCosker and Ross in press; Fernholm and Quattrini in review) and some soon to be described (e.g., Nizinski et al. unpubl. data).

3A. Qualitatively and quantitatively describe the composition, diversity, assemblage organization and distributional patterns of DWCE benthic and water column fauna (invertebrates and vertebrates).

TASK 1: Develop a network of taxonomic experts and support comparative studies (e.g., validation, or inter-regional comparisons).
TASK 2: Assess biodiversity of all groups at different spatial scales (including molecular approaches for phylogeny, phylogeography, genetic connectivity, population dynamics and species boundary assessment).
TASK 3: Make products accessible through appropriate databases (e.g., Council's Internet Mapping Server, Ocean Planning and Information System, OPIS; Southeast Regional Taxonomic Center, SERTC; Coral Reef Information System, CORIS; Census of Marine Life).

3B. Determine relative abundance and occurrence of economically and ecologically important species associated with DWCE.
Sampling will require the use of multiple, standardized methods to allow for counting of individual species. Techniques will need to be adapted based on the fauna of interest and locations to be sampled (e.g., water column, benthic, surface). Methods may range from visual/video surveys with selective collections to quantitative sampling using coring devices or nets.

PHASE II: DETERMINE ECOLOGICAL ROLE OF DWCE, INCLUDING THE ROLE OF DEEPWATER CORAL HABITAT AS ESSENTIAL FISH HABITAT TO EXPAND UNDERSTANDING OF STRUCTURE-FORMING SPECIES' BIOLOGY AND ECOLOGY

Justification/Background
The southeastern United States may have the most extensive aphotic DWCEs in U.S. waters (Hain and Corcoran 2004); however, these large habitats are poorly documented and understood. Based on available data, DWCEs appear to occur abundantly on the southeastern United States slope (Stetson et al. 1962; Paull et al. 2000; Popenoe and Manheim 2001; Reed et al. 2005a, 2006; Ross and Nizinski in press). Prior to this century, these unique habitats had not been examined in detail in this region because of the great depths at which they are found, the rugged bottom topography, and extreme currents (e.g., Gulf Stream).

Ongoing research on DWCE in the southeastern United States has been based on the premise that these habitats are ecologically important and productive, yet very little is known about their ecological roles. The southeastern United States harbors over 100 deepwater coral species (Ross and Nizinski in press.), some of which create extensive, complex reef structures. These complexes are hotspots of increased biodiversity. Many coral species are very long lived (hundreds to thousands of years), and serve as natural repositories of data on climate, ocean physics, and ocean productivity (Adkins et al. 1998; Williams et al. 2006; Williams et al. in press). However, research on this topic is just beginning, as is research on population and community genetics. There are no studies on trophic ecology or energetic models for DWCE of the southeastern United States.

Deepwater coral habitat now appears to be more important to northwestern Atlantic slope species than previously known. However, it is unclear whether this habitat is essential to selected fishes or invertebrates or whether they occupy it opportunistically (Rogers 1999; Auster 2005; Costello et al. 2005). Coral thickets, coral rubble, and the less structured nearby non-reef habitat all support diverse faunas in the southeastern United States (Reed et al. 2002, Reed et al. 2005a, 2006; Ross and Quattrini in press.). Analyses indicate that many species of fishes (Ross and

Quattrini in press.) and invertebrates are closely associated with the unique deepwater reef habitat (Reed et al. 2006), including commercially-exploited deepwater species (e.g., wreckfish and golden crabs) and potentially exploitable species (e.g., royal red shrimps, blackbelly rosefish, bericiform fishes, eels). However, reef-invertebrate associations may be more opportunistic than those found in certain fishes (Ross et al. unpubl. data), but more data are required to confirm these associations.

Our understanding of DWCEs within the U.S. EEZ has progressed rapidly over the past decade, primarily though a series of exploratory cruises that have provided information on the distribution and general characteristics of these valuable resources. The next steps involve addressing ecosystem function and resilience to change, both anthropogenic and natural. In the South Atlantic region, DWCEs dominated by *Lophelia pertusa* and *Enallopsammia profunda* create extensive and complex structural framework, which provides settlement substrate and microhabitat for a diverse benthic fauna. An understanding of individual and population level biology of these foundation species is a pre-requisite to effective ecosystem management. All ecosystems are subject to disturbances of various types, both natural and anthropogenic. Pristine ecosystems are generally resilient to disturbance, meaning that they can return to an original state via natural recovery processes. Resilience is an important ecosystem characteristic that needs to be fostered and protected via proactive management. As far as we know, the DWCE of the southeast region are relatively unimpacted; this could change rapidly with the advent of new energy proposals (liquefied natural gas ports and pipelines), development of deepwater fisheries and more subtle impacts such as pH reduction through global alterations in CO^2 cycles. Increasing our understanding of the biology of the keystone species, at an individual and population level will provide baseline data from which to assess ecosystem response to future stressors. At the individual level, factors such as growth rate, skeletal density, and fecundity can change in response to environmental stress.

Resilience at the population level may be largely dependent on the genetic composition and richness. Genetic and genotypic diversity provide scope for species to adapt to changing conditions such as warmer temperatures and/or altered pH. Branching corals such as *L. pertusa* and *E. profunda* reproduce asexually via fragmentation (i.e., branches break off and reattach to the substrate to form a new colony that is genetically identical to the parent). It is important to understand the extent of genotypic diversity present in *L. pertusa* populations to assess their potential for adaptation to global changes. Understanding patterns of genetic connectedness (i.e., gene flow) is important to contextualize and predict larval recruitment pathways, and ultimately to incorporate such information into design of deepwater coral HAPCs.

Considering the above, research priorities of locating, describing, and mapping deepwater corals and conducting basic biological studies in these habitats are necessary baseline data for developing appropriate management schemes. The goal of research described herein is to address major data gaps to facilitate management of deepwater coral habitat and allow increased understanding of its role in deepwater ecology.

Objective 1: Describe logistic and coordination efforts that could improve the efficiency and effectiveness of deepwater coral biological studies.

Given the expense and difficulty of studying deepwater organisms it is prudent to consider aspects of coordination of data collection within the scientific community that would enhance the value and effectiveness of all possible observations and samples over a wide range of objectives. For example, video footage is probably the most common data collected from deepwater coral habitats, but it is not collected in a standardized format that will allow comparison of information from different sites or cruises (e.g., size, percent cover, proportion live/partial mortality, growth or color morphs). A handbook of 'Deep Sea Coral Collection Protocols' by Etnoyer et al. (2006) has been compiled in an effort to standardize data collection from deepwater coral habitats. This will be available on-line in the near future, and includes protocols for video and photographic documentation as well as sample preparation for different purposes. A cooperative effort among the scientific community to abide by common protocols will potentially increase the utility of data collected during each expedition. Another example of cooperation among groups that would maximize cruise time would be to formalize a chain-of-custody or clearing house for samples (e.g., corals, associated animals, pieces of skeleton etc.) that are collected during research cruises, and are not used by the cruise scientists. This would partition material to as many types of studies as possible (e.g., live material for lab experiments, ethanol-preservation for genetic analysis, surface treatments for microbial studies, tissue fixative for histological study, etc.) and make use of samples that would otherwise not be processed.

TASK 1: To the extent possible, use standardized protocols for data collection so that information may be exchanged among investigators and agencies.
TASK 2: Develop standardized chain-of custody for samples to optimize use of opportunistic or excess samples from deepwater coral habitats.

Objective 2: Describe the population dynamics, movements and habitat associations of both economically and ecologically important species (including potentially exploitable species) associated with DWCEs.

Many aspects of the ecology and biology of deepwater coral communities of the southeastern U.S. are either unknown or poorly understood, especially as it pertains to population dynamics. Population dynamics data are essential for understanding the historical and current status of populations, as well as modeling future population projections. For example, understanding how populations respond to extractive activities (fisheries) or respond to natural mortality requires knowledge of age and growth rates. Such studies are integral to understanding how populations might respond to climate change.

Information on spawning seasonality and locations are important for protecting reproductive integrity. Reproduction data (e.g., fecundity and spawning behavior) are needed to understand and model population fluctuations. Putting boundaries on population parameters requires studies on gene flow. Although determining barriers to gene flow that may isolate populations has been problematic for marine species (Palumbi 1994), various slope species exhibit unexpected degrees of population heterogeneity (Rogers 2002). Appropriate genetic techniques could facilitate inferences regarding organism dispersal and recruitment dynamics. Such data have important implications for how populations sustain themselves.

Many studies of the various aspects of population dynamics should concentrate (at least initially) on economically important, potentially economically important, and key ecological species.

Although an appropriate species lists needs to be developed, these taxa of interest should include wreckfish, scorpionfishes (particularly blackbelly rosefish), alphonsinos, roughies, conger eel, red crabs, shrimps, galatheid squat lobsters, squids, and sponges. To date the only species of this grouping that has published information for the southeastern U.S. slope is the wreckfish (Sedberry et al. 1994; Weaver and Sedberry 2001; Vaughn et al. 2001). For most deepwater reef organisms of the southeastern United States there are no published data on age, growth, reproduction, genetic structure, movements, recruitment, and habitat relationships.

Note: Sampling for trophodynamic patterns (see objective 3) could easily be adapted to gather data for most population dynamics aspects below. While this might require little additional funding for field efforts, accessory funding for laboratory analyses and reporting would be needed.

2A. Determine the habitat relationships between deepwater corals and the species associated with them.

The lack of habitat association data hampers our understanding of deepwater reef communities and the roles of complex habitats in structuring or maintaining deepwater communities. If fauna are less explicitly associated with habitats in deepwater, this supports the hypothesis that slope fauna are more opportunistic because the deep sea environment has fewer resources (compared to the shelf). However, in contrast to the northwestern Atlantic (Auster 2005), data support hypotheses that southeastern U.S. deepwater coral banks host a unique, probably obligate, fauna and that the reefs concentrate food resources (Ross and Quattrini in press.). How deep does this pattern extend and is it true throughout the southeastern United States' slope?

TASK 1: Characterize habitat associations of invertebrate and fish faunas on and surrounding DWCEs. Sampling should include the full geographic and depth ranges of this habitat in the southeastern U.S., as well as all seasons. Direct observation methods (submersible or ROV) coupled with collections of habitat and fauna are the best way to sample these rugged areas for habitat association data (see Parker and Ross 1986; Sulak and Ross 1996; Ross and Quattrini in press.). It is important in this task to sample non-reef and non-coral habitats in order to adequately judge degrees of habitat association.

2B. Determine the migratory pathways of the economically and ecologically important species associated with DWCEs.

TASK 1: Characterize both the vertical and horizontal movements (at different spatial and temporal scales) of species associated with DWCEs, including all relevant life history stages. To infer vertical movement, sample the water column for species associated with DWCE at various depths over the appropriate time scale. To infer horizontal movement (especially of benthic species), sampling would be required that is logistically difficult (tagging) in the deep-sea, intensive, and expensive. In the near-term, the inference of horizontal movements may not be feasible.

2C. Determine the age structure and growth rates of economically and ecologically important species associated with DWCE as well as the sex ratio within each species.

TASK 1: Collect the full size range (juvenile to adult) of the species available within the study site across seasons.
TASK 2: Determine appropriate aging methods based on taxa examined and age samples.
TASK 3: Construct growth models.

2D. Determine the recruitment processes for the economically and ecologically important species associated with DWCE.

TASK 1: Conduct high-intensity temporal sampling using appropriate methods (e.g., settling plates and traps) to determine larval settlement processes including sites, periodicity, and relevance to oceanography. For traps, samples should be collected by setting multiple settlement traps within the deepwater coral habitat of interest and the adjacent non-reef habitat. Replication and placement of the settlement traps is critical for determining whether settlement is random or based on specific cues. It would be important to record various physical data (e.g., current, temperatures) near these samples.
TASK 2: Determine larval duration, distribution, and vertical migration in the water column. Sample the water column for species associated with DWCE at various depths over the appropriate time scale. For fish species, determine daily ages of fishes from otoliths to determine larval duration. Understanding horizontal and vertical water column physics is important here, and if appropriate models are not available, they should be developed (see next task).
TASK 3: Model the information collected under the two previous tasks with horizontal scale physics (e.g., currents) to improve the understanding of recruitment processes and population connectivity.

2E. Examine the reproductive biology of economically and ecologically important species associated with DWCE.
Characterize the spawning seasonality and reproductive potential of the species of interest by collecting the full size range (juvenile to adult) of the species available within the study site. Adequate sampling will require collection of data on monthly or quarterly intervals and ensuring that there are sexual differences in the population. Samples should be analyzed for sex, reproductive state, and fecundity (for females only). Method details may vary by taxa examined.

2F. Determine the genetic structure of the economically and ecologically important species associated with DWCE.

TASK 1: Sample coral and associated species at a regional scale to make inferences about the mechanisms structuring local assemblages (e.g., community genetics). Using a community genetics approach (Agrawal 2003; Neuhauser et al. 2003; Whitman et al. 2003), patterns of genetic structuring should be compared among taxa and with environmental variables. This study should also include examining the genetic structuring of fauna closely associated with *Lophelia* and other habitat-forming corals and sponges, such as galatheid "crabs" (*Eumunida picta*), eunicid polychaetes (Roberts 2005), urchins and some fishes. If associations between *Lophelia* and co-occurring invertebrates are strong, similar genetic patterns may result, suggesting that similar mechanisms may influence community structure of associated organisms.

Objective 3: Describe food web dynamics of DWCEs.

To assess natural and anthropogenic impacts, the degree of connectivity among ocean zones (e.g., benthic, abyssal, and neustonic) must be better understood. The execution of research within these zones has led to an implicit assumption of compartmentalization. However, ocean waters and many of their inhabitants regularly move across perceived boundaries, and systems are much more connected than previously reported (Knight et al. 2005) as evidenced by improved tracking of animal movements and energy flow (trophodynamics).

Input of energy to the deep seafloor was thought to be from the top down and mostly passive. In the northeastern Atlantic, the energy source of *Lophelia pertusa* is derived from particulate matter drifting down from the upper water column (Duineveld et al. 2004), but trophic data for the broader community are lacking. A hypothetical trophic web was developed for the deepwater *Oculina* ecosystem which consists of the coral biogenic refuge for hundreds of species of invertebrates and fishes which in turn receives plankton/particulate input from the Florida Current (Gulf Stream) and cold-water upwelling events providing influxes of nutrients (George et al. in review). It is likely that active vertical movements of animals provide a substantial, regular flow of energy through the water column to the seafloor (Kinzer 1977; Genin 2004; Gartner et al. in review). Such movements may be diel, ontogenetic, or both and move resources in both directions, variously impacting a large section of the water column.

During past submersible observations (coupled with depth-discrete sampling) off the southeastern U.S. large concentrations of mesopelagic (midwater) fauna were noted on the bottom near deepwater (360 to 700 m) coral banks (Gartner et al. in review). Mesopelagic fauna were observed acting as both predator and prey of benthic organisms. Whether this activity is sporadic or whether various animals depend on such interactions is unknown. If the migrating mesopelagic fauna is a major conduit of energy through the water column, human (or other) perturbations of the bottom and midwater faunas may have significant impacts on pelagic fishes, seabirds, and marine mammals through effects on trophic relationships. However, open ocean ecological coupling (expressed by food web inter-connection among benthic and water column nekton) is poorly studied.

Research described here will begin to define faunal connectivity in terms of trophic linkages over and around DWCE. Characterization of trophodynamics and benthic-pelagic interactions of organisms associated with deepwater corals would provide important information on food resources and sources, feeding periodicity, and how various habitats from the bottom to the surface are linked. In addition to traditional diet analyses of collected specimens, stable isotope ratios (of carbon, nitrogen, and possibly sulfur) of deepwater coral area organisms (whole water column) would establish trophic signatures that help define community relationships (Thomas and Cahoon 1993; Kwak and Zedler 1997; MacAvoy et al. 2001). From these data we could answer important questions about the broad impacts to a particular habitat or group of organisms from natural or anthropogenic events. An added advantage of a trophodynamic study is that the process of collecting organisms to describe feeding relationships can provide valuable additional data (e.g., species-habitat associations, distributions, abundances, sizes, reproductive states, etc.).

3A: Characterize the trophodynamics and the benthic-pelagic interactions of organisms associated with deepwater coral habitat using both traditional and novel approaches.

The *traditional approach* is to capture organisms, determine species, and analyze their stomach contents.

A *novel approach* to couple with the above method is to analyze stable isotopes in the tissues of the captured fauna. Naturally occurring isotopic concentrations in various tissues identify sources of dietary components (e.g., from plankton or benthic sources) provided there is a good understanding of the isotopic signatures of potential food sources.

Sampling should be conducted using the appropriate temporal and spatial scales.

Temporal scale: For the traditional approach, it is important to collect data on a seasonal basis and if possible on a diel basis because stomach content data reflect only a snap-shot of the diet of a species. Sampling for the novel approach method can be conducted at any time of the year because isotopic signatures represent an integration of diet over time in the tissues.

Spatial scale: For both the traditional and novel approaches, organisms should be collected in both the water column above the deepwater coral habitat of interest, within that habitat itself, and in the adjacent benthic non-reef habitats. Since reef habitat varies throughout this region, the ideal sampling scheme would have replicate samples collected from a minimum of three previously studied sites between Cape Lookout and the Florida Straits in which preliminary analyses have suggested differing benthic populations.

Objective 4: Describe relationships among DWCE composition, structure and distribution and abiotic and biotic factors.

4A. Identify relationships between the distribution and development of DWCEs and abiotic and biotic factors.

As noted previously, no time-series data exist on the hydrographic or physicochemical characteristics of the water column associated with DWCEs in the region. Detailed data on temporal and spatial patterns and ranges of variation in abiotic factors, e.g., temperature, salinity, dissolved gases, hydrodynamics (bottom currents, upwelling, tides, eddies), turbidity levels and the nature of suspended material, represent a baseline of information required for understanding DWCE composition, growth, structure and distribution. Similarly, no data exist on the composition of seston (i.e., plankton, suspended organic detritus and inorganic particles) available to DWCEs or the patterns, abundances and rates of its import to DWCEs. Such data are critical to understanding DWCE trophodynamics and growth patterns.

TASK 1: Collect time-series data of abiotic and other water column factors using a variety of deployed instrument packages (e.g., time-lapse cameras, current meters, CTDs, sediment traps, larval settlement panels).

TASK 2: Conduct multivariate analyses of abiotic factors versus organism distributions and DWCE structure.

4B. Develop models to enable predictions of DWCE status and trends.

TASK 1: Identify suitable models and conduct model-data comparisons to validate models specifically for DWCE application:

a. Ocean circulation (physical, chemical parameters) and
b. Sedimentation.

4C. Determine long-term temporal (decadal to epochal scales) relationships between DWCE structure and distribution relative to overlying hydrodynamic regime.
Although the broad-scale geology of the region is reasonably well understood, no cores have been taken through local DWCEs that might contribute to understanding their development, particularly with respect to climate change. Such coring (or drilling) was quite valuable in determining the origins and history of deepwater coral banks in the northeastern Atlantic (Williams et al. 2006).

TASK 1: Examine historical records of pollution, productivity, climate and oceanography across the South Atlantic region.
TASK 2: Determine age, growth and senescence of DWCE (bioherms and lithoherms) by:
a. Radioisotope and amino acid racemization analysis of corals,
b. Cores of coral mounds and
c. Sub-bottom profiling across mounds and hard bottoms.

Objective 5: Describe reproductive strategies (gametogenic cycles, sex ratio, fecundity, larval development modes) of priority structure–forming groups, including scleractinians (*Lophelia pertusa*, *Enallopsammia profunda*, *Madrepora oculata*), octocorals, antipatharians and Stylasterines.
Gametogenesis has been described for several species of structure-forming scleractinians, from the Eastern and Western Atlantic and the Pacific. Generally they are gonochoristic (i.e., separate sexes), seasonal broadcast spawners, with small eggs, and probably dispersive larvae. This is the extent of our information for most of these species. *Lophelia pertusa* has been studied more extensively than other species, using samples from Norway, the Gulf of Mexico and the Florida Straits. Seasonality of gametogenesis appears to vary with location. The gametogenic cycle of samples collected from the Norwegian Fjords began in April and terminated with spawning in March the following year (Brooke and Jarnegren in prep.). In the Gulf of Mexico, however, gametogenesis begins in November and spawning probably occurs in late September/October (S. Brooke unpubl.). Fecundity of both sets of samples is high but quantified data have not yet been compiled. Research into reproduction of octocorals from Alaska and New England is also underway (Simpson unpubl), and some work has been done on reproduction in Alaskan stylasterines, which are all brooders and produce short-lived planulae (Brooke and Stone in review). Larval biology has been described for *O. varicosa* (Brooke and Young 2005) but not for any of the other deepwater corals.

Hydrodynamic models can provide probability distributions for larval dispersal under a variety of environmental scenarios but they require basic biological input data on parameters such as timing of spawning/larval release, larval duration, and behavior. Such data are not currently available for the southeastern U.S. deepwater corals but are needed to enhance the effectiveness of modeling efforts.

5A: Determine the gametogenic cycles and spawning periods for structure-forming corals.

TASK 1: Collect samples for histological examination. Characterization of these cycles requires repeated sampling at individual sites over time (e.g., monthly). Such sampling can be done opportunistically (i.e., haphazard collections during other cruises) but would be accomplished much more efficiently with targeted sampling effort.

5B: Determine larval development and settlement processes for structure-forming species.

TASK 1: Collect samples of important structure-forming species at the end of the gametogenic cycle to spawn for larval studies.

Objective 6: Describe patterns and processes of colony growth and mortality (e.g., calcification, carbon and energy budgets) of important structure-forming species, and determine how they are affected by environmental factors and stressors.

The growth of *L. pertusa* has been measured using various methods (Duncan 1877; Dons 1944; Freiwald 1998; Gass and Roberts 2006), which have estimated growth rates between 4-26 mm per year, with the most likely estimates at approximately 5mm per year (Mortensen and Rapp 1998). These methods have measured linear extension rather than calcification rates, but the latter could potentially be calculated from growth rates and skeletal density. Growth rates of some gorgonians and antipatharians have also been measured using rings in the gorgonian skeleton and isotopic analysis (e.g., Sherwood et al. 2005, Andrews et al. 2002, Risk et al. 2002; Williams et al. 2006) and in some cases the colonies are extremely old (hundreds to thousands of years) and have very slow growth rates (e.g., Druffel et al. 1995; C. Holmes et al. unpubl. data).

Field observations on distribution of *L. pertusa* indicate that the upper thermal limit for survival is approximately 12^{o}C, and laboratory studies on *L. pertusa* tolerance to temperature extremes corroborate these observations (S. Brooke unpubl. data). Preliminary experiments with heat shock proteins show expression of HSP-70 in response to exposure of temperature greater than 10^{o}C (S. Brooke unpubl. data). Experiments on tolerance to sediment load indicate that samples of *L. pertusa* from the Gulf of Mexico show >50% survival in sediment loads of 103 mgL-1 for 14 days, and can survive complete burial for up to 2 days (Continental Shelf Associates in review). Given the proximity of some coral habitats to oil and gas extraction sites, tolerance to drilling fluids and fossil fuels should also be investigated.

Further laboratory and field experiments are needed to examine the individual and interactive effects of environmental conditions such as temperature, sedimentation, and toxins. A range of responses or endpoints should be examined including more modern techniques such as cellular diagnostics. These include examination of levels of stress proteins produced by cells in response to external conditions such as heat shock proteins, ubiquitin, etc. There are general classes of cellular products that are known to be indicative of specific stressors such as nutritional stress, xenobiotics, metals, and temperature. These techniques are being increasingly used in shallow coral systems as a more sensitive organismal response to stress (i.e., more sensitive than mortality). These responses should be measured in combination with more standard parameters such as growth, respiration, and fecundity.

Coral growth rates provide information on the rates of habitat production in DWCEs while coral mortality and bioerosion counterbalance this production with destruction. Understanding the positive and negative sides of this balance, particularly under the changes in environmental conditions that are anticipated in the coming decade or two, is crucial to the management and conservation of deepwater coral habitat and habitat function (e.g., fishery production).

6A: Determine rates of colony growth (i.e. habitat production).

TASK 1: Conduct in-situ tagging or staining and revisit individual colonies for selected coral species. This activity should be in concert with in-situ monitoring station such as a benthic lander or other instrumentation to allow correlation of coral growth performance with in situ environmental conditions. Radiometric aging and growth estimates should also be conducted for selected corals (e.g., antipatharians)

6B: Determine physiological responses to stress (sediment, temperature, pollutants, CO^2) and how growth rate is affected by environmental factors (i.e., how is habitat production affected by environmental factors?).

TASK 1: Conduct manipulative laboratory dose-response experiments on live coral colonies, where various responses (e.g., molecular biomarkers, growth, and respiration) to stress levels can be documented under controlled conditions. This requires collection of live samples and post cruise maintenance in a temperature-controlled facility.

6C: Determine temporal patterns of coral mortality and bioerosion (habitat loss).

TASK 1: Characterize succession of boring/bioeroding community in coral skeleton. Ideally the degree of bioerosion would be correlated with ageing data to obtain information on bioeroder succession.
TASK 2: Drill cores and age dead skeletons from a range of sites and physiographic features.
TASK 3: Develop techniques for amino acid racemization or other techniques with high temporal resolution.

Objective 7: Describe the genetic characteristics of structure forming coral populations.
Little is known about basic biology of deepwater coral species, including larval dispersal potential and connectivity between reefs (hence vulnerability). Given the difficulty of tracking movements of coral larvae, especially at depth, genetic methods hold great promise for estimating important factors in the longevity of deepwater reefs that could not otherwise be inferred from their biology. Levels of gene flow among adjacent sites, relative contributions of clonal (asexual) and sexual reproduction and inferences regarding larval dispersal and levels of historical connectivity obtained from genetic data can provide valuable insights for appropriate management of these unique habitats.

Co-dominantly inherited genetic markers are required to fully assess population structure and to estimate parameters such as gene flow, the extent of clonal reproduction, and possible hybridization. Microsatellites are codominant markers made up of short (2-6 bases), tandemly repeated units of DNA that do not code for gene products (i.e., are effectively neutral to selection) and vary in number of repeats between individuals. Due to the relatively high mutation rate observed in microsatellite DNA markers, they have been useful in analysis of population structure at a finer level than is possible using DNA genomic sequences, and have been remarkably successful at identifying recently diverged lineages in marine invertebrates (e.g., King et al. 2005). Given sufficiently large numbers of microsatellite markers and sufficient sampling coverage from throughout the species range, microsatellites can be utilized to obtain a precise measure of population structure, including an assessment of gene flow between populations, allowing identification of sources of recruitment and estimation of effective population size.

An analysis of population structure of *L. pertusa* from the northeast Atlantic and Scandinavian fjords, based upon microsatellites and nuclear ITS DNA sequences, concluded that very low levels of gene flow occurred between offshore and fjord habitats, and that population structure among fjords was substantial, indicating localized recruitment of larvae (Le Goff-Vitry et al. 2004a). This has significant conservation implications, because destruction of reefs may be permanent if they are unlikely to be re-seeded with new larvae. Attempts to utilize the microsatellite markers developed by LeGoff-Vitry et al. (2004b) for Western Atlantic *L. pertusa* have not been successful, so additional markers have been developed (C. Morrison et al. unpubl. data) for the southeastern United States and Gulf of Mexico. Generally, microsatellite markers are species-specific, and additional markers may need to be developed for other reef-forming species in the future. Preliminary results from *L. pertusa* collected in the southeastern U.S. and Gulf of Mexico revealed high variability in population structure, low clonality, and variation over small spatial scales (C. Morrison et al. unpubl. data). Such results indicate that loss of any living *Lophelia* could seriously impact genetic diversity.

7A: Determine the clonal structure of *L. pertusa* across spatial scales.

<u>TASK 1</u>: Conduct targeted sampling on small spatial scales to characterize patterns of genotypic structure at as many geographical locations as possible.

7B: Determine the extent of genetic connectivity among populations of *L. pertusa*.

<u>TASK 1:</u> Conduct combined opportunistic and targeted (to fill in gaps) sampling across the entire geographic and depth range of the species.

<u>Objective 8: Determine the nature, patterns, and processes of communities of microbial coral associates.</u>

The role of microbes (bacteria, fungi and archaea) in the biology of *L. pertusa* is essentially unknown and yet these organisms likely play an important role. In tropical shallow-water coral species, some microbes appear unique markers of the surrounding water column and may be associated with certain coral species or tissues (Rohwer et al. 2001, 2002), suggesting ecological interactions between the microbes and corals. Lacking algal symbionts found in shallow-water corals, deepwater corals may rely more heavily on microbes in order to remain healthy, such as fixing nitrogen, carbon cycling, chelating iron, producing antibiotics to ward off harmful bacteria, or other beneficial roles yet to be defined (C. Kellogg, pers. comm.). Microbes have been found to play key chemosynthetic roles in cold seep communities (e.g., Boetius et al. 2000; Knittel et al. 2005) that are often found in close proximity to *Lophelia* corals. Preliminary microbial data from Gulf of Mexico *Lophelia* colonies indicated a unique and diverse community that exhibited considerable variability (C. Kellogg, unpubl. data).

A combination of techniques will be necessary to characterize the microbial communities found within *Lophelia* corals. First, since the microbial community can change when exposed to varying pressures, temperatures and light conditions during sampling (C. Kellogg, pers. comm.), some corals should be fixed at depth in order to establish a baseline dataset. This will require special, sterile sampling devices for submarine or ROV work. Both culturable (capable of growing on agar plates), and non-culturable (assayed through DNA sequencing) microbes should be surveyed from *Lophelia* in as many locations as possible. Characterization of microbes from Gulf of Mexico *Lophelia* is on-going and will provide interesting comparisons with *Lophelia* from the Southeastern Atlantic coast (C. Kellogg, pers. comm.). Molecular probes targeting certain microbes may eventually allow fast assessment of presence or absence of associated microbes. Other coral species and other fauna closely associated with corals should be sampled for microbial communities as well and comparisons made among microbes found in different species.

8A: Identify the symbiotic microbial community of coral colonies in different places and environmental conditions.

TASK 1: Conduct microbial screening of opportunistic coral (and other species) samples.
TASK 2: Target sampling with "clean" in-situ sampler.

9.1.2.4 Sargassum

Habitat and species-specific research needs identified in Council fishery management plans are presented below for pelagic Sargassum habitat.

Summarized from Pelagic Water Column Workshop, Research and Monitoring Workshop, and Settle (1997):

1. What is the areal abundance of pelagic Sargassum off the southeast U.S.?
2. Does the abundance change seasonally?
3. Can pelagic Sargassum be assessed remotely using aerial or satellite technologies (e.g., Synthetic Aperture Radar)?
4. What is the relative importance of pelagic Sargassum weedlines and oceanic fronts for early life stages of managed species?
5. Are there differences in abundance, growth rate, and mortality?
6. What is the age structure of reef fishes (e.g., red porgy, gray triggerfish, and amberjacks) that utilize pelagic Sargassum habitat as a nursery and how does it compare to the age structure of recruits to benthic habitats?
7. Is pelagic Sargassum mariculture feasible?
8. What is the species composition and age structure of species associated with pelagic Sargassum when it occurs deeper in the water column?

9. Additional research on the dependencies of pelagic Sargassum productivity on the marine species using it as habitat.
10. Quantify the contribution of nutrients to deepwater benthic habitat by pelagic Sargassum.

In addition, the following research needs were identified in the NMFS Biological Opinion and are included:

1. Studies should be performed on the abundance, seasonality, life cycle, and reproductive strategies of Sargassum and the role this species plays in the marine environment, not only as an essential fish habitat, but as a unique pelagic algae. The research recommendations of this FMP were based primarily on managing Sargassum as essential fish habitat for species managed under the MSFCMA. Research needs should also be identified that consider the Sargassum community, as well as the individual species of this community that are associated with, and/or dependent on, pelagic Sargassum. Human-induced (tanker oil discharge; trash) and natural threats (storm events) to Sargassum need to be researched for the purpose of protecting and conserving this natural resource.
2. Cooperative research partnerships should occur between the council, NMFS Protected Resources Division, and state agencies since many of the needs to a) research pelagic Sargassum, and b) protect and conserve pelagic Sargassum habitat, are the same for both managed fish species and listed sea turtles.
3. Specific research needs should be included in the plan which further address the association between pelagic Sargassum habitat and post-hatchling sea turtles.

9.1.2.4 Dolphin Wahoo

Prioritized EFH Research Needs (from 2003 FMP)
This determination was developed based on research needs identified through the Pelagic Water Column Workshop, Research and Monitoring Workshop, Settle (1997) and the NMFS Biological Opinion for the Sargassum FMP (SAFMC, 2002) as they apply to dolphin and wahoo.

1. What is the areal and seasonal abundance of pelagic Sargassum off the southeast U.S.?
2. Develop methodologies to assess remotely assess Sargassum using aerial or satellite technologies (e.g., Synthetic Aperture Radar)?
3. What is the relative importance of pelagic Sargassum weedlines and oceanic fronts for early life stages of dolphin and wahoo?
4. Are there differences in abundance, growth rate, and mortality?
5. What is the age structure of all fishes that utilize pelagic Sargassum habitat as a nursery and how does it compare to the age structure of recruits to pelagic and benthic habitats?
6. Is pelagic Sargassum mariculture feasible?
7. Determine the species composition and age structure of species associated with pelagic Sargassum when it occurs deeper in the water column?
8. Additional research on the dependencies of pelagic Sargassum productivity on the marine species using it as habitat.
9. Quantify the contribution of nutrients to deepwater benthic habitat by pelagic Sargassum.

10. Studies should be performed on the abundance, seasonality, life cycle, and reproductive strategies of Sargassum and the role this species plays in the marine environment, not only as an essential fish habitat, but as a unique pelagic algae.
11. Research to determine impacts on the Sargassum community, as well as the individual species of this community that are associated with, and/or dependent on, pelagic Sargassum. Human-induced (tanker oil discharge; trash) and natural threats (storm events) to Sargassum need to be researched for the purpose of protecting and conserving this natural resource.
12. Develop cooperative research partnerships between the Council, NMFS Protected Resources Division, and state agencies since many of the needs to a) research pelagic Sargassum, and b) protect and conserve pelagic Sargassum habitat, are the same for both managed fish species and listed sea turtles.
13. Direct specific research to further address the association between pelagic Sargassum habitat and post-hatchling sea turtles.

Prioritized Research Needs
The determination is based on Prager, 2000 and SAFMC, 1998a research workshop recommendations. Research needs include but are not limited to the following:

- In the short-term effort should be directed at examining all existing seasonality (effort and landings), mean size, and life history data for dolphin from the northern area.
- Additional data are needed to develop and/or improve estimates of growth, fecundity, etc. Research in this area is encouraged.
- There are limited social and economic data available. Additional data need to be obtained and evaluated to better understand the implications of fishery management options.
- Trophic data should be considered in support of an ecosystem management approach.
- Essential fish habitats for dolphin and wahoo need to be identified.
- An overall design should be developed for future tagging work. The Working Group could do this. In addition, existing tagging databases should be examined.
- Long-term work should continue and expand on current research investigating genetic variability of dolphin populations in the western central Atlantic.
- Observer programs should place observers on longline trips directed on dolphin. Catch and bycatch characterization, condition released (alive or dead), etc. should be collected. Observers could also be used to collect bioprofile data (size, sex, hard parts for aging, etc.).
- High levels of uncertainty in inter-annual variation in abundance of dolphin should be investigated through an examination of oceanographic and other environmental factors.
- Release mortality should be investigated as a part of the evaluation of the effectiveness of current minimum size limits in the dolphin fishery.
- Establish a list serve for dolphin and wahoo, which would facilitate research and the exchange of information.

Note: An additional recommendation of the workshop was to establish a regional working group to develop and implement a coordinated research program for dolphin and wahoo.

9.1.3 Other Managed Species

9.1.3.1 Interjurisdictional Prioritized Research Needs

(Source: ASMFC 2004) (Revised Draft presented in Appendix A)

American Eel

1. Documentation of the commercial eel fishery should be more accurate so that our understanding of participation in the fishery and the amount of directed effort could be known.
2. A stock assessment committee should identify the best stock assessment methods for American eel.
3. Investigate survival and mortality rates of different life stages (leptocephalus, glass eel, yellow eel, and silver eel) to assist in the assessment of annual recruitment. Such research could be aided by continuing and initiating new tagging programs with individual states.
4. Regular periodic stock assessments and determination of fishing mortality rates (F) are required to develop a sustainable harvest rate in addition to determining whether the population is stable, decreasing, or increasing.
5. Evaluate the impact, both upstream and downstream, of barriers on eel with respect to population and distribution effects. Determine relative contribution of historic loss of habitat to potential eel population and reproductive capacity.
6. Triggering mechanism for metamorphosis to mature adult, silver eel life stage with specific emphasis on the size and age of the onset of maturity, by sex. A maturity schedule (proportion mature by size or age) would be extremely useful in combination with migration rates.
7. A coast wide sampling program for American eel should be formulated using standardized and statistically robust methodologies. A critical review of the existing sampling plan should be conducted.
8. Investigate: fecundity, length and weight relationships for females throughout their range; growth rates for males and females throughout their range; predator-prey relationships; behavior and movement of eel during their freshwater residency; oceanic behavior, movement and spawning location of adult mature eel; and all information on the leptocephalus stage of eel.
9. Assess characteristics and distribution of eel habitat and value of habitat with respect to growth and sex determination.
10. Age at entry of glass eel into estuaries and fresh waters should be examined.
11. Location and triggering mechanism for metamorphosis from leptocephalus to eel should be examined.
12. The historic participation level of subsistence fishers in wildlife management planning needs to be reviewed, and relevant issues brought forth with respect to those subsistence fishers involved with American eel.
13. Investigate, develop, and improve technologies for American eel passage upstream and downstream of various barriers for each life stage. Emphasis should be placed on evaluation of low-cost alternatives for passage.
14. Economics studies are necessary to determine the value of the fishery and the impact of regulatory management.

15. Examination of the mechanisms for exit from Sargasso Sea and transport across the continental shelf.
16. Mechanisms of recognition of the spawning area by silver eel, mate location in the Sargasso Sea, spawning behavior, and gonadal development in maturation should be researched.
17. Contaminant effects on eel and the effects of bioaccumulation with respect to impacts by age on survival and growth and effect on maturation and reproductive success should be researched.
18. Migratory routes and guidance mechanisms for silver eel in the ocean should be examined.
19. Examine the mode of nutrition for leptocephalus in the ocean.
20. Provide analysis of food habits of glass eel while at sea.
21. The degree of dependence on the American eel resource by subsistence harvesters such as Native American Tribes, Asian and European ethnic groups, etc. needs to be investigated.
22. Workshop on aging and sexing techniques should be considered to increase the accuracy of data collected in coastwide sampling program.
23. Determine mortality rates at different life history stages (leptocephalus, glass eel, yellow eel, silver eel), and mortality rates with size of the yellow eel stage.
24. Determine sustainable fishing mortality rates (F) for eel.
25. Investigate fecundity, length and weight relationships for females throughout their range, and growth rates for males and females throughout their range.

Research Needs Identified As Being Met:

- Evaluate the use of American eel as a water quality indicator.
- Investigate practical and cost-effective methods of re-establishing American eel in underutilized habitat.

American Shad/River Herring

1. Continue to assess current aging techniques for American shad and river herring, using known age fish, scales, otoliths, and spawning marks. Conduct bi-annual aging workshops to maintain consistency and accuracy of aging of fish sampled in state programs.
2. Determine and update biological benchmarks used in assessment modeling (fecundity at age, mean weight at age for both sexes, partial recruitment vector/maturity schedules) for American shad and river herring stocks in a variety of coastal river systems, including both semelparous and iteroparous stocks.
3. Validate the different values of M for shad stocks through verification of shad aging techniques and repeat spawning information and develop methods for calculating M.
4. Determine which stocks are impacted by coastal intercept fisheries (including bycatch fisheries). Methods to be considered to differentiate among stocks could include otolith micro-chemistry, oxytetracycline otolith marking and/or tagging.
5. Identify pheremones or other chemical substances used by American shad to locate conspecifics. Develop methods to isolate or manufacture these chemicals and use them to attract shad into fish passage facilities to improve fish passage and efficiency.

6. Develop effective culture and marking techniques for river herring.
7. Develop and implement techniques to determine shad and herring population targets for tributaries undergoing restoration (dam removals, fishways, supplemental stocking, etc.).
8. Evaluate and ultimately validate large-scale hydroacoustic methods to quantify American shad escapement (spawning run numbers) in major river systems. Identify how shad respond (attract/repelled) by various hydroacoustic signals.
9. Refine techniques for hormone induced tank spawning of American shad. Secure adequate eggs for culture programs using native broodstock.
10. Characterize tributary habitat quality and quantity for Alosa reintroductions and fish passage development.
11. Identify and quantify potential American shad spawning and rearing habitat not presently utilized and conduct an analysis of the cost of recovery.
12. Develop comprehensive angler use and harvest survey techniques for use by Atlantic states to assess recreational fisheries for American shad.
13. Determine the effects of passage impediments on all life history stages of shad and river herring, conduct turbine mortality studies and downstream passage studies.
14. Evaluate additional sources of mortality for shad, including bait and reduction fisheries.
15. Conduct studies on energetics of feeding and spawning migrations of shad on the Atlantic coast.
16. Encourage university research on hickory shad.
17. Conduct studies of egg and larval survival and development.
18. Conduct and evaluate historical characterization of socio-economic development (potential pollutant sources and habitat modification) of selected shad rivers along the east coast.
19. Review studies dealing with the effects of acid deposition on anadromous alosids.
20. Conduct population assessments on river herrings -- particularly needed in the south.
21. Quantify fishing mortality (in-river, ocean bycatch, bait fisheries) for major river stocks after ocean closure of directed fisheries.

Research Needs Identified as Being Met:

- Determine the stock/recruitment relationships for American shad and river herring stocks.

Atlantic Croaker

High Priority

- Criteria should be cooperatively developed for aging croaker otoliths.
- Studies of croaker growth rates and age structure need to be conducted throughout the species range.
- Age-length keys that are representative of all gear types in the fishery should be developed.
- Fishery dependent and independent size, age and sex specific relative abundance estimates should be developed to monitor long term changes in croaker abundance.
- Improve catch and effort statistics from the commercial and recreational fisheries, along with size and age structure of the catch.
- Examine reproductive biology of croaker with emphasis on developing maturity schedules and estimates of fecundity.

Medium Priority

- Conduct stock identification research on croaker.
- Cooperative coastwide croaker juvenile indices should be developed and validated to clarify stock status.
- Evaluate hook and release mortality under varying environmental factors and fishery practices.
- The effects of mandated bycatch reduction devices (BRD's) on croaker catch should be evaluated and compiled.
- In trawl fisheries or other fisheries that historically take significant numbers of croaker, states should monitor and report on the extent of unutilized bycatch and fishing mortality on fish less than age-1. Incorporate bycatch estimates into croaker assessment models.
- The optimum utilization (economic and biological) of a long term fluctuating population such as croaker should be evaluated.
- Continue monitoring of juvenile croaker populations in major nursery areas.
- Cooperatively develop a yield per recruit analysis to establish a minimum size that maximizes YPR.
- Determine the onshore vs. offshore components of the croaker fishery.
- Identify essential habitat requirements.

Low Priority

1. Determine migratory patterns and mixing rates through cooperative, multi-jurisdictional tagging studies.
2. Determine species interactions and predator/prey relationships for croaker (prey) and other more highly valued fisheries (predators).
3. Determine the impacts of any dredging activity (i.e. for beach re-nourishment) on all life history stages of croaker.

Atlantic Menhaden

- Evaluate effects of selected environmental factors on growth, survival and abundance of juvenile and adult menhaden, particularly in Chesapeake Bay and other coastal nursery areas.
- Develop and test methods for estimating size of recruiting year-classes of juveniles using fishery-independent survey techniques.
- Determine how loss/degradation of critical estuarine and nearshore habitat affects growth, survival and abundance of juvenile and adult menhaden abundance.
- Monitor landings, size, age, gear, and harvest area in the reduction and bait fisheries, and determine age composition by area. Enhance biostatistical sampling of bait samples in purse seine fisheries for Virginia and New Jersey to improve stock assessment.
- Study the ecological role of menhaden (predator/prey relationships, nutrient enrichment, oxygen depletion, etc.) in major Atlantic coast embayments and estuaries. The feasibility of estimating year-class strength using biologically stratified sampling design should be evaluated. The efforts could be supported by process studies linking plankton production to abundance of young menhaden (need resources).

- Evaluate use of coastal power plant impingement data as a possible means to estimate young-of-the-year menhaden abundance.
- Monte Carlo simulations should be conducted to evaluate precision of VPA.
- Alternative measures of effort, including spotter pilot logbooks, trip length, or other variables, should be evaluated. Spotter pilot logbooks should be evaluated for spotter plane search time, GPS coordinates, and estimates of school sizes observed by pilots.
- Re-evaluate menhaden natural mortality, by age and response to changing predator population sizes.
- Determine the effects of fish diseases (such as ulcerative mycosis and toxic dinoflagellates) on the menhaden stock.
- Determine the effects of regulations on the fishery, the participants and the stock.
- Growth back-calculation studies should be pursued to investigate historical trends in growth rate. The NMFS has an extensive database on scale growth increments which should be utilized for this purpose.
- Monitor fish kills along the Atlantic coast and use the NMFS Beaufort Laboratory as a repository for these reports.
- Develop bycatch studies of menhaden by other fisheries.
- Periodically monitor the economic structure and sociological characteristics of the menhaden reduction industry.

Striped Bass

1. Develop refined and cost-efficient coastal monitoring regime for striped bass stocks, including spawning stock biomass modeling and virtual population analysis (VPA).
2. Conduct sensitivity analysis on current state and federal fishery dependent and independent monitoring programs to determine which, if any, may be eliminated.
3. An evaluation of the overfishing definition should be made relative to uncertainty in biological parameters.
4. Simulation models should be developed to look at the implications of overfishing definitions relative to development of a striped bass population, which will provide “quality” fishing. Quality fishing must first be defined.
5. Quota calculation methods should be refined which allow better estimates among various components of the fishery.
6. Examine differential reporting rates between commercial and recreational fishermen using high reward tags.
7. Develop studies to provide information on the magnitude of hook and release and bycatch mortality, including factors that influence their magnitude and means of reducing or eliminating this source of mortality.
8. Further study should be conducted on the discrepancy in ages between scale-based and otolith-based ages. Particular emphasis should be placed on comparisons with known age fish determined from coded wire tags. Comparisons should be made among age readers and areas.
9. Increase sea sampling of commercial fisheries, such as the dogfish gillnet fishery, which may have high levels of discards.
10. Continue in-depth analysis of migrations, stock composition, etc. using mark-recapture data.

11. Continue to conduct research to determine limiting factors affecting recruitment and possible density implications.
12. Determine inherent viability of eggs and larvae.
13. Additional research should be conducted to determine the pathogenicity of the IPN virus isolated from striped bass to other warm water and marine species, such as flounder, menhaden, shad, largemouth bass and catfish.
14. Juvenile and adult surveys should be continued to determine the most cost-effective release strategies including age at release and optimal release conditions such as salinity, temperature, and time of day for future potential stocking programs.
15. Review relationship between tag-based survival estimates and VPA estimate of mortality in a management framework.
16. Improve methods for determining population sex ratio for use in estimates of spawning stock biomass and biological reference points.
17. Develop maturity ogive applicable to coastal migratory stock.

Atlantic Sturgeon

1. Obtain baseline data on habitat condition and quantity in important sturgeon rivers. Data should address both spawning and nursery habitat.
2. Characterize size, condition, and relative abundance of Atlantic sturgeon by gear and season taken as bycatch in various fisheries.
3. Determine the extent to which Atlantic sturgeon are genetically differentiable among rivers.
4. Develop methods to determine sex and maturity of captured sturgeon.
5. Research should be conducted to determine the susceptibility of Atlantic sturgeon to sturgeon adenovirus and white sturgeon iridovirus. Methods should be developed to isolate the sturgeon adenovirus and an Atlantic sturgeon cell line should be established for infection trials.
6. Develop sperm cryo-preservation techniques and refine to assure availability of male gametes. Refine induced spawning procedures.
7. Encourage shortnose sturgeon researchers to include Atlantic sturgeon research in their projects.
8. Develop and implement long-term marking/tagging procedures to provide information on individual tagged Atlantic sturgeon for up to 20 years.
9. Evaluate aging techniques for Atlantic sturgeon with known age fish. Emphasis should be placed on verifying current methodology based on fin rays. Determine length, fecundity, and maturity at age for North, Mid and South Atlantic stocks.
10. Conduct basic cultural experiments to provide information on: a) efficacy of alternative spawning techniques, b) egg incubation and fry production techniques, c) holding and rearing densities, d) prophylactic treatments, e) nutritional requirements and feeding techniques, and f) optimal environmental rearing conditions and systems.
11. Establish stocking goals and success criteria prior to development of stock enhancement or recovery programs.
12. Conduct research to identify suitable fish sizes, and time of year for stocking cultured fish.
13. Conduct and monitor pilot-scale-stocking programs before conducting large-scale efforts over broad geographic areas.

14. Identify rates of tag loss and tag reporting.
15. Evaluate existing sea sampling data to characterize at-sea migratory behavior.
16. Establish tolerance of different life stages to important contaminants and levels of such environmental factors such as DO (dissolved oxygen), pH, and temperature.
17. Standardize collection procedures and develop suitable long-term repository for biological tissues for use in genetic and other studies.
18. Develop the capability to capture wild broodstock and develop adequate holding and transport techniques for large broodstock.
19. Research should be conducted to identify the major pathogens of Atlantic sturgeon and a cell line for this species should be developed.
20. Conduct a cost benefit analysis of various stocking protocols.
21. Conduct further analyses to assess the sensitivity of F50 to model inputs.

Research Needs Identified As Being Met:
Establish a tag recovery clearinghouse and database for consolidation and evaluation of tagging and tag return information including associated biological, geographic, and hydrographic data.

Black Sea Bass
High Priority

- Sampling should be increased for commercial landing in black sea bass fisheries, specifically the fish pot fisheries in the Mid-Atlantic. Age sampling should be increased across all components of the commercial fishery.
- Sampling should be increased in the recreational fisheries. Age data should be collected from the total catch, and length sampling should be done to characterize size structure of discards.
- Develop fishery independent surveys and expand existing surveys to capture all sizes and age classes in order to develop independent catch-at-age and CPUE.
- Investigate the effect of sex transition rates, sex ratio and differential natural mortality by sex on the calculation of spawning stock biomass per recruit and eggs per recruit. Also, investigate the impact on reproduction of removal of large males from the population.
- Studies on sex-specific mortality rates and growth are needed.
- Increase sea sampling to verify information from commercial logbooks to provide better estimates of discards.
- A tagging program should be initiated through state fisheries agencies to estimate mortality independent of traditional methods.
- Further delineation of essential fish habitat (EFH), particularly in nursery areas. Further investigation of possible gear impacts on EFH.

Medium Priority

- Explore alternative assessment models, including non-age based alternatives.
- Consideration should be given to a pot survey for an index of abundance.
- Identify transport mechanisms or behaviors that move early juvenile black sea bass into estuaries.
- Evaluate habitat use by overwintering yearling, young-of-the-year, and adult black sea bass.

- Evaluate food habits of black sea bass larvae and overwintering adults.

Low Priority

1. Develop mariculture techniques.
2. A study determining the value of artificial reefs for increased production of black sea bass would be valuable in estimating potential yield.

Bluefish

1. Data needs:
   a) Sampling of size and age composition of the fisheries by gear type and statistical area should be increased.
   b) Commercial and recreational landings of bluefish should be targeted for biological data collection wherever possible.
   c) Increase intensity of biological sampling of the NER commercial and coastwide recreational fisheries.
2. Continue research on species interactions and predator/prey relationships. A scale-otolith age comparison study needs to be completed for bluefish.
3. Explore alternative methods for assessing bluefish, such as length-based and modified DeLury models.
4. Measures of CPUE under different assumptions of effective effort should be evaluated to allow evaluation of sensitivity of results.
5. Initiate fisheries dependent and independent sampling of offshore populations of bluefish during winter months.
6. Conduct research to determine the timing of sexual maturity and fecundity of bluefish.
7. Work should continue on catch and release mortality.
8. Any archived age data for bluefish should be aged and used to supplement North Carolina DMF keys in future assessments.
9. Conduct research on oceanographic influences on bluefish recruitment, including information on migratory pathways of larval bluefish.
10. Study tag mortality and retention rates for the American Littoral Society dorsal loop and other tags used for bluefish.
11. A coastal surf-zone seine study needs to be initiated to provide more complete indices of juvenile abundance.
12. Test the sensitivity of the bluefish assessment to assumptions concerning age-varying M, levels of age 0 discard, and the selection pattern.
13. Increase sampling frequencies when bluefish are encountered, especially when medium size fish are encountered.
14. Scientific investigations should be conducted on bluefish to develop an understanding of the long term, synergistic effects of combinations of environmental variables on various biological and sociological parameters such as reproductive capability, genetic changes, and suitability for human consumption.
15. Studies on the interactive effects of pH, contaminants, and other environmental variables on survival of bluefish.
16. Investigate the relationship of epidemic dermatological disease of bluefish exhibited in the Tar-Pamlico estuary to environmental toxics or other parameters.

17. Investigate the distribution of adult bluefish (particularly the spring-spawned cohort) in the South Atlantic Bight and juvenile bluefish (including the pelagic stage); and develop precise information on the distribution and relative abundance of bluefish in inshore areas, especially estuaries and embayments.

Source: NEFSC EFH Source Document on Bluefish (NEFSC 2006).

We lack information on the reproductive biology of bluefish. Observed patterns of spawning may be based on the population level rather than on information on individual reproductive traits. We presently do not know whether individuals spawn serially, and if so, how many times they are capable of spawning in a year. We also do not know if these reproductive characteristics vary with age. It is apparent that more study of the distribution of older stages needs to be correlated with spawning events. Since bluefish school in like-sized (and supposedly like-aged) groups, we need to know what groups are where and when, and how those aggregations are associated with the observed densities of eggs. Simply describing how many spawning events are occurring cannot solve the issue of the number of manageable stocks.

Our understanding of the "pelagic-juvenile" stage is limited despite its obvious importance. We need to better understand the details of transport mechanisms that provide progeny of reproduction in the South Atlantic Bight (SAB) to nurseries in the Middle Atlantic Bight (MAB). Increased sampling of the neuston or near-surface layers of the ocean between production areas and estuarine nursery areas, associated with appropriate oceanographic observations, would provide much-needed insight into factors affecting transport and estuarine recruitment.

There has been a tight correlation between population size and the contribution of the spring spawned cohort to fall trawl collections in the last three decades. Yet our knowledge of reproduction in the SAB is limited to a brief, under-sampled period in the 1970s when the population was at a relatively low level of abundance. Furthermore, larvae produced in June in the southern part of the MAB appear not to survive [unless recruits to Maine estuaries result from this output, see Creaser and Perkins (1994)], the fate of the remaining MAB summer offspring remains enigmatic.

There is some evidence for spawning during the fall in the Cape Canaveral region of Florida that appears to be discrete, rather than a continuation of spawning in the MAB. This evidence has been demonstrated in this document with larval occurrences and a disjunct autumn distribution of fish between 26 and 40 cm. Hare and Cowen (1993) present gonadosomatic data that suggest the same thing. Admittedly, some of this evidence is weak and based on incomplete sampling, and should be improved to determine the origin of these spawning fish, the magnitude of spawning, and the fate of any progeny.

Horseshoe Crab

<u>High Priority</u>

Evaluate the effectiveness of currently used benthic sampling gear for stock assessment.

<u>Medium Priority</u>

1. Investigate larval and juvenile survival and mortality to assist in the assessment of annual recruitment.
2. Further evaluate life table information including sex ratio and population age structure.
3. Evaluate the effect of mosquito control chemicals on horseshoe crab populations.
4. Determine beach fidelity by horseshoe crabs to determine habitat use.
5. Evaluate the impacts of beach nourishment projects on horseshoe crab populations.
6. Evaluate the importance of horseshoe crabs to other marine resources such as sea turtles.
7. Estimate the proportion of sub-tidal spawning and determine if this affects spawning success (i.e., egg survivability).
8. Develop a young-of-year or age 1 recruitment index from the Delaware 16-foot trawl survey.
9. Conduct tagging studies (mark-recapture) to determine the incidence of repeated spawning and dispersal parameters.

<u>Low Priority</u>

10. Estimate fishing discard numbers and associated mortality rates.
11. Conduct additional stock assessments and determine harvest mortality rates (F). Use these data to develop a more reliable sustainable harvest rate.
12. Develop biological reference points (such as natural mortality rates, growth rates, fecundity, etc.).

Spanish Mackerel (from the 2006 ASMFC FMP review)

<u>High Priority</u>

- Length, sex, age, and CPUE data are needed for improved stock assessment accuracy. Simulations on CPUE trends should be explored and impacts on VPA and assessment results determined. Data collection is needed for all states, particularly those north of North Carolina.
- Evaluation of weight and especially length at age of Spanish mackerel.
- Development of fishery-independent methods to monitor stock size of Atlantic Spanish mackerel (consider aerial surveys used in south Florida waters).
- Timelier reporting of mid-Atlantic catches for quota monitoring.
- Provide better estimates of recruitment, natural mortality rates, fishing mortality rates, and standing stock. Specific information should include an estimate of total amount caught and distribution of catch by area, season, and type of gear.
- Develop methodology for predicting year class strength and determination of the relationship between larval abundance and subsequent year class strength.
- Commission and member states should support and provide the identified data and input needed to improve the SAFMC's SEDAR process.
- The full implementation of ecosystem-based management and the implementation of monitoring /research efforts needed to support ecosystem-based management needs should be conducted.

<u>Medium Priority</u>

- Yield per recruit analyses should be conducted relative to alternative selective fishing patterns.

- Determine the bycatch of Spanish mackerel in the directed shrimp fishery in Atlantic Coastal waters (partially met: Branstetter, 1997; Ottley et al., 1998; Gaddis et al., 2001; Page et al., 2004).
- Evaluate potential bias of the lack of appropriate stratification of the data used to generate age-length keys for Atlantic and Gulf Spanish mackerel.
- Evaluate CPUE indices related to standardization methods and management history, with emphasis on greater temporal and spatial resolution in estimates of CPUE.
- Consideration of MRFSS add-ons or other mechanisms for collection of socioeconomic data for recreational and commercial fisheries.
- Determine normal Spanish mackerel migration routes and changes therein, as well as the climatic or other factors responsible for changes in the environmental and habitat conditions, which may affect the habitat and availability of stocks.
- Determine the relationship, if any, between migration of prey species (i.e., engraulids, clupeids, carangids), and migration patterns of the Spanish mackerel stock.

Low Priority

- Final identification of Spanish mackerel stocks through multiple research techniques.
- Complete research on the application of assessment and management models relative to dynamic species such as Spanish mackerel.
- Delineation of spawning areas and areas of larval abundance through temporal and spatial sampling.

Red Drum

1. Support fishery-independent sampling of sub-adult and adult red drum in each state from North Carolina to Florida. The purpose of this survey would be to: 1) verify escapement to the spawning population, 2) provide an index of recruitment to age 1, and 3) provide an estimate of the biomass of adult red drum.
2. Develop a more reliable estimate of natural and fishing mortality through directed sampling of the adult population.
3. Determine habitat preferences, environmental conditions, growth rates, and food habits of larval and juvenile red drum throughout the species range along the Atlantic coast. Assess the effects of environmental factors on stock density.
4. Identify spawning areas of red drum in each state from North Carolina to Florida so these areas may be protected from degradation and/or destruction. Determine the impacts of dredging and beach re-nourishment on red drum spawning and early life history stages.
5. Continue tagging studies to determine stock identity, inshore/offshore migration patterns and mortality estimation.
6. Determine the survival rate of red drum following regulatory and voluntary discard from commercial and recreational gear, including recreational net fisheries. Evaluate effects of water temperature and depth of capture.
7. Improve catch/effort estimates and biological sampling from recreational and commercial fisheries for red drum, including increased efforts to intercept nighttime fisheries for red drum by the NMFS MRFSS. Characterize magnitude of commercial and recreational discards.

8. States with significant fisheries should be encouraged to collect socio-economic data on red drum fisheries through add-ons to the MRFSS or by other means so as to determine the economic value of the Atlantic coast recreational red drum fishery.
9. Quantify relationships between red drum production and habitat.
10. Investigate and evaluate new stock assessment techniques as alternatives to age-structured models. Conduct yield modeling on red drum.
11. Investigate the concept of estuarine reserves to increase the escapement rate of red drum along the Atlantic coast.
12. Fully evaluate the efficacy of using cultured red drum to restore native stocks along the Atlantic coast, including cost-benefit analyses.
13. Identify the effects of water quality degradation on the survival of red drum eggs, post-larvae, larvae, and juveniles.
14. Refine maturity schedules on a geographic basis, determine relationships between annual egg production over a range of sizes, ages and across latitude.
15. Determine methods for restoring red drum habitat and/or improving existing environmental conditions that adversely affect red drum production.
16. Document and characterize schooling behavior for Atlantic coast red drum.

(from 2006 ASMFC review of Red Drum FMP)
Prioritized Research & Monitoring Recommendations (H)=High, (M)=Medium, (L)=Low
Stock Assessment and Population Dynamics

- Design an appropriate state fishery-independent survey of sub-adult and adult red drum to be implemented in Virginia, North Carolina, South Carolina, Georgia, and Florida. (H) (in progress for sub-adult and adult surveys).
- Each state should develop an on-going red drum tagging program that can be used to estimate both fishing and natural mortality and movements. This should include concurrent evaluations of tag retention, tagging mortality, and angler tag reporting rates. (M)
- Improve catch/effort estimates and biological sampling from recreational and commercial fisheries for red drum, including increased effort to intercept night fisheries for red drum. This should include significant efforts to determine the size and age structure of regulatory discards of live red drum. (H)
- States should maintain annual age-length keys. (H)
- Determine the chronic mortality rate of red drum following regulatory and voluntary discard from commercial and recreational fishing gear, including recreational net fisheries. Evaluate effects of water temperature and depth of capture. (M)
- Evaluate alternatives to VPA for red drum stock assessment. (M)

Biological

- Fully evaluate the effects and effectiveness of using cultured red drum to restore native stocks along the Atlantic coast. (H)
- Explore methods to effectively sample the adult population in estuarine, nearshore, and open ocean waters. (H)
- Continue tagging studies to determine stock identity, inshore/offshore migration patterns of all life stages (i.e. basic life history info gathering). Specific effort should be given to developing a large-scale program for tagging adult red drum (M) (in progress)

- Determine habitat preferences, environmental conditions, growth rates, and food habits of larval and juvenile red drum throughout the species range along the Atlantic coast. Assess the effects of environmental factors on stock density/yearclass strength. (M)
- Refine maturity schedules on a geographic basis. Thoroughly examine the influence of size and age on reproductive function. Investigate the possibility of senescence in female red drum. (L)

Social

- Examine the effectiveness of controlling fishing mortality and minimum size in managing red drum fisheries.
- Encourage the NMFS to conduct socioeconomic add-on surveys via the MRFSS that are specifically oriented to red drum recreational fishing (Example: the 2000 Northeast Summer Flounder Survey).

Economic

- Encourage the NMFS to continue funding socioeconomic add-on surveys via the MRFSS that include data elements germane to red drum recreational fisheries management.
- Where appropriate, encourage member states to conduct studies to evaluate the economic costs and benefits associated with current and future regulatory regimes impacting recreational anglers including anglers oriented toward catch and release fishing trips.
- Fully evaluate the efficacy of using cultured red drum to restore native stocks along the Atlantic Coast including risk adjusted cost-benefit analyses.
- Conduct a special survey and related data analysis to determine the economic and operational characteristics of the "for-hire sector" targeting red drum especially fishing guide oriented businesses in the South Atlantic states.
- Estimate the economic impacts (e.g. sales, jobs, income, etc.) of recreational red drum fisheries at the state and regional level including the "for-hire sector" (e.g. fishing guides).
- Encourage the NMFS to continue funding research on projecting future participation in marine recreational fishing in the Atlantic states with an emphasis on forecasts for major fisheries such as red drum.
- States with significant fisheries (over 5,000 pounds recorded by MRFSS) should collect socioeconomic data on red drum fisheries through add-ons to the MRFSS or by other means.

Habitat

- Identify spawning areas of red drum in each state from North Carolina to Florida so these areas may be protected from degradation and/or destruction. (H) (In progress, NC State University)
- Identify changes in freshwater inflow on red drum nursery habitats. Quantify the relationship between freshwater inflows and red drum nursery/sub-adult habitats. (H)
- Determine the impacts of dredging and beach re-nourishment on red drum spawning and early life history stages. (M)
- Investigate the concept of estuarine reserves to increase the escapement rate of red drum along the Atlantic coast. (M)

- Identify the effects of water quality degradation (changes in salinity, DO, turbidity, etc.) on the survival of red drum eggs, larvae, post-larvae, and juveniles. (M)
- Quantify relationships between red drum production and habitat. (L)
- Determine methods for restoring red drum habitat and/or improving existing environmental conditions that adversely affect red drum production. (L)

Spot

High Priority

- In trawl fisheries or other fisheries that take significant numbers of spot, states should monitor and report on the extent of unutilized bycatch and fishing mortality on fish less than age-1. Incorporate bycatch estimates into spot assessment models.
- The effects of mandated bycatch reduction devices (BRD's) on spot catch should be evaluated in those states with significant commercial harvests.
- Fishery dependent and independent size and sex specific relative abundance estimates should be developed.
- Cooperative coastwide spot juvenile indices should be developed to clarify stock status.
- Monitor long term changes in spot abundance, growth rates, and age structure.
- Continue monitoring of juvenile spot populations in major nursery areas.
- Improve spot catch and effort statistics from the commercial and recreational fisheries, along with size and age structure of the catch, in order to develop production models.
- Criteria should be cooperatively developed for aging spot otoliths and scales, and an age validation study should be conducted.

Medium Priority

- A yield per recruit analysis should be cooperatively developed.
- Develop stock identification methods.
- Determine migratory patterns through tagging studies.
- Determine the onshore vs. offshore components of the spot fishery.

Summer Flounder

High Priority

- Monitor abundance of juvenile summer flounder on a yearly basis.
- The NEFSC domestic sea sampling program should continue the collection of data for summer flounder, with special emphasis on a) improved areal and temporal coverage, b) adequate length and age sampling, and c) continued sampling after commercial fishery areal and seasonal quotas are reached and fisheries are limited or closed.
- Encourage research to determine the length and age frequency and discard mortality rates of commercial and recreational fishery summer flounder discards.
- Investigate the source of bias in estimating terminal parameters of the VPA (fishing mortality and stock size). Partially addressed in SARC 25 assessment.
- Undertake research to determine hooking mortality on summer flounder by circle, kahle, and regular “J” hooks and make the results of work already completed available to the Management Board.

- Develop fishery independent surveys and expand existing surveys to capture all sizes and age classes in order to develop independent catch-at-age and CPUE.
- Further delineation of EFH particularly in nursery areas. Further investigation of possible gear impacts on EFH.
- Collect and analyze age/length samples and catch/effort data from the commercial and recreational fisheries throughout the range of summer flounder.

Medium Priority

- Develop a consistent and accurate sampling program to determine the mesh selectivity for summer flounder and other commercial fisheries taken in mixed fisheries, and to determine discard mortality.
- Conduct a detailed socio-economic study of the summer flounder fisheries.
- Research directed at evaluating the mesh exemption program should be continued, with increased sample sizes to allow reliable statistical testing of results.
- Continue research to determine if the maturity ogive accurately reflects spawning potential of summer flounder.
- Investigate allocation of NEFSC sea sampling trips to optimize sampling effort.
- Develop stock identification methods via meristics, morphometrics, biochemical research and tagging; particularly off Virginia and North Carolina.
- Develop fish excluder devices to reduce bycatch of immature flatfish in fisheries that target species other than flounder.

Low Priority

- Develop a standardized index of abundance from NEFSC sea sampling data to provide a commercial fishery index that accounts for all removals by the fishery.
- Investigate the utility of alternative strata sets for the NEFSC spring trawl survey time series for summer flounder.
- Develop information on optimum length/age at capture and optimum mesh size.
- Conduct the basic research necessary to develop land and pen culture techniques.
- Evaluate effects of DO and water current requirements for adult summer flounder and summer flounder eggs.
- Evaluate the relationship between recruitment of summer flounder to nursery areas and Ekman transport or prevailing directions of water flow.

Weakfish

High Priority

- Collect catch and effort data including size and age composition of the catch, determine stock mortality throughout the range, and define gear characteristics. In particular, increase length-frequency sampling, particularly in fisheries from Maryland and further north.
- Develop latitudinal / seasonal / gear specific age length keys for the Atlantic coast. Increase sample sizes to consider gear specific keys.
- Derive estimates of discard mortality rates and the magnitude of discards for all commercial gear types from both directed and non-directed fisheries. In particular,

quantify trawl bycatch, refine estimates of mortality for below minimum size fish, and focus on factors such as distance from shore and geographical differences. Update the scale – otolith comparison for weakfish.

Medium Priority

- Define reproductive biology of weakfish, including size at sexual maturity, maturity schedules, fecundity, and spawning periodicity. Continue research on female spawning patterns: what is the seasonal and geographical extent of "batch" spawning; do females exhibit spawning site fidelity?
- Conduct hydrophonic studies to delineate weakfish spawning habitat locations and environmental preferences (temperature, depth, substrate, etc.) and enable quantification of spawning habitat.
- Compile existing data on larval and juvenile distribution from existing databases in order to obtain preliminary indications of spawning and nursery habitat location and extent.
- Continue studies on mesh-size selectivity; up-to-date (1995) information is available only for North Carolina's gill net fishery. Mesh-size selectivity studies for trawl fisheries are particularly sparse.
- Assemble socio-demographic-economic data as it becomes available from ACCSP.
- Additional investigation is needed in developing consistent otolith-based catch matrices including the EM algorithm.
- The impact of aging errors and other statistical uncertainties in the catch-at-age matrix on virtual population analysis (VPA) should be included. Retrospective analyses are needed on all VPA approaches investigated.
- Develop a spawner recruit relationship and examine the relationships between parental stock size and environmental factors on year-class strength.

Low Priority

- Identify stocks and determine coastal movements and the extent of stock mixing, including characterization of stocks in overwintering grounds. (e.g. tagging).
- Biological studies should be conducted to better understand migratory aspects and how this relates to observed trends in weight at age.
- Continue studies on recreational hook-and-release mortality rates, including factors such as depth, warmer water temperatures, and fish size in the analysis. Further consideration of release mortality in both the recreational and commercial fisheries is needed, and methods investigated to improve survival among released fish.
- Document the impact of power plants and other water intakes on larval, post larval and juvenile weakfish mortality in spawning and nursery areas, and calculate the resultant impact to adult sock size.
- Define restrictions necessary for implementation of projects in spawning and overwintering areas and develop policies on limiting development projects seasonally or spatially.
- Determine the onshore versus offshore components of the weakfish fishery.
- Develop a coastwide tagging database.
- Develop a spawner recruit relationship and examine the relationships between parental stock size and environmental factors on year-class strength.

Research Needs Identified as Being Met:

- Study the north-south gradient in weakfish growth rates.
  The study of the north-south gradient in weakfish growth rates is partially being addressed by Charlie Wenner, SC, through a MARFIN grant.
- Monitor long-term changes in abundance, growth rates, and age structure.

9.1.3.2 Recent and Ongoing Research on HMS Species

(Source: NMFS 2006)

Atlantic Bluefin Tuna

As part of its commitment to the Bluefin Program, research supported by the United States has concentrated on ichthyoplankton sampling, reproductive biology, and methods to evaluate hypotheses about movement patterns, spawning area fidelity, stock structure investigations and population modeling analyses.

Ichthyoplankton surveys in the Gulf of Mexico during the bluefin spawning season were continued in 2004 and 2005. Data resulting from these surveys, which began in 1977, are used to develop a fishery-independent abundance index of spawning West Atlantic bluefin tuna. This index has continued to provide one measure of bluefin abundance that is used in ICCAT's SCRS assessments of the status of the resource. During the 2004 U.S. ichthyoplankton survey, a plankton net of a type used in the Spanish surveys was fished in addition to the nets normally used to determine the impact of using a wider net mouth and larger mesh on the size and catch rates of bluefin in the Gulf of Mexico. The results of this work will be reported as they become available. U.S. scientists also collaborated in development of the larval working group agenda for the Climate Impacts on Oceanic Top Predators (CLIOTOP) program managed by GLOBEC (Global Ocean Ecosystem Dynamics) initiated by SCOR and the IOC of UNESCO in 1991.

Since 1998, researchers from Texas A & M University and the University of Maryland with assistance of researchers from Canada, Europe, and Japan have studied the feasibility of using otolith chemical composition (microconstituents and isotopes) to distinguish bluefin stocks.

Recent research has investigated the value of using additional microconstituent elements (transitional metals) to enhance classification success. By themselves the transitional metals provided little discriminatory power, but when combined with the other trace elements (for 13 elements in all), the classification success for several year-classes has been moderate ranging from 60 – 90 percent, and classification functions show strong year-to-year variability. In SCRS/2005/083 the utility of an alternative chemical marker in otoliths, carbon and oxygen stable isotopes, to discriminate bluefin tuna from natal regions were reported upon. The discriminatory power of stable isotopes (δ13C, δ18O) in otoliths of yearlings (age-1) was high, with 91 percent of individuals classified correctly to eastern and western nurseries. These stable isotopes and in particular δ18O can be used to reliably predict nursery origin of Atlantic bluefin tuna. An initial application compared otolith core material (corresponding to the first year of life) of large school, medium, and giant category bluefin tuna to reference samples of yearling signatures to determine their origin. A large fraction (~43 – 64 percent) of the Atlantic bluefin tuna collected in the western Atlantic fishery (comprised primarily of large school and medium category fish) originated from nurseries in the east. Alternatively, medium and giant category bluefin tuna from the Mediterranean were largely (~82 – 86 percent) of eastern origin. Thus, initial evidence suggests that the western fishery received high input from the Mediterranean population. (See generally SCRS/2003/105, and Rooker et al 2001a, 2001b and 2003).

Scientists from the University of Maryland, Virginia Institute of Marine Science, and Texas A&M University have continued to sample specimens for genetic and otolith chemistry studies of stock structure. Roughly 10 – 20 young of the year were collected in 2004. In addition, limited sampling of ages 1 and older continues. Efforts are also continuing to obtain samples from juveniles and mature bluefin from the Mediterranean Sea and adjacent waters.

In response to the ICCAT Commission's request for options for alternative approaches for managing mixed populations of Atlantic bluefin tuna, SCRS/2005/108 further examined some implications of incorporating electronic tagging information on transfer rates into virtual population analyses. SCRS/2005/084 examined yield and spawner per recruit consequences of different assumed levels of mixing between eastern and western bluefin stocks to provide guidance to the Commission as requested at the 3rd Meeting of Working Group to Develop Coordinated and Integrated Bluefin Tuna Management Strategies. Researchers at the Imperial College, London, continue work with the University of Miami, the University of New Hampshire and the National Marine Fisheries Service to develop methods to estimate bluefin movement and fishing mortality rate patterns (SCRS/2005/048). Operating models are being developed which will use conventional and electronic tagging data and fishing effort by management area. These models will be used to examine possible harvest control rules and the evaluation of possible management procedures.

U.S. scientists from Stanford and Duke University along with the Monterey Bay Aquarium and NMFS have placed over 700 electronic tags in bluefin tuna in the region along the U.S. coast of North Carolina. The data from implantable archival tags has been critical for establishing the basic biology of Atlantic bluefin and the patterns of movements to feeding and breeding grounds. Results from a large number of these tags were interpreted in a paper in the journal Nature in 2005 (Block et al. 2005). Tagging off the Carolinas, in the Gulf of Maine, and elsewhere continued in 2004 and 2005 and more than 90 tags were placed in fish off the Carolinas in 2005. The tags are due to report 7 – 9 months from the deployment dates and will be further reported upon as results become available.

U.S. scientists from the University of New Hampshire have placed over 200 pop-up satellite archival tags on New England bluefin tuna. Ongoing efforts include examining short and long-term dispersals of bluefin in the Gulf of Maine, the identification of spawning grounds, the spatial correlation between bluefin locations and oceanographic features and continuing to determine Atlantic-wide migratory paths. Results from much of this tagging effort were recently published in the journal Marine Biology (Wilson, et al. 2005).

A new research initiative in 2005 involving scientists from the University of New

Hampshire, the Virginia Institute of Marine Science, and Virginia Sea Grant will place electronic tags on juvenile bluefin from off the U.S. coast of Virginia. As results become available, they will be reported upon.

A recent publication by Fromentin and Powers (2005), titled "Atlantic bluefin tuna: population dynamics, ecology, fisheries and management" provides an extensive summary of old and new information on the biology and ecology of Atlantic bluefin tuna and associated fishery management implications. The abstract reads as follows:

> *Both old and new information on the biology and ecology of Atlantic bluefin tuna have confronted scientists with research challenges: research needs to be connected to current stock-assessment and management issues. We review recent studies on habitat, migrations and population structure, stressing the importance of electronic tagging results in the modification of our perception of bluefin tuna population dynamics and behavior. Additionally, we question, from both scientific and management perspectives, the usefulness of the classical stock concept and suggest other approaches, such as Clark's contingent and metapopulation theories. Current biological information confirms that a substantial amount of uncertainty still exists in the understanding of reproduction and growth. In particular, we focus on intriguing issues such as the difference in age-at-maturity between West Atlantic and Mediterranean bluefin tuna. Our description of Atlantic bluefin tuna fisheries places today's fishing patterns within the two millennium history of exploitation of this species: we discuss trap fisheries that existed between the 17th and the early 20th centuries; Atlantic fisheries during the 1950s and 1960s; and the consequences of the recent development of the sushi–sashimi market. Finally, we evaluate stock status and management issues since the early 1970s. While important uncertainties remain, when the fisheries history is confronted with evidence from biological and stock-assessment studies, results indicate that Atlantic bluefin tuna has been undergoing heavy overfishing for a decade. We conclude that the current exploitation of bluefin tuna has many biological and economic traits that have led several fish stocks to extreme depletion in the past.*

In 1982, ICCAT established a line separating the eastern and western Atlantic management units based on discontinuities in the distribution of catches at that time in the Atlantic and supported by limited biological knowledge. The United States is allocated quota from the western Atlantic management unit where the U.S. fisheries primarily occur. However, the overall distribution of the catch in the 1990s is much more continuous across the North Atlantic than was seen in previous decades. Tagging evidence indicates that movement of bluefin across the current east/west management boundary in the Atlantic does occur, that movements can be extensive (including trans-Atlantic) and complex, that there are areas of concentration of electronically tagged fish (released in the west) in the central North Atlantic just east of the management boundary, and that fisheries for bluefin tuna have developed in this area in the last decade. At least some of these fish have moved from west of the current boundary.

Complementary studies, which might show east to west movement, are less advanced. The composition and natal origin of these fish in the central North Atlantic area are not known. The SCRS emphasizes that "it is clear that the current boundary does not depict our present understanding of the biological distribution and biological stock structure of Atlantic bluefin tuna." The SCRS also notes that "the current boundary is a management boundary and its effectiveness for management is a different issue." There has been an accumulation of evidence on bluefin tuna mixing in the last few years through the collection of tagging data and its examination through the modeling of mixing scenarios for evaluating their effect on management. However, the origin of fish older than one year still remains unknown. Mixing results were reviewed in 2001 by the Workshop on Bluefin Tuna Mixing. This research led to a long-term plan for modeling finer scale spatial mixing and to short-term strategies for assessment to assist the advice for management. The data and research were reviewed again in 2002.

ICCAT, at its 2002 Meeting in Bilbao, called for a Working Group to Develop Integrated and Coordinated Atlantic Bluefin Tuna Management Strategies, which met in 2003 and again in 2004. In response to the recommendations from these meetings, the SCRS is developing a revised proposal for initiating a coordinated Bluefin Tuna Research Program to address priority research and data needs for providing scientific advice to ICCAT related to revised management procedures for bluefin tuna. Uncertainty exists regarding the importance and impacts of mixing on western stocks. The most important uncertainty regarding management advice by the SCRS for the eastern stock is the uncertainty in the catch data that are being taken.

More than 20 scientific documents related to bluefin tuna biology were presented to the 2005 SCRS. Many of the contributions dealt with the important issue of stock structure and mixing, and new information is available for both stocks. In particular, studies of otolith microchemistry and genetics have resulted in advances in our understanding of this component of the biology of bluefin tuna. These results continue to advance our knowledge about the overlapping distribution of fish originating from the east and the west. Therefore, the SCRS continues to question present hypotheses on stock identification. While these results are promising, more complete sampling and development of appropriate analytical approaches are required. The SCRS also received contributions relating to age and growth, sampling, parasitology and condition of bluefin tuna.

Atlantic Bigeye Tuna

In addition to monitoring catch and effort statistics for tropical tunas that include bigeye tuna, United States scientists participated in the 2005 ICCAT Workshop on Methods to Reduce Mortality of Juvenile Tropical Tunas, held in Madrid from 4 – 8 July, 2005. Document SCRS/2005/063 used the ICCAT Task 2 catch and effort data to estimate expected changes in the catches of tropical tunas attributable to replacing the current moratorium with a time-area closure (Recommendation 04-01). The results indicate that catches of tropical tunas are expected to increase substantially if the time-area closure replaces the current moratorium. Considering that the current ICCAT hypothesis is that purse-seine fleet efficiency gains three percent per year, the net change could in fact be a large overall increase to levels above the pre-moratoria fishing mortality rate levels. SCRS/2005/079 explored the expectations for catches of undersized bigeye tuna considering the agreement reached in Recommendation 04-01. In all cases examined, total catches can be expected to increase from 5.5 to 6.7 percent as a result of Recommendation 04-01, and catches of bigeye tuna can be expected to increase from 16 to 22.1 percent. In all cases, catch of juvenile bigeye tuna increases.

U.S. scientists from the University of Miami's Rosenstiel School of Marine and Atmospheric Science continue to collaborate with EC scientists on the EU-funded assessment and management modeling project titled Framework for the Evaluation of Management Strategies (FEMS) project, on management strategy evaluations related to tropical tuna fisheries.

Atlantic Yellowfin Tuna

In addition to the United States research findings for tropical tunas discussed above under bigeye tuna, one document was presented to the SCRS in 2005 that gave an overview of fishery trends and stock status for yellowfin tuna worldwide. It was noted that the natural mortality vector used by ICCAT in the Atlantic, while the same as that used by the IOTC for the Indian Ocean, is lower than is used by other scientific bodies for other oceans, particularly for the youngest ages. It was further noted that more recent information and methodologies may be available to potentially improve the estimates of natural mortality. Another document considered the estimation of natural mortality from multi-species tagging data. Due to limitations in the data (such as unbalanced design and different size distributions of released fish) and potential fishing differences between fleets, conclusions were limited to ratios of total mortality between fishing periods rather than any direct statement about natural mortality.

Considering the importance of natural mortality estimates in the assessment of the stock, the improvement of natural mortality estimates remains a high research priority. It was noted that future stock assessments should include an evaluation of the sensitivity of results to the uncertainty in natural mortality estimates. Differences were also noted for other biological parameters used by the various scientific bodies, such as growth and maturity vectors, the extent to which these differences reflect estimation methodology, data quality, or real differences between stocks warrants investigation.

Atlantic Albacore Tuna

U.S. scientists prepared document SCRS/2005/081 which described population models for North Pacific albacore (*Thunnus alalunga*) that have been developed and reviewed within the North Pacific Albacore Workshop (NPALBW) forum since 2000. Currently, the NPALBW relies on a Virtual Population Analysis (VPA) model for the purposes of formulating an international-based consensus regarding the "status" of this fish stock. Recently, an equally important research directive from the NPALBW has been to develop alternative, more detailed statistical-based models, in efforts to evaluate more fully the relationship between this species' population dynamics and associated fishery operations (i.e., areas of uncertainty in an overall stock assessment). Participants on the NPALBW developed one candidate model based on the Age-structured Assessment Program (ASAP), which generally represents a maximum likelihood-based numerical approach for conducting relatively straightforward, forward-simulation catch-at-age analyses. In addition, the document presents a brief discussion concerning development of other alternative stock assessment models, particularly length-based/age-structured platforms (e.g., MULTIFAN-CL and Stock Synthesis 2).

Atlantic Skipjack Tuna

U.S. small tuna research is directed mainly on king and Spanish mackerel stocks, as the amount landed of other small tunas such by U.S. fishermen is generally low. The focus of research on skipjack research by the international scientific community is on basic stock structure and abundance and the influence of FADs on increase in efficiency of the various fleets.

During the ICCAT Workshop on Methods to Reduce Mortality of Juvenile Tropical Tunas in July 2005 (Document SCI-032), a re-analysis on the tagging data in the Senegalese area showed however that the parameters of the skipjack growth curve obtained in this region were in fact closer to the growth estimates made in the Gulf of Guinea or in other oceans than those done previously in Senegal. In 2004 and 2005, U.S. scientists collaborated with Caribbean nations under the banner of the Caribbean Regional Fisheries Mechanism in initiating stock assessment analyses for small tuna (and other) stocks of mutual concern.

Swordfish

In 2005, data from observer samples were compared against self-reported information from the U.S. large pelagic mandatory logbook reporting system, and estimates of discard mortality of swordfish, billfish, sharks and other species from the U.S. fleet were developed from that analysis for the 2005 SCRS. Estimates of small swordfish bycatch for 2002 – 2004 were compared to the average levels estimated for the late 1990's and were found to be substantially lower. Reported and observed swordfish catches, and size and catch rate patterns through 2004 were examined in support of monitoring the recovery of north Atlantic swordfish. Standardized indices of abundance were updated for the Western North Atlantic using data from the U.S. pelagic longline fleet (SCRS/2005/085). Collaborative research between various ICCAT nations and Venezuelan scientists continues on estimating the age-structure of the catch of swordfish. Results of this research will be available for the next assessment of north Atlantic swordfish.

Scientists from the United States collaborated with Brazilian scientists to improve catch rate standardization procedures by offering a course on the topic in Brazil in mid-2005. Central to this collaboration is development of fisheries research capacity in Brazil through graduate student training and of stronger scientific cooperation between Brazil and the United States.

Research on measures to mitigate the interactions between pelagic longline and bycatch of marine turtles continued under a cooperative research program involving the U.S. Atlantic pelagic longline fishery. The Northeast Distant Fishery Experiment was conducted from 2001 through 2003 on the high seas of the Western Atlantic Ocean, in an area off Newfoundland known as the Grand Banks. Results of this research which was focused on reducing mortality of marine turtles interacting with pelagic longlines was recently published (Watson et. al. 2005. Fishing methods to reduce sea turtle mortality associated with pelagic longlines. Can. J. Fish. Aquat. Sci. 62(5): 965-981). Additional cooperative research in the Gulf of Mexico was carried out in 2004 and in additional regions in 2005.

Atlantic Billfish

The NMFS SEFSC played a substantial role in the ICCAT Enhanced Research Program for Billfish in 2004, with SEFSC scientists acting as the coordinator for the western Atlantic Ocean. Major accomplishments in the western Atlantic in 2004 were documented in SCRS/04/028. Highlights include 11 at-sea sampling trips with observers on Venezuelan industrial longline vessels in September 2004. Of the trips accomplished to date, 4 observer trips were on Korean type vessels fishing under the Venezuelan flag. Most of these vessels are based out of Cumana targeting tuna, swordfish, or both at the same time. Biological sampling of swordfish, Istiophorids, and yellowfin tuna for reproductive and age determination studies, as well as genetics research were continued during the 2004 sampling season. Shore-based sampling of billfish landings for size frequency data, as well as tournament sampling was obtained from Venezuela, Grenada, U.S. Virgin Islands, Bermuda, Barbados, and Turks and Caicos Islands. Program participants in Venezuela, Grenada, and Barbados continued to assist in obtaining information on tag-recaptured billfish, as well as numerous sharks, in the western Atlantic Ocean during 2004; a total of 44 tag recovered billfish and sharks were submitted to the Program Coordinator in 2004. Age, growth, and reproductive samples from several very large billfish were also obtained during 2004.A study conducted by the Virginia Institute of Marine Science (VIMS) to evaluate post release survival and habitat use from the recreational fishery for Atlantic white marlin using popup satellite archival tags (PSATs) was finalized in 2004 and published in the peer review literature. A separate study conducted by VIMS on U.S. longline vessels to evaluate post release survival of marlin, as well as evaluating hook performance and related mortality was also finalized in 2004. These data have been submitted to a peer-reviewed journal and are currently under review.

The SEFSC has conducted several studies in the Northwest Atlantic and the Pacific coast of Central America to evaluate habitat use and reproductive biology of billfish using PSAT technology. About 200 PSATs have been deployed in this effort over the last 4 years with deployments ranging from a month to 5.5 months. Several peer-reviewed papers summarizing these results are in press at this time, while other papers are currently in preparation.

In addition, SEFSC is also currently conducting pelagic longline research to evaluate gear behavior, and the effects of gear modification on catch rate and survival of target and non-target species. Three cruises have been completed to date. This work in ongoing and should be finished in 2006. Cooperative billfish research between US and Brazilian scientists was initiated in 2005.

The Fishery Management Group of the University of Miami is carrying out research on Atlantic billfish on three areas, population parameter estimation, population modeling and development of socio-economic indicators. Others at the University of Miami's Rosenstiel School and elsewhere are conducting research on early life history, reproductive biology and ecology of billfishes, as well as age and growth estimation. Updates of standardized CPUE for blue and white marlin from the United States pelagic longline fishery in the NW Atlantic and Gulf of Mexico and the U.S. recreational tournament fishery in the NW Atlantic and Gulf of Mexico were developed and presented to ICCAT in 2005 (Document SCRS/2005/30 and SCRS/2005/31). Numerous additional papers were presented regarding standardization of CPUEs. Please see http//:www.iccat.es for additional information.

Multiple papers on habitat use were submitted to the ICCAT SCRS in 2005. These included papers on: vertical habitat use of white marlin in numerous locations of the western North Atlantic using PSAT tags (SCRS/2005/034); the depth distributions of 52 blue marlin in relation to exposure to longline gear using PSAT tags (SCRS/2005/035); and, a quantitative framework and numerical method for characterizing vertical habitat use by large pelagic animals using pop-up satellite tag data (SCRS/2005/). Additional information on spawning area research and other topics can be found at http//:www.iccat.es.

Atlantic Sharks

Stock Assessments of Pelagic, Large Coastal, and Prohibited Sharks

The ICCAT Subcommittee on Bycatch conducted a stock assessment of blue sharks and shortfin makos in Tokyo, Japan, in June 2004. All information available on biology, fisheries, stock identity, catch, CPUE, and size of these species was reviewed and an evaluation of the status of stocks conducted using surplus production, age-structured, and catch-free stock assessment models. U.S. scientists contributed eight working documents for this meeting on various aspects of shark biology and methods to assess stock status; SEFSC scientists participated in the assessment process and authored or co-authored six of those documents. A stock assessment of dusky shark, a prohibited species under the shark FMP and candidate for listing under the ESA, is under way with expected completion in summer of 2006. Biological and fishery information available for this species is being synthesized and stock status will be evaluated using multiple stock assessment methodologies. The next assessment of large coastal sharks is planned for FY06, but data collection, synthesis, analysis, and preliminary stock evaluations will begin in late FY05.

Update on Catches of Atlantic Sharks

An update on catches of large and small coastal and pelagic sharks in U.S. Atlantic, Gulf of Mexico, and Caribbean waters was generated in FY 05 for inclusion in the 2005 SAFE Annual Report and future shark stock assessments. Time series of commercial and recreational landings and discard estimates from several sources were compiled for the large coastal shark complex and sandbar and blacktip sharks. In addition, recent species-specific commercial and recreational landings were provided for sharks in the large coastal, small coastal, and pelagic groups. Species-specific information on the geographical distribution of commercial landings by gear type and geographical distribution of the recreational catches was also provided. Trends in length-frequency distributions and average weights and lengths of selected species reported from three separate recreational surveys and in the directed shark bottom-longline observer program were also included. Another update on catches of Atlantic sharks will be generated in FY 06.

Ecosystem Modeling

A dynamic mass-balance ecosystem model was used to investigate how relative changes in fishing mortality on sharks can affect the structure and function of Apalachicola Bay, Florida, a coastal marine ecosystem. Simulations were run for 25 years wherein fishing mortality rates from recreational and trawl fisheries were doubled for ten years and then decreased to initial levels. Effect of time/area closures on ecosystem components were also tested by eliminating recreational fishing mortality on juvenile blacktip sharks. Simulations indicated biomass of sharks declined up to 57 percent when recreational fishing mortality was doubled. Simulating a time/area closure for juvenile blacktip sharks caused increases in their biomass but decreases in juvenile coastal shark biomass, a competing multispecies assemblage that is the apparent competitor. In general, reduction of targeted sharks did not cause strong top-down cascades. Another update on catches of Atlantic sharks was generated in FY05.

Elasmobranch Feeding Ecology and Shark Diet Database

The current Fishery Management Plan for Atlantic Tunas, Swordfish, and Sharks gives little consideration to ecosystem function because there is little quantitative species-specific data on diet, competition, predator-prey interactions, and habitat requirements of sharks. Given this, several studies are currently underway describing the diet and foraging ecology, habitat use, and predator prey interactions of elasmobranchs in various communities. In 2005, a study on latitudinal variation in diet and daily ration of the bonnethead shark from the eastern Gulf of Mexico was completed and a manuscript is being prepared for publication. A database containing information on quantitative food and feeding studies of sharks conducted around the world has been in development for several years and presently includes over 200 studies. This fully searchable database will continue to be updated and fine-tuned in FY 06. The goal is to make this tool available to researchers in the relatively near future.

Cooperative Gulf of Mexico States Shark Pupping and Nursery Survey (GULFSPAN)

The SEFSC Panama City Shark Population Assessment Group manages and coordinates a survey of coastal bays and estuaries between the Panhandle of Florida and Texas. Surveys identify the presence/absence of neonate and juvenile sharks and attempt to quantify the relative importance of each area as it pertains to essential fish habitat requirements for sharks. The SEFSC Panama City Shark Population Assessment Group also initiated a juvenile shark abundance index survey in 1996. The index is based on random, depth-stratified gillnet sets conducted throughout coastal bays and estuaries in northwest Florida monthly from April to October. The species targeted for the index of abundance are juvenile sharks in the large and small coastal management groups.

Angel Shark Life History

The Atlantic Angel Shark is a benthic species inhabiting deep waters of the Gulf of Mexico and the Atlantic Ocean. This species is listed as prohibited by the 1999 Fisheries Management Plan for Atlantic Tunas, Swordfish, and Sharks due to the lack of biological data and a precautionary approach for species thought to be highly susceptible to exploitation. Life history studies began in 2003. Samples are obtained from commercial fishers and fishery independent surveys. Preliminary reproductive parameters were determined in 2004 and results presented at the annual American Elasmobranch Society meeting held in Norman, Oklahoma, in May 2004.

Life History Studies of Elasmobranchs

Biological samples are obtained through research surveys and cruises, recreational fishers, and through collection by onboard observers on commercial fishing vessels. Age and growth rates and other life history aspects of selected species are processed and data analyzed following standard methodology. This information is vital as input to population models incorporating variation and uncertainty in estimates of life-history traits to predict the productivity of the stocks and ensure that they are harvested at sustainable levels. The age and growth parameters of bull shark (*Carcharhinus leucas*) and spinner shark (*C. brevipinna*) were completed and submitted for publication in 2004.

Cooperative Research – Definition of Winter Habitats for Blacktip Sharks in the Eastern Gulf of Mexico

A collaborative effort between SEFSC Panama City Shark Population Assessment Group and Mote Marine Laboratory is underway to define essential winter habitats for blacktip sharks (*Carcharhinus limbatus*). Deployment of archival Pop-Up Archival Transmitting (PAT) tags on sharks during January and February of FY05 in the Florida Keys and north Florida will be executed with the cooperation of the charterboat industry. PAT tags will be programmed to detach from individuals during late spring and early summer when sharks have recruited to coastal areas.

Cooperative Research – Habitat Utilization among Coastal Sharks

Through a collaborative effort between SEFSC Panama City Shark Population Assessment Group and Mote Marine Laboratory, the utilization of coastal habitats by neonate and young-of-the-year blacktip and Atlantic sharpnose sharks will be monitored through an array of underwater acoustic receivers (VR2, Vemco Ltd.) placed throughout each study site.

Movement patterns, home ranges, activity space, survival, and length of residence of individuals will be compared by species and area to provide information to better manage critical species and essential fish habitats.

Cooperative Research – Characterization of Bycatch in the Gulf Butterfish, (*Peprilus burti*), Trawl Fishery, with an Emphasis on Identification of Life History Parameters for several Potentially High-Risk Species

A proposal with the SEFSC Panama City Shark Population Assessment Group and the University of Florida was submitted to MARFIN to quantify and qualify the elasmobranch bycatch in the butterfish, (*Peprilus triacanthus*), trawl fishery in the Gulf of Mexico. Determination of life history parameters for the roundel skate, (*R. texana*), the clearnose skate, (*R. eglanteria*), the spreadfin skate (*Dipturus olseni*), and the Atlantic angel shark, (*Squatina dumerili*) will be developed ultimately for the estimation of vital rates. Vital rate information will be used to determine the productivity of the stocks and ensure that they are harvested at sustainable levels.

Using elemental chemistry of shark vertebrae to reconstruct large-scale movement patterns of sharks

A project examining ontogenetic shifts in habitat utilization of bull sharks using Sr:Ca ratios of vertebrae will begin in FY06, funds permitting. Laser ablation ICPMS will be used to assay transects across the entire vertebral section along the corpus calcareum. Given the relationship of Sr:Ca to habitat developed from the reference samples, habitat type (freshwater, estuarine, or marine) will be assigned to each growth band, thereby reconstructing the migration history of the shark on a year-by-year basis over its lifetime.

Coastal Shark Assessment Research Surveys

The SEFSC Mississippi Laboratories in Pascagoula have been operating annual research cruises aboard NOAA vessels since 1995. The objectives of this program are to conduct bottom longline surveys to assess the distribution and relative abundance of coastal sharks along U.S. and Mexican waters of the Gulf of Mexico and the U.S. eastern seaboard. This is the only long-term, nearly stock-wide, fishery-independent survey of Atlantic sharks conducted in U.S. and neighboring waters. Ancillary objectives are to collect biological and environmental data, and to tag-and-release sharks. Starting in 2001 and under the auspices of the Mex-US-Gulf Program, the Pascagoula Laboratories have provided logistical and technical support to Mexico's Instituto Nacional de la Pesca to conduct a cooperative research cruise aboard the Mexican research vessel *Onjuku* in Mexican waters of the Gulf of Mexico. The cruise also took place in 2002, but was suspended in 2003 and 2004 because of mechanical problems with the research vessel and other issues.

A proposal was submitted in 2005 to gather data to help clarify the uncertainty on the current status of oceanic whitetip sharks in the western North Atlantic Ocean. Data on behavior and movement patterns will be collected using on-board observers on pelagic longline vessels. Archival satellite pop-up tags will be utilized to monitor the movement patterns, depth, and temperature preferences of this species. In addition, time-depth recorders, and hook-timers will be used to determine the depth and times at which sharks take baits. These data will be incorporated with sea surface temperature data from satellites and incorporated into new habitat-based analyses of the data to provide a better understanding of the status of oceanic whitetip sharks.

<u>Cooperative Research – The capture depth, time, and hooked survival rate for bottom longline caught large coastal sharks</u>
A collaborative effort between SEFSC Panama City Shark Population Assessment Group and the University of Florida to examine alternative measures in the shark bottom longline fishery to reduce mortality on prohibited sharks such as reduced soak time, restrictions on the length of gear, and fishing depth restrictions will be tested using hook timers. Funding is being sought through the NMFS Cooperative Research Program.

<u>Utilizing Bioenergetics and Matrix Projection Modeling to Quantify Population Fluctuations in Long-lived Elasmobranchs: Tools for Fisheries Conservation and Management</u>
Under the supervision of SEFSC scientists at the Panama City Laboratory, the NMFS Sea Grant Fellow in Population Dynamics and Resource Economics conducted research that sought to use a bioenergetics and matrix approach to examine the population dynamics of the cownose ray (*Rhinoptera bonasus*). Laboratory experiments and field data were used to obtain basic life history information, and that information configured the individual-based bioenergetics model. The bioenergetics model was coupled to a matrix projection model, and the coupled models were used to predict how warmer and cooler water temperatures would affect the growth and population dynamics of the cownose rays. Changes in growth rates under the warmer and cooler conditions lead to changes in age-specific survivorship, maturity, and pup production, which were used as inputs to a matrix projection model. Faster growth of individuals under the cooler scenarios translated into an increased population growth rate (4.4 – 4.7 percent/year versus 2.7 percent/year under baseline), shorter generation time, and higher net reproductive rates, while slower growth under the warmer scenarios translated into slower population growth rate (0.05 – 1.2 percent/year), longer generation times, and lower net reproductive rates.
Elasticity analysis indicated that population growth rate was most sensitive to adult survival. Reproductive values by age were highest for intermediate ages.

<u>Cooperative Research – Definition of Winter Habitats for Blacktip Sharks in the Eastern Gulf of Mexico</u>

A collaborative effort between SEFSC Panama City Shark Population Assessment Group and Mote Marine Laboratory is underway to define essential winter habitats for blacktip sharks (*Carcharhinus limbatus*). Deployment of two pop-off satellite archival tags (PAT) on sharks during January and February of 2005 in the Florida Keys was accomplished with the cooperation of the charter boat industry. Preliminary results from these two sharks indicate one shark remained in the Keys while the other moved to an area southwest of the coast of Cuba. Additional PAT tags will be placed on sharks during the summer of 2005.

<u>Cooperative Research – Definition of Summer Habitats and Migration Patterns for Bull Sharks in the Eastern Gulf of Mexico</u>
A collaborative effort between SEFSC Panama City Shark Population Assessment Group, University of Florida, and Mote Marine Laboratory is underway to determine summer habitat use and short-term migration patterns of bull sharks (*Carcharhinus leucas*). Sharks are being outfitted with Pop-Up Satellite Archival Tags (PSAT) during July and August of 2005 and scheduled to deploy in autumn. This project is driven by the lack of data for this species and its current prominence within the Florida coastal community. A better understanding of this species is required to effectively manage this species for both commercial and recreational fishers as well as the general public. Concerns regarding this species will continue to be an issue as fishers and the public demand that state and federal governments provide better information concerning the presence and movements of these sharks.

Other Agencies

9.1.5 The Clean Water Action Plan – Coastal Research and Monitoring Strategy

The Coastal Research and Monitoring Strategy Workgroup was formed in 1999 with representatives from Federal, State, Tribes, and Non-Governmental Organizations (NGO) to prepare the Coastal Research and Monitoring Strategy. Simply stated, the intent of the Strategy is to replace traditional single-issue, single-agency, single-discipline problem solving with a coordinated, multi-agency, interdisciplinary approach to address problems of coastal water quality and coastal resources.

As directed in the Clean Water Action Plan, EPA, NOAA, USGS, and the USDA led the development of this Coastal Research and Monitoring Strategy and provided leadership for strategic planning, coordination, and prioritization of research and monitoring objectives.

Executive Summary
In terms of surface area, coastal waters of the United States represent the largest economic and environmental zone of the Nation. Because a disproportionate percentage of the Nation’s population lives in coastal areas, the activities of municipalities, commerce, industry, and tourism have created environmental pressures that threaten the very resources that make the coast desirable.

To address these pressures, the Clinton Administration has called for a renewed effort to restore and protect our Nation’s estuarine and coastal areas. The Clean Water Action Plan, announced by President Clinton and Vice President Gore on February 19, 1998, is intended to redirect the Nation's water programs to "protect public health and restore our Nation's waterways". The Clean Water Action Plan specifically calls for the development of a strategy for coastal research (Action Item 59) and a plan for coastal monitoring (Action Item 60) including a comprehensive review of existing programs related to the generation, transport, and effect of pollutants on coastal waters, habitats, and living and economic resources. This document addresses both Action Items because they are intrinsically linked for the purposes of assessing regional and national trends, determining cause and effect relationships, and implementing adaptive management principles.

While the national investments made as a result of environmental legislation have had a dramatic effect on improving the Nation's coastal water quality, there are still environmental problems in the coastal zone. Examples of environmental issues common to most coastal States include nutrient enrichment, habitat change, protection of living aquatic resources, invasive species, pathogens, toxic contaminants, and harmful algal blooms.

The Federal government invests annually about $225 million conducting research and monitoring programs addressing these and other specific environmental issues in the coastal zone. Despite these investments, the importance of the coastal region to the Nation's economy, and the high potential for human use to adversely impact coastal resources and ecosystems, information about the status and trends of critical environmental variables in coastal regions is often lacking. Other than programs for coastal weather, water levels, commercial fisheries, and point source discharges, there are currently no nationally consistent, comprehensive monitoring programs to provide the information necessary for effective management of coastal systems.

The Coastal Research and Monitoring Strategy employs a monitoring-research-assessment-management cycle that integrates coastal monitoring and research objectives to enable cross-cutting and comprehensive assessments of the Nation's coastal resources. The objectives of the Strategy are to:

- Document the status and assess trends in environmental conditions at the scales necessary for scientific investigation and policy development;
- Evaluate the causes and consequences of changes in environmental status and trends;
- Assess environmental, economic, and sociological impacts of alternative policies for dealing with these changes; and
- Implement programs and policies to correct observed environmental problems.

The key attributes of the proposed Coastal Research and Monitoring Strategy include co-funding by Federal and State programs; nested designs to allow State-specific issues to be addressed in a national context; collective reporting; and cross-system comparisons.
The strategy for a national coastal monitoring design is based on the three-tiered approach developed by the U.S. Environmental Protection Agency (Messer et al. 1991) and a similar version was recommended by NSTC (1997) and has the following components:

- Characterization of Problem (Tier 1) -- Broad-scale ecological response properties as a base determined by survey, automated collection, and/or remote sensing;

- Diagnosis of Causes (Tier 2) -- Issue- or resource-specific surveys and observations concentrating on cause-effect interactions; and
- Diagnosis of Interaction and Forecasting (Tier 3) -- Intensive monitoring and research index sites with higher spatial and temporal resolution to determine specific mechanisms of interaction needed to build cause-effect models.

Data and information generated at each tier help interpretation of results from the other tiers. For example, Tier 1 (Characterization) data provide geographic context for data collected at Tiers 2 and 3 (e.g., how widespread is the problem and how much of the nation's resources are affected by its occurrence). Likewise, Tiers 2 (Diagnosis of Causes) and 3 (Diagnosis of Interactions and Forecasting) aid in understanding how serious a particular relationship or issue is.

The focus of the Strategy and conceptual framework is monitoring in the coastal zone. However, important research activities must occur concurrently at each level of the monitoring framework. Research plays a vital role in increasing our ability to interpret data from our monitoring programs and enhance our monitoring tools and methods. Research is the foundation underlying all tiers of the monitoring framework, and is critical to achieving the objectives of integrated assessments.

The objectives and the conceptual framework for a Coastal Research and Monitoring Strategy have been defined by the Workgroup and are included in this document. However, the Workgroup recognizes that further development of an implementation strategy which contains specific action plans for each of the following recommendations is necessary to execute the concepts of this Strategy. The final section of this document suggests issues that should be considered during implementation. However, development of an implementation plan is beyond the scope of this Workgroup.
The following six recommendations are offered:

1. Enhance and adapt existing programs to support an integrated and effective national coastal monitoring program. A high priority is placed on the development of a national coastal survey based on State-level coastal monitoring programs. The data collected from coastal States could provide a comprehensive and consistent picture of the "coastal health" of each State which would complement the partial requirements of Section 305(b) of the Clean Water Act. The data generated as a result of these monitoring activities could be used to support States' 303(d) listing processes.
2. Enhance and integrate interagency research efforts to fill data gaps, to increase the understanding of physical and ecological processes in the coastal zone, and to improve monitoring and assessment tools. Opportunities must be developed to foster interagency solicitation, review, and support of research proposals. Appropriate methods include both competitive and external grant processes, and internal Federal competition and interagency agreements.
3. Conduct periodic national and regional coastal assessments. These would include national summary assessments, national habitat assessments, national issue-specific assessments, and regional assessments.

4. Improve data management in support of the periodic assessments. These activities include development and maintenance of an Internet-based coastal environmental data clearinghouse and directory of meta-data resources, development of performance-based standards for data management and data submission, and development of national data quality standards.
5. Establish mechanisms to assess and adjust monitoring and research with changing national coastal priorities. User-advisory and technical committees, composed of representatives from Federal, State, and local governments; academia; not-for-profit organizations; and the private sector would be established to ensure that the products and services of the system are relevant and stay on track and to ensure that development and implementation of the system uses the best available scientific methods and technologies.
6. Establish a mechanism to define and develop an implementation plan for each of the Recommendations 1 -5 and to oversee efficient execution of a national program. To carry out the above recommendations and develop an implementation plan for a national strategy, the formulation of an interagency oversight committee is recommended. Long-term viability of the committee is essential.

9.2 Research Programs

9.2.1 Fishery-Independent

9.2.1.1 MARMAP

For thirty years, the Marine Resources Research Institute (MRRI) at the South Carolina Department of Natural Resources (SCDNR), through the Marine Resources Monitoring, Assessment and Prediction (MARMAP) program, has conducted fisheries-independent research on groundfish, reef fish, ichthyoplankton, and coastal pelagic fishes within the region between Cape Lookout, North Carolina, and Ft Pierce, Florida. The overall mission of the program has been to determine distribution, relative abundance, and critical habitat of economically and ecologically important fishes of the South Atlantic Bight (SAB), and to relate these features to environmental factors and exploitation activities. Research toward fulfilling these goals has included trawl surveys (from 6-350 m depth); ichthyoplankton surveys; location and mapping of reef habitat; sampling of reefs throughout the SAB; life history and population studies of priority species; tagging studies of commercially important species and special studies directed at specific management problems in the region. Survey work has also provided a monitoring program that has allowed the standardized sampling of fish populations over time and development of an historical base for future comparisons of long-term trends.

Current Objectives

Annual MARMAP cruises to assess relative abundance of reef fishes in the sponge-coral and shelf edge (live bottom) habitats of the South Atlantic Bight (SAB) have been conducted since

1978. MARMAP currently samples natural live bottom habitat from Cape Lookout, NC to the Ft. Pierce area, FL. The current main MARMAP objectives are to:

- sample reef fishes in the snapper-grouper complex at using a variety of gears in live bottom, rocky outcrop, high relief, and mud bottom habitats,
- collect detailed data for time series description of species for annual composition and relative abundance,
- obtain population characteristics on fish species of interest through life history information analysis, including age and growth, sex ratio, size and age of sexual maturation and transition, spawning season, fecundity, and diet. Priorities are dictated by the SEDAR schedule and other management considerations,
- collect hydrographic data (e.g. depth, temperature, salinity, etc.) for comparison to fish abundance and composition indices,
- collect DNA samples from selected fish species for stock identification
- expand sampling area in North Carolina and south Florida as well as reconnoiter new live bottom areas with underwater video (UWTV) to add to the MARMAP site database.

Since the inception of the MARMAP program various gear types and methods of deployment have been used. In recent years MARMAP has mostly used the Chevron trap (CHV), short (or vertical) long line (VLL), and the long (or horizontal) long line (HLL) using standard deployment and retrieval methods. At each sampling site CTD profiles are taken to record water conditions (e.g. temperature, salinity, etc.). The gears and methodology has been consistent over the years to allow for long term analysis and comparisons.

Chevron fish trap

The chevron trap is an arrowhead-shaped trap (maximum dimensions of 1.5 m x 1.7 m x 0.6 m.; 0.91 m3 volume) constructed of 35 mm x 35 mm square mesh plastic-coated wire, with one funnel entrance and one release panel. Each trap is baited with a combination of whole or cut herrings (*Brevoortia*, family Clupeidae). Bait is suspended on 4 stringers (approximately 4 fish per string) within the trap, with 6-8 loosely placed fish in the in the trap. The traps are tethered individually using 8-mm (5/16 inch) polypropylene line to a polyball buoy and a Hi-Flyer buoy attached to a 10-m trailer line. Chevron traps are deployed during daytime hours at stations randomly selected by computer from a database of approximately 2,500 live bottom and shelf edge locations and soaked for approximately 90 minutes. Up to six traps, separated by a minimum distance of 200 m, are fished at the same time. Chevron traps have been used since 1988 and the majority of trap sampling has occurred between 16 to 91 m.

Short (vertical) long line

Short longlines have been used where bottom topography is rough at depths to about 220m. This gear type consists of a 26 m (84 ft) groundline with 20 baited hooks brommelled to an 8-mm (5/16 inch) polypropylene line attached to a polyball buoy and a Hi-Flyer buoy attached to a 10-m trailer line to the surface. The hooks, attached at 1.2 m intervals, are baited with double hooked squid. Weights are attached to each end of the groundline. The weights and groundline are deployed such that the line is draped over bottom relief. Each line is soaked for approximately 90 minutes and six lines may be fished at the same time. This gear type has been used since 1997.

Long (horizontal) long line
Horizontal longline is deployed at depths ranging from 180 to 235 m over smooth mud bottom, areas that are prime habitat for golden tilefish. The horizontal longline consists of 1500 to 1700m of 0.32 mm galvanized cable deployed from a longline reel. Approximately 1220 m of the cable is used as groundline and the remaining line is buoyed to the surface. Two weights are attached to the terminal end and 100 gangions baited with double hooked squid are attached at 12 m intervals. At the end of the groundline, two weights are attached and at the end of the cable one or two polyballs and a Hi-Flyer trailer buoy are attached. The gear is soaked for 90 minutes and two lines are soaked at the same time.

Underwater TV
UWTV recordings were made using a Simrad-Osprey Subsea low light camera attached to a vane stabilized frame during day light hours. The camera was maintained off the bottom 1 - 2 m off the bottom as the vessel either drifted with the wind and/or current or was towed at low speeds. Recordings for fish identification on bottom habitat and to document new live bottom sites for the MARMAP data base were made on VHS tape and archived for future analysis.

In addition to these gears, hook and line fishing is occasionally used to supplement sampling for life history studies. Historical hook and line data are currently used for the development of a possible standard hook and line survey in the future.

All individuals in each catch (trap or line) are sorted and identified to species level. All individuals of each species are weighed together, while length is individually measured for all fish. All Individuals of selected species are kept for life history work-up, but abundant species such as black sea bass, vermilion snapper, and red porgy are randomly subsampled. All other fish are returned to the ocean. Species selected for life history work-up are: all groupers and snappers, red porgy, white grunt, gray triggerfish, black sea bass, and occasionally other species of interest.

Life History
Fish used for life history studies are measured to the nearest mm (total length, fork length, and standard length) with an electronic fish measuring board interfaced with a personal computer. Individual weights are measured to the nearest gram. Otoliths (mostly sagittae) and gray trigger fish spines, and gonad sections are removed at sea. Otoliths and spines are stored dry in coin envelopes. The otoliths and spines are used to determine the age of the fish in the MARMAP laboratory. This is a done by examining the whole otolith or 0.5-1.0 mm thick sections of otoliths and spines, depending on the species. Increments, one translucent and one opaque zone, or "ring" in the otoliths are counted by independent readers to determine the age of each fish.

Each gonad section is fixed in 10% seawater formalin for 1-2 weeks, and then transferred to 50% isopropanol for 1-2 weeks. Gonad samples are then processed to produce thin, stained sections on microscope slides. These preparations are examined under the microscope to determine sex and reproductive state using histological criteria.

Data

MARMAP has developed a long-term database for reef fish that has proven valuable in interpreting fisheries landings data and developing regulations for protecting reef fish resources. Restrictions on minimum sizes of most commercially important species make it difficult to monitor life history parameters and abundance data from samples collected from the fishery landings. MARMAP has the only existing long-term program off the Atlantic coast of the southeastern United States that monitors reef fish composition, length frequency, abundance, and life history based on fishery-independent data. These data provide critical input for the assessments of stock status conducted by NOAA Fisheries, and greatly assist stock assessment scientists and the Council in the management of snapper/grouper complex of the South Atlantic Bight.

MARMAP Vessels

Three research vessels have been used by MARMAP since 1972: the R/V Dolphin, R/V Oregon I, and R/V Palmetto. During 1973-1980, MARMAP used the R/V Dolphin. This was a 105' converted ocean tugboat that was outfitted for trawling, plankton work, hydro casts, and trapping. The data collected were used to describe the seasonal distribution and abundance of groundfish and fish larvae throughout the region. The R/V Oregon I was used by MARMAP during 1981-1988. It was a 105' vessel that was outfitted for trawling, plankton work, hydro casts, and trapping. From 1989 to the present, MARMAP has used the R/V Palmetto. The R/V Palmetto is 110', maintains a 5 permanent member sea-going crew, 1 or 2 temporary deckhands, and has accommodations for 9 scientists. There is a 200 sq. ft. wet lab on the main deck with counter space, electronics rack, freshwater and seawater, and freezers. The main deck has 1,014-sq. ft. of open deck space. There is a Sea Crane 120 on the main deck for loading, distributing and deploying gear, as well as the zodiac. It has two hydraulic long-line reels, two hydraulic reels for CTD casts and plankton work and a pot-hauler for retrieving traps.

Table XX. List of commonly collected species.

Almaco Jack
Bank sea bass
Black sea bass
Blueline tilefish
Gag
Golden tilefish
Gray triggerfish
Greater amberjack
Knobbed porgy
Red grouper
Red porgy
Red snapper
Sand perch
Scamp
Scup
Snowy grouper
Speckled hind
Spottail pinfish

Spotted moray
Tomtate
Vermilion snapper
White grunt

9.2.1.2 SEAMAP

The Southeast Area Monitoring and Assessment Program (SEAMAP) is a cooperative State/Federal/university program for collection, management and dissemination of fishery-independent data and information in the southeastern United States. The organizational structure of the program presently includes three operational components, SEAMAP-Gulf of Mexico, which began in 1981, SEAMAP-South Atlantic, implemented in 1983 and SEAMAP-Caribbean, formed in 1988. Each SEAMAP component operates independently, planning and conducting surveys and information dissemination. Funding allocations to participants are administered through State/Federal cooperative agreements, managed by SERO and the Southeast Fisheries Science Center (SEFSC), National Marine Fisheries Service (NMFS).

SEAMAP has sponsored long-term (1982 to present) and standardized research vessel surveys that have become the backbone of fisheries and habitat management in the region. The long-term dataset obtained through SEAMAP surveys provides the only region-wide, inter-jurisdictional mechanism for monitoring the status of populations and habitats. Through its cooperative nature, SEAMAP has the ability to sample the entire coastline from North Carolina through Texas during the same time period and describe the distribution and abundance of fish populations throughout their range in order to better evaluate the status of recreational and commercially utilized fish stocks.

Surveys by each program component reflect distinct regional needs and priorities; however, survey operations in one geographic area often provide information useful to researchers in all three regions. In the South Atlantic region, surveys include Coastal Survey (previously known as the Shallow Water Trawl Survey), Pamlico Sound Survey, and Bottom-Mapping and Fish Characterization and Assessment (all described further below). In addition to these surveys, SEAMAP participates in a variety of other projects such as the Cooperative Winter Tagging Survey Cruise, a coordination role for assessing striped bass population structure and estimating fishing rates of the migratory Atlantic Coast stock. SEAMAP-SA also has a Crustacean Workgroup that continues to be a forum for state biologists and scientists from the South Atlantic region to discuss and address issues regarding shrimp and blue crab management and research.

SEAMAP-SA Coastal Survey

The SEAMAP-SA Coastal Survey collects fishery-independent data concerning species abundance, distribution, and habitat, which provide valuable fishery information to managers, scientists, and students in the South Atlantic Bight region. The South Atlantic Coastal Survey samples waters from 0-10 fathoms from Cape Canaveral, Florida to Cape Hatteras, North Carolina during the three seasonal quarters of spring, summer, and fall. Gear and survey procedures are standardized to ensure collection of quality data with a synoptic view of the relative abundance and distribution of the stocks. Effort is made to obtain age-growth and reproductive stage data, as well as analyze gut contents of key sciaenid species (weakfish, Atlantic croaker, and southern kingfish).

Current state surveys are directed primarily at shrimp and are sufficient for some basic management needs; however, the coordinated, standardized SEAMAP survey provides fishery and ecological data covering the entire region. Most sciaenids, king and Spanish mackerel, menhaden, mullet, bluefish, blue crabs, herrings, jacks, horseshoe crabs, sea turtles and numerous forage species spend part or most of their early life in shallow shrimp trawling grounds in the South Atlantic area. These species have immense commercial and recreational value and form the basis of many of the principal South Atlantic fisheries. Community level data obtained via the Coastal Survey are applicable to management and monitoring of all sampled species. Data collected include distribution and abundance of various life history stages, recruitment to nursery grounds and subsequent recruitment to fisheries, spawning stock size, and the effects of various environmental fluctuations on abundance and distribution.

FWC-FWRI is poised to assist South Carolina Department of Natural Resources (SCDNR) to enhance database usability and dissemination through the creation of GIS products. The SEAMAP data and associated GIS have been incorporated into the South Atlantic Habitat and Ecosystem Internet Mapping System (IMS) of the South Atlantic Fishery Management Council. This system is being developed in cooperation with the Florida Fish and Wildlife Research Institute. The IMS is a living repository of historic and current information to be used by the general public, recreational and commercial fishermen, researchers and resource managers.

North Carolina Pamlico Sound Survey

The North Carolina Pamlico Sound Survey (PSS) is a program component of the SEAMAP South Atlantic and is conducted by the North Carolina Division of Marine Fisheries (NCDMF). This seasonal trawl survey is designed to provide a long-term (since 1989) fishery-independent database on the distribution, relative abundance, and size composition of target species of estuarine fish and decapod crustaceans for the waters of Pamlico-Albemarle Sound. Cruises sample approximately 52 stations each in June and September. The data are processed by NCDMF and are made available to the SEAMAP DMS.

During FY 2007, fifty five species of finfish, and invertebrates, were captured during the June cruise. The top five species that are considered economically important include: spot, Atlantic croaker, blue crab, *Callinectes sapidus*, weakfish, and white shrimp which made up 91% of the catch by number. Seventy-one species of finfish and invertebrates were captured during the September cruise. The top five species of spot, Atlantic croaker, weakfish, pink shrimp and southern kingfish made up 84% of the total catch by number. More information on the results of these surveys is available at www.asmfc.org under the Research & Statistics section of the website.

Bottom-Mapping and Fish Characterization and Assessment

- *Mapping and Assessment of Hard Bottom Resources (Biotic and Abiotic)*

Because substrate is a major determinant of faunal distribution and composition, a detailed description of superficial geology is being compiled for the South Atlantic area. Knowledge of the presence and extent of hard bottom areas, coupled with fish abundance estimates from certain areas, are essential to determine standing stocks or carrying capacity estimates for reef species. A protocol for mapping hard bottom habitats has been developed by SEAMAP-SA (Ross et al. 1987a and b). Features of the data include the location and extent of hard bottom, water depth, relief of bottom type, and detailed information on the source and type of information available in order to facilitate investigators in querying original data sources. Once existing data sources are summarized to document known hard bottom areas, future surveys will focus on areas where no data exist and on determining whether hard bottom areas are stable, increasing, or diminishing due to both natural factors, such as storm waves and shifting sands, and human activities, such as mining and trawling. The Minerals Management Service, as well as other state and federal agencies have already gathered a great deal of information, but it has not been made generally available. The area from the shoreline to the 200m-depth contour from Cape Hatteras southward to Florida has been examined, and the data are included in the SEAMAP Information System, and are published in two SEAMAP-SA completion reports, and on a CD-ROM in a GIS format.

The South Atlantic Bottom Mapping Work Group has compiled a database of bottom habitats from North Carolina to the Florida Keys, in a searchable GIS format available on CD-ROM. Those data were adopted as the primary definition of essential fish habitat by the SAFMC. In addition, all SEAMAP surveys record data on the distribution of fish both geographically and within environmental variables such as temperature and salinity, which is the first step in defining environmental limits in essential habitats utilized by each species of fish. SEAMAP hardbottom data have been used by the SAFMC to develop alternative management options to protect coral areas from rock shrimp trawling, define essential fish habitat, and investigate marine protected areas.

- *Assessment of Adult Red Drum Populations on the Southeast Atlantic Coast*

SEAMAP-SA is designating some new funds towards work supporting the states of South Carolina, Georgia and Florida to continue their adult red drum survey. These efforts contribute to the understanding of adult red drum populations along the southeastern Atlantic coast (North Carolina to Florida) by expanding the currently available data, thereby allowing for more effective and responsible management of the stock. Access to important information on the red drum stock could be used for a coastal shark assessments in the South Atlantic.

The expansion of adult red drum sampling, both spatially and temporally, is essential to the development of area specific information on stock status. Fishery-independent surveys will allow for determination of catch per unit effort (CPUE), which is necessary to determine population size and trends in abundance. Age structure of the spawning stock permits the estimation on the level recruitment (escapement) into the spawning population. This will act as a check on the results of available assessments based on data for sub-adults. Additionally, better estimates of escapement and age composition will allow comparison of the findings with the recommended Spawning Potential Ratio (SPR). Tagging and releasing efforts will assist with identifying migration within and among strata. Combined efforts from North Carolina to Florida will be utilized to gain a better understanding of stock size, composition and movement so the species can be managed responsibly.

The proposed research was developed and adopted by the South Atlantic Committee to address high priority assessment needs for the region as highlighted by the SEDAR research and monitoring needs report.

- *Collaboration with MARMAP*

A major tenet of the SEAMAP program is to "maximize effective capability of fishery independent and associated survey activities to satisfy data and information needs of living marine resource management and research organizations in the region. The primary means of performing that task is to optimize coordination and deployment of sampling platforms used in the region to obtain regional, synoptic surveys and provide access to the collected data through documents and accessible computerized databases." Also, while the foundation of the program is in long-term data series, SEAMAP is also involved with special resource and environmental studies that may enhance survey information and are important to the region. Furthermore, the coupling of activities maximizes the cost-effectiveness of survey activities.

Forthcoming SEAMAP projects complement and expand from MARMAP sampling to address high priority needs for providing access to data and supporting refined stock assessments in the region. This collaboration between programs maximizes researchers' ability to collect data for high priority over-fished species in the snapper grouper complex managed by the South Atlantic Fishery Management Council in cooperation with their South Atlantic State partners.

Recommendations from a recent SEDAR report involve expanding and modifying the MARMAP and SEAMAP programs as well as initiating new programs. Besides developing comprehensive independent surveys in South Atlantic areas, it is also recommended that spatial and age composition information should be enhanced for existing surveys. Concerns have been raised with the MARMAP survey primarily related to geographic and temporal coverage and thus SEAMAP funds could include additional sites to expand this coverage.

SEAMAP-SA plans to develop a phased in SEAMAP sampling protocol for a nearshore ocean larval/sub-adult/adult finfish survey associated with live/hard bottom habitat from Cape Hatteras, North Carolina to Sebastian Inlet, Florida to complement offshore sampling conducted through the MARMAP survey. In addition, additional expansion of offshore site sampling through SEAMAP will result in more complete coverage and address identified shortfalls of the MARMAP sampling regime. Standardized regional fishery-independent sampling of representative live/hard bottom habitat identified in the bottom mapping project would provide extremely useful data that will enhance stock assessments and refine essential fish habitat information on early life stages use of nearshore live/hard bottom habitat. The SEAMAP survey would target larval, juvenile, sub-adult and adult finfish dependant on live/hard bottom habitat on a year-round basis with high priority target species including black sea bass, gag and red drum. Regional fishery-independent sampling through SEAMAP supported surveys will provide essential stock identification and characterization data (geographic distribution, relative abundance) needed to improve overall abundance indices and assessments of southeastern finfish populations and fully complement ongoing management and research efforts. The project would also conduct phase 1 of juvenile tagging to track movement through inlets to nearshore and mid-shelf bottom habitats (supplement North Carolina effort with companion test in South Carolina) and tagging of emigrants out of estuaries into nearshore and mid-shelf benthic habitats.

Additionally the SEAMAP-South Atlantic has been working towards complete bottom mapping in coastal waters (shore-200m) with associated bottom type -sediment and/or live bottom (including coral, leptogorgia, hydroids, SAV, shell bottoms, etc). Along with the mapping, fish/habitat characterization needs to be refined and thus coordination on this topic with MARMAP is very important. Expanding the scope of fishery independent sampling through a collaboration of MARMAP and SEAMAP program data collection would meet stock assessment needs and address several SEDAR recommendations, demonstrating the importance of new SEAMAP surveys and data collection.

9.2.1.3 NOAA Fisheries SEFSC

When fisheries scientists collect fisheries information independent of commercial or recreational fishing operations, this information is considered fisheries-independent data. Such data are needed to accurately assess marine fish populations and are used in conjunction with fisheries-dependent data for estimating total population size and mortality rates.

Fisheries independent data are collected by scientists conducting resource surveys, such as trawl and seine surveys. These surveys are specifically designed to sample in an objective manner. Consequently, the research vessels do not necessarily sample where fish are most abundant. Instead, the sampling objective is to collect information on a fish population throughout its entire geographic range.

Sea Turtle Program

Scientists in the Sea Turtle Program of the Southeast Fisheries Science Center implement research to support the conservation and recovery of threatened and endangered sea turtle species by conducting population assessments; research on stock structure (age and genetics); assessments of sea turtle mortality, strandings, and unusual events; and revision of Stock Assessment Reports for populations of sea turtles in the western North Atlantic Ocean. They also participate in research to reduce the bycatch of sea turtles and conduct in-water studies to evaluate population trends and habitat requirements. They participate in technology transfer of successful bycatch reduction measures. Scientists undertake this work in collaboration with other SEFSC and NOAA protected species staff, academic colleagues, and contractors. SEFSC scientists provide information and analytical results on species status and threats to the NMFS Southeast Regional Director and NMFS Headquarters for the effective management of marine turtles. The information is critical for evaluating the appropriate conservation measures, as required under the Endangered Species Act. Scientists also provide information to scientists in Mexico through MEXUS-GULF Turtle Working Group; and contribute to the proceedings of the

Annual Sea Turtle Symposia. Scientists also take part in implementing the NMFS Atlantic Sea Turtle Strategy that is aimed at addressing the incidental capture of turtles in commercial and recreational fisheries along the Atlantic coast.

Marine Mammal Strandings
The Marine Mammal Protection Act (MMPA) mandates that the National Marine Fisheries Service (NMFS) monitor the status of all marine mammals in the southeast region and maintain the Marine Mammal Health and Stranding Response Program. In compliance with that act, stranding programs, biomonitoring programs, and population surveys have been developed and implemented in the various regions of the United States and territories.

Specifically, the Southeast Fisheries Science Center is responsible for marine mammal responses in the southeast region of the United States including the beaches from North Carolina to Texas, Puerto Rico and the U.S. Virgin Islands.

The NMFS, Southeast Fisheries Science Center (SEFSC) is the base for the Southeast United States Marine Mammal Stranding Program. NMFS authorizes organizations and volunteers under the Marine Mammal Protection Act (MMPA) to respond to marine mammal stranding throughout the United States. These organizations form the stranding network whose participants are trained to respond to, and collect samples from live and dead marine mammals that strand along southeastern United State beaches. Scientists at the SEFSC are responsible for coordinating stranding events, monitoring stranding rates, monitoring human caused mortalities, maintaining a stranding data base for the southeast region, and conducting investigations to determine the cause of unusual stranding events including mass strandings and mass mortalities.

Ship surveys are used to assess the abundance and distribution of cetaceans over large areas of the Gulf of Mexico, Atlantic Ocean, and Caribbean Sea. Surveys are conducted from the 68-m NOAA Ship Gordon Gunter and the 52-m NOAA Ship *Oregon II*. Visual line-transect surveys are conducted from the ship's flying bridge using 25X binoculars during the day. Acoustic surveys are conducted day and night using towed hydrophone arrays and sonobuoys. Biopsy samples for genetic and contaminant studies are obtained during the surveys. Environmental and oceanographic data are also collected. From 23 ship surveys conducted since 1990, we have learned that about 30 cetacean species inhabit southeastern U.S. waters. These include large whales, such as the right whale, sperm whale, and humpback whale, and dolphins, such as the pantropical spotted dolphin, bottlenose dolphin, and spinner dolphin. Smaller whales, such as killer whales, pilot whales, and beaked whales, also inhabit these waters. Typically bottlenose dolphins and Atlantic spotted dolphins are found in continental shelf waters, whereas most of the other species occur in oceanic waters. Data from these surveys are used to make management decisions mandated by the Marine Mammal Protection Act.

Multi-year aerial surveys of the nearshore waters of the southeast Florida coast, including the Florida Keys, and of Florida Bay are being conducted by the SEFSC with the support of the U.S. Coast Guard Air Station Miami. Conducted since September 1992 and March 1995, respectively, these surveys from a Coast Guard HH65 helicopter provide opportunistic sightings of bottlenose dolphin that can be used as rough estimates of their relative abundance in these waters. A total of 1,851 sightings of bottlenose dolphins were recorded in 109 surveys from inception through

December 1997. Herd sizes, seasonality, and encounter rates were compared between the two areas, as well as with previous studies in nearby areas, in a SEFSC Technical Memorandum. These surveys were initiated to monitor marine animals along the southeast coast, to document vessel usage in Biscayne National Park and the Florida Keys National Marine Sanctuary, and to census water birds in Florida Bay.

The SEFSC also conducts a bottlenose dolphin, *Tursiops truncatus*, monitoring program in Biscayne Bay, Florida, using photo-identification techniques as a method of identifying individual dolphins for population studies. Initiated in August 1990, a total of 180 individuals have been identified from 390 sightings during 250 surveys. Of these, approximately 75% are considered to be full time residents of Biscayne Bay. The study area runs from Haulover Inlet, south to Card Sound Bridge encompassing an area of approximately 250 square miles. The behavioral studies component includes observing and monitor habitat use, movement patterns, and other behaviors exhibited by Biscayne Bay bottlenose populations. Currently, a website is being developed to allow researchers to compare dolphin dorsal fin images from the photo-id projects in adjoining study areas to determine the extent animal ranges.

SEFSC, Beaufort Lab, conducts small-vessel surveys in North Carolina and some nearby areas, including Georgia, Virginia, and New Jersey, focusing on bottlenose and Atlantic spotted dolphins. This research involves collection of skin samples for stock identification from a number of different estuarine, coastal and offshore habitats along the coast. The bottlenose dolphin work examines both latitudinal (inshore-offshore) distribution of the coastal form of bottlenose, examining the degree of overlap with the offshore form, and longitudinal (north-south) distribution of populations. Photographs taken during this work are also being used to examine movements between sites.

SEFSC, Beaufort Lab, is also coordinates an effort to define the number and range of stocks of the coastal morphotype of bottlenose dolphins along the Atlantic coast. This project involves the simultaneous application of multiple techniques, including genetics, stable isotope ratios, photo-identification (with over 20 collaborators along the coast), and telemetry. Preliminary results have identified seven management units. The data being collected will also help with defining habitat preferences and ranging patterns. In addition, the SEFSC Beaufort Lab, conducts studies of age, growth, and reproduction of a number of cetacean species. Particular emphasis is on the bottlenose dolphin because, despite its prevalence in coastal waters of the Atlantic and Gulf of Mexico, estimates of reproductive rates and other basic life-history parameters, do not exist.

9.2.2 Fishery-Dependent

9.2.2.1 MARFIN

(text below excerpted from http://sero.nmfs.noaa.gov/grants/marfin.htm)

The Marine Fisheries Initiative (MARFIN) program, administered through the National Marine Fisheries Service Southeast Regional Office, promotes and endorses programs which seek to optimize economic and social benefits from marine fishery resources through cooperative efforts that evoke the best research and management talents of the Southeast Region. Preference is given to cooperative planning efforts with up to 3-year time horizons. The intent is to focus projects funded by MARFIN into cooperative efforts that provide clear answers for fishery needs covered by the NMFS Strategic Plan, particularly goals one, two and four are important. For example, a geographically restricted age and growth study of a local fishery resource is of limited value unless it is coordinated with, or verified by, similar studies, which span the range of the resource. The value of such studies is also relatively limited unless the results can be combined with other studies to provide a regional assessment of the resource. MARFIN provides this necessary programmatic integration through cooperative planning, accomplishment of program activities and an annual MARFIN Conference.

History of the MARFIN program

The MARFIN program received its initial impetus from a 1983 discussion paper entitled "Research Needs For Information Leading To Full and Wise Use of Fishery Resources In The Gulf of Mexico" by Dr. Thomas D. McIlwain of the Gulf Coast Research Laboratory while he was in the office of Rep. Trent Lott. This paper, sometimes referred to as the Lott-McIlwain paper, proposed an additional investment in fisheries research and development in the Gulf of Mexico to increase the economic contribution of marine fisheries, develop more valuable products from existing fisheries, develop export markets, forecast variation in yields and conserve and maintain presently exploited resources.

The next step in the evolution of MARFIN was the preparation and publication of the Marine Fisheries Initiative - Gulf Of Mexico Phase. This plan was developed by a joint industry, federal, state and academic task force, detailing the research and development efforts necessary to enhance, restore and maintain fisheries in the Gulf of Mexico. The program focused on funding projects which had the greatest probability of maintaining and improving existing fisheries, increasing revenues for the domestic industry, increasing yields from fisheries and generating increased recreational opportunity and harvest potential.

In 1992, the MARFIN program was expanded to include a South Atlantic component (North Carolina, South Carolina, Georgia and the Atlantic coast of Florida). The goals and objectives of the South Atlantic phase of MARFIN are described in Special Report No. 13 of the Atlantic States Marine Fisheries Commission, Marine Fisheries Initiative (MARFIN) South Atlantic Phase.

MARFIN Program Organization and Administration

The NMFS Southeast Regional Administrator organized the MARFIN Panel in Fiscal Year 1992 when the program was expanded to cover the South Atlantic. Each member of the MARFIN Panel provides individual recommendations to the Regional Administrator on MARFIN priorities and financial assistance applications. The MARFIN Panel membership is as follows: One state marine conservation agency representative each, from the Gulf of Mexico and the South Atlantic areas; one representative each from the Gulf of Mexico and the South Atlantic commercial fishing industries; the Executive Directors of the Gulf of Mexico and South Atlantic Fishery Management Councils; the Executive Directors of the Gulf and Atlantic States Marine Fisheries Commissions; one representative each from the Gulf of Mexico and the South Atlantic recreational fishing industries; one representative each from the Gulf of Mexico and the South

Atlantic Sea Grant Universities and a NMFS Southeast Fisheries Science Center Technical representative.

The NMFS Southeast Financial Aid Program Officer provides guidance to the Regional Administrator and the MARFIN panels members concerning Federal, Department of Commerce and NOAA financial assistance administration requirements.

Alternate representatives to the MARFIN Panel serve when necessary. The MARFIN Panel Chair is elected for up to three-years. Individual Panel members are appointed by the NMFS Southeast Regional Administrator for staggered terms.

The Administrator of the NMFS Southeast Regional Office relies on recommendations from individual members of the MARFIN Panel, the NOAA Assistant Administrator for Fisheries, the public through their response to MARFIN Federal Register notices and the NMFS staff to develop each year's MARFIN program.

Each year the MARFIN Panel members and NMFS administrators and scientists identify areas of emphasis for the next year's competitive financial assistance program. These areas of emphasis are published in the Federal Register for public comment. After public review and comment, an announcement of funding availability through the competitive MARFIN financial assistance program is published as a solicitation in the Federal Register.

The NMFS Southeast Regional State/Federal Liaison Office staff is responsible for the overall administration of all NMFS Southeast grants and cooperative agreement programs, including MARFIN. Their responsibilities include planning, application and selection, negotiation, performance, monitoring and close-out of all assigned competitive and noncompetitive financial assistance programs. A NMFS Southeast scientific or technical expert is assigned as the Technical Monitor for each MARFIN project. The Technical Monitor is responsible for all technical and cooperative aspects of assigned projects. The NOAA Grants Officer is responsible for the overall administration of each NMFS financial assistance award issued to recipients outside of the Federal government and cooperates with the NMFS Southeast State/Federal Liaison Office in administering each financial assistance award.

9.2.2.2 Cooperative Research Program

(text below excerpted from the FY07 Federal Funding Opportunity announcement available through the SERO grants website)

The NMFS' Cooperative Research Program (CRP) is a competitive Federal assistance program that funds projects seeking to increase and improve the working relationship between researchers from NMFS, state fishery agencies, universities, and fishermen. The principal goal of the CRP is to provide a means of involving commercial and recreational fishermen in the collection of fundamental fisheries information to support the development and evaluation of management and regulatory options.

Applicants are encouraged to address one of the priority areas listed below as they pertain to federally managed species or species relevant to Federal fisheries management plans, but proposals in other areas will be considered. Projects funded through the CRP focus on collecting data that aids in recovering, maintaining, or improving the status of stocks upon which fisheries depend; improving the understanding of factors affecting recruitment success and long-term sustainability of fisheries; and/or generating increased values and opportunities for fisheries.

Projects are evaluated as to the likelihood of achieving these objectives, with consideration of the magnitude of the eventual economic or social benefits that may be realized.

Finfish
There are several priorities within this general category that pertain to the collection of catch, effort, size frequency, bycatch, and detailed data on fishing area by vessels in the fisheries for finfish species.

1. Characterize the total catch (from all fleets affecting the stocks), including catch composition and disposition of the catch.

    (a) Projects are needed to collect detailed information on the composition and disposition of bycatch and discards.

    (b) Investigations are needed to determine more efficient methods to record catches and associated effort accurately on a real-time basis during fishing operations (e.g. electronic logbooks).

    (c) Projects are needed to develop methods to increase the amount of at-sea observations without relying on direct observers. One suggested approach is to use electronic imaging systems.

    (d) Projects are needed to utilize fully scientific observers on-board vessels as a means of collecting detailed catch, effort and disposition data. In cases where vessel space does not permit adding an observer, it may be possible to designate the captain or a crew member to record these data. Projects must specify the type of training and equipment that is required to assure that reliable data are collected. (e) Data collection projects are needed to determine the effects on discard rates of increasing size limits or reducing possession limits. If discard mortality rates are high, changes in size or bag limits may unintentionally lessen conservation benefits. Discard mortality rates currently used in assessments are generally based on small numbers of observations or are unknown. Research is needed to improve estimates of discard mortality rates and must account for the effects of fish size, gear, area, season and depth of fishing.

    (f) Data collection projects are needed to improve life history information to improve stock assessments. Improved information about the age-structure of the catch (both retained and discarded), based on otolith or other hard-part aging techniques, will provide insight on a stock's resilience to fishing. Improved information on the reproductive characteristics of the stock will provide information to refine estimates of long-term biological productivity of the stock. Development of new techniques for age and growth and reproductive information are especially important. (g) Improved age sampling (i.e., representative, randomized collection of structures) is needed for many species. For some species (i.e., protogynous ones) information is needed to characterize landings by sex.

2. Population evaluation. Needs under this category include abundance measures and expanded age composition sampling across all fisheries. Other needs include: (1) Research is needed to identify stock boundaries and evaluate stock mixing. Methods could include tagging studies to evaluate movements, otolith microchemistry, and genetics. (2) Data are needed to characterize length, age and, for some species, sex composition of landings and discards in commercial and recreational fisheries. (3) Data are needed to estimate and characterize commercial and recreational discard removals.

3. Monitoring stock abundance through study-fleet applications. This type of cooperative research requires long-term commitment in terms of funding and application.

> (a) One objective is to develop a consistent sampling methodology that will permit monitoring of the relative abundance of a fishery resource over time. An initial step for such a project is to develop sampling designs and protocols for sampling fleet catches to estimate relative abundance, including standardization of fishing power of individual vessels.
>
> (b) Projects are needed to develop methods to determine appropriate sampling designs and pilot studies to estimate recruitment to selected fisheries. An example is the development of a recruitment index for Young-of-the-Year swordfish in the Gulf and along the southeastern U.S. coast - areas that are now closed to longlining.

4. Projects are needed to develop and test gear and fishing strategies designed to reduce or eliminate unintended catch.

5. Fishing Capacity Investigations. There appears to be a wide disparity between the current capacity of regional fishing fleets and the productivity of regional stocks.
Cooperative research to optimize the capacity of regional fishing fleets is needed. A number of possibilities ranging from Individual Quota Systems to Vessel Capacity
Control programs should be considered. It is likely that regional/fishery differences may require different approaches.

6. Monitor the effects of closed Marine Protected Areas. Research is needed to measure the response of marine resources to creation or expansion of Marine Protected Areas (MPAs). Projects should utilize fishermen's knowledge of critical habitat of harvested species. An example is the large MPA designed to protect small swordfish and other highly migratory species off the US southeastern coast.

> (a) Projects are needed to assess the impacts of time/area closures in the Southeast Region that have been designated to protect finfish spawning aggregations and/or concentrations of sub-legal fish.
>
> (b) Projects are needed to collect fine-scale catch-effort data to define the spatial and temporal dimensions of MPAs.

Recreational and Charter Fishery

1. Socioeconomic research.

> (a) Research is needed to determine the number of recreational fishermen and related trips.

(b) Data are needed to describe the socioeconomic characteristics of the recreational and charter boat industries.
(c) In addition to data collection activities, research is needed to determine the economic benefits and costs associated with recreational fishing.

2. Research on Management Alternatives. Investigations should include benefits and costs to the stocks, as well as socioeconomic benefits/costs to participants in the fishery.
(a) Research is needed to determine the effects of seasonal closures and MPAs on the recreational and charter boat industries.
(b) Research is needed to determine the effects of seasonal closures and MPAs on spawning stocks and resulting recruitment.
(c) Research is needed to determine the impacts of bag and size limits on species that are important to recreational and charter boat industries. Projects should emphasize the effects of alternative size limits.
(d) Research is needed to determine discard mortality rates. This research should include data on length and age composition of discarded fish. At-sea observers on recreational and charter boat trips are one way to perform this type of research and should be considered.

3. Catch/Effort Data. Projects are needed to improve catch and effort data for private recreational fishermen. The projects should identify sample sizes, including number of intercept interviews and dock samples, required to achieve statistical levels of accuracy and precision.

4. Habitat Research.
(a) Research is needed to evaluate the effectiveness of artificial reefs. Projects should examine the value of artificial reefs to fishing communities, and estimate associated economic impacts.
(b) Research is needed to determine the impacts and effects of harmful algal blooms, such as red tide, on recreational and charter boat fisheries.
(c) Investigations are needed to determine essential fishery habitat for certain species such as gag, goliath grouper and sharks. This encompasses more than just a recreational issue, could be moved to a general habitat section.

Commercial Shrimp Harvest

1. Social and economic impact of fluctuations in domestic shrimp values:
(a) Research is needed on the effects on the domestic shrimp fishery of shrimp imports from foreign countries.
(b) Research is needed to determine the social and economic impacts of imports on fishermen and fishing communities. Research should include impacts on communities and the industry as a whole.

2. Identifying Non-Trawlable Areas. Research is needed to investigate how habitat enhancements of non-trawlable areas could benefit shrimp fisheries. For example, artificial reefs could be established in non-trawlable areas and the impacts on shrimp and finfish populations could be evaluated. Such research should determine if enhancements would increase habitat for juvenile and adult fish (i.e. red snapper).

3. Quantification of Effort. Research is needed to improve shrimp effort data. Projects need to consider recommendations derived from negotiations with the shrimp industry. Areas of concern are insurance for at-sea observers, acceptable gear and protection of confidential data collected by the project.

4. Bycatch Reduction Device Testing Protocols. There is a need to develop more efficient methods to certify bycatch reduction devices. Protocols should benefit both the resource and the shrimp industry.

5. Quantification of Bycatch Rates. Statistical research is needed to ensure that extrapolation of the results of individual trawl bycatch surveys to the fleet are statistically valid. The procedures should account for the total range of conditions found in all major fishing areas. The research should estimate the number of scientific fishery observers that should be employed to collect bycatch information for prevailing conditions and areas. The project should describe the statistical accuracy and precision of estimates for each major fishing area in addition to the total fishing area. This is critical to improving stock assessments, especially in the Gulf of Mexico.

9.2.2.3 Saltonstall-Kennedy

(text below excerpted from online report to Congress doc available at http://www.ncseonline.org/NLE/CRSreports/04May/RS21799.pdf)
The Saltonstall-Kennedy (S-K) Act, as amended (15 U.S.C. §713c-3), established a fund (known as the S-K Fund) that the Secretary of Commerce uses to finance projects and cooperative agreements for fishery research and development. Under this authority, projects or cooperative agreements are selected annually on a competitive basis to assist the National Marine Fisheries Service in addressing concerns related to U.S. commercial and recreational fisheries. The S-K Fund is capitalized through annual transfers under a permanent appropriation to the Secretary of Commerce of 30% of the gross receipts collected by the Secretary of Agriculture under the customs laws on imports of fish and fish products.

The objective of the S-K program is to address the needs of fishing communities in providing economic benefits for rebuilding and maintaining sustainable fisheries, and in dealing with the impacts of conservation and management measures. The S-K program has become very important in addressing issues of immediate concern to the commercial fishing industry, by producing many new gear innovations, markets, and management options. Issues addressed have included fish harvesting, seafood quality improvements, domestic and foreign market development, efficiency and productivity improvements, and the costs/profitability of potential fishing industry investments.

In Fiscal Year 2004 appropriations, congressional earmarks designated funds for specific activities outside the regular competitive award process, and the S-K competitive program was cancelled.

9.2.2.4 Wallop-Breaux

(text below excerpted from USFWS site http://federalasst.fws.gov/sfr/fasfr.html)

The Federal Aid in Sport Fish Restoration Act, commonly referred to as the Dingell-Johnson Act -- passed on August 9, 1950 -- was modeled after the Pittman-Robertson Act to create a parallel program for management, conservation, and restoration of fishery resources.

The U.S. Fish and Wildlife Service's Sport Fish Restoration Program is funded by revenues collected from the manufacturers of fishing rods, reels, creels, lures, flies and artificial baits, who pay an excise tax on these items to the U.S. Treasury.

An amendment in 1984 (Wallop-Breaux Amendment) added new provisions to the Act by extending the excise tax to previously untaxed items of sport fishing equipment. The major element of the Wallop-Breaux Amendment established a new Trust Fund, named the Wallop-Breaux Trust Fund or the Aquatic Resources Trust Fund (ARTF). Funds are also received from import duties on sport fishing equipment, pleasure boats and yachts. Another source of revenue is a tax from motorboat fuel sales. These motorboat fuel taxes are collected by the U.S. Treasury and then transferred to the Fish and Wildlife Service for distribution among the States and territories.

Appropriate state agencies are the only entities eligible to receive grant funds. Each state's share is based 60 percent on its licensed anglers (fishermen) and 40 percent on its land and water area. No state may receives more than 5 percent or less than 1 percent of each year's total apportionment. The program is a cost-reimbursement program, where the state covers the full amount of an approved project then applies for reimbursement through Federal Aid for up to 75 percent of the project expenses. The state must provide at least 25 percent of the project costs from a non-federal source.

Since its creation, the Sport Fish Restoration Act has been refined and expanded by Congress. It is one of the most valuable federal legislation for anglers and fishery resources. In 2006, the total funding for national programs obtained through this legislation exceeded $5 billion according to the USFWS's annual allotment news release *(http://www.fws.gov/news/newsreleases/showNews.cfm?newsId=754069A2-D32C-3722-22DDAA5E1602C1D6).*

(excerpt below from FWC site http://myfwc.com/fishing/Fishes/SFR.html)
In 1994, passage of the Transportation Equity Act (TEA-21) authorized a National Outreach and Communications Program to increase participation in angling and boating and to impress on boaters and anglers the importance of healthy aquatic habitats. It also increased the minimum level of spending for boating access to 15% and raised the maximum allowable expenditure of SFR apportionments for aquatic education and outreach to 15%. TEA-21 further created a Boating Infrastructure Grant program (BIG) for construction, maintenance, or renovation of transient facilities for non-trailerable recreational boats (boats longer than 26 feet) TEA-21 raised the amount of Federal gas tax credited to the Wallop-Breaux Trust Fund and established a "permanent" appropriation for the Boating Safety Account. The result is one of the most successful "user pays--user benefits" programs in the world.

9.2.2.5 NOAA Fisheries SEFSC

Commercial Programs

Accumulated Landings System (ALS)

These data consists of information on the quantity and value of seafood products caught by fishermen and sold to established seafood dealers or brokers. These data are reported by dealers or brokers to the fisheries agency in each state. The National Marine Fisheries Service in the Southeast Region has established cooperative agreements with all of the states in the Southeast and rely on the states to collect and process these data. The general canvass data set maintained by the Southeast Fisheries Science Center is a continuous data set that begins in 1960. Landings data for some species and areas go further back in time and are available in print in the Fisheries of the United States.

The landings data, maintained by the SEFSC, are monthly totals of the quantities landed and the value of the landings for each species. Because these data are summaries, they do not contain information on the identification of the fishermen or vessel. However, several states in the Southeast do collect landings statistics for individual trips. The state of Florida was the first to implement a trip ticket program in 1985. In 1995, the state of North Carolina passed a license to sell law that required seafood dealers to report all landings statistics by trip and identify the vessel or individual that sold the product. In 1997, the state of Louisiana initiated their trip ticket program and in 1999 Georgia also initiated a trip ticket program.
In addition to the quantity and value (or price per pound), information on the gear used to catch the fish and the area where the fishing occurred are also recorded in the general canvass data.

In many coastal areas, trained field agents assist with the collection of fisheries statistics. These individuals are strategically located so they can maintain contact with the fishermen and are integrally involved with the fishing communities. Among other duties, these port agents provide information on the types of gear, fishing area and distance from shore for the general canvass data. The port agents are also involved in the collection of Gulf shrimp statistics, biological data collection and the operating unit survey.

There are two shortcomings associated with fishery statistics that are collected from seafood dealers. First, dealers do not always record the specific species that are caught and second, fish or shellfish are not always purchased at the same location where they are unloaded, i.e., landed.

Dealers have always recorded fishery products in ways that meet their needs, which sometimes make it ambiguous for scientific uses. Although the port agents can readily identify individual species, they usually are not at the fish house when fish were being unloaded and thus, cannot observe and identify the fish. Species identification is a critical part of the biological sampling program (also known as the Trip Interview Program) operated jointly by the National Marine Fisheries and the fishery agency in each coastal state in the Southeast Region. The second problem is accurate information on the gear used and the location where the fish were caught. For the states with trip ticket programs, information on the gear and area fished is collected on the trip ticket form. For other states, this information is estimated, usually by the local port agent.

U.S. Domestic Longline Database
Before the mid-1980s, only limited data on the fishing activities from the U.S. pelagic longline fleet were collected. Data were collected by various state agencies, Fishery Management Councils, and university biologists from 1978 to 1983. These data consisted of weights for individual swordfish (headed, gutted and tailed) recorded on the weigh-out receipts (tally sheets) for the sales to vessels for an individual trip. In 1984, this database became the responsibility of the NMFS Southeast Fisheries Science Center. As part of this transition, the data were standardized and entered into a computer database. In order to expand the coverage, biologists at the SEFSC contacted vessel captains/owners and fish dealers and requested that they voluntarily submit their tally sheets to the SEFSC for use in scientific investigations of the swordfish fishery.

All of the data are coded and stored for the individual vessel that caught the fish. Quality control procedures established to compare with data previously entered to avoid duplication. Although swordfish were the primary commercial species caught and recorded on the sales receipts, the weights of other species were also listed on the tally sheets. Prior to 1985, the weigh-out data for the other (non-swordfish) species were not recorded. Beginning in 1986, the SEFSC began to enter all the weigh-out data for all species listed on the tally sheets received. The individual dress weights of other species listed on tally sheets from earlier years were entered as well.

Each record includes a vessel code, date of landing, state and port landed, code of the dealer purchasing the catch, gear fished, data source, location code of general fishing area, total hooks fished, days of actual fishing, total number of sets, and a species code along with the individual carcass weights for each species. All records from a specific trip are identified by their respective vessel codes and date of landing. Prior to 1986, effort (hooks, days fished, number of sets) information was recorded from personal vessel logbooks voluntarily submitted by vessel captains/owners. Beginning in 1986, all pelagic longline vessels that actively fished are required to submit daily logbook set records for each trip. Based upon this information, fishing effort is determined and, subsequently, added to the longline database.

The database contains information from the early 1960s (limited data) to the present and is almost exclusively comprised from data collected from the U.S. domestic pelagic longline fishery. Other gear types (harpoon, gillnet, handline, rod and reel, etc.) have been recorded from vessels voluntarily submitting the information or that were mandated to report by regulations in the past years. This database is continually updated as new information becomes available.

Fisheries Logbook System (FLS)
The Fisheries Logbook System records the fishing and non-fishing activity of fishermen who are required to report their fishing activity via logbooks submitted for each trip.

As the need for conservation of the Nation's marine resources increases the need for more and better quality data on how these resources are utilized also increases. One of the most useful types of data is catch per unit effort. To meet these needs, the Southeast Fisheries Science Center has implemented several vessel logbook programs. In 1986, a comprehensive program was initiated for the pelagic longline fisheries along the eastern seaboard, in the Gulf of Mexico and in the Caribbean. In 1990, logbook reporting was initiated for the vessels catching species in the reef fish management plan managed by the Gulf of Mexico Fishery Management Council.

Similar to the logbook program for reef fish, a program for vessels catching species in the South Atlantic snapper-grouper fishery, managed by the South Atlantic Fishery Management Council, was initiated in 1992. In 1993, a comprehensive logbook was initiated for the federally managed shark fisheries (Highly Migratory Species, National Marine Fisheries Service). In 1999, logbook reporting was initiated for vessels catching king and Spanish mackerel (Gulf of Mexico and South Atlantic Fishery Management Councils).

Although these programs were initiated at various times and cover many different fisheries and types of gear, the SEFSC has attempted to make the logbooks relatively easy to complete. There are 2 types of reporting forms currently in use (although separate forms are used for the limited vessels that are permitted in the wreckfish and golden crab fisheries).

One form is used for the pelagic longline fisheries. Because this fishery uses gear that is deployed for a relatively long period (6 to 10 hours), catch and effort data are collected for each set. Thus, a separate form is required for each set. Fishermen are required to report the numbers of each species caught, the numbers of animals retained or discarded alive or discarded dead (longline gear is nonselective and unwanted or prohibited species such as, billfishes, sea turtles, etc., must be returned to the water), the location of the set, the types and size of gear, and the duration of the set.

Because some of the needed catch/effort information for pelagic longline fisheries remains the same for the entire trip (i.e., it would be redundant to report it for every set), a supplemental form is used to report this type of data. Information on the port of departure and return, unloading dealer and location, number of sets, number of crew, date of departure and landing are reported on the Trip Summary form. In addition, information on costs associated with the trip can be reported on this form.

This type of economic data is critical to the evaluation of existing and proposed management regulations. The National Marine Fisheries Service is required by law to assess (estimate) the economic consequences of proposed management regulations.
Without accurate data from the fishing industry, such estimates are not likely to reflect the true effects.

The second type of logbook form is used to report catch and effort data for the Gulf reef fish, South Atlantic snapper-grouper, coastal shark and king and Spanish mackerel fisheries. Because the soak time for these fisheries is relatively short, it is not feasible to require fishermen to complete a separate form every time the gear is deployed. Thus, the catch and effort data for the entire trip are reported on a single form (i.e., one form per trip).

The types of information required on this trip form are nearly the same as the pelagic longline logbook. Information on the quantity (reported in pounds) caught for each species, the area of catch, the type and quantity of gear, the date of departure and return, the dealer and location (county and state where the trip is unloaded), the duration of the trip (time away from dock), an estimate of the fishing time, and the number of crew are included on this form.

In response to the increased need for data on the amount of fish that are discarded, the Southeast Fisheries Science Center is now using a supplementary form that selected fishermen use to report quantities of fish that are discarded.

Trip Interview Program (TIP)
(text below excerpted from the SEFSC website)
Estimates of the age distribution of fish in the population and how the distribution has changed over time is critical information for the assessment of the population. The Trip Interview Program (TIP) was developed by the Southeast Fisheries Science Center as a shore-based sampling program. The primary focus of the TIP is the collection of random size-frequency data and biological samples from commercial marine fisheries. Biological samples include age, reproductive, prey, and genetic data. In addition to collecting biological data, the TIP serves as a quality assurance on catch and effort data. It validates species composition of catch and type and quantity of gear through first hand, trained observation. Other important information, obtained through personal interviews with the fishermen and dealers, also serves the quality assurance purpose. Like the other statistics gathering programs, this one is also a joint or cooperative effort with the state fishery agencies in the Southeast Region.

The Trip Interview Program was principally developed to provide two types of information: size frequency data and age at length data. In addition, this program also provides catch per unit effort data and information on the composition of the species being caught and landed.

The collection of data for this program is conducted by port agents located in coastal area in the South Atlantic and Gulf of Mexico. These field biologists visit docks and fish houses to interview the fishermen and take length and weight samples from their catch. For some trips, the port agents are at the location when the fish are being unloaded and can measure and weigh individual fish as they are being unloaded. At other times, the fish have already been unloaded and the port agent is given permission to measure and weigh a sample of the catch from the storage containers at the fish houses. In addition to the length and weight data, the port agents also attempt to interview the captain or a crew member to collect data on the fishing trip, i.e., fishing area, type and quantity of gear, fishing time, etc.

The port agents also take hard part and tissue samples for some of the fish they measure. These samples are sent to one of two Southeast Fisheries Science Center laboratories for biologists to analyze and determine the age of the fish. The age, along with the length of the fish, are used to determine the age-at-length for a sample of the fish population, which then is used to estimate the age distribution for the entire population or stock of the species.

The TIP is a major component of the Atlantic Coastal Cooperative Statistics Program (ACCSP) in the southeastern U.S. Atlantic coastal region and the Commercial Fisheries Information Network (COMFIN) in the U.S. Gulf of Mexico coastal region. It also collects data from Puerto Rico and the U.S. Virgin Islands.

Vessel Operating Units (VOU)
Prior to 1970 the Bureau of Fisheries and the U.S. Fish Commission, which were the predecessor agencies of the National Marine Fisheries Service, collected little information on vessels actively

participating in commercial fisheries. In 1979 NMFS initiated a system that provided data on vessels that actively participate in commercial fishing during each calendar year. The object of this system is to provide an inventory of vessels that answer two fundamental questions: How many vessels are fishing commercially? What are the characteristics of these vessels?

This inventory only includes vessels that are greater than five net tons and have a current US Coast Guard documentation number. This system is referred to as the NMFS vessel operating units. Data are available for the years from 1979 to 2002.

Because the vessel operating units data only include larger documented vessels, a count of the smaller, undocumented boats was conducted once a year by NMFS and state port agents from 1979 to 1995. Unlike the vessel operating units data, characteristics of the individual boats are not recorded. These annual counts of boats are referred to as boat and shore data.

Recreational Programs

Marine Recreational Fisheries Statistics Program (MRFSS)
The Marine Recreational Fisheries Statistics Program team provides essential marine recreational fisheries information to government, scientists, and the public.

The team of fisheries biologists, statisticians, and data managers provides accurate, precise, and timely fisheries-dependent information for US marine waters by:

- Conducting and evaluating the Marine Recreational Fisheries Statistics Survey (MRFSS) to produce catch, effort and participation estimates, and to provide biological, social and economic data,
- Ensuring quality control and quality assurance of the MRFSS,
- Researching new survey designs,
- Providing statistical advice and promoting quality recreational fisheries information within NMFS and to other natural resource management agencies and organizations,
- Participating in NMFS planning efforts to improve internal fisheries-dependent data collection and management,
- Participating in coastal State/Federal efforts to plan and implement coordinated and cooperative recreational fisheries data collection and management programs,
- Communicating survey and research results, and
- Educating the public about the survey and new research.

In September 2004 the NMFS requested the National Research Council (NRC) of the National Academy of Sciences (NAS) to review current recreational fishing surveys funded or conducted by NMFS. This review was completed and published in April 2006 and includes recommendations that will result in an improved survey program that will better meet the needs of fishery managers.
Beginning in January 2006, every fisherman who is interviewed dockside by the Marine Recreational Fisheries Statistical Survey receives a series of questions about the money they spent on that trip. They are also be asked to participate in a longer follow-up mail survey that collects information on annual expenditures and durable goods, like boats, trailers, rods and

reels. When completed, these data allow NOAA Fisheries to estimate daily expenditures by fishing mode (i.e. private boat, charter, shore) and resident type (resident and non-resident). These expenditure estimates are then used to estimate the economic impacts of saltwater recreational fishing. Economic impacts demonstrate the importance of recreational fishing and help managers make decisions to make recreational fishing better. The last time this survey was conducted in 2000, U.S. saltwater fishermen spent $22.6 billion generating an economic impact of over $30.5 billion and supporting 350,000 jobs (not including Texas, Alaska, and Hawaii).

Headboat Survey
Researchers at the SEFSC Beaufort Laboratory have studied reef fish off the southeastern United States since the late 1960s and have addressed both applied fishery issues and basic reef fish ecology. The Laboratory's Southeast Region Headboat Survey collects fisheries and biological data to support stock management activities. These data sets are also used to examine patterns in the fishery and to study the structure and distribution of reef fish communities.

Cooperative Tagging Center (CTC)
The Southeast Fisheries Science Center formed the Cooperative Tagging Center (CTC) in 1992 in response to the recent expansion of tag release and recapture activities, data requests from other tagging agencies, and domestic and international tagging research needs. The CTC encompasses a variety of functions and responsibilities. The CTC also includes the Cooperative Tagging System (CTS), as well as other research projects such as tag development and performance research and cooperative work with endangered species.

The NMFS Cooperative Tagging Center has been impacted by the downsizing of the Federal Government and is being restructured.

9.2.3 Habitat and Ecosystem Research

9.2.3.1 General Coral Reef Conservation Grant Program

Each year, subject to the availability of funds, the NOAA Coral Reef Conservation Program publishes its Coral Reef Conservation Grant Program Funding Guidance, as authorized by the Coral Reef Conservation Act of 2000, to solicit proposals for coral reef conservation activities.

Funds are awarded under the following six program categories:
- State and Territory Coral Reef Management (Applicants: State and Territory Management Agencies);
- State and Territory Coral Reef Ecosystem Monitoring (Applicants: State and Territory Management Agencies);
- Coral Reef Ecosystem Research (Applicants: Academia, NGO's, etc.);
- Projects to Improve or Amend Coral Reef Fishery Management Plans (Applicants: South Atlantic, Caribbean, Gulf of Mexico, and Western Pacific Fishery Management Councils);
- General Coral Reef Conservation (Applicants: Academia, NGOs, Local and Tribal governments, community organizations, etc.); and
- International Coral Reef Conservation (Applicants: International governments, NGOs).

9.2.3.2 Coral Reef Ecosystem Studies

9.2.3.3 NOAA Fisheries SEFSC

South Florida Ecosystem Restoration

South Florida Restoration Team provides oversight and coordination of NOAA research in Florida Bay to ensure that scientific information is provided to water management agencies in south Florida to improve the ecological functioning of Florida Bay and other Florida estuaries. Scientists also conduct ecological studies of south Florida species as indicators of water quality, conduct associated research, and provide scientific information to management plans for the Florida Keys National Marine Sanctuary.

9.2.3.4 EFH Research

Information/Research Needs for Mangrove Habitat

Thayer et al. (In press) discussed research needs for mangrove systems based on a NOAA Coastal Ocean Program-sponsored workshop held in 1988. The following summarizes this paper and is separated into six priority areas of information needed.

<u>Food web-related information needs</u>

The prevailing paradigm regarding food webs of mangrove-dominated estuarine ecosystems is that they are based on particulate mangrove detritus, but recent research indicates that dissolved organics may be equally important. Research is needed to determine the contribution of mangroves to estuarine secondary productivity relative to contributions by phytoplankton, benthic micro- and macroalgae, and seagrasses. The studies by Fry et al (1999) and Fry and Smith (2002) have yielded some information, but more stable isotope work is needed.. Food web research needs to evaluate the significance of dissolved organic matter relative to particulate organic matter in trophic linkages and the distribution of higher trophic level organisms in various mangrove habitats in relation to gut contents and food linkages (e.g., as through the use of multiple stable isotopes).

<u>Information needs on productivity and structure of mangroves</u>

Little effort has been devoted to understanding the relationships between structural and functional attributes of mangrove communities or how these relations change with development of the mangrove stand over time. There is a need to characterize the dynamic nature of mangrove productivity and its influence on the productivity of adjacent coastal habitats. Protocols need to be developed that will enable investigators to remotely characterize forest structure, successional status and type.. The proportional contribution of mangroves to the total primary production of a given watershed or estuary is not well known. Rates of primary production of various components should be quantified and predictive models of primary productivity, as controlled by major factors, should be developed and tested. Research is needed on the ecological processes associated with recovery and succession of mangrove ecosystems, including research on the restoration and resiliency of restored mangrove systems and research on the significance of hydrology on succession patterns in mangrove habitats. The close coupling of mangroves to other hydrologic units in the landscape suggests that alterations in regional hydrology may induce changes in mangrove vegetation and functional patterns.

Habitat use information needs
Past research on the importance of mangrove habitats for fishes and invertebrates has focused primarily on fringing red mangroves, and that has been limited. The white and black mangrove habitats have been poorly studied. Each habitat type may export organic matter that generates chemical cues regulating the presence or absence and abundance of estuarine organisms and thus, the predictable spatial and temporal patterns of marine life. Determining the types and numbers of organisms that exploit these habitats, the functional aspects of habitat use, and how mangrove organic matter is transferred to higher trophic levels is critical, as are requisites for modeling linkages between variations in mangrove productivity and variations in faunal abundances. This requires work that compares spatial and temporal variation in use, feeding ecology and growth patterns.

Nutrient cycling information needs
Mangroves may influence nutrient dynamics and associated coastal productivity by either removing or contributing nutrients to these systems, and data on their function in maintaining water quality of estuarine ecosystems is limited. Processes associated with the immobilization of nutrients within mangrove ecosystems such as microbial decomposition and enrichment processes, and recycling, need to receive attention.

Restoration and Succession of damaged mangrove ecosystems
The effectiveness of mangrove restoration and creation projects in terms of mangrove community productivity, stability and faunal utilization patterns are poorly understood. The time frame for reaching natural growth and production rates has not been followed nor have the time courses for development of biogeochemical cycles and natural fish and invertebrate communities. Research also is needed to determine the effects of natural and human-induced perturbations on microbial decomposition and enrichment processes and on the significance of sea-level variations as factors contributing to successional patterns, habitat loss, and nutrient cycling processes.

Synthesis and modeling needs
Ecological models can be used in conjunction with field and laboratory approaches to obtain a better understanding of the role of mangroves in coastal ecosystems and to develop predictions of success of restoration designs. Scientists and managers need to synthesize extant information of ecological processes that address key management issues of mangrove habitats. Mapping efforts need to be expanded to provide information on the distribution of this important habitat type.

9.2.4 NMS Research Programs

Gray's Reef

Characterization of the Fish, Benthos, and Marine Debris at the Grays Reef National Marine Sanctuary

Gray's Reef National Marine Sanctuary (GRNMS) expressed interest in obtaining a baseline characterization of the benthic resources within Gray's Reef. To meet this need, the Center for

Coastal Monitoring and Assessment's Biogeography Team, in consultation with the Sanctuary, is conducting a characterization to identify spatial correlations between fish communities, benthic features, and fishing impacts at Gray's Reef National Marine Sanctuary.

GRNMS encompasses approximately 58 square kilometers of seafloor located 17 nautical miles off the coast of Georgia in approximately 60 feet of water. Baseline characterization of GRNMS benthic fish and sessile invertebrates has not been conducted comprehensively throughout the Sanctuary. This project quantifies those resources through a robust, statistically defensible sampling design. The project builds upon the previously completed benthic maps for the sanctuary (completed in 2003 by CCMA Biogeography Team). Such an assessment is needed to support the many activities and responsibilities of sanctuary staff including natural resources management, education, research, and even for promoting responsible recreational use by fishermen and divers. An understanding of the distribution of benthic resources provides the spatial framework within which to conduct sanctuary monitoring activities, identify and protect essential fish habitat, and properly address other spatially explicit research and management goals. This baseline characterization is also the first step in monitoring temporal changes in the Gray's Reef landscape and understanding more about the dynamic nature of this region of the continental shelf. To meet this need, the Biogeography Team mapped benthic habitats of the Sanctuary using sonar imagery. Completed maps include ledges of varying heights, flat live bottom, flat sand, and rippled sand. These maps are used to stratify sampling design of fish and benthic cover. Fish communities, fishing gear, marine debris, and cover of sessile invertebrates are surveyed along diver transects within each habitat type.

Benthic Macroinfaunal Communities Assessment
The Center for Coastal Environmental Health and Biomolecular Research (CCEHBR), through its Coastal Ecology Program, conducts research within several sanctuaries to support long-term science and management needs within the National Marine Sanctuaries. At Gray's Reef NMS and surrounding shelf waters, they are assessing benthic macroinfaunal communities and chemical contaminant concentrations in sediments and biota. Key objectives are to document existing conditions of these resources as a benchmark for tracking changes due to natural or human disturbances; examine cross-shelf patterns in contaminant concentrations; and identify potential environmental factors associated with observed patterns.

Gray's Reef National Marine Sanctuary Assessment Project
In 2002, the Reef Environmental Education Foundation (REEF) initiated a fish-monitoring program within GRNMS. The project uses the REEF Advanced Assessment Team (AAT) to conduct annual visual fish surveys within GRNMS. The surveys are conducted using the Roving Diver Technique (RDT) to measure species composition and estimate abundances. Beginning in 2004, REEF added a quantitative size-monitoring component for targeted species (black sea bass, lutjanids and serranids). The primary goals of this project are to 1) to provide GRNMS with a taxonomic inventory of fish species found within the Sanctuary as well as a dataset that can be used through time to measure spatial and temporal trends, 2) to assess the size structure and biomass of key targeted fish species within the GRNMS, 3) to complement the current stationary visual fish counts that have been conducted at GRNMS since 1995, and 4) to increase local and national awareness on the Sanctuary resources and give constituents a comparative fish data resource that can be used for the better management of GRNMS.

This project has provided a substantial increase of effort in the REEF database. Prior to the start of this project in 2002, there were only 18 surveys from the Sanctuary in the database. As of July 2006, there are over 300 surveys from GRNMS in the REEF database. Several new fish records for the Sanctuary have also resulted from the REEF project.

Florida Keys

9.2.5 NOS NCCOS

Benthic Habitat Mapping of Florida Coral Reef Ecosystems
Southern Florida's coral ecosystems are extensive. They extend from the Dry Tortugas in the Florida Keys as far north as St Lucie Inlet on the Atlantic Ocean coast and Tarpon Springs on the Gulf of Mexico coast. Using 10 fm (18 m) depth curves on nautical charts as a guide, southern Florida has as much as 84 percent (30,801 sq km) of 36,812 sq km of potential shallow-water (<10 fm; <18 m) coral ecosystems the tropical and subtropical U.S. Moreover, southern Florida's coral ecosystems contribute greatly to the regional economy. Coral ecosystem-related expenditures generated $4.4 billion in sales, income, and employment and created over 70,000 full-time and part-time jobs in the region during the recent 12-month periods when surveys were conducted.

Working with state, local, university, and other federal partners, NOAA initiated an effort to map and characterize the coral ecosystems of southern Florida. The Southern Florida Shallow-water Coral Ecosystem Mapping Implementation Plan (MIP) that was recently finalized discusses the need to produce shallow-water (~0-40 m; 0-22 fm) benthic habitat and bathymetric maps of critical areas in southern Florida and moderate-depth (~40-200 m; 22-109 fm) bathymetric maps for all of Florida. The ~0-40 m depth regime generally represents where most hermatypic coral species are found and where most direct impacts from pollution and coastal development occur. The plan was developed with extensive input from over 90 representatives of state regulatory and management agencies, federal agencies, universities, and non-governmental organizations involved in the conservation and management of Florida's coral ecosystems.

The MIP summarizes the map product needs of the southern Florida coral ecosystem conservation and management community. These needs include detailed, georeferenced, thematically accurate shallow-water benthic habitat and bathymetry maps. While considerable scientific interest and management requirements exist for coral ecosystems of the entire southern Florida region, priority areas were identified. Priority areas include the approximately 13,000 sq km of shallow-water coral ecosystems found in Martin, Broward, Palm Beach, and Miami-Dade Counties, Biscayne National Park, Tortugas Ecological Reserve, Dry Tortugas National Park, Florida Bay, and the Florida Keys National Marine Sanctuary. While considerable scientific and management interest exists in the West Florida Shelf, this area was considered to be a secondary priority area. As opportunities arise, targeted mapping activities will be conducted to characterize this area.

Based on geographic priorities and costs, the MIP recommends developing maps of approximately 13,000 sq km of southern Florida's shallow-water coral ecosystems. The estimated cost to generate a detailed shallow-water benthic habitat map using high-resolution satellite or similar imagery is approximately $4.35 million. This cost estimate includes purchasing commercial high-resolution satellite imagery, producing the actual benthic habitat map from the imagery, and completing an independent thematic accuracy assessment of the map. Because of the technical and logistic challenges and financial costs associated with imagery collection and map production, it is anticipated that four or more years will be required to complete shallow-water benthic habitat maps of southern Florida.

National Coral Reef Ecosystem Monitoring Program

This suite of projects is accomplished through cooperative agreements between NCCOS and State, Territory, and Commonwealth partner programs to monitor the status and condition of coral reef ecosystems throughout the U.S. Past objectives focused on filling in gaps in local monitoring. However, based on program evolution via consultation with island partners, the National Coral Reef Ecosystem Monitoring Program has developed into a full cooperative partnership between states, territories, commonwealths, and NOS-NCCOS. The programs objectives are as follows:

1. To work closely with jurisdictional partners and stakeholders throughout the US and its Territories to develop and implement a nationally coordinated, long-term program to assess, inventory, and monitor U.S. coral reef ecosystems; and,
2. Prepare a biennial report on the State of U.S. Coral Reef Ecosystem condition, with particular emphasis on assessing the impacts of threats to coral reefs worldwide, including: climate change and coral bleaching, coral disease, tropical storms, coastal development, pollution, over fishing, and many others.

The objective of the State and Territory Coral Reef Monitoring Grant program is to provide support for NOAA partners towards implementing a nationally coordinated, comprehensive, long-term monitoring program to assess the condition of U.S. coral reef ecosystems, and to evaluate the efficacy of coral ecosystem management. This program was requested by the U.S. Coral Reef Task Force, which, along with the nation's coral reef program managers and the public, endorsed and called for implementation of "A National Program to Assess, Inventory, and Monitor U.S. Coral Reef Ecosystems."

NOAA began implementing the Program in 2000 and continues to administer it with Congressional appropriations for coral reef conservation. The Program includes the collection, analysis, and reporting of long-term coral reef ecosystem monitoring data pursuant to scientifically valid methodologies and protocols and is a key priority of the "National Coral Reef Action Strategy."

The Coral Reef Monitoring Grant Program, as authorized under the Coral Reef Conservation Act of 2000 (16 USC 6401-6409), provides matching grants to Governor - appointed point of contact agencies for the jurisdictions of Puerto Rico, the U.S. Virgin Islands (USVI), Florida, Hawaii, Guam, the Commonwealth of the Northern Mariana Islands (CNMI), the Republic of Palau, the

Federated States of Micronesia (including Chuuk, Yap, Kosrae, and Pohnpei), and American Samoa for State and Territory Coral Reef Monitoring activities.

NOAA's National Ocean Service (NOS), through the National Centers for Coastal Ocean Science (NCCOS) provides funding for cooperative agreements to support state and territorial coral reef monitoring activities under the priority areas listed below, which have been recommended by the Nation's coral reef resource managers. These key biotic and abiotic parameters should be monitored at all local sites in the National monitoring network:

1. Benthic habitat characterization: e.g., depth, habitat delineation, and/or percent live/dead cover of corals, submerged aquatic vegetation, macroalgae, sponges, rugosity, diversity, etc.);
2. Associated biological community structure: including fish condition (e.g., abundance, density, size, diversity, disease, harvest trends, etc.) and large motile and sessile invertebrates condition (abundance, density, size, diversity, disease, harvest trends, etc.); and,
3. Water/substrate quality: (e.g., temperature, nutrient enrichment, toxic chemicals, turbidity, etc.).

9.2.7 Ocean Exploration and Research

The Office of Ocean Exploration is NOAA's center for new activities to explore and better understand our oceans. This office supports expeditions, exploration projects, and a number of related field campaigns for the purpose of discovery and documentation of ocean voyages. Bringing scientists to ocean frontiers requires rigorous planning, mission staging, and well coordinated marine operations.

Education and outreach rank high as office priorities. Through ocean exploration, NOAA is committed to raising America's science literacy and developing the next generation of ocean explorers, scientists and educators.

Four crucial components comprise the NOAA Ocean Exploration Mission:

1. Mapping the physical, biological, chemical and archaeological aspects of the ocean;
2. Understanding ocean dynamics at new levels to describe the complex interactions of the living ocean;
3. Developing new sensors and systems to regain U.S. leadership in ocean technology, and;
4. Reaching out to the public to communicate how and why unlocking the secrets of the ocean is well worth the commitment of time and resources, and to benefit current and future generations.

National Undersea Research Center

The National Undersea Research Center at the University of North Carolina Wilmington is funded by a grant from the National Oceanic and Atmospheric Administration as part of the National Undersea Research Program (NURP). NURP includes headquarters in Silver Springs, MD and seven regional centers. The center at UNCW supports undersea research off the southeastern United States from North Carolina to Texas. Center facilities and staff are located at the university's Center for Marine Science in Wilmington, NC and Key Largo, FL.

9.3 Ocean Observing Systems and Fisheries Oceanography

Ocean Observing Systems are an integral part of the transition to ecosystem management in the Southeast region. A brief review of atmospheric and oceanographic characteristics is provided in Section 9.3.1; the present status of real time observing elements in the SE Coastal Ocean is reviewed in Section 9.3.2; Data Management considerations are provided in Section 9.3.3 and Modeling approaches in Section 9.3.4.

9.3.1 Fisheries Oceanography in the South Atlantic Region

The Southeast Coastal Ocean Report (2005; http://seacoos.org/documents/report) provides a basis for the atmospheric and oceanographic characteristics of the US Southeast Coastal Ocean.

Atmospheric Characteristics

The atmospheric characteristics of the southeast coastal ocean are summarized in terms of the wind fields, and severe storms including winter cold air outbreaks and hurricanes.

Seasonal Wind Fields: Five seasonal wind regimes have been associated with the South Atlantic Bight and East Florida Shelf regions (Weber and Blanton, 1980; *Journal of Physical Oceanography*, 10:1256-1263).

- *Winter* (November to February/March): winds are persistently southeastward in North Carolina and turn more southward over Florida;
- *Spring transition* (March to May): winds shift to westward from Florida to South Carolina, with the winds elsewhere in the region being more variable;
- *Summer* (June and July): westward winds dominate the southern reaches of the domain, and northward flow sets in for the central to northern portions of the SAB (Georgia to North Carolina);
- *Fall* (August): the summer wind patterns break down and become generally disorganized except for Florida's westward and southwestward winds; and,
- *"Mariner's fall"* (September and October): southwestward winds (at times strong) occur over the domain, with westward winds at times over Florida.

Winter Cold Air Outbreaks (extra-tropical winter cyclones). During the winter months, extra-tropical cyclones often travel across the southeastern states and out over the Atlantic Ocean and are known for the devastating weather they sometimes bring. These storms frequently produce ice, heavy snow and gale force winds that can cause property damage and loss of life. Perhaps the most infamous of these cold air outbreaks contributed to the tragic loss of the space shuttle Challenger in January of 1986. Coincidentally, also in 1986, the Genesis of Atlantic Lows

Experiment (GALE) investigated these storms and their effect on the SE coastal ocean (J. Geophysical Research, Vol. 94, number C8, 1989).

Hurricanes -- Tropical Cyclones: The Southeast US region typically experiences weekly easterly waves and several tropical cyclones (in some instances hurricanes) each year. Neumann (1993) quantified the mean direction of the tropical cyclone (TC) tracks from 1886-1989. Generally, if storms do not recurve east of 60°W, they will make landfall along the US coastline. The number of TC occurrences during this period was 70 in the Gulf of Mexico and 85 off Cape Hatteras, North Carolina. Given the high frequency of TC landfall in the SE and the large areas of low-lying land along the SE coast, accurate prediction of the oceanic interaction with, and response to, tropical storms is vital to ensure timely action by coastal emergency response personnel. The official Atlantic hurricane season runs from June 1 through November 30, with a peak from mid-August through mid-October.

Oceanographic Characteristics

Geographic Setting: We define the Southeast Coastal Ocean as the domain extending from the Florida Panhandle to the North Carolina shelf north of Cape Hatteras, acknowledging overlap with the Gulf of Mexico coastal ocean domain in the west and the Mid-Atlantic Bight north of Cape Hatteras. Major geographical sub-regions with the SE Coastal Ocean are the West Florida Shelf (WFS), Straits of Florida (SOF), and the South Atlantic Bight (SAB), with the common boundary point between the former two at the Dry Tortugas and between the latter two at Cape Canaveral. Within SEACOOS, the functional sub-regions are the West Florida Shelf, East Florida Shelf (EFS), and the Carolina-Georgia Shelf (CGS). As is the case with other large regional coastal ocean domains, there is overlap between sub-regions in a number of areas.

The regional geomorphology of the SE United States defines a number of the key oceanographic characteristics of the SE coastal ocean. Much of the coastal area of Florida, Georgia, South Carolina and North Carolina is relatively low relief topography. Two sub-regions have relatively broad continental shelves. The WFS is a gently sloping carbonate platform, extending to >200 km from the coast to the shelf break. The SAB shelf (largely lithogenic deposits, with some carbonate strata) reaches a width of 100-120 km off Georgia and South Carolina, tapering to a much narrower width at its northern and southern ends, at Cape Hatteras and Cape Canaveral, respectively. In contrast, the SE Florida shelf along the SOF is rather narrow, being only several km wide in parts.

Local and Deep-Ocean Forcing: One of the key considerations regarding variability in material property distributions and exchange processes in the SE coastal ocean is the relative influence of local and deep-ocean forcing. Here we refer to material properties in a broad sense, including physical characteristics, such as sea level, water velocity, temperature, salinity, as well as chemical and biological constituents, such as nutrients, non-living particulate and dissolved organic matter, inorganic materials such as suspended clay particles, and organisms of various trophic levels.

A very simplified picture of some of the key local and deep-ocean forcings is represented in Figure 1. Local forcings include inputs of momentum through winds and pressure gradients, and inputs of buoyancy resulting from river discharge at the coast (and by ground water), from local precipitation/evaporation differences, and through surface heat flux. Deep-ocean effects include the influence of the ocean boundary current and associated frontal eddies on the shelf circulation and material exchange, and through tides.

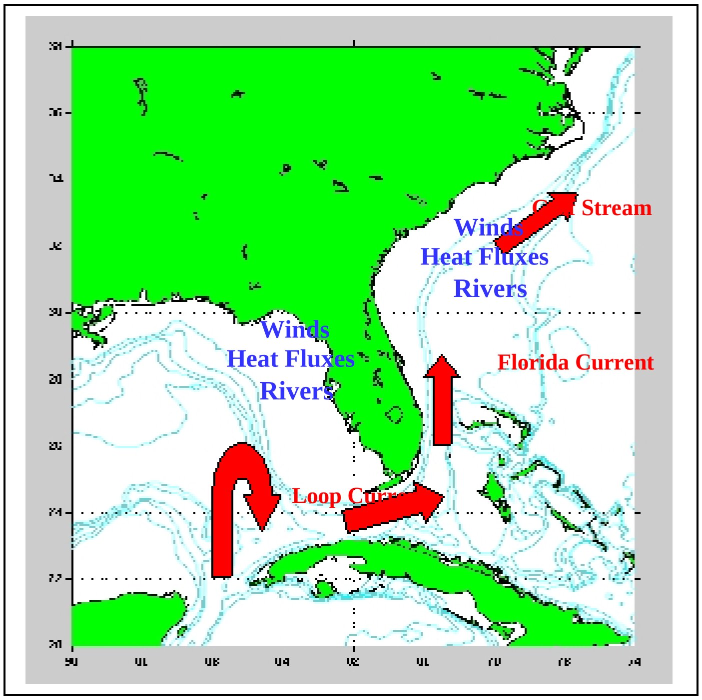

Figure 1. A simplified representation of some of the key local and deep-ocean forcings that drive water motions and determine material property distributions in the SE Coastal Ocean.

The coastal waters are linked by the Loop Current/Florida Current/Gulf Stream complex that runs along the shelf margin. Shelf waters respond strongly to atmospheric forcing by winds and air-sea fluxes. Freshwater is input along the coast from a number of rivers fed by the regional drainage basins.

Starting with the deep-ocean forcing, one of the defining characteristics of the SE Coastal Ocean is the presence of a major western boundary current system. The Loop Current/Florida Current/Gulf Stream complex (LC/FC/GS) provides a mechanism of rapid transport of materials along the ocean margin throughout the region, and strongly influences outer shelf circulation and material exchange processes along the shelf margins through formation and dissipation of meanders, fronts, eddies and sub-mesoscale vortices. Another deep-ocean forcing is from tides. The largest tides in the SE coastal ocean are found in the central portion of the South Atlantic Bight, with tidal ranges of 2.5-3.0 m near Savannah, Georgia and peak mid-shelf tidal currents of 40-50 cm/s. Tidal ranges are of the order of 1 m or less over much of the rest of the domain.

On the more local scale within the various sub-regions of the SE coastal ocean, variability in winds is obviously one of the major factors driving shelf circulation patterns. The general picture for seasonal and synoptic scale patterns of local wind forcing in the SE was summarized in the preceding section. Another local forcing is the input of buoyancy at the coast in the form of river discharge. Most of the river discharge along the coastline of the SE Coastal Ocean comes from drainage basins that are contained within the SE region. Thus, seasonal and interannual variability in regional rainfall and river discharge strongly influences coastal currents and hydrographic structure of the broader shelf region. However, the Mississippi River discharge can also impact the WFS and, at times is evident in lower salinity water along the shelf margin of the EFS and CGS due to transport in the LC/FC/GS system.

Known variations in cross- and along-shelf transports dictate regular monitoring at the shelf-break, mid-shelf, inner shelf at a minimum. In the more complex inshore waters, where spatial gradients are highly structured, relatively high-resolution observations will be required. There clearly is a need for ocean-side boundary conditions. This is particularly challenging for the Southeast coastal ocean domain because of the presence of the Loop Current - Florida Current - Gulf Stream system.

Summary Remarks on the Processes Defining Coastal Ocean Observing Systems

The basic design of an Ocean Observing System for the SE US coastal ocean must take into account a number of key geographic and physical characteristics of the region that control coastal ocean processes. These include:

- The presence of a western boundary current system (the Loop Current-Florida Current-Gulf Stream) along the shelf margin throughout most of the SE states (Florida-Georgia-South Carolina-North Carolina) coastal ocean, including the influence of its meandering jet and front and the mesoscale eddies it sheds;
- A wide range of shelf widths, from <10 km to >100 km;
- Several major estuaries and coastal lagoons (e.g., in Florida: Apalachicola, Tampa Bay, Charlotte Harbor, Florida Bay, Indian Lagoon, St. Johns River; in Georgia: Altamaha River, Savannah River; in South Carolina: Broad River, St. Helena's Sound, Charleston Harbor; and in North Carolina: Cape Fear River, Albemarle-Pamlico Sound) that exchange physical and biogeochemical properties and biota with the open shelf;
- Variable input of freshwater to the coastal zone from distributed SE river (and groundwater) sources, with the additional influence of the Mississippi River on the region that create cross-shelf density gradients;
- Seasonal patterns of heating and cooling that result in widely varying cross-shelf density structure which influence exchange with the deep ocean;
- The influence of synoptic weather systems, and especially major episodic storm events, including easterly waves and tropical cyclones in summertime and extra-tropical cyclones and frontal systems in wintertime, in producing turbulent mixing, coastal upwelling and downwelling, and other transient flows; and

- A highly variable diurnal and semidiurnal tide regime that is dominant in certain shallow water regimes.

Development of a complete system will likely take decades. What is described below is a design to be implemented over a 5-year timeline that concentrates on developing a viable information system for the continental shelf region of the SECOORA domain. Thorough testing of the adequacy of the system to satisfy the needs of the chosen applications is anticipated to result in revisions after the 5-year build-out. Designing an RCOOS for the SE US that can effectively address the IOOS societal goals requires consideration of a number of factors, including the SE environmental/oceanic setting, existing capabilities, and anticipated resources. Implementation of the SE RCOOS will be an incremental process. Due to the range of temporal and spatial scales over which coastal ocean processes operate, use of both observations and models is essential for creation of a robust and multi-purpose estimation (or prediction) system. The range of applications implied by the broad societal goals for the IOOS also dictates that a "nested" strategy will be required for the allocation of resources. Some degree of sub-regional to local focus will also be required for the RCOOS to serve in an R&D role for the RA (e.g., conducting data assimilation experiments, and providing technology testbeds).

While the initial focus for observations in the developing RCOOS will be physical variables, this does not imply that the RCOOS will serve only as a physical oceanographic estimation system. Rather, this reflects the present state of sensor development and maintenance issues for the existing biological and chemical sensors, and recognition of the importance of physical processes for driving biogeochemical and ecological processes. As more robust, cost-effective technologies become available for measuring chemical and biological properties, these will be incorporated into the RCOOS in a coordinated, multidisciplinary manner. Given the close coupling of physical processes with biogeochemical processes in the coastal ocean, an initial physics-based RCOOS observational design will also serve interdisciplinary needs, including implementing ecosystem-based management practices in the SE coastal ocean.

9.3.2 Status of Coastal Ocean Observing Systems in the Southeast

Some of the descriptions below on the status and possible enhancements of the southeast’s regional observing system are taken from the article by Seim, H.E., C.N.K. Mooers, J.R. Nelson, R.H. Weisberg and M. Fletcher (2008) “Towards a regional coastal ocean observing system design for the southeast coastal ocean observing regional association”, *Journal of Marine Systems*, in press.

Regional System

The definition of the structure of the U.S. Integrated Ocean Observing System (IOOS) has been developed in large part through the actions of Ocean.US, an interagency planning office established in 2000 to advance the development of IOOS. The U.S. coastal ocean component of the IOOS is envisioned to consist of a federal network (the “National Backbone”) which will provide sustained support for *in situ* and satellite remote sensing observations, predictive models, and data management elements on the national scale, augmented by Regional Coastal Ocean Observing Systems (RCOOSs) (Ocean.US, 2002). Each RCOOS will be an integral component of its respective regional association (RA) of stakeholders (*viz*., data providers and users), which in turn is a member of the National Federation of Regional Associations (NFRA) (Ocean.US, 2004). Through the RA, the RCOOS will be responsive to regional and local needs and augment the National Backbone accordingly. As a pioneering activity associated with the regional development of a coastal ocean observing system (COOS), the Southeast Atlantic Coastal Ocean Observing System (SEACOOS; Seim et al., 2003) has considered the scientific and technical design criteria of the operational RCOOS that will be a central element of the Southeast Coastal Ocean Observing Regional Association (SECOORA). SECOORA and its RCOOS are required to be fully interactive and interoperable with other regional associations, especially with the neighboring GCOOS for the Gulf of Mexico and MACOORA for the mid-Atlantic, as well as with the National Backbone provided by the federal agencies (Figure 2). Discussed here are preliminary thoughts on the design of a RCOOS for SECOORA, some aspects of how this RCOOS may interact with the National Backbone, and how elements of the RCOOS will transition to certified components of IOOS.

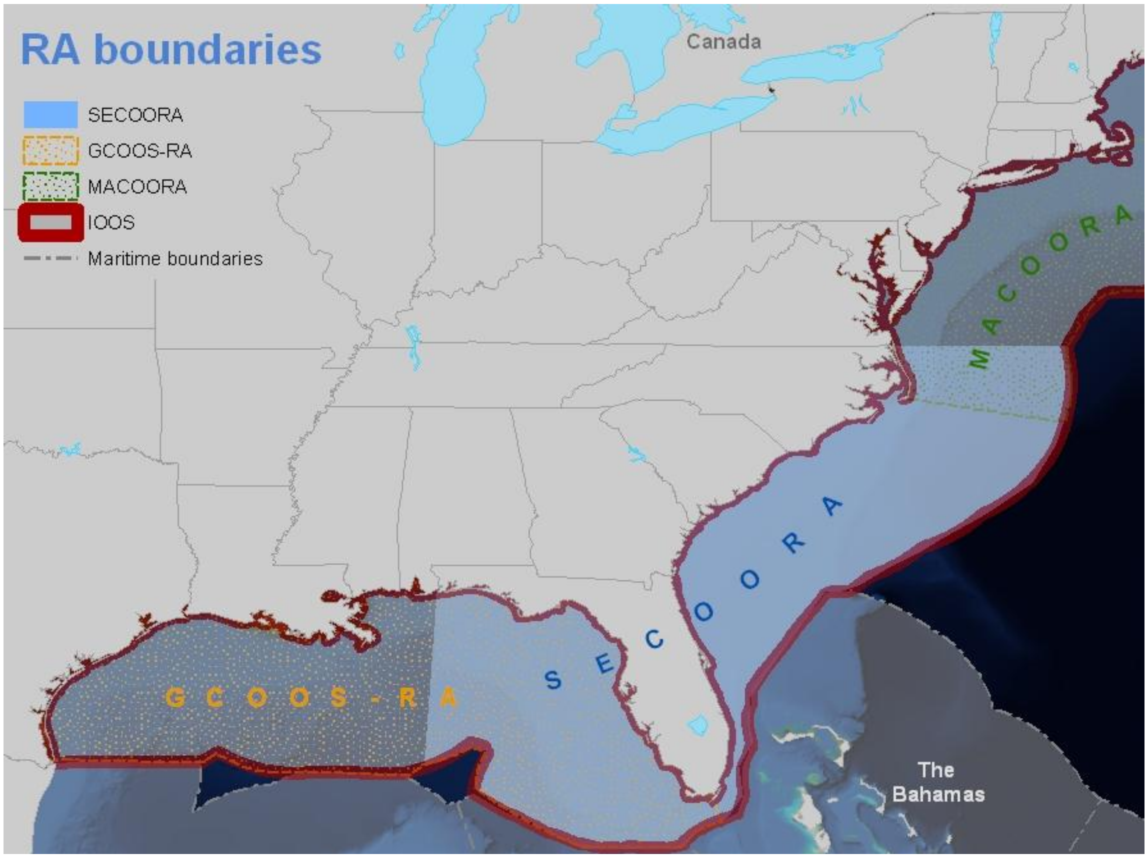

Figure 2. Approximate boundaries of regional associations (RAs) and the coastal component of the U.S. Integrated Ocean Observing System (IOOS).

Since ocean processes are three-dimensional, time-dependent, and occur on many space-time scales, no single measurement system (*in situ* or remote) will be sufficient for describing any of the ocean state variables. A "multi-platform, multi-variable" observational approach is required, integrated with models (including data assimilation approaches). Furthermore, the fundamental value of continuous time series data should be recognized in the design process, such that real-time telemetry systems are backed up with internal recording of data, and delayed-mode and historical data are also integrated into the regional data management structure.

The following sections describe the existing observing system in the southeast Atlantic and possible enhancements are broken out by observing platform. The inventory of existing assets indicates a wide range of observing activities shoreward of the coastline in estuarine waters; because of this little augmentation is suggested. On the continental shelf there is a relatively sparse set of observing assets; the federally-funded program provides some measure of atmospheric and ocean surface properties but provide no subsurface observations except for some experimental current profilers. Regional and sub-regional programs like SEACOOS have effectively doubled the number of observing platforms on the continental shelf and provide the only near real-time subsurface observations. As examples of the impact made by the regional programs, SEACOOS HF radar provide surface currents over more than 20,000 km^2 where no other observations exist, and regional buoys and moorings increase the number of locations where bottom temperature is monitored from zero to fifteen. Because the only sustained observing elements in the coastal ocean are the federally-operated assets, the proposed observing system design focuses on implementing consistent regional coverage to provide reliable information on physical ocean state that can also be used to assess the accuracy of coastal ocean models.

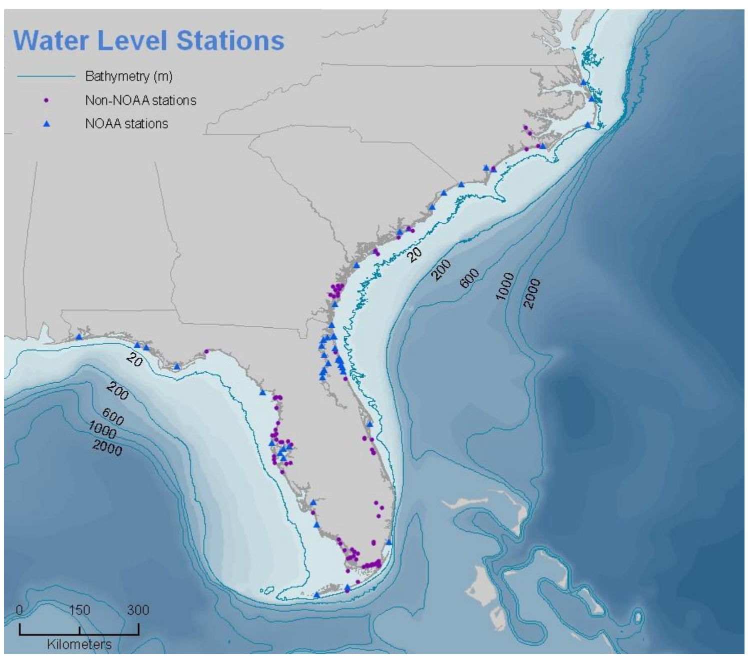

Figure 3. Distribution of existing water level observation stations that are tidally influenced.

<u>Coastal Stations.</u> Existing federally operated coastal stations, largely established by NOAA (in particular the National Water Level Observation Network of the National Ocean Service and the Coastal Monitoring Automated Network of the National Weather Service), US Geological Survey, National Park Service, and US Army Corps of Engineers are geared primarily to sea level and coastal meteorology. Within Florida the Water Management Districts also support a large number of water level gages. The distribution of stations that are tidally-influenced (Figure 3) indicates that these stations provide a foundation for further development of shore

stations by the RCOOS, which should be approached in coordination/partnership with federal agencies and state and local coastal management and emergency response agencies. At present three areas in Florida are heavily instrumented, the St. Johns River/Jacksonville area in the NE of the state, the Everglades in the south, and the Tampa Bay area on the west coast.

Noticeable gaps in coverage exist along the east coast of Florida and in the Big Bend of NW Florida. Augmentation of water level stations in these locations and at commercial ports is warranted, since even small changes in water depth can impact the efficiency and safety of deep-draft vessel operations. Ten additional water level stations should be sufficient to fill the existing major gaps. Further regional partnering with the NOAA Physical Oceanographic Real-Time System (PORTS) program could be an effective approach in the ports. In terms of spatial coverage, there is a need for sufficient coastal water level stations to assess the predictive skill of both (1) high-resolution coastal inundation models, and (2) lower resolution coastal ocean circulation models. For coastal inundation/storm surge applications, there is a practical need to "over-sample" sea level, since many stations are subject to failure of instruments or communications during major storm events.

Fixed Moorings. The SECOORA domain includes regions with very narrow shelves (near DeSoto Canyon, the SE Florida shelf from Key West to West Palm Beach, and near Cape Hatteras) and broad, gently sloping shelves (off West Florida and in the central South Atlantic Bight). Obviously the deployment of observational assets will have to take this variability in shelf width and coastal ocean properties into account. For the broader shelf sub-regions, three basic sub-domains can be defined:

- A baroclinic (density-stratified) outer shelf/slope zone where the physical state is directly influenced by the boundary current (Loop Current/Florida Current/Gulf Stream);

- An inner shelf/coastal zone where the water column is shallow enough that there is interaction between surface and bottom boundary (Ekman) layers and wind, wave, and tide forcing are significant; in many locations, there is also a near shore zone in which the influence of relatively fresh estuarine outflows leads to additional buoyancy-driven flows;

- An intermediate/mid-shelf zone (if the shelf is wide enough to separate the inner and outer portions) where circulation is largely forced by winds and tides.

Existing shelf observation platforms include the buoys and coastal stations of the National Data Buoy Center (NDBC) and a collection of academically-supported sub-regional systems off the west coast of Florida, off Georgia, and off the Carolinas (Figure 4). The type of sensors each platform supports varies but in general the NDBC buoys emphasize meteorological instrumentation and currently provide limited ocean measurements. Coverage of oceanic variables is very sparse with the possible exception of near-surface temperature.

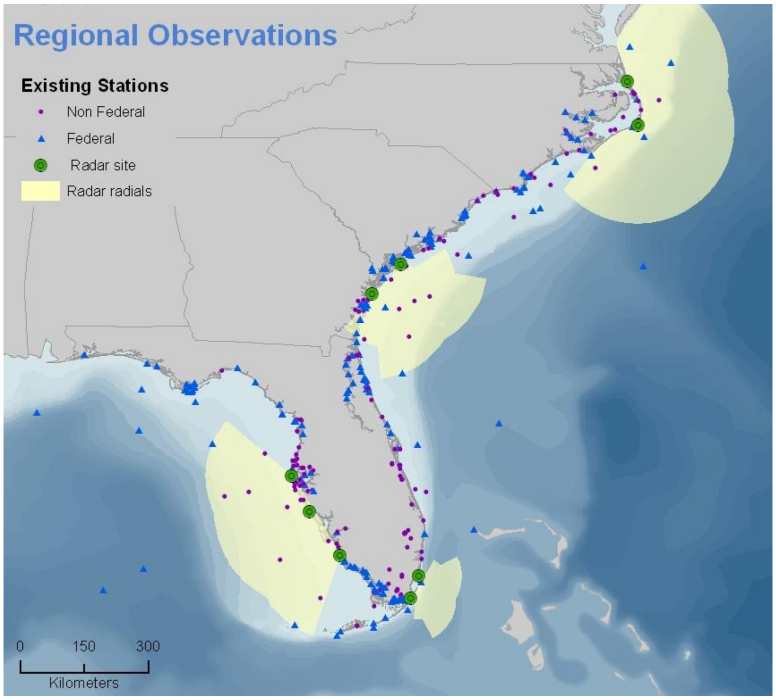

Figure 4. Depiction of the existing observing subsystem showing coastal stations, buoys, and radar coverage. Note that all radar sites are non-federal.

Based on the above considerations of the ocean physics, a regular array of moored or fixed platform offshore observing elements distributed over the SECOORA domain is advanced (Figure 5). A detailed description of possible platform and instrument configurations is beyond the scope of this discussion. Here the focus is on an initial distribution of these assets on the continental shelf and a set of core variables to be measured. The proposed initial array consists of a series of cross-shelf deployments, at roughly 150 km spacing in the along-shelf direction, and linked, to the extent possible, to seaports, major topographic anomalies, and other special features. The along-shelf spacing is needed to resolve

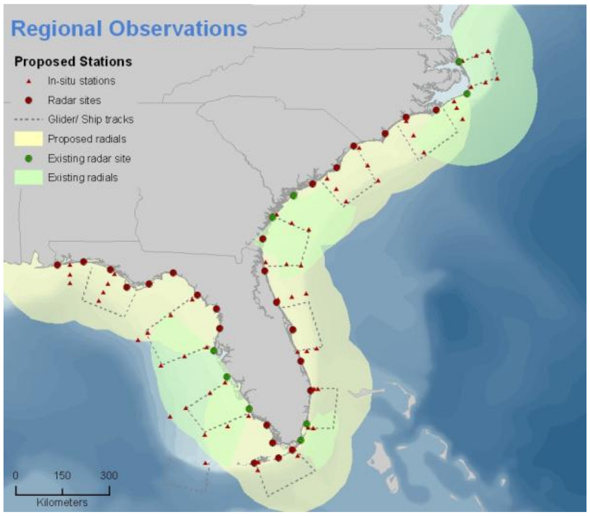

Figure 5. Proposed enhanced observing subsystem asset distribution to provide region-wide coverage on the continental shelf from HF radar, *in-situ* moorings and glider or ship transects. Note: these transects are for discussion purposes only. Local phenomenology will lead to finer tuning of the RCOOS array

variability in the circulation; many features of coastal circulation in the SE occur at this scale or smaller (e.g., Florida Current and Gulf Stream meanders). For all but the narrowest shelves, each cross-shelf section would have three measurement sites, supplemented in the near-shore with additional deployments at major locations of estuarine outflow or population centers. The core set of instrumented buoys or platforms should all be equipped for measurements of temperature and salinity at multiple depths, current profiles, wind, and some should be equipped to determine directional waves and net surface heat flux. Given the ten existing NDBC buoys there is a need for an additional 50 moorings under this scenario.

Full water column measurements of current, temperature and salinity in each of the three coastal ocean regimes defined above are necessary to specify the flow and hydrographic (temperature, salinity, and density) fields. The surface and bottom boundary (Ekman) layers warrant particular attention given their roles in cross-isobath exchange. Full water column measurements are also required to assess key processes, including boundary current interactions on the shelf-slope, exchange at the shelf break between the coastal ocean and the deep ocean, coastal responses to local wind forcing, transport of organisms by internal tides, and direct estuarine interactions with the coastal ocean.

Another essential observation throughout the coastal ocean domain is surface winds. Due to the complication of land-sea interactions, the quality of numerical weather predictions over the coastal ocean can often be compromised. Most *in situ* moorings or platforms should therefore be equipped with surface wind and barometric pressure sensors. The complete suite of sensors required for heat flux estimates (incoming short- and long-wave radiation, air and sea temperatures, relative humidity) should be supported at a distributed subset of the offshore sites.

Other ancillary measurements are recommended (although not required at all sites), the foremost among these being surface waves. Directional wave spectrum measurements at the shelfbreak can provide the boundary conditions needed for coastal ocean wave models, and wave measurements nearshore can be used both to gauge the performance of these models and provide real-time data of immediate societal importance. Provisions for incorporation of additional chemical, geological and biological sensors, as these evolve, should also be included in the design of instrument, power, and communications packages.

Not addressed in this initial mooring design is an observation program for the slope and deep-water regions of the domain. The presence of the western boundary current makes these areas particularly challenging environments in which to maintain conventional moorings. Coordination with the National Backbone will be critical to deploying and maintaining an adequate array of slope and deep-water moorings and a leading role for NDBC and associated federal agencies in establishing this portion of the regional network will be strongly encouraged by SECOORA. Other possible observing technologies include cable-based transport estimates and inverted echo sounders.

Additional moored and fixed platform *in situ* assets (not represented here nor budgeted for below) will likely be positioned in areas of regional and local interest (e.g., major ports and shipping lanes, inshore areas subject to shoreline erosion and rip currents, and Marine Protected Areas) and supported through local initiatives. Measured variables at these sites will necessarily be tailored to the local applications (e.g., directional waves, wind, and nearshore currents). There may also be a need for strategic (or "targeted") observational arrays in critical locales to support the requirements of data assimilation. It is recognized that the RCOOS should provide some discretion in the organization of observational resources to serve local needs, and to best exploit available resources and infrastructure, including those supported by the National Backbone and state and local agencies.

Coastal High Frequency (HF) Radar. Coastal HF radar mapping of surface currents provides one of the more important of the potential RCOOS measurement systems, offering a field of surface velocity vectors as opposed to the point measurements typical of fixed offshore assets (Paduan et al., 2004). Two commercially available systems are operated in the SECOORA domain by academic institutions, CODAR and WERA, each offering varying range and resolution based on frequency and bandwidth (Figure 4). There are presently no HF radar installations operated by federal agencies. HF radar is a topic area where the RCOOS can play an important role in technology assessment. Given the wide range of shelf widths off the SE U.S. and the rather unique oceanic configuration of a western boundary current on the continental slope, careful assessment of options to provide HF radar coverage over the entire region is advisable. Regional coverage using long-range systems is critical to achieve because of their ability to discern the position of the boundary current and its influence on the shelf and is a necessary first stage of development (Figure 5). In addition to surface currents, continued evaluation of other potential products from HF radar (such as a spatial grid directional wave estimates from WERA) should be pursued. Deploying HF radar on islands or offshore platforms and transmitting shoreward should also be tested as a means to provide nearshore surface current coverage that is otherwise difficult to obtain, especially for convex coastlines. Assuming the existing radar systems will continue to be operated, an additional 30 installations are needed to provide region-wide coverage.

Satellite Remote Sensing. While not an asset class to be deployed, operated or controlled by the RCOOS, satellite remote sensing represents a critical resource for coastal ocean applications. Sea surface temperature, surface ocean color products (including upper layer chlorophyll and suspended materials), sea surface height, surface winds and other products from passive and active satellite sensor systems are routinely available. Such satellite information is being used for assimilation into models and for descriptive purposes. While the satellite programs themselves would not be an RCOOS function, RCOOS support for utilization of satellite data and production of enhanced products, tuned and/or calibrated to regional applications, will provide strong justification for continued federal agency support of satellite missions targeting the coastal ocean. In the SE coastal ocean, applications of passive satellite imagery could include detection of near-surface phytoplankton blooms (some of which may be harmful algal bloom species), identifying and tracking waters of riverine origin and episodic cross-shelf transport, and detection of sediment resuspension events. An RCOOS role in the support of regional capabilities for downloading, processing, and distributing satellite data, as well as for analysis products and presentation tools, will be critical for effective integration of the satellite information with *in situ* observations and application in regional modeling programs.

Profilers and Gliders. The conventional method for observing 3D fields of temperature, salinity, and other properties (such as chlorophyll and nutrients) is by ship survey. This approach is, however, slow (and often non-synoptic) and costly. At present there are no regularly scheduled spatial surveys occurring on the continental shelf in the SECOORA domain. Needed are techniques for synoptic mapping at intervals sufficient for assimilation into models, particularly for the internal density (Temperature/Salinity) field. Through a combination of profiling floats, moored profilers, autonomous underwater vehicles (AUVs), and gliders it should be possible to obtain regular (i.e., routine, standardized, and sustained) mapping of the vertical and horizontal T/S structure, as well as that of other variables with the addition of appropriate sensors. Several systems are presently being assessed in field trials in the SE. It is envisioned that an appropriate mix of platforms would be used to occupy offshore transects that align roughly with the mooring lines (Figure 5). Ten operations areas are envisioned, each with a offshore leg that in most cases will be sampled while moving with the western boundary current.

Ship Transects. Since robust, accurate, automated biogeochemical sensors will likely not be available near-term, it will be necessary to include some repeated shipboard surveys of biogeochemical variables and biota. Such surveys should be designed to optimize synergy with the deployed observational elements and real-time prediction systems, and take into account what is known of natural variability in the coastal ocean. There may also be a role here for airborne surveys equipped with remote sensors, expendable profilers, and other air-deployable systems.

Voluntary Observing Ships. With the large volume of commercial shipping and recreational boating activity in the SE, it may be possible to obtain additional valuable regional coverage by installing automated instrumentation packages on a voluntary basis, as has been done in the International SeaKeepers program on a global scale on private vessels (www.seakeepers.org) and on commercial vessels. On the more local scale, the FerryMon (http://www.unc.edu/ims/paerllab/research/ferrymon/index.html) project in North Carolina has made use of an inshore ferry as a monitoring platform.

Surface Drifters. Satellite-tracked surface drifters provide a quasi-Lagrangian view of surface circulation and, with caveats regarding their performance relative to Lagrangian trajectories (not necessarily surface-confined), provide excellent tools for surface trajectory analyses. Drifters are essential for establishing the error attributes of predicted trajectories; conversely, they are invaluable for estimating the dispersive properties of varying coastal ocean circulation regimes. Nearshore deployments can be useful for filling data gaps in coastal HF radar coverage, and for examining connectivity between adjacent estuaries and sources of fresh water along many sections of the SECOORA domain. A regular program of drifter releases on the shelf that complements existing drifter programs in deep water should be initiated. Release of drifters from various locations in the domain is suggested, using 150 drifters per year (e.g. monthly releases at a dozen locations). Deep-water examples are the collation of drift tracks by the Atlantic Oceanographic and Meteorological Laboratory, NOAA and those tracks made available by Horizon Marine, Inc in the Gulf of Mexico. Coordination with the US Coast Guard, the marine services industry and NOAA will maximize coverage.

Sub-regional Systems

Smaller within-region observing systems exist and can be considered as contributing to the overall regional system.

Coastal Ocean Monitoring and Prediction System (COMPS) is based at the University of South Florida and includes the only Physical Oceanographic Real-Time System (PORTS) facility in the southeast (*http://comps.marine.usf.edu/index.html*). PORTS is a NOAA/NOS CO-OPS program. COMPS utilizes shore stations, coastal moorings with buoys and high frequency radar (HF radar, which measures surface current velocities) to observe the coastal ocean along the WFS. A broad range of variables is measured at the shore stations and offshore moorings. These include those measured by NDBC, plus additional variables at selected sites that may include short -and long-wave radiation, precipitation, water temperature and salinity at multiple depths, current profiles, and various optical properties.

The South Atlantic Bight Synoptic Offshore Observational Network (SABSOON, *http://www.skio.peachnet.edu/research/sabsoon*) is based at a set of offshore Navy air tactical control towers on the Georgia continental shelf. The system hosts a wide range of equipment, similar to COMPS, and includes underwater video used for fisheries studies. Additional nearshore sites off South Carolina and Georgia have been added by from the University of South Carolina and the Georgia Institute of Technology (Savannah campus; *http://wavebuoy.gtrep.gatech.edu*). These systems are focusing on nearshore directional wave measurements.

The North Carolina Coastal Ocean Observing System (NCCOOS, *http://nccoos.unc.edu/*) operates a HF radar system on the Outer Banks and has instrumented one of the Navy platforms off Georgia with meteorological sensors.

The Carolinas Coastal Ocean Observing and Prediction Systems (Caro-COOPS, *http://www.carocoops.org*) operates offshore moorings that report meteorological and ocean conditions and have installed three meteorological and augmented water level stations along the SC and south NC coast that are now considered part of NWLON.

The Coastal Ocean Research and Monitoring Program (CORMP, http://www.cormp.org) has deployed a series of real time weather and sea state buoys off of the NC coast, as well as partnering with Camp Lejune Marine Corp Base and the National Data Buoy Center (NDBC) to deploy a collaborative buoy in Onslow Bay, NC. In addition to the programs noted above, there are several other institutions making real-time observations available. These include the FDEP and a directional wave gauge at Melbourne Beach, Florida (*http://beach13.beaches.fsu.edu/melbourne/melbourne.asp*). Real-time but proprietary observing systems are operated by WeatherFlow (*www.weatherflow.com*) in North Carolina, South Carolina and Florida.

9.3.3 Regional Observing System Information Management

Information Management (IM) is fundamental to the operation of the RCOOS. Establishing a network of local-to-regional-to-national-to-global IM systems will enable the collection, aggregation, accessing, utilization, archival, and dissemination of coastal ocean data and information products. This has been an area of emphasis in Ocean.US IOOS planning. To advance the IOOS Data Management and Communications (DMAC) Subsystem, it will be necessary to establish a coordinated and cooperative network among the various regional systems and the users of IOOS products. New capacities will be needed to establish this network and ensure its functionality at a range of temporal and spatial scales. The IOOS DMAC is envisioned to comprise the following components (described in the first IOOS Development Plan, Ocean.US, 2006).

- *Metadata* -- These data describe data sets for the national system, including development and use of a common vocabulary, identification of required metadata fields, agreement upon sites for publication of metadata, and commitment to publish metadata in a timely fashion.
- *Data Discovery* -- The capacity for searching and locating desired data sets and products and for manipulating accessed data must be established.
- *Data Transport* -- Data and products must be capable of transport over the Internet in a transparent, interoperable manner.
- *On-Line Browse* -- Data must be readily accessed and evaluated through common Web browsers.
- *Data Archive* -- Mechanisms for secure, short-term and long-term data storage must be established.
- *Data Communications* -- The communications infrastructure for accessing and transporting data and data products must be identified and maintained to meet standards.

Regional and sub-regional observing systems in the SECOORA region have established a number of the necessary components described by IOOS DMAC. Where the capability for addressing specific requirements does not yet exist, progress has been made in identifying and characterizing those needs, with a view towards "filling the gaps." In general, efforts focused primarily in SEACOOS, with support from the Carolinas Coastal Ocean Observing and Prediction System (Caro-COOPS), have established a system that enables the aggregation, access, and dissemination of real-time and delayed-mode data from *in situ* observations, model output, and remotely sensed imagery. This aggregation and subsequent visualization of distributed data requires development of a process that can be utilized by other regional and sub-regional systems, and can help the community push towards interoperability. The steps being taken to establish this system of aggregated data include:

- Inventory of existing and potential data types;
- Identification of standard data ontologies, file formats, and transport protocols;

- Software for data applications and for interfacing different applications; e.g., Web mapping;
- Database schemas for the variety of data types.

Experience has shown that an effective approach toward a regional IM system is to engage distributed information providers through standards that promote interoperability. This type of construct has been commonly termed a "services-oriented architecture." Each of the observation and model data providers should be required to adhere to a set of standards and practices that enable information exchange among and between all of the partners. There is also a need to have a central aggregation site or hub that is a clearinghouse for standards and that maintains a database of the aggregated information and/or links to data sources. This central hub need not be physically located in a single location but does require a single presence on the Internet. Given the volume of information involved and the vulnerabilities related to natural and other hazards, it is strongly recommended that at least two physical locations be established that can support the central site activities. Two sites would enable a minimum level of redundancy and fail-over capability in case of interruptions in services.

Thus the design recommendations are that SECOORA should:

- Establish a regional "hub" for RCOOS IM that provides coordination, guidance, and centralized data aggregation, distribution, and storage functions;

- Maintain and strengthen distributed foci of IM expertise at the major observational and modeling sub-system locations. This step will provide in-house management of data, assurance of implementation of standards, and technical support, with assistance from the central hub;

- Establish one or two back-up sites to provide redundancy and ensure continuous operations in case of infrastructure failures at the central hub;

- Establish an agreement with a NOAA archive(s) (e.g., National Ocean Data Center or National Climatic Data Center) for long-term security and archival of observational and model data. Separate regional archives are needed for more "specialized" or region-specific data products (e.g., data aggregations, high-resolution model outputs);

- Identify robust satellite telemetry system(s) for transmission of real-time data, and establish or secure the necessary land-based connectivity and bandwidth for information dissemination;

- Identify appropriate standards with respect to common vocabulary, metadata format and content, metadata publishing protocol, data formats, and transport protocols; and

- Establish a portal that serves as a single site for accessing regional IOOS observational data and model/prediction products, as well as links to other user-targeted portals that utilize/provide specialized treatments of regional data.

9.3.4 Modeling systems

Within an initial build-out plan, the majority of applications envisioned to be served by Observing Systems can provide predictive capabilities through the development of a set of models:

Physical state models. These include models for circulation (3D time-varying representations of coastal ocean currents, sea level, temperature and salinity), waves (2D representation of the surface gravity wave field and sediment transport), and the marine atmosphere (3D time-varying representation of the coastal atmosphere). Enhanced spatial resolution can be provided and/or improved through the nesting of models. The model set includes tidal and storm surge inundation models (separate or components of circulation models) capable of incorporating wetting and drying and that can accurately represent the flooding of lowlands during high-water events (e.g., hurricanes, extra-tropical cyclones).

Biogeochemical and ecosystem models. These must be coupled to circulation models for prediction of nutrient fluxes and the responses of various trophic levels to environmental variability. The existing models are complicated, have many free parameters, and require a broad spectrum of observations to calibrate and validate. It will likely require many years of R&D to develop full operational capabilities in this area.

Socio-economic models. This broad class of models would address a range of topics, including the role of humans in the coastal ocean ecosystem (e.g., changes of land and water use, changes in population distributions), how socio-economic systems may respond to manifestations of climate and global change in the coastal ocean, and the broader implications of alternate management strategies. Some simple implementations exist but development of models that interface and are eventually coupled to physical state and biogeochemical/ecosystem models will also require many years of R&D to develop full operational capabilities.

At present there are no regional scale coastal ocean circulation, storm surge or surface gravity wave modeling activities that enjoy sustained support; the modeling efforts that are sustained are those that occur on a national or ocean basin scale. Existing elements of regional and basin-scale modeling systems that include the US Southeast coastal ocean are outlined below, focusing on components that provide near real-time hindcasts and forecasts of the coastal ocean includes:

HYCOM (*http://www7320.nrlssc.navy.mil/GLBhycom1-12/ATLANTIC.html*)*:* Output from the "toward-operational" HYCOM/GODAE North Atlantic model is available to downscale into regional model domains. The HYCOM products can provide estimates of the regional hydrography, as well as offshore surface elevations due to the proximity of the western boundary current to the continental shelf, on a frequency of once per week.

Though impressive depictions of the basin-scale ocean are possible, the existing implementations are limited to water depths greater than 15 m (and hence do not accurately represent nearshore or inland waters), and do not include tidal forcing. However, these types of basin-scale models are vital because they can provide boundary conditions for coastal models (Figure 6).

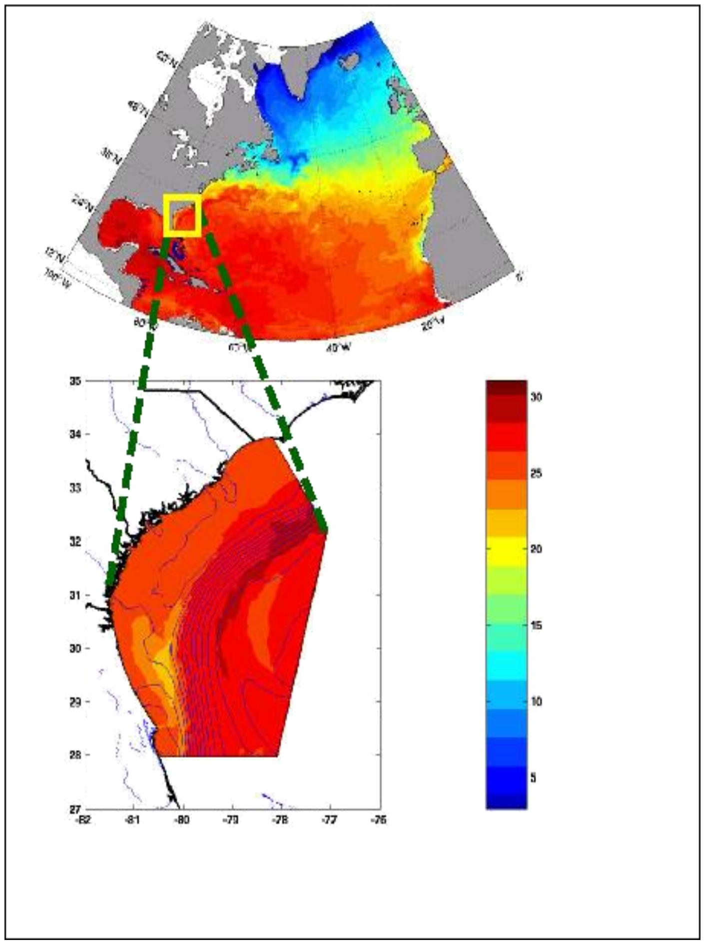

Figure 6. HYCOM model fields can be used as initial and boundary conditions for sub-regional model runs (the SAB in this case). Color scale is surface seawater temperature (˚C).

NLOM & NCOM (*http://www7320.nrlssc.navy.mil/global_nlom/*): An effort by the Naval Research Lab (NRL) Layered Ocean Models (NLOM) generates real-time nowcast/forecast results. Model products relevant to regional applications include sea surface height (SSH), sea surface temperature (SST) and surface currents. The 1/8° global Navy Coastal Ocean Model (NCOM) is an operational product run daily by the Naval Oceanographic Office (NAVOCEANO) with atmospheric forcing from the Navy Operational Global Atmospheric Prediction System (NOGAPS) and assimilation of SST and satellite altimeter data obtained via the NAVOCEANO Altimeter Data Fusion Center. As for the HYCOM model, the NLOM/NCOM forecast fields can be considered in the initialization and forcing of regional model solutions.

RTOFS (*http://polar.ncep.noaa.gov/ofs/*): The Real-Time Ocean Forecast System is based on HYCOM and simulates temperature, salinity, surface elevation, and currents for the North Atlantic. The model is driven at the ocean surface boundary by heat, moisture, and momentum fluxes provided by NCEP's Eta mesoscale atmospheric forecast model.

Next steps in establishing a regional circulation modeling system

Given the present state of development of regional-scale modeling systems for the SE coastal ocean, it is proposed that the initial focus be on creating, testing and operationalizing model systems to predict the physical state of the coastal ocean. The initial three ocean components to be emphasized are circulation modeling, storm surge modeling, and surface gravity wave modeling. There is also a need for regional-scale atmospheric modeling to better incorporate coastal ocean-atmosphere interactions. In all cases, adequate resolution to address specific applications is to be achieved through nesting regional or subregional scale models within national modeling systems. How best to achieve adequate resolution will need to be determined through thorough testing, but at a minimum there should be some redundancy in effort. It is suggested that several modeling groups in each of the modeling component areas be supported initially.

Based on the experiences gained through SEACOOS of operating three subregional-scale circulation models to nowcast coastal ocean conditions, a series of design principles are suggested.

- The importance of simulation experiments (e.g. OSSEs) to aid with the evolving design of the RCOOS should be recognized.
- The diversity of the model/prediction subsystem should be embraced. No one model is sufficient for the range of desired applications and this diversity provides the potential for ensemble forecasting.
- A hierarchical, distributed approach to operational modeling/prediction sub-systems should be followed. For example, Global-NCOM and Atlantic-HYCOM models can be sub-sampled for regional-scale circulation estimation products. Similarly, even higher-resolution local-scale models can use output from sub-regional models for open boundary conditions.
- The RCOOS design should foster the further evolution of modeling/prediction sub-systems. This would include: accommodation of the nesting of very high-resolution inner shelf and estuarine/lagoonal models; the coupling of dynamical models (coastal mesoscale meteorological, coastal hydrological, and coastal wave models); the coupling of (one-way, embedded) applications models (e.g., ecosystem, sediment transport, and wave models); and the utilization of advanced numerical modeling methods (e.g., data assimilation schemes, non-hydrostatic models, and unstructured and adaptive grids).
- The RCOOS modeling program must encompass comprehensive baroclinic operational circulation models (essential for advective and turbulent transport estimates, water quality and ecosystem models) and integrated barotropic operational tide, storm surge, and wave models (essential for coastal inundation estimates, sediment transport models).
- Output from sub-regional model/prediction sub-systems (together with in situ and satellite remote sensing observations) should be directed to sub-regional marine forecast centers. These should be operated in a partnership fashion with the NWS Weather Forecast Offices, value-added industry, media, and academia.

The models needed to predict the physical state of the coastal ocean have information requirements beyond the observations already identified. Access to accurate measures of freshwater fluxes (from rivers, precipitation and groundwater) is needed for the circulation models to accurately represent the mass field. For storm surge modeling, high-resolution bottom and coastal topography is required, registered to appropriate datums and with sufficient spatial resolution to support local emergency management needs. High-resolution bottom topography in the surf zone and nearshore is needed for surface gravity wave models to accurately represent modifications of the wave field near the coastline. Where existing information is lacking (e.g., poor quality bottom topography) the RCOOS can advocate for improvements.

Establishing an Ecosystem Modeling Approach

Ecosystem models are envisioned to describe the variability of nutrient and lower trophic levels (phytoplankton and zooplankton) and their links to target fish species in the SECOORA region. These activities will support the regional move to Ecosystem Based Fisheries Management as directed by the President's Ocean Action Plan and embraced by the South Atlantic Fishery Management Council's (SAFMC) Fishery Ecosystem Plan. One target fish species could be Gag (*Mycteroperca microlepis*) and is a member of the grouper family in the snapper/grouper complex managed by the SAFMC. (See below for a list of other target species to be considered.) Gag has high commercial and recreational fishery value; and its distribution ranges throughout the SECOORA region ranging from the continental shelf and shelf-edge, into the nearshore and estuarine regions. As such it requires integration across all SECOORA assets, to obtain sufficient information to aid the SAFMC in its assessments.

Considering gag as an example, a modeling approach would require that both abiotic and biotic effects be considered. The role of circulation on gag recruitment would be evaluated, including the effect of on- and offshore positions of the deep ocean currents (e.g., the Gulf Stream) on the transport of larvae from their spawning locations to the mid-shelf, where a combination of wind- and tidal currents modulated by larval behaviors, subsequently carries them to their juvenile estuarine habitats. Additionally the development and implementation of a suite of ecosystem models ranging from point- to 3D formulations, including uncoupled or dynamic linkages between lower and higher trophic levels.

Anticipated specific tasks include:

<u>Obtain hydrodynamic fields.</u> The fields need to be computed at ecologically relevant space and time scales to characterize the flow field in the SECOORA region relevant to the transport (dispersal and retention) of gag larvae from offshore spawning locations to estuarine nursery areas. The 3D circulation fields will be spatially and temporally comprehensive fields, including offshore forcing, meanders, gyres and upwelling events. Downscaling to "ecological hotspots", e.g., individual reefs or inlets will proceed with local higher resolution models forced by boundary conditions derived from the domain-wide circulation.

<u>Formulation of spawning model and model seeding.</u> Gag spawning aggregation sites have been identified throughout most of SECOORA's offshore/shelf edge regions at shelf break sites

between the 50-100 m isobaths. Spawning will be specified to occur over time based on hatch date distributions, and model runs will determine the temporal and spatial trajectories of particles onto the shelf and near-inlet regions.

Adapt Lower Trophic Level models (LTLs) to the SECOORA region. Presently there are no LTLs for the southeast Atlantic ecosystem. They need to be developed to represent the main phytoplanktonic and zooplanktonic groups in SECOORA, beginning with point models and building complexity to include the full 3D structure embedded in existing realistic circulation models. Computation of monthly-to-seasonal-to-yearly descriptions of the SECOORA region would serve as a baseline against which longer (interannual) variability can be assessed.

Develop a conceptual model of the food web. Characterize primary production in region for incorporation into Ecosystem models (e.g., Ecopath and Ecosim).

Combine circulation and LTL nowcast-forecast system. Combined with the circulation fields, the ecosystem model will provide short-term forecasts of oceanographic fields. This information will refine Essential Fish Habitat designations intended to reduce or eliminate the impact of fishing and non-fishing activities on habitats essential to managed species and their prey as federally mandated.

Recruitment forecasts. Development of nowcasting capabilities of the oceanographic and ecosystem models and provide relevant information for use in the South-East Data, Assessment, and Review (SEDAR) recruitment forecast process. Our model results will be used in the SEDAR process in its gag stock assessment for the region.

Other potential target species for the US Southeast Atlantic Coastal Ocean.

1. ***Reef fishes in general, Gag and Red Grouper in particular:*** Gag Grouper (and other reef fishes) spend their adult lives offshore and their juvenile phases in nearshore and inshore seagrass beds or oyster reefs. Evidence exists on adult spawning regions (shelf break) and times (late winter to spring) as well as on the juvenile settlement times (late spring to summer). However, the 3D pathways and mechanisms by which the larvae transit to settlement, both of these being significant factors in larval survival and recruitment, remain to be determined.
2. ***Shallow and Deep coral reefs:*** habitat characterization and restoration of shallow coral reefs, as well as deep *Oculina* and *Lophelia* coral reefs require understanding the physical and biological processes determining the environment at the shelf-edge, over the shelf, and near the coast, including the importance of self-seeding, sensitivity to changes in feeding and hydrographic fields, connectivity with other parts of a larger ecosystem, regional water quality, etc.
3. ***Interactions and linkages between various populations; scallops in particular:*** Bivalves such as scallops and other commercial species are not distributed uniformly along the coast. Are there relationships between species distributions and the seasonally varying currents and other physical factors such as temperature and salinity? Are there significant inter-annual variations that impact these population linkages and resultant abundances?
4. ***Forage species and their role in supporting pelagic species biomass:*** Pelagic fishes depend on the abundances and distributions of smaller forage species. What environmental factors control the abundances and distributions of the forage species and thus the migrations/distributions of the

pelagic species?

5. ***Species life history for those fish that spend part of their life in the estuaries and part offshore, i.e., estuarine-dependent species such as mullet, menhaden, spot, flounder, croaker, gag, gray snapper, Spanish mackerel, etc.:*** Specific pathways (to be determined) exist between the major estuaries and the coastal ocean that depend on buoyancy (salinity in particular), winds and tides. Mullet, menhaden and others may be target species; however, this topic pertains to many commercially and recreationally important species. Modeling and observational tools presently exist to make this a tractable problem for scientific investigation.
1. ***The benthic connection, e.g., shrimp:*** Three-dimensional studies must include the benthos since the bottom boundary layer likely provides an important connection in the general pathways/mechanisms framework. Hence primary and secondary productivity within the bottom boundary layer is likely important for the higher trophic levels considered above. Shrimp, as a commercially important species provides a focus.

9.4 Ecosystem Modeling

9.4.1 South Atlantic Ecopath Model

An Ecopath model is a quantitative description of energy flows in a food web. The model creates a static, mass-balanced snapshot of the resources in an ecosystem and their interactions, represented by trophically linked functional groupings. These groupings consist of a single or multiple species representing ecological guilds. The model is constructed by defining a model area and time, organizing species (and detritus) into the above mentioned functional groupings, and estimating the biological (i.e., energy) characteristics of each grouping. Ecopath models and their defined components are then 'balanced' in terms of mass or energy to gain insights into an ecosystem and its biotic components, and to obtain a whole-system view of the biological community. The Ecopath mass-balance approach was initially developed by Polovina (1984). Since that initial application, over 100 Ecopath models have been constructed, mostly in marine ecosystems, and the approach has been refined considerably.

Ecopath models can be analyzed in their static form (Christensen and Pauly 1992), but the dynamic simulation routines Ecosim and Ecospace (Walters et al. 1997, Walters et al. 1999) have expanded the utility of the approach considerably. These dynamic routines use the information in an Ecopath model to simulate how a the ecosystem's biota would respond to changes in fisheries harvest strategies or disturbance regimes (Ecosim). Such analyses can also be conducted in a habitat-based context (Ecospace). Ecosim also enables exploration of social, economic, and ecological trade-offs in harvest strategies.

These complimentary approaches, Ecopath and Ecosim, provide a rigorous and relatively simple framework to provide testable insights into the causes of ecosystem changes. Most importantly, they can be used to implement ecosystem-based management by aiding in the design of policies that account for indirect impacts of human activities. The relative importance of factors that shape communities can be explored by comparing (temporal and spatial) simulations to empirical information about such changes. Simulation results are often consistent with ecological theory (Christensen 1995, Vasconcellos et al. 1997), but they can be even more useful when simulation results are counterintuitive. Either way, Ecopath with Ecosim analyses can provide useful insights into marine ecosystem organization and functioning.

Physical forces are not explicitly included in Ecopath models, though they can be included in the Ecosim routine to distinguish their role from that of trophic forces. Approaches such as physical forcing, trophic mediation, and time-series fitting are available to compare and combine simulated biological and physical forces.
These approaches are discussed by Christensen et al. (2000).

Ecopath models are never final because ecosystem knowledge is never complete. The usefulness of such models can improve considerably, however, through iterative combinations of simulation and empirical research in a whole ecosystem context (Pauly et al. 2000).

The Ecopath master equation
The parameters necessary for the construction of an Ecopath model are found in the Ecopath master equation (Equation 1.1):

$$Bi \cdot (P/B)i \cdot EEi = Yi + \sum Bj \cdot (Q/B)j \cdot DCji + BAi + NMi \qquad \text{Equation 1.1}$$

where,
Bi and Bj = biomasses of prey (i) and predators (j) respectively;
P/Bi = production / biomass; equivalent to total mortality (Z) in most circumstances (Allen 1971);
EEi = ecotrophic efficiency; the fraction of the total production of a group that is utilized in the system;
Yi = fisheries catch per unit area and time (i.e., Y = F*B);
Q/Bj = food consumption per unit biomass of j; and
DCji = contribution of i to the diet of j;
BAi = biomass accumulation of i (positive or negative);
NMi = net migration of i (emigration less immigration).

This equation expresses a balance between a group's net production (terms to the left of the equal sign) with all sources of its mortality (terms to the right). It states that the net production of a functional group equals the sum of (1) the total mass (or energy) removed by predators and fisheries, (2) the group's total natural senescence (i.e., flow to detritus), (3) the net biomass accumulation of the group, and (4) the net migration of the group's biomass.

The thermodynamic constraints implied by Equation 1.1 underscore the power of Ecopath models as a focal point for refinement of ecosystem information. The need to reconcile energy production and demand among components of the food web narrows the possible ranges of parameter estimates for particular groups.

The law of conservation of mass or energy is expressed in this master equation, but the biomass accumulation and migration terms distinguishes this 'energy continuity' approach from a strictly 'steady state' approach. This basic 'continuity' constraint enables representation of changes in populations (i.e., functional groups) when expressed in dynamic form (not discussed here).

Because the Ecopath model of the entire system is a set of these linear (master) equations solved simultaneously, the Ecopath routine can solve for any of the four basic input parameters; B, P/B, Q/B, and EE (Christensen and Pauly 1992). These along with diet compositions, are the main parameters derived. Other information such as spatial and temporal distributions, habitat preferences, assimilation efficiencies, detritus fate, and other pertinent information are also covered in these parameter estimation sections.

Development of the South Atlantic Bight Ecopath Model
A preliminary South Atlantic Bight Ecopath model (Okey and Pugliese, 2001) was developed as part of the Sea Around Us project funded through the PEW Charitable Trust Foundation.

This preliminary Ecopath model covered the area from Cape Hatteras in North Carolina to the easternmost extent of the Florida Keys, and from the intertidal and the entrance of estuarine systems to the 500 m isobath. The time period characterized by this preliminary model is four years during in the late 1990s (1995-1998). The area covered was estimated to be 174,300 km^2. The slope of the sea floor steepens seaward of the 200 m isobath (and sometimes shallower); for example, the area delineated by the 200 m isobath is estimated to be 133,300 km^2, which is only 24% less than the area delineated by the 500 m isobath.

Four main sources were used to assemble the list of over 600 species for the area covered by the initial model: summary data from the Southeast Area Monitoring and Assessment Program (SEAMAP) including a species list reviewed by SEAMAP personnel (P. Webster), the National Marine Fisheries Service (NMFS) commercial and recreational fish landings for North Carolina, South Carolina, Georgia, and the east coast of
Florida (www.st.nmfs.gov/st1/); a species list developed for the West Florida Shelf system (Mackinson et al. 2000); the NMFS marine mammal stock assessments; and two sea turtle the web sites; www.nmfs.noaa.gov/prot_res/PR3/Turtles/turtles.html and www.cccturtle.org/species.htm.

A semi-systematic approach was taken to aggregate all species into 42 functional groups. This was accomplished by organizing the list of species into groupings that were based on the functional roles of the species. Usually, this was operationally defined by diet compositions, but also by natural history characteristics. Special groups in the model included groups managed under a federal fishery management plan and fish groups for which commercial or recreational landings exceeded 200 tonnes in any of the states within each area. Specialists were consulted to identify groups of special concern (e.g., baleen whales).

This preliminary Ecopath model of the South Atlantic continental shelf was constructed to provide a quantitative framework for the refinement of the model's input parameters so that a cohesive view of the whole marine ecosystem could emerge, and so that system-wide questions about the workings of the system could be explored. This model constituted a focal point for scrutiny and criticism of input parameters, and thus acted the foundation for further refinement and expansion. The refined model, will be expanded to cover the area that coincides with the South Atlantic Council's jurisdiction, i.e. from the NC/VA border through the Florida Keys, and from the upper reaches of wetlands to the 300 m isobath.

Procedure for model construction

Thomas A. Okey
CSRIO

Procedures for deriving model input parameters and constructing Ecopath models include literature reviews, empirical studies, or coordinated approaches by broad collaborations of experts (e.g., Okey and Pauly 1999). The South Atlantic Bight model was constructed by a core group of researchers based on contributions by expert collaborators. These regional and topical experts contributed written sections to this compendium describing basic parameter derivations for each functional group. Inputs to this model were based on the latest available information on the entire suite of biotic components of the South Atlantic Bight.

Eight steps can be taken to construct an Ecopath model:
1. Define the ecosystem in space and time – the spatial extent of the system and the represented time period must be clearly defined. Parameter estimates are expressed in annual units, but any time period can be represented.

2. Define functional groups – Myriad species comprise interaction webs, but these species must be aggregated into related groupings that make sense in terms of ecological function, and the types of questions of interest.

3. Estimate basic parameters for each functional group. These parameters are listed and documenting these derivations makes up the bulk of this chapter.

4. Estimate fisheries information – Landings, discards, discard fates, and economic information can be entered for each fisheries gear type.

5. Estimate additional Ecopath parameters – detritus fates, assimilation rates, multiyear trends, spatial and temporal distributions, and habitat associations.

6. Enter parameters into the windows-based input interfaces (see www.Ecopath.org).

7. Characterize model pedigree by ranking parameter quality (i.e., confidence).

8. Balance the model according to thermodynamic constraints.

The biological components of the ecosystem are generally represented in Ecopath using average values, or other meaningful measures of central tendency that take into account both annual (seasonal) changes and ontogenetic changes. Production rates, consumption rates, and diet compositions vary among seasons and life history stages for most species in aquatic systems. However, explicit inclusion of seasonal information into Ecopath with Ecosim modeling merely makes answers messy rather than changing the basic results of analyses (based on experience with a large number of Ecopath models; C. Walters, UBC Fisheries Centre, personal communication.).

Ontogenetic changes can be incorporated using Ecopath with Ecosim using two approaches. First, groups can be split into adult and juvenile 'pools' that are linked through and age structured growth and recruitment parameters; Second, numerous ontogenetic 'stanzas' can be specified for an integrated calculation of a given Ecopath parameter. This latter approach in particular enables real-time incorporation of variable growth, production, or consumption models into the representation of Ecopath parameters (C. Walters, UBC Fisheries Centre, personal communication).

Still, the assumption of 'average' representation of parameters is a useful convenience for modeling at the scale of entire systems because these values describe the basic interaction and energy structure of a food web. 'Energy continuity' offers a powerful mass-balance-type constraint to model parameterization and construction. Section X describes the balancing methodology employed for the South Atlantic Bight model.

Additional parameters
Steven Mackinson
CEFAS Fisheries Lab, Lowestoft, UK

(i) Unassimilated / Consumption
Only a fraction of the food eaten by organisms is assimilated to the body; non-assimilated food is expelled. Proportions of unassimilated food must be specified in Ecopath, and this fraction flows to specified detritus pools. A default value of 0.2 was used for carnivorous fish groups (Winberg 1960) since assimilation efficiency information for particular fish species was scarce. This means that 80% of the food was considered assimilated. Values of 0.4 and 0.3 were applied to herbivores and planktivores since these groups preying on harder-to-digest food.

(ii) Detritus Fate
The fate of detritus is the defined pool of detritus that unassimilated food and dead organisms are specified to flow in to. A portion of the dead and decaying animals falling through the water column (including fishery discards) is directed to 'dead carcasses.'
The specific proportions are assumed based on a subjective judgment relating to the habitat and niche of the various organisms (Appendix 2). The majority of detritus from non-assimilated food is directed to water column detritus and sediment detritus, but these ratios vary depending on the types of organisms. Approximately 50% of the detritus from birds is considered to be exported from the system (i.e., corpses and feces end up on land). All dead and decaying macroalgae and seagrasses contribute to the drift macrophytes detritus pool. Ultimately, detritus from the 4 detritus groups flow to the sediment detritus pool which is then exported from the system as sediment detritus is buried and rendered unavailable to the system.

"Balancing" the model
Steven Mackinson
CEFAS Fisheries Lab, Lowestoft, UK
Thomas A. Okey
University of British Columbia, Fisheries Centre

Ecopath models must be 'balanced' in the sense of achieving continuity among energy fluxes in the defined ecosystem, not in the sense of 'static equilibrium.' Continuity of energy fluxes must likewise be achieved for each particular group within the overall system.

Because an attempt is made to account for all fluxes, Ecopath models do not inherently assume 'steady state.' If the total combined demand of energy on a particular group exceeds the production of that group (plus the energy needed for respiration), the group is commonly said to be out of 'balance,' in the sense of energy discontinuity. Ecopath models constructed with good information for most or all components in a system tend to require minimal 'balancing.' This is because energy continuity is a true property of real world ecosystems.

The degree of discontinuity, or "imbalance," in each functional group is revealed by the calculated 'ecotrophic efficiency' values. Ecotrophic efficiency (EE) is the proportion of the net production of a group that is consumed by predators or fisheries (or directly exported). These EE terms are calculated after initial input parameters have been derived and entered. An ecotrophic efficiency value of greater than one is impossible, as it indicates that total energy demand on a functional group exceeds total production and maintenance of that group. EE values greater than one are thus used as diagnostic indicators of model discontinuity or "imbalance." This is the handle for balancing, and changes in these values are monitored while adjusting model inputs.

Model balancing strategies

Strategic approaches are implemented when balancing Ecopath models to optimize the representation of the system, and to avoid erosion of contributed information. For example, adjustments to input parameters are best made after prioritization according to 'degree of imbalance,' 'quality of estimates,' or other criteria applicable to the system at hand. The quality of estimates can be characterized by specified confidence bounds for each parameter or by ranking the data 'pedigree' of parameters.

Some experienced Ecopath modelers suggest that model balancing should focus on diet composition adjustments because diet composition data tends to be very high relative to other parameters (V. Christensen, UBC Fisheries Centre, personal communication). However, this relative uncertainty among parameters should be assessed on a case-specific basis. Indeed, for some functional groups, the uncertainty of input parameter estimates such as biomass might rival or surpass uncertainties associated with diet compositions. Finally, model users can introduce bias into the model through a one sided approach to balancing. For example, a model can be erroneously inflated by increasing prey biomasses, or production rates, or both, rather than taking a balanced approach by including the reduction of predator consumption rates, or by re-allocating diet compositions.

Commonly, 'top-down' balancing strategies have been applied to balancing Ecopath models, in that the production and/or biomass estimates of lower trophic levels (where uncertainty can be more common) is increased to meet the demands of upper trophic levels. The result of such a method is that the biomass or production rates at the lower trophic levels can be inflated unrealistically to achieve a balanced model (T. Dean in Okey and Pauly 1999). Clearly, such a result is unrealistic and this potential interjection of bias points to the need to make a conscious effort to apply a more evenhanded approach during balancing. Not only should the accounts tally, but more importantly they should stay within the specified bounds of confidence and make intuitive sense in terms of ecological interactions. The fundamental importance of the balancing procedure as a crucial bridge to the ecology of a system must be emphasized to users who might otherwise view the balancing step as merely a necessary technical modeling procedure.

Parameter pedigree assessment

Parameter 'pedigree' index values can be assigned to each input parameter of an Ecopath model. Ecopath's parameter pedigree routine is an approach to convert qualitative rankings of parameter quality to quantitative confidence intervals. The output of this routine can be used during manual balancing, automated balancing and analysis routines, such as the Monte Carlo routine 'Ecoranger,' or in meta-analyses that compare various models in terms of relationships between model attributes and overall data pedigree. Assigning pedigree values to functional groups whose parameters are derived from combined estimates from many data sources of varying quality is a subjective task, but nevertheless instructive. In a more general sense, it is informative to future users of the model to be as explicit as possible about the level of confidence in input parameters. The parameter pedigree routine thus enhances model transparency beyond a description of parameter derivation. The pedigree index value represents the quality or relative confidence assigned to each parameter estimate.

9.5 Indicators of Ecosystem Health and Habitat Conservation Targets

(Source: SARP Aquatic Habitat Plan, SARP, 2008)

The National Coastal Condition Report II (NCCR II) (USEPA 2004) utilized data from the EPA's National Coastal Assessment (NCA), which gathers data on biota and environmental stressors; NOAA's National Standards and Trends Program, which utilizes site-specific data on toxic contaminants and their ecological effects; and the Fish and Wildlife Service's National Wetlands inventory (NWI), which provides information on the status of the nation's wetlands. In the NCCR II, five primary indices were developed using these data sources for (1) water quality, (2) sediment quality, (3) benthic habitat quality, (4) coastal wetlands and (5) fish tissue contaminants. Although these indices do not address all characteristics of estuaries and coastal waters, they do provide

information on ecological conditions. Characterizing coastal condition was a two-step process. The first step was to assess conditions at individual sites for each indicator. In the second step a regional rating for each indicator using a scale of five (1= poor, 2-4 = fair, 5 = good) was determined, based on the percentage of the area of each region in a given condition. The mean of the indices for the five indicators was then calculated to yield an overall condition index for each region. Using these indices, the NCCR II found that the overall condition for the Southeast Coast estuaries North Carolina, South Carolina, Georgia and east Florida coasts) was 3.8, and for the Gulf Coast estuaries,

2.4. Although the more recent National Estuary Program Coastal Condition Report (USEPA 2006) also assessed estuarine condition for these same regions using this process, only four of the five indicators were used.

9.5.1 National Fish Habitat Action Plan

The National Fish Habitat Action Plan is addressing a crisis for fish nationwide: loss and degradation of aquatic habitats. The plan was initiated in 2001 through the efforts of the Sport Fishing and Boating Partnership Council to explore development of a partnership effort for fish similar to that implemented for waterfowl in the 1980s through the North American Waterfowl Management Plan. The waterfowl plan has been cited as the mechanism that, over the past two decades, has given rise to the boost in waterfowl populations by forming strong local and regional partnerships to protect key habitats.

In 2004 the International Association of Fish and Wildlife Agencies, which represents all state wildlife agencies, voted to lead the National Fish Habitat Action Plan with the U.S. Fish and Wildlife Service and NOAA Fisheries as principal Federal partners.

The plan is bringing together fisheries professionals and partners with a shared interest in protecting, restoring and enhancing our waterways and fisheries. The strength of the National effort is the unique and diverse blend of industry, government, tribal, academic, and conservation groups and individuals with a determination to focus national attention and resources on restoring fish habitats.

The Action Plan will be implemented through the following four strategies which together will lead to results that can be measured against protection, restoration and enhancement goals: 1) Support existing fish habitat partnerships and foster new efforts; 2) Mobilize and focus national and local support for achieving fish habitat conservation goals; 3) Measure and communicate the status and needs of aquatic habitats; and 4) Provide national leadership and coordination to conserve fish habitats.

9.5.2 National Fish Habitat Board

The National Fish Habitat Board which held its inaugural meeting on September 22, 2006, is charged with leading the implementation of the National Fish Habitat Action Plan. The Board includes representatives of outdoor industries, federal, regional and state natural resource agencies, Native American tribes, and conservation and recreation organizations.

The Board has met five times since its formation in 2006 and is closely coordinating with a Federal Caucus of nearly 20 federal agencies that are in the process of realigning priorities and resources to better support the plan. The Association of Fish and Wildlife Agencies is identified as a lead participant ensuring state agencies are well represented. The Board is addressing the criteria and process for formal recognition of Fish Habitat Partnerships which are the basic work units of the Action Plan. As the National Fish Habitat Action Plan is modeled after the North American Waterfowl Management Plan, the establishment of Fish Habitat Partnerships is integral to its success in protecting, restoring and enhancing fish and aquatic habitats. Board recognition as a Fish Habitat Partnership will be contingent upon meeting criteria that identify strong and diverse partnerships, work within a defined geographic focus, remain strategic and consistent with national goals, and contain the potential for measurable progress. In addition, each Fish Habitat Partnership will be expected to implement the National Fish Habitat Action Plan under the guidance from the board. Guidance for Establishing Fish Habitat Partnerships

9.5.3 Southeast Aquatic Resources Partnership Habitat/Ecosystem Conservation Targets

The Southeast Aquatic Resources Partnership (SARP) was initiated in 2001 to address issues related to the management of aquatic resources in the southeastern U.S.
These issues include significant threats to the aquatic resources and habitats of the Southeast.

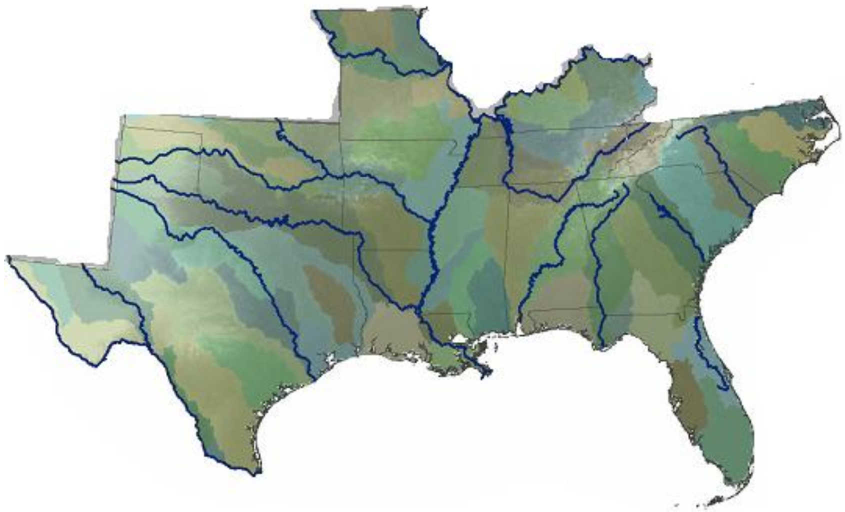

Figure 7. Watersheds and Marine Habitats Encompassed by the Southeast Aquatic Resources Partnership (SARP).

SARP is one of five Fish Habitat Partnerships named by the National Fish Habitat Action Plan and endorsed recently by the National Fish Habitat Board. As the regional partnership in the Southeast, SARP provides a method for state, regional and federal agencies, conservation groups, tribes, landowners, industry, and the public to interact in the development of regional aquatic habitat priorities and the implementation of projects to address those priorities. This partnership envisions a southeastern United States with healthy and diverse aquatic ecosystems that support sustainable public use. Relationships have developed between State and Federal agencies, private organizations, conservation groups, and other regional stakeholders that extend beyond the traditional boundaries of aquatic resource management agencies and establish a commitment to truly work together for the benefit of the resource. SARP is currently developing a regional aquatic habitat plan for the Southeast that will help guide the implementation of the National Fish Habitat Initiative efforts on a regional scale. Pilot watershed conservation action plans have already been developed for four major southeast river systems (Duck River, TN, Roanoke River, NC, Altamaha River, GA and Pascagoula River, MS) that detail specific actions to improve and protect aquatic habitats and biological integrity in these systems. SARP actively seeks funding and local partners to implement specific local actions that are prioritized on a regional and national scale.

The South Atlantic Fishery Management Council as a member of SARP, supports the implementation of aquatic habitat conservation and restoration projects including those proposed through the newly designated NOAA Community-based Restoration Program (CRP) run through SARP. The Council views this partnership as an effective mechanism to accomplish the National Fish Habitat Initiative's National Fish Habitat Action Plan goals on a regional scale in our coastal watersheds. The commitment of our federal and regional partners to work closely with the states is critical to achieving the National Fish Habitat Action Plan. The Council envisions the state habitat conservation recommendations included in the Fishery Ecosystem Plan for the South Atlantic region will serve as or expand on the South Atlantic portion of the SARPs Southeast Aquatic Habitat Plan (SAHP) to present recommendations on conservation, management and restoration of Essential Fish Habitat down to individual watersheds where possible.

Drawing on the technical expertise of regional ecosystem partners involved in the development of the Fishery Ecosystem Plan and on the recommendations presented in the FEP the SARP/NOAA partnership will find support in identifying, selecting and implementing coastal habitat restoration projects in the South Atlantic region.

SARP provides an excellent opportunity to strengthen federal-state partnership for implementation of projects that directly benefit living marine resources and to engage coastal communities throughout the Southeast. A fully realized SARP supported with enhanced funding through the National Fish Habitat Plan will achieve conservation of high priority fish habitat (including Essential Fish Habitat). This effort will be enhanced especially if South Atlantic State and regional conservation recommendations and projects are presented in both the Fishery Ecosystem Plan for the South Atlantic Region and SARP's Aquatic Habitat Plan.

9.5.4 Synergy of National and Regional Habitat Conservation and Ecosystem Based-Management

In addressing the habitat directives established by the Magnuson-Stevens Fishery Conservation and Management Act, the South Atlantic Fishery Management Council designated many priority aquatic fish habitats occurring primarily in State waters as Essential Fish Habitat or Essential Fish Habitat Areas of Particular Concern for federally managed species. The Council's Fishery Ecosystem Plan for the South Atlantic Region will bridge the gap between State and regional needs by highlighting priorities (to watershed where possible) for South Atlantic States developed with input from State Sub-Panels of the Council's Habitat and Environmental Protection Advisory Panel.
In addressing the directive of the National Habitat Plan, National Habitat Board, SARP has developed the Aquatic Habitat Plan to facilitate regional coordination on meeting high priority habitat conservation and restoration goals. Funded projects in South Atlantic watersheds from the headwaters of the rivers to the coastal ocean will support and facilitate conservation of Essential Fish Habitat and enhance biological, economic and social values provide by a healthy ecosystem structure and function in the region.

9.5.5 Southeast Aquatic Habitat Plan

SARP is developing a Southeast Aquatic Habitat Plan to identify regional priorities for aquatic habitat conservation and restoration, and facilitate action at the local level that addresses regional and national priorities. The development of the Southeast Aquatic Habitat Plan is currently underway with two of four pilot river basin conservation plans initially developed to serve as models for the development of a complete regional plan The Altamaha Watershed Report and

The Roanoke River Watershed Report are in the South Atlantic. Workshops were held by SARP in October 2006 and April 2007 to gain stakeholder input on the technical aspects of the Plan and develop the implementation and partnership aspects of the plan. The following public draft with stated conservation targets, was finalized in March 2008.

Southeast Aquatic Habitat Plan
Southeast Aquatic Resources Partnership - April 2008

This document was prepared by the Habitat Subcommittee of the partnership known as the Southeast Aquatic Resources Partnership (SARP). It was funded by the Multistate Conservation Grant Program (Grant GA M-1-P), a program supported with funds from the Wildlife and Sport Fish Restoration Program and jointly managed by the association of Fish and Wildlife Agencies and the U.S. Fish and Wildlife Service, 2007.

SARP was formed in 2001 to address the here-to-fore uncoordinated management of aquatic resource issues in the southeastern United States. It is a voluntary collaboration of natural resource managers and professionals, both inland and coastal, working together to protect, conserve and restore aquatic resources throughout the Southeast. The core members of the partnership include the natural resource agencies in Alabama, Arkansas, Florida, Georgia, Kentucky, Louisiana, Mississippi, Missouri, North Carolina, Oklahoma, South Carolina, Tennessee, Texas and Virginia, the U.S. Fish and Wildlife Service, National Oceanic and Atmospheric Administration National Marine Fisheries Service, the Gulf States Marine Fisheries Commission, the Atlantic States Fisheries Commission, and the Gulf and South Atlantic Fishery Management Councils. Nongovernmental organizations, industries and private citizens with goals and objectives that parallel those of the SARP member agencies participate in the partnership as well.

The plan was developed as a joint effort of all the member agencies and partners of SARP plus many other stakeholders throughout the region. It is broad and regional in nature, given the geographic and biological range of SARP's 14 member states.

SARP is recognized as an official partnership of the National Fish Habitat Initiative to implement its Action Plan (NFHAP) to conserve inland and coastal fishery habitats throughout the nation. This plan will be support NFHI restoration projects in the Southeast.

For additional information about SARP, see http://www.sarpaquatic.org, and on NFHI, see http://www.fishhabitat.org.

Because this is a regional plan, the targets to quantitatively and qualitatively evaluate progress towards achievement of objectives are based upon the best available data at the regional level from scientifically respected sources. The majority of the data came from reports by the U.S. Environmental Protection Agency and the H. John Heinz III Center for Science, Economics and the Environment.

Executive Summary

Habitats are the cornerstones of wildlife resources and provide the necessary food, water, shelter and space for plants, animals, and other organisms to thrive. The southeastern United States harbors a diversity of aquatic habitats and species unparalleled in the nation, and the states of the Southeast Aquatic Resources Partnership (SARP) – Alabama, Arkansas, Florida, Georgia, Kentucky, Louisiana, Missouri, Mississippi, North Carolina, Oklahoma, South Carolina, Tennessee, Texas, and Virginia – have recognized the importance of protecting habitats found in this region.

The quality and quantity of these spectacular and valuable aquatic resources have been in decline since European colonization. Deteriorating and disappearing habitats have led to reductions in biodiversity, as well as critical declines in some plant and animal populations. The problems and issues leading to these circumstances have many sources, natural and human-induced. Ongoing research is identifying new sources, like climate change, every day.

Government agencies, private organizations, businesses, and citizens recognize the value of aquatic resources and work every day to conserve aquatic habitats independently on state and local scales. By addressing aquatic habitat conservation at the regional and national scales, SARP will increase the effectiveness of individual efforts and bring greater funding and public support to aquatic habitat conservation.

During 2005, the SARP Aquatic Habitat Conservation Work Group sponsored research projects in four representative, geographically separate southeastern watersheds. Assessments of these ecosystems yielded much information about various aquatic habitats, and identified similarities and differences in the problems and issues plaguing them. The results of these studies on the Duck, Altamaha, Pascagoula and Roanoke watersheds led to development of this Southeast Aquatic Habitat Plan (the Plan). State Wildlife Action Plans (also known as Comprehensive Wildlife Action Strategies) provided a great deal of background and reference information for it, and the simultaneous development of the National Fish Action Plan (NFHAP) provided an opportunity to coordinate regional conservation and restoration efforts nationally. SARP is recognized as an official partnership to implement the National Fish Habitat Action Plan (NFHAP).

This science-based, landscape-style system for habitat conservation seeks to effectively apply limited resources to priority areas on a regional basis in order to reverse current trends and protect the Southeast's aquatic resources well into the future. The purpose of the Plan is to maintain, restore, and conserve the quantity and quality of freshwater, estuarine, and marine habitats to support healthy, sustainable fish and aquatic communities and sustain public use for the benefit of all in the southeastern region and the entire U.S. In order to achieve this goal, multiple projects at many different levels will focus on eight objectives:

Objective 1: *Establish, improve and maintain riparian zones*
Objective 2: *Improve or maintain water quality*
Objective 3: *Improve or maintain watershed connectivity*
Objective 4: *Improve or maintain appropriate hydrologic conditions for the support of biota in aquatic Systems*

Objective 5: *Establish, improve or maintain appropriate sediment flows*
Objective 6. *Maintain and restore physical habitat in freshwater systems*
Objective 7: *Restore or improve the ecological balance in habitats negatively affected by nonindigenous invasive or problem species*
Objective 8: *Conserve, restore, and create coastal estuarine and marine habitats*

The Plan is a living document, focused on adaptive management. It will be revised utilizing lessons and data from every project. For this initial version of the Plan, objectives are based on the major aquatic habitat types and attributes in the Southeast, focusing on broad indicators of habitat integrity, function and overall ecosystem health. Objectives and regional targets have been developed using the best available scientific data. These are described in detail in Section 2 of the Plan. Additional data and tools, currently under development, will assist SARP's adaptive management process of updating and maximizing the outcomes of this Plan.

Because of the size and variety of habitats in the southeastern region, habitat conservation needs are varied and spread out. In order to effectively use limited resources to reverse current trends and conserve the region's aquatic habitats, geographic priorities must be set periodically. Several tools will play a role in the prioritization process. In the long term, the implementation of the National Fish Habitat Science and Data Committee's assessment tool will allow a science-based approach for prioritizing aquatic habitat conservation and restoration projects nationwide. This assessment tool will help SARP refine its geographic priorities. SARP is developing a geo-referenced database with aquatic system condition data to help identify geographic priorities at a regional scale for the Plan. Details about this adaptive prioritization process are included in Section 3.

Conservation and restoration of specific aquatic habitats will be accomplished through many projects, utilizing implementation strategies to address location, threats, problems and issues. SARP members will be engaged in many of these projects, directly addressing the Objectives and Targets in Section 2, in partnership with other entities. However, effective implementation of the Plan depends upon SARP's collective management and facilitation at an integrated systems level. While on-the-ground projects will focus on the goal and one or more of the eight objectives, SARP must integrate and coordinate these projects to maximize outcomes and leverage dollars. To that end, stakeholders provided four strategies for SARP to integrate habitat conservation projects throughout the region. These four strategies are:

Integrated Conservation Strategy 1: *Information collection and dispersal*
Integrated Conservation Strategy 2: *Capacity building*
Integrated Conservation Strategy 3: *Management and restoration*
Integrated Conservation Strategy 4: *Law and policy.*

Details about each of these strategies are found in Section 4.

Monitoring will contribute to an understanding of the complex ecological systems within which the Plan's conservation and restoration projects are implemented. Analysis of these data will help SARP identify areas of habitat improvement and establish a record of conditions and trends. These data can also warn SARP of environmental decline, and identify gaps in existing scientific knowledge. Monitoring will provide the basis for a rigorous review of habitat project planning and implementation to determine whether project results are being achieved and if mid-course corrections are needed. Monitoring and evaluation will be conducted on two levels in order to assess the Plan's performance and each project's performance towards improving or sustaining the Southeast's aquatic habitats. Monitoring to provide data for both levels will be built into all projects at the planning stage. GIS-based data will play a large role in monitoring and evaluation and will be used along with other monitoring processes. Details about monitoring and evaluation are found in Section 5.

When SARP was established in 2001, members identified six areas upon which the partnership would focus: public use, fishery mitigation, imperiled fish and aquatic species recovery, interjurisdictional fisheries, aquatic habitat conservation, and aquatic nuisance species. Over time, members realized that many of the issues and problems in all six areas could be addressed through a regional habitat conservation plan. This Plan is a blueprint for that effort.

5 Southeast Aquatic Habitat Plan 2008

Table of Contents

Why the concern about the habitats in Southeast Region of the U.S. ?

The southeastern United States harbors a diversity of aquatic habitats and species unparalleled in the nation. Over 1,800 species of fishes, freshwater mussels, freshwater snails, turtles and crayfish can be found in southeastern watersheds. More than 500 of these are endemic to these states or in individual watersheds within them. More than 70 major river basins in the region link with the south Atlantic-Gulf of Mexico coastline to nourish and support rivers, streams, lakes, bays, estuaries, reservoirs, and the bulk of the country's wetlands. The drainage basin for the Gulf of Mexico, which includes the area drained by the Mississippi River, is almost 60% of the land in the Continental U.S. (Beck et al. 2000). In addition, approximately 16% of the nation's coastal wetlands are located in the South Atlantic region, which includes Florida (White et al. 2002), and almost half of the nation's coastal wetlands are in Louisiana.

The freshwater and marine systems in the region provide tremendous economic and aesthetic benefits through angling opportunities, recreational and commercial activities, water supply and natural assimilation of wastes. For example, in 2001, over 48% of the anglers in the U.S. fished in the Southeast, accounting for over 42% of the nation's total fishing days. These sportsmen spent over $13 billion, accounting for almost 37% of the total recreational fishing expenditures nationwide (USFWS/USCB, National Survey of Fishing, Hunting and Wildlife Associated Recreation 2001). Public lands like the region's 171 National Wildlife Refuges, over 700 state parks, multiple wildlife management areas and scenic waterways provide opportunities for nonconsumptive nature tourism (hiking, camping and birding) that also contribute to local economies. In 2005, despite the impacts of hurricanes on commercial fishing capacity, over 1.75 billion pounds of finfish and shellfish were harvested in the SARP member states, with a direct economic value of almost $900 million, representing some 23% of the economic value of all commercial fisheries in the United States (NMFS, Fisheries of the United States 2005).

Regrettably, the quality and quantity of these spectacular and valuable aquatic resources have been in decline since European colonization. Nearly 100 species have become extinct across the region in the last century. Further, in its 1998 report entitled *Rivers of Life: Critical Watersheds for Protecting Freshwater Biodiversity*, The Nature Conservancy, looking at more than 2000 small watersheds across the continental U.S., identified 87 subwatersheds in the U.S. with 10 or more "at risk" species of freshwater fish and mussels. Seventy-five of these 87 "hot spots" are contained in the 14 SARP states, and 18 of the top 19 are in four basins within their boundaries – the Tennessee, Ohio, Cumberland, and Mobile (Master et al. 1998).

These declines have many sources, including hydrologic alteration, habitat destruction, reduced water quality, loss of connectivity and the negative effects of nonindigenous species. Some sources of habitat stress are direct such as stream piping, relocation, shoreline armoring, excessive siltation, introductions of nonindigenous species and/or contaminants, and often associated with development, commerce, agriculture, forestry and mining. For example, roughly one half of the exotic fish species introduced into the Southeast have become established, stressing or altering ecological systems (Benson et al. 2001). In coastal areas, upstream alterations in freshwater flows and sediment supply, including reductions in volume, can result in loss of vegetative habitat and changes in sediment deposition and nutrient transport (Sklar and Browder 1998). The indirect stress from greenhouse gases may exacerbate these declines because many river basins have already lost their ability to adjust (Palmer et al. 2008).

Less direct stressors, especially human population growth and climate change, cumulatively exert a persistent and growing landscape-level effect on fish and their habitats. As more people use increasingly limited natural resources, habitats are impacted. U.S. Census data from April 2000 indicates the human population of the 14 SARP states exceeds 90 million (97,371,542) and, when compared to 1990 figures, points to an increase of over 14 million (14,656,552) people in 10 years. Significant population growth in the Southeast is expected.

The pressures from human population growth have been especially heavy on coastal areas. Populations along the Gulf Coast increased 45% between 1980 and 2003. Atlantic coastal counties experienced an increase of 58%, the largest increase during that period of any coastal region in the continental U.S. (U.S. Census 2000, Population in Coastal Counties).

In tandem with human population growth, climate change has already affected and will more profoundly affect aquatic habitats in the Southeast over the remainder of this century. Climate models project that the Southeast's temperatures will increase on average by 4-10 degrees F over this period, with increasingly hotter summers and higher heat indices (Carter 2000). Based on recent precipitation trends in the region, increases and decreases in precipitation and temperature will be variably manifested geographically, potentially exacerbating existing droughts and developing water shortages in parts of the region. There is also an existing measurable trend in the Southeast for precipitation to occur in more intense events. This trend could intensify during the remainder of the century.

Some predicted environmental effects of these climate changes in the Southeast include fewer continuous acres of forests, reduced agricultural productivity, diminished fish and shellfish populations, and increased electricity demand (Titus 1989). While uncertainties in precipitation projections make it difficult to predict effects on stream and river flows, areas experiencing drought may respond with greater pressure on groundwater for irrigation and water supply, exerting indirect consequent impacts on natural systems. A study of possible effects from climate change on the world's major river systems indicates that by 2050, every populated basin in the world will experience changes in river discharge and many will experience serious declines in water quality and quantity. (Palmer et al. 2008.)

It is reasonable to expect these climate trends to increasingly stress species that are near the upper ranges of their temperature tolerances in the Southeast and those requiring specific habitats that may be affected by the associated hydrological changes. These factors, combined with already fragmented and degraded habitats, will likely cause increased rates of extinction and imperilment of some native species across the region. Additionally, increasing temperatures may enlarge the area of the Southeast vulnerable to establishment of populations of tropical aquatic nuisance species currently restricted to south Florida.

The most dramatic and predictable effect of climate change in the Southeast will be coastal wetland loss and major coastline changes. During the 20th century sea levels rose by 4-8 inches (Burkett et al 2001). The International Panel on Climate Change predicts that this trend will increase 2-5 fold during the 21st century. Under this scenario a sea level rise of approximately one meter is possible by the end of the century. A one-meter rise in sea level would inundate all of coastal southeast Louisiana (UA 2006). The Louisiana coastline would variably move from 10 to over 100 miles inland, inundating New Orleans and many other coastal communities, while altering just about all of the coastal wetlands that support the bulk of the productive fisheries of the northern Gulf of Mexico. Similar impacts, but on a lesser scale would occur in all coastal areas of the Southeast, including all of the keys, the Everglades and much of the city of Miami, Florida, would be under water.

Although the earth has always undergone climate variation, and people have always affected natural systems, the effects from these indirect stressors appear to be in a period of acceleration. They must be considered in planning actions to ameliorate the effects of direct stressors (Technical Review Committee on Global Climate Change and Wildlife, 2004).

Clearly, the public supports actions to conserve and restore healthy aquatic habitats. A study conducted in 2005 by Responsive Management for the Southeastern Association of Fish and Wildlife Agencies indicated that the value placed by the public on programs to conserve fish and wildlife habitat and to protect threatened and endangered species transcends state and local levels of action. This study also noted that water quality is a major fish and wildlife issue facing the southeastern states, and that water resources are of concern for the health of people, fish and wildlife. (Responsive Management, 2005, Executive Summary). Many government agencies, private organizations, businesses, and citizens recognize the value of aquatic resources and work every day to conserve them, but past efforts to halt their decline have been conducted independently on state and local scales. A regional approach is necessary.

Multiscale Approach to Conservation

SARP, comprised of state natural resource agencies from 14 southeastern states plus several federal agencies with natural resource responsibilities, along with concerned nongovernmental organizations (NGOs), was formally organized in 2001 to effectively approach the decline in the region's aquatic resources by integrating state, federal and individual interests and efforts. SARP's mission is – *with partners, to protect, conserve, and restore aquatic resources including habitats throughout the Southeast, for the continuing benefit, use, and enjoyment of the American people.* This partnership takes a comprehensive and systemic approach to watershed conservation. It coordinates the use of new and existing science-based data and expertise, and combines conservation dollars to improve outcomes and stem or possibly reverse aquatic resource decline.

The need to address the decline in fisheries habitats throughout the nation was recognized on a national scale at the same time as SARP's formation, when the U.S. Fish and Wildlife Service (FWS), the Association of Fish and Wildlife Agencies, and the American Fisheries Society sponsored a series of aquatic habitat stakeholder meetings, resulting in the National Fish Habitat Initiative (NFHI) with a mandate to develop an integrated landscape approach to conserve inland and coastal fishery habitats throughout the nation. The National Fish Habitat Action Plan (NFHAP), a non-regulatory, science-based program, implemented through partnerships, has resulted from the NFHI.

SARP has embraced this national initiative while pursuing a similar approach in the region. During 2005, the SARP Aquatic Habitat Conservation Work Group sponsored conservation assessments led by The Nature Conservancy in four representative, geographically separate southeastern watersheds. Assessment of water, flora and fauna of the interconnected ecosystems yielded much information about various habitats, and identified similarities and differences in the problems and issues plaguing them. The results of these studies of the Duck, Altamaha, Pascagoula and Roanoke watersheds provided guidance and parameters for SARP to develop this Southeast Aquatic Habitat Plan (Plan). It offers a science-based, landscape-scale model for habitat conservation, aimed at the protection, restoration, recovery, and sustainable use of aquatic resources in the Southeast. (The assessments can be found at http://www.sarpaquatic.org.)

Also in 2005, by Congressional direction, SARP member states submitted their Comprehensive Wildlife Conservation Strategies (CWCS) to the FWS for approval. The state CWCS plans (also known as State Wildlife Action Plans, or SWAPs) encompassed the variety of problems facing state-identified species of greatest conservation need (SGCN) and strategic conservation actions aimed at improving habitats and

populations of SGCNs. Recognizing the importance and value of incorporating related issues and strategies from its member states' CWCS or SWAP plans into the regional plan, SARP and The Nature Conservancy compiled a database of information related to aquatic habitats from the state plans. These data will help to support habitat restoration and protection strategies at the ground level that cross programmatic and political boundaries, increasing the effectiveness of existing agencies and organizations while leveraging and maximizing available funding to achieve regional-scale conservation objectives.

Proper land and resource management is crucial at multiple levels to protect the natural aquatic treasures found throughout the SARP states and to ensure that future generations will be able to enjoy them. Selecting one scale at which to implement strategies is difficult, especially considering that rivers, lakes, reservoirs and streams may be integrated with estuarine and marine systems, and watersheds often cross multiple jurisdictions. Federal, state, local, public and private agencies and organizations must join together with coordinated strategies to abate current and future threats to the aquatic systems in a comprehensive, landscape manner that minimizes infringements on the rights and needs of specific user groups and maximizes the participation of all stakeholders. As research continues, restoration and management must be adapted to sustain the region's aquatic resources.

This Plan seeks to effectively apply limited resources and adaptive management to priority areas on a regional basis in order to reverse current trends and protect the region's aquatic resources far into the future. The Plan is a living document. It will be revised often, utilizing lessons and data from every project implemented under the Plan's sponsorship. Additional data and tools, currently under development, will assist SARP's adaptive management process of updating and maximizing the outcomes of this Plan.

How can this plan conserve the Southeast's aquatic habitats?

Vision

The Plan will engage stakeholders and the public in protecting, maintaining, restoring and enhancing the Southeast's fish and aquatic communities through partnerships that foster habitat conservation, and improve the quality of life for the American people. Implementation of the plan will result in habitats with the biological, chemical, and physical integrity to sustain healthy communities. As such, the Plan's vision, its overriding spirit, is the:

> *Cooperative conservation of southeastern streams, rivers, lakes and reservoirs, estuaries, and coastal marine habitats to support fish and aquatic resources, and sustainable public use.*

Guiding Principles

Five principles framed the crafting of the Plan and will provide the fundamental underpinnings for its implementation. They are:

•*Communicate the value of the Southeastern aquatic habitats and the imperative for conserving them.*

Properly functioning aquatic habitats are vital and necessary attributes of aquatic ecosystems. They support healthy fish and wildlife populations, and sustainable public use. Knowledge and awareness of desirable functions stimulate action. The regional plan will be a vital tool in efforts to obtain the funding, public and political support, and other resources necessary to meet the goal and objectives that will achieve the plan vision.

•*Provide regional aquatic conservation planning based on sound science, rigorous research, open and inclusive planning processes, and input from a broad and diverse group of stakeholders.*

Application of regional conservation strategies and implementation targets will be guided by the best available information on aquatic systems and species. The Plan will also recognize the importance of research that expands our knowledge base and increases our ability to craft meaningful land and water management strategies and measure the success of strategic implementation.

•*Establish regional aquatic conservation priorities.*

Identifying and articulating regional priorities for habitat conservation efforts will focus scarce resources to maximize conservation benefits in the Southeast. Establishment will be based upon abating threats and conserving balanced, healthy ecological conditions in aquatic habitats. Regional priorities, identified as focal geographic areas, habitat types and species or species groups, will change as conditions change, problems are addressed, and new issues arise.

•*Support existing partnerships, and facilitate new ones, to effectively conserve southeastern aquatic systems.*

The challenges facing the southeastern region's aquatic resources demand new approaches to conserve them.

This regional plan will be designed to support existing partnerships and foster effective creation of new ones at scales appropriate to meeting conservation challenges.

•Integrate conservation strategies and measures within identified watersheds and across scales from watershed to region to national plans.

The connectivity of aquatic ecosystems across local and state political boundaries improves consistency in conservation measures among different portions of watersheds, and the management of species across watersheds. This will be accomplished by increasing communication and project integration between freshwater, estuarine, and marine resource managers and practitioners to reduce the administrative barriers to working across ecosystem boundaries, and to ensure that the strategies implemented at all scales are mutually supportive, relevant, and effective in aquatic habitat conservation.

Goal

Living organisms and their habitats interact in changing ecological systems. These systems support human life by providing drinking water and food, and involve human activities such as farming, aquatic recreation, forestry and industry. Plants, animals, *and* people need healthy aquatic habitats. Although many healthy aquatic habitats thrive in the southeastern region of the U.S., some have disappeared. Others are endangered or declining. These losses in the Southeast have both natural and human-induced causes. Such reductions in habitat quantity, quality and function have negative impacts on animal, plant and human populations *and* their quality of life. Humans have the resources and abilities to conserve and restore these habitats. The goal is to:

Maintain, restore, and conserve the quantity and quality of freshwater, estuarine, and marine habitats to support healthy, sustainable fish and aquatic communities and sustainable public use for the benefit of all in the southeastern region and the entire U.S.

This goal of the Southeast Aquatic Habitat Plan will be achieved by taking collective action on eight primary objectives.

Limitations for all Objectives and Targets

Although the Plan was developed primarily to explain SARP's approaches in preserving, conserving and restoring aquatic habitat, it is designed for use by all groups with similar aims throughout the Southeast. Achievement of the Plan's objectives will be ongoing, with each project contributing in specific ways to the emergence of strong, healthy communities of fish, wildlife and people utilizing thriving aquatic habitats. While improving habitats, project results will also provide lessons learned and meet research needs to support continued planning and additional projects.

The relationship between healthy habitats and robust fish and wildlife populations is assumed in the Plan, and individual species will be one of many filters used to set project priorities and assess project outcomes. SARP

has captured data from the member states' CWCS or SWAP plans to effectively coordinate habitat restoration and protection strategies with states' identified species of greatest conservation need at the ground level across programmatic and political boundaries. However, it is important to remember that this is a plan to conserve and restore aquatic habitats in the region.

This Plan generally adheres to the principles of Strategic Habitat Conservation (SHC) (USGS 2006). However, this initial version of the Plan does not strictly apply that approach because data and models essential for doing so are incomplete or do not exist. In addition, the SHC approach utilizes population-based objectives, and at least for this initial version, the Plan's objectives are based on the major aquatic habitat types and attributes in the Southeast. The objectives focus on broad indicators of habitat integrity, function and overall ecosystem health. Consistent with SHC, objectives and regional targets have been developed using the best available scientific data. A systematic GIS-based system is being developed for refining future objectives and monitoring outcomes. Conservation delivery will be based on defined objectives and targets, and partnerships will be key to achieving those objectives. Adaptive management will be used to help refine objectives and conservation actions.

Although the following objectives focus individually on critical components of aquatic habitats, they function as an interrelated whole. The order of their mention in the document does not indicate any order of priority. All are important because the impacts from specific threats in a specific location must be considered cumulatively and on multiple scales. Using this Plan, individual threats to the health, quality, and function of aquatic habitats will be considered as part of interrelated processes, problems, and issues with interrelated outcomes.

Unless these outcomes can be measured, the effectiveness of actions to achieve outcomes cannot be assessed. Therefore, one or more resource targets (scientifically based quantitative and/or qualitative descriptions of desired changes) have been proposed for each objective. These targets attempt to establish a quantifiable basis for assessing progress in achieving the associated objective. In developing these regional targets, an attempt was made to adhere to the format and recommendations in the Proposed Interim National Targets (February 2007) developed by the National Fish Habitat Board's Science and Data Committee. The Plan's targets are primarily resource-based outcome targets, focusing on changes in the resource as a result of SAHP actions. Developing quantifiable targets for most of the objectives presents real challenges, primarily due to the lack of regionally analyzed and integrated data. For this reason some targets focus on measures that indirectly assess the resource attributes related to the objective and some targets are actions than can be pursued during implementation. The following quantitative targets are subjectively proposed as reasonable measures of improvement over 15 years, assuming that focused efforts are brought to bear and adequate resources are available. With the adaptive management process in mind, ideal targets are also described, even though the interim targets sometimes do not measure against them. Ideal targets provide the opportunity to identify data gaps for effective evaluation, and suggest needed research to better focus targets.

An additional challenge for some of the targets is presented when positive change may not be reflected in assessment and evaluation because of continuing research about various conditions. This challenge will be considered as applicable when assessing progress towards achieving each of the objectives.

It should be possible to develop resource-based targets that are more specific to the objectives once the first assessment of the nation's aquatic habitats, as proposed in *A Framework for Assessing the Nation's Fish Habitat* (NFHSDC 2006) is completed in about 2010. The targets in this version of the Plan should generally be viewed as interim targets subject to revision. Many of the current targets have their basis in information presented in *The State of the Nation's Ecosystems* (The Heinz Center 2002, 2003, 2005) and the *National Coastal Condition Report II* (USEPA 2004). The underlying data for both of these documents have been
 periodically updated, reassessed and published by the USEPA and the Heinz Center. The Plan assumes that
those updates will continue in the future. (Further explanation of these resources can be found on page 2.) In a

few cases, targets are based on local data or proposed need. Note that in a few cases, targets are not structured on five-year intervals due to insufficient data or it was not meaningful to do so for a specific target. Unless otherwise stated, all targets are intended to be achieved over a 15-year time period following plan adoption (i.e., by 2022).

Objective 1: *Establish, improve and maintain riparian zones*

Riparian zones buffer the impacts on adjacent waterbodies from human land use activities while supporting aquatic as well as terrestrial habitats. Wenger (1999) defines riparian zones as land areas located adjacent to waterbodies, often naturally vegetated with grasses, shrubs and trees. Effective riparian zones function as efficient traps, filtering out sediments and nutrients. They provide structure for ephemeral or intermittent channel flow. Vegetation closest to the waterbody provides cover and habitat for wildlife, helps maintain normal water temperatures, slows over-bank flows, and provides energy in aquatic systems. Vegetative roots, especially from woody plants and trees, decrease erosion of the banks and shorelines (Pollen and Simon 2005). During certain periods or under certain circumstances, riparian zones play significant roles in changing water quality as well as in the life stages and life-sustaining activities of many aquatic animals. Natural riparian areas also provide important habitat and travel corridors for terrestrial wildlife. Both grassed and forested buffers trap sediment. Forested buffers provide other benefits as well, such as better runoff control while also allowing input of large woody debris and other matter necessary for aquatic organisms (Wenger 1999).

Urbanization, industrialization, agriculture and other types of development often degrade or reduce the size or health of riparian areas. Ideally, appropriately sized riparian zones in every watershed in the southeastern region should be permanently protected. In areas where vegetated riparian areas are already lost or loss is unavoidable, such as urban areas, methods to restore or provide the functions of healthy, natural riparian areas should be explored and utilized. The challenge is to maintain, conserve, permanently protect, construct or restore riparian zones in the southeastern region that can support healthy aquatic habitats and their populations of fish and other aquatic organisms while meeting public needs.

Target

An ideal riparian zone would extend over all land adjacent to a waterbody to the extent necessary for effective buffer and support. Buffer slope and the presence of wetlands have been determined to be the most important and useful factors in determining ideal buffer width. Long-term studies suggest that a 30 m (100 foot) riparian buffer is sufficiently wide to trap sediments under most circumstances, although they can vary based on type of soil, hydrology, slope and vegetation. Native forest vegetation should be maintained or restored to provide optimal benefit (Wenger 1999). Riparian buffers should extend along both sides of rivers and streams, including intermittent and ephemeral channels, and completely around natural lakes and impounded waters.

One ideal target for this objective would include a measure of habitat quality and quantity utilizing satellite data and geographic information system (GIS) analysis to determine the magnitude of change in percentage of 100-year floodplain areas of natural vegetative cover. Other target strategies may involve assessing maintenance of acres of existing riparian areas or determining the percentage of or number of new riparian areas in a watershed or the southeastern region. Permanently protected riparian areas may be included in the assessment of change. However, regional data have not been compiled or analyzed in a fashion that would allow development of such targets at this time. The initial target for this objective is limited by available regional data on riparian areas.

Using data compiled and processed by the U.S. Environmental Protection Agency's (EPA) National Exposure Research Laboratory that used the U.S. Geological Survey's (USGS) National Hydrography Dataset, the Heinz Center (2002) determined that, nationally, 23% of the lands within 100 feet of the waters' edge along streams nationwide were either farmlands or urban development in the early 1990s. Although those data are for the nation as a whole rather than only the Southeast and appear low for the southeastern region, they were used when developing the following targets for this objective pending development of current regional data for assessing the Southeast's riparian condition.

Target 1A. Ensure that adequate non-urban/non-agricultural riparian buffer habitats exist on at least 85% of the lands within 100 feet of rivers and streams in the Southeast by 2022.

- By 2012 ensure that at least 78% of the lands within 100 feet of rivers and streams in the Southeast have adequate riparian buffers.
- By 2017 ensure that at least 81% of the lands within 100 feet of rivers and streams in the Southeast have adequate riparian buffers.
- By 2022 ensure that at least 85% of the lands within 100 feet of rivers and streams in the Southeast have adequate riparian buffers.

Objective 2: ***Improve or maintain water quality***

The quality of water includes physical, chemical, and biological characteristics that sustain plant and animal life and support a variety of human uses including drinking water, fishing and boating, agriculture and industry, and other types of recreation and transportation. Water quality characteristics can be altered by storms and seasonal changes; industrial, manufacturing or residential discharges and runoff; urbanization; agriculture; and other land uses, sometimes for many miles from the contamination site (e.g., the dead zone in Gulf of Mexico impacted by drainage from the Mississippi River Basin). Plants and animals in any aquatic community are sustained by the balance of temperature, nutrients, and organic material in the habitat. Maintaining good water quality and preventing, halting, or reversing alterations support these life-sustaining balances and reduce treatment costs for human use. The challenge is to maintain or adjust the balance of water quality characteristics in aquatic systems to meet the needs of fish, other aquatic and terrestrial organisms, and the public.

Targets

Ideally the magnitude of change for this objective will be measured by the maintenance of or increase in the percentage of, or the number of miles of, streams and rivers, or acres of estuaries, wetlands, lakes, reservoirs, and ponds with water quality characteristics that meet the designated use. An example of a designated use might be fishable/swimmable waters or waters supporting aquatic life and recreation, such as addressed in Section 303(d) of the federal Clean Water Act. A decrease in the percentage of waterbodies in the southeastern region with water quality unable to support healthy ecological systems is desirable.

The EPA maintains a database of waterbody segments/areas that are classified as impaired in accordance with Section 303(d). Although the data in that system are not consistently expressed quantitatively in terms of stream miles or areal extent, the 303(d) list includes a total number of impaired waterbody segments/areas. That number (7,073 as of June 2007) is used as an interim basis for Target 2A for this objective. Note that states have different listing criteria for these data. Some criteria are primarily anthropogenic in focus, some don't consider emerging contaminants such as pharmaceuticals, and some may be less suitable for describing impairment in some of the Southeast's low gradient systems, such as some habitats of the lower Mississippi River floodplain. However, these are the best available data upon which to base many of the following targets. In addition, ongoing research has resulted in an increase in the number of 303(d) listings of impaired waterbodies every two years, presenting the challenge described on page 13. Data are available to meet this challenge in the target's assessment.

Several other targets were also developed for this objective focusing on specific water quality characteristics, as further described below, using data from The Heinz Center (2002). Although those data apply to the nation as a whole and not to the Southeast specifically, they were, nevertheless, used when developing targets pending future development of more specific targets when better data are available. Note that these targets are regional, and are not meant to apply at every individual site.

Target 2A. Restore at least 710 waterbody segments/areas in the Southeast (10% of impaired segments/areas as of June 2007) to nonimpaired status per the EPA 303(d) list.

•By 2012 restore at least 140 waterbody segments/areas in the Southeast to nonimpaired status per the EPA 303(d) list.

•By 2017 restore at least 350 waterbody segments/areas in the Southeast to nonimpaired status per the EPA 303(d) list.

•By 2022 restore at least 710 waterbody segments/areas in the Southeast to nonimpaired status per the EPA 303(d) list.

According to the Heinz Center (2002), the USGS National Water Quality Assessment (NAWQA) found that 77% of stream sites nationwide during the period 1992-1998 were exceeding at least one standard or guideline for contaminants that may affect aquatic life in water. This was used as a basis for Target 2B.

Target 2B. Reduce to 70% the stream sites in the Southeast exceeding at least one standard or guideline for contaminants or emerging contaminants affecting aquatic life.

•By 2012 reduce to 76% the stream sites in the Southeast exceeding at least one standard or guideline for contaminants or emerging contaminants in water affecting aquatic life.

•By 2017 reduce to 75% the stream sites in the Southeast exceeding at least one standard or guideline for contaminants or emerging contaminants in water affecting aquatic life.

•By 2022 reduce to 70% the stream sites in the Southeast exceeding at least one standard or guideline for contaminants or emerging contaminants in water affecting aquatic life.

The NAWQA (Heinz Center 2002) also found that 48% of stream sites nationwide during 1992-1998 were exceeding at least one standard or guideline for contaminants in sediments that affect aquatic life. This was used as a basis for Target 2C.

Target 2C. Reduce to 45% the stream sites in the Southeast exceeding at least one standard or guideline for contaminants in sediments affecting aquatic life.

•By 2012 reduce to 47% the stream sites in the Southeast exceeding at least one standard or guideline for contaminants in sediments affecting aquatic life.

•By 2017 reduce to 46% the stream sites in the Southeast exceeding at least one standard or guideline for contaminants in sediments affecting aquatic life.

•By 2022 reduce to 45% the stream sites in the Southeast exceeding at least one standard or guideline for contaminants in sediments affecting aquatic life.

The NAWQA (Heinz Center 2002) also found that during 1992-1998 approximately 48% of farmland streams and 18% of urban/suburban streams nationwide had nitrate levels in excess of 2 parts per million (ppm). These data were used as bases for Targets 2D and 2E.

Target 2D. Reduce to 40% the farmland stream sites in the Southeast exceeding 2 ppm nitrate concentration.

•By 2012 reduce to 47% the farmland stream sites in the Southeast exceeding 2 ppm nitrate concentration.

•By 2017 reduce to 44% the farmland stream sites in the Southeast exceeding 2 ppm nitrate concentration.

•By 2022 reduce to 40% the farmland stream sites in the Southeast exceeding 2 ppm nitrate concentration.

Target 2E. Reduce to 10% the urban/suburban stream sites in the Southeast exceeding 2 ppm nitrate concentration.

•By 2012 reduce to 17% the urban/suburban stream sites in the Southeast exceeding 2 ppm nitrate concentration.

•By 2017 reduce to 15% the urban/suburban stream sites in the southeast exceeding 2 ppm nitrate concentration.

•By 2022 reduce to 12% the urban/suburban stream sites in the Southeast exceeding 2 ppm nitrate concentration.

The NAWQA also found that during 1992-1998, approximately 73% of farmland streams, 68% of urban/suburban streams, and 54% of large river [defined as having average flows over 1,000 cubic feet per second (cfs)] sampling sites nationwide exceeded the EPA's recommended goal of 0.1 ppm concentration for phosphorus in order to prevent excess algal growth. These data were used as bases for Targets 2F, 2G, 2H.

Target 2F. Reduce to 65% the farmland stream sites in the Southeast exceeding 0.1 ppm phosphorus concentration.

17 Southeast Aquatic Habitat Plan 2008

•By 2012 reduce to 71% the farmland stream sites in the Southeast exceeding 0.1 ppm phosphorus concentration.

•By 2017 reduce to 68% the farmland stream sites in the Southeast exceeding 0.1 ppm phosphorus concentration.

•By 2022 reduce to 65% the farmland stream sites in the Southeast exceeding 0.1 ppm phosphorus concentration.

Target 2G. Reduce to 60% the urban/suburban stream sites in the Southeast exceeding 0.1 ppm phosphorus concentration.

•By 2012 reduce to 67% the urban/suburban stream sites in the Southeast exceeding 0.1 ppm phosphorus concentration.

•By 2017 reduce to 64% the urban/suburban stream sites in the Southeast exceeding 0.1 ppm phosphorus concentration.

•By 2022 reduce to 60% the urban/suburban stream sites in the Southeast exceeding 0.1 ppm phosphorus concentration.

Target 2H. Reduce to 45% the large river sampling sites in the Southeast exceeding 0.1 ppm phosphorous concentration.

•By 2012 reduce to 52% the large river sampling sites in the Southeast exceeding 0.1 ppm phosphorous concentration.

•By 2017 reduce to 49% the large river sampling sites in the Southeast exceeding 0.1 ppm phosphorous concentration.

•By 2022 reduce to 45% the large river sampling sites in the Southeast exceeding 0.1 ppm phosphorous concentration.

The NAWQA (Heinz Center 2002) found that 83% of farmland stream sites nationwide during 1992-1998 had at least one pesticide with concentrations exceeding aquatic life guidelines. This was used as a basis for Target 2J.

Target 2J. Reduce to 75% the farmland stream sites in the Southeast with at least one pesticide exceeding aquatic life guidelines.

•By 2012 reduce to 81% the farmland stream sites in the Southeast with at least one pesticide exceeding aquatic life guidelines.

•By 2017 reduce to 78% the farmland stream sites in the Southeast with at least one pesticide exceeding aquatic life guidelines.

•By 2022 reduce to 75% the farmland stream sites in the Southeast with at least one pesticide exceeding aquatic life guidelines.

Objective 3: ***Improve or maintain watershed connectivity***

Watershed connectivity in a habitat context can be described as physical, chemical, and biological conditions that accommodate the movements of aquatic organisms, nutrients, water, or energy into various necessary habitats or habitat types. Waterbodies, whether flowing or static, require regular and, at times, unrestricted movements of these to support their ecological systems. Watersheds need similar connectivity within and between rivers, streams, lakes and reservoirs, and between terrestrial and aquatic habitats. Some physical impediments to connectivity such as dams, levees, incised channels, armored shorelines, and culverts can block or change these movements. Impediments such as chemical, biological, and thermal barriers, invasive species, impervious areas, and reduction of the vegetated canopy can also affect connectivity. These impediments are more easily adjusted than the physical ones, although no adjustments are simple. Often barriers to connectivity have a positive use in one part of a watershed, but negatively affect the productivity of some ecosystems in other parts of the same watershed. Occasionally, the purpose for a barrier has disappeared altogether, but the barrier remains. The objective is to conserve or improve watershed connectivity in a manner that will maintain or improve the health of habitats, ecological systems, and populations of fish and other aquatic organisms and meet public needs within a watershed and the region.

Targets

For this objective the ideal targets would be measures of the maintenance of or increase in the number of watersheds in the Southeast with minimal (lowest number and degree of) impediments to connectivity. Since connectivity can be seen to support human needs as well as the life needs of aquatic plant and animal populations, an increase in the percentage or number of healthy aquatic habitats with minimal impediments to connectivity should demonstrate progress. Indicators of change might include chemical or physical changes in water quality, level or flow attributable to operations adjustments, number of dams removed, number of channels connected to floodplains, or alterations in land use patterns accompanied by increases in populations of certain species or functional guilds while continuing to meet human needs. While there are currently no compiled data on connectivity or aquatic habitat health as specific attributes per se, there are a few data sets that may be useful in assessing progress in meeting this objective. The FWS, in its Fish Passage Decision Support System database (FWS 2007), indicated as of June 2007 that there were at least 39,821 barriers to fish passage in the SARP states. Although the data in this database may not be complete, they have utility as a basis for identifying targets for this objective.

Target 3A. Restore 1,000 miles of fish access to rivers and streams in the Southeast by effectively removing* barriers to fish passage.

•By 2012 restore fish access to 500 miles of rivers and streams in the Southeast.

•By 2017 restore fish access to 750 miles of rivers and streams in the Southeast.

•By 2022 restore fish access to 1,000 miles of rivers and streams in the Southeast.

Target 3B. Restore 20,000 acres of fish access to lakes, reservoirs, and coastal estuaries in the Southeast by effectively removing* barriers to fish passage.

•By 2012 restore fish access to 10,000 acres of lakes, reservoirs and coastal estuaries in the Southeast.

* "Effectively removing" can mean physical removal, breaching of a barrier, installation of fish passage structures, or implementation of other fish passage strategies to result in effective fish passage around or through a barrier.

19 Southeast Aquatic Habitat Plan 2008

•By 2017 restore fish access to 15,000 acres of lakes, reservoirs and coastal estuaries in the Southeast.

•By 2022 restore fish access to 20,000 acres of lakes, reservoirs and coastal estuaries in the Southeast.

Objective 4: ***Improve or maintain appropriate hydrologic conditions for the support of biota in aquatic systems***

The quantity and flow of freshwater in waterbodies varies naturally by season and precipitation, and unnaturally by human alteration and withdrawal of water from rivers and lakes as well as groundwater from aquifers. Both are important to aquatic communities. High flows and elevated water levels are part of the natural renewal of some habitats and coastal waters. In rivers, reservoirs or natural lakes, high flows during spring and summer greatly enhance reproductive success and survival of offspring for many species of fish and other animals. These same water levels support public needs for transportation, irrigation, drinking water and recreation.

Estuaries, highly productive habitats for fish and other aquatic organisms, are formed in protected coastal areas where fresh water flows into and mixes with tidally-driven saline waters. Estuarine habitats are supported by the regularity and balance of volume, timing, and periodicity of these occurrences. When people dredge rivers to enhance navigation, create reservoirs and build levees, they may change the hydrologic conditions of waterbodies and watersheds. (Sklar and Browder 1998). The objective is to maintain and/or adjust the quantity and flow of freshwater in rivers, streams, reservoirs and estuaries in a manner that will enhance or sustain the habitats and populations of fish and other aquatic organisms while meeting public needs.

Targets

The magnitude of change for this objective should be measured as a percentage of increase in or increased number of miles of freshwater streams and rivers with instream flow protection plans; or acres of lakes, reservoirs, ponds, aquifers, and estuaries with hydrologic conditions that support sustainable populations of fish and other aquatic organisms compared to a referenced condition. The number of miles or acres of permanently protected freshwater bodies may be included in the measurement. However, data to assess these measures are currently either not available or have not been compiled and assimilated in a manner to allow such assessments to be made. Specific, quantifiable targets may be established for individual watersheds but would require further study to establish.

The Heinz Center (2002) analyzed changes in high and low flows and timing of those flows for 1930-1949 as a reference period and compared those data to the 10-year periods of the 1970s, 1980s and 1990s using USGS stream gauge data nationwide. The data showed in the 1970s that 55.1% of rivers had experienced a greater than 75% increase or decrease in flows or more than a 60-day change in timing of flows. For the 1980s and 1990s the data showed that 56.9% and 60.8%, respectively of rivers had experienced those changes from the reference period. Although these data are nationwide rather than specific to the Southeast, they were, nevertheless, used to formulate Target 4A pending future development of more specific targets after better data are available.

Target 4A. Reduce the percentage of rivers in the Southeast that have experienced more than a 75% change in high or low flows or more than a 60-day change in timing of flows since the 1940s to 58%.

•By 2012 reduce the percentage of rivers in the Southeast that have experienced more than 75% change in high or low flows or more than a 60-day change in timing of flows since the 1940s to 60%.

20 Southeast Aquatic Habitat Plan 2008

•By 2017 reduce the percentage of rivers in the Southeast that have experienced more than 75% change in high or low flows or more than a 60-day change in timing of flows since the 1940s to 59%.

•By 2022 reduce the percentage of rivers in the Southeast that have experienced more than 75% change in high or low flows or more than a 60-day change in timing of flows since the 1940s to 58%.

Using data from the USGS Circular Series *Estimated Use of Water in the United States*, which has been published every five years since 1950, The Heinz Center (2005) assessed freshwater withdrawals nationwide from all sources, for most purposes (such as public supply, domestic, irrigation, livestock, aquaculture, industrial, mining, and thermoelectric, not including freshwater diversions), using withdrawals in 1980 as an index. The year 1980 was chosen because it was the year of greatest water withdrawal (i.e., index value of 1.00) over the data series (1960-2000). Data showed that water withdrawals in the Southeast almost doubled between 1970 and 1980, declined to an index value of 0.77 in 1985, but then rose back to an index value of approximately 0.96 in 2000. Total freshwater withdrawals in the Southeast that year were 120.5 billion gallons per day (bgd). By contrast, human populations in the Southeast rose steadily in a nearly linear fashion from an index value of 0.72 in 1960 to 1.35 in 2000 (1.00 in 1980). These data were used as the basis for Target 4B.

Target 4B. Using freshwater withdrawal in 1980 as an index of 1.00 (125.56 bgd), reduce freshwater withdrawals in the Southeast from all sources to an index of 0.90 (113.0 bgd).

•By 2012 reduce freshwater withdrawals from all sources, using withdrawal in 1980 as an index of 1.00, to an index of 0.95 (119.2 bgd).

•By 2017 reduce freshwater withdrawals from all sources, using withdrawal in 1980 as an index of 1.00, to an index of 0.93 (116.7 bgd).

•By 2022 reduce freshwater withdrawals from all sources, using withdrawal in 1980 as an index of 1.00, to an index of 0.90 (113.0 bgd).

Areas of impervious surfaces (e.g., roads, parking lots, driveways, sidewalks, buildings) in urban and suburban areas can have major impacts on hydrology and water quality in these and downstream portions of watersheds. Although there are currently no data available to assess impervious surface area, The Heinz Center (2002), using data from the National Land Cover Dataset, a product of the Multi-Resolution Land Characterization Consortium [a partnership of USGS, U.S. Forest Service, the National Oceanic and Atmospheric Administration (NOAA) and EPA], determined the percentages of "natural" area patches in urban and suburban settings that fell into specified size groupings. Natural areas were defined as forest, grassland, shrubland or wetlands. They determined that in the Southeast 30% of urban/suburban natural areas in 1992 were patches of forest, grassland, shrubland or wetland, each 10-100 acres in size. Although not perfect, this approximate indicator for urban/suburban impervious area was used to formulate Target 4C.

Target 4C. Increase the percentage of urban/suburban natural area patches 10-100 acres in size in the Southeast to 35%.

•By 2012 increase the percentage of urban/suburban natural area patches 10-100 acres in size in the Southeast to 31%.

21 Southeast Aquatic Habitat Plan 2008

•By 2017 increase the percentage of urban/suburban natural area patches 10-100 acres in size in the Southeast to 32%.

•By 2022 increase the percentage of urban/suburban natural area patches 10-100 acres in size in the Southeast to 35%.

Objective 5: *Establish, improve or maintain appropriate sediment flows*

In a watershed, some sediment is carried in suspension by flowing water from inland to coastal waters, while some is deposited on banks and channel beds, supporting and sustaining aquatic habitats and their ecological systems. Sediment can positively and negatively affect the size and health of wetlands, rivers, streams, lakes, reservoirs, and coastal areas. Increased sediment can raise costs of water purification and navigation channel maintenance as well as damage fisheries and aquatic habitat. It can also build or renew wetlands, banks and benthic areas. Sediment transport varies because of factors such as soil particle type and local geology, precipitation and runoff as well as barriers to flow due to channelization, roadways, dams and land-use-induced erosion. The challenge is to maintain or improve the balance of sediment flow within aquatic systems in a manner that sustains water resources and maintains or improves the health of the habitats and their populations of fish and other aquatic organisms. This multifaceted challenge includes the need to a) maintain or improve the balance of sediment transfer to support the waterbody's structure, habitats and their associated communities, and b) ensure sufficient sediment supply to nurture adjacent wetlands and coastal marshes, and offset subsidence and sea level rise while sustaining water resources for human use.

Targets

The magnitude of change for this objective could be measured by maintenance of or increase in the number of watersheds in the Southeast with a balance of sediment flows supporting healthy habitats with populations of fish and other aquatic organisms while meeting human needs. However, sediment needs vary from habitat to habitat, watershed to watershed. There is no regional norm. For example, White et al. (2002) concluded that upstream reservoirs have reduced sediment loads in the Trinity, Lavaca-Navidad, and Nueces river systems in Texas below those needed to maintain or improve the associated marshes and coastal areas. In some cases, the opposite is true within impounded areas. Reservoirs and small impoundments are especially susceptible to excessive sedimentation.

Determining a baseline to assess progress on this objective is equally difficult. On a nationwide basis The Heinz Center (2002) found in general that croplands most prone to water erosion decreased significantly from 30.3% in 1982 to 21.6% in 1997, but this measure does not address non-agricultural erosion that occurs along large rivers and stream banks. Under section 303(b) of the Clean Water Act, the regional offices of the EPA work with state water regulatory agencies to list impaired waterbodies and develop total maximum daily loads (TMDLs) for the contaminants (U.S. EPA 2007). TMDLs describe the amounts of a pollutant that a waterbody can receive and still meet water quality standards, and allocate loadings among point and nonpoint pollutant sources. Excess sediment can impair waterbodies. To establish a baseline for Targets 5A and 5B, SARP could work with data managed by EPA Regions 3, 4, 6, and 7 to identify those waters currently listed as impaired by excess sedimentation and in need of a load allocation strategy. Future targets and timelines for load reduction could be set in cooperation with EPA and state programs charged with implementing the load allocations.

Initially, the relationship of this objective with those on water quality, connectivity, and hydrologic condition, for which measurable targets have been proposed, can be used for indirect, qualitative assessment until baseline

data can be secured. Results from monitoring and assessing projects focusing on those objectives can, over time, provide some local and regional interim indicators that can be combined with emerging TMDL data. After 2010, development of additional data sources through the NFHI aquatic habitat assessment may provide other avenues to select targets. For this version of the Plan, Targets 5A and 5B are qualitatively described without specific milestones.

Target 5A. Reduce the number of stream miles impaired by excess sediment.

Target 5B. Rehabilitate estuarine or reservoir habitat where hydrological alteration has decreased sediment flows, resulting in aquatic habitat loss.

The portion of the Southeast where the lack of appropriate sediment transport is most profound and critical is the Louisiana coastal area. Since the 1930s, Louisiana has lost over 1.2 million acres (485,830 ha) of coastal wetlands (USACE 2004). In 2000 it was estimated this loss would continue at approximately 6,600 acres

(2,672 ha) per year over the next 50 years. The Mississippi River transports a suspended sediment load of about 70 million cubic yards (5.4 million cubic meters) to its mouth each year. However, most of the material flows to deep waters of the Gulf of Mexico instead of being deposited on surrounding wetlands. The lack of sediment and nutrient input has reduced deposition rates to a point where they are not able to offset relative sea level change being caused by marsh subsidence and actual sea level rise. Besides its impact on local habitats, fisheries and economies, this sediment transport through one of the largest watersheds in the nation most likely is affecting a large portion of the habitats in the Southeast.

The USACE and the State of Louisiana have developed the Louisiana Coastal Area (LCA) Plan (USACE 2004) as a large scale effort to offset much of the projected future loss from this condition. The LCA Plan recommended five near-term critical restoration features for authorization. These were determined to address the most critical needs to offset losses projected to occur over the next 50 years if no action was taken. Target 5C is based on the LCA Plan. Three of the LCA Plan features specifically incorporate attempts to increase sedimentation rates into coastal wetlands through relatively large-scale diversions of river water and sediment. They seek large scale action at specific locations: the Hope Canal Diversion, the Bayou Lafourche Reintroduction, and the Myrtle Grove Diversion. Because the effects from achievement of these could have a significant effect on the achievement of this objective at the regional level while providing data and information about methods and problems related to sediment flow restoration projects, they are included as milestones for Target 5C. This target is based on the LCA Plan.

Target 5C. By 2050 offset approximately 62.5 percent (288,750 acres/116,853 ha) of the 462,000 acres (186,965 ha) of wetlands projected to be lost within the Louisiana Coastal Area if no action is taken.

•Achieve an annual sedimentation rate of at least 1,000 grams per square meter per year using the Hope Canal Diversion for a total benefit of restoring 36,000 acres of freshwater swamp by 2050.

•Achieve a net gain of 2,500 acres of coastal marsh through the Bayou Lafourche Reintroduction by 2050.

•Create/preserve 6,563 acres (2,656 ha) of coastal marsh through the Myrtle Grove Diversion by 2050.

The LCA Plan specifically incorporates attempts to increase sedimentation rates into coastal wetlands and through medium-scale diversions of river water and sediment. These include a 5,000 cubic foot per second23
Southeast Aquatic Habitat Plan 2008
project and two smaller-scale projects. Because these three projects would have a moderately significant effect on achieving the overall LCA objective while providing data and information on methods and problems related to sediment flow restoration, they are incorporated into this Plan.

Objective 6. *Maintain and restore physical habitat in freshwater systems*

Physical habitats are the structural elements that make streams, rivers, lakes, reservoirs and wetlands suitable for aquatic species. Examples of physical habitat in southeastern waters include stream channel morphology, substrate composition (gravel, rocks, sediment, etc.), benthic contours of lakes and reservoirs, aquatic vegetation, shoreline vegetation, overhead canopy cover, and woody debris. Physical habitat plays an important role in healthy ecosystems, providing shelter, spawning sites, nursery areas, and foraging areas for fish and other aquatic animals. It also affects water quality and energy production. When physical habitat is changed by natural storm or flood events, aging and decomposition, or anthropogenic activities, the health of the waterbody may change suddenly, slowly, or sometimes in stages following a 'domino' effect. Not all changes are bad, but some activities such as draining wetlands or rerouting streams through pipes or channels can result in destruction of physical habitat. Of major importance has been the large-scale loss of wetland habitats such as forested large-river floodplain, oxbow, and backwater areas, coastal marsh and seagrass beds. The structural elements of many streams and rivers, degraded by an assortment of land use practices or natural events, can be improved using stream restoration techniques. In reservoirs, managers add new structure to offset the loss of the original woody debris, but it is difficult to add enough to maintain optimum fisheries. Reservoirs also tend to develop problems related to the presence or absence of aquatic vegetation due to water level fluctuations. The challenge is to prevent the destruction of physical habitat and promote its restoration and improvement in a manner that meets both ecological and human needs.

Targets

Achievement of this objective will be measured as a reduction in alterations of aquatic habitats, and as the total amount (miles, acres and numbers) of protected, restored and enhanced habitat. Sources of data to help in establishing such baselines may include but are not limited to the AFS Reservoir Committee, U.S. EPA procedures for calculating stream habitat metrics, the U.S. Army Corps of Engineers (USACE) and the National Wetlands Inventory (NWI). Historical data may also be helpful. Note that only those habitat characteristics that can be attributed to maintenance, restoration or establishment of one or more identified structural elements will be used to determine the magnitude of change.

As noted by The Heinz Center (2002), there is general agreement on key elements that should be measured to evaluate aquatic habitat quality, and work is underway by entities such as the EPA, USGS and the USACE to assimilate data and develop habitat quality indices. However, generally accepted methodologies for assessing data on either a local or regional basis are not yet available. Habitat values for particular systems must also take into account the habitat needs of the biota in those areas, so habitat indices need to be tailored to different communities, habitat types or areas.   The FWS National Wetlands Inventory (NWI - http://www.fws.gov/nwi/) provides readily available data on wetlands nationwide. As of 2002, most of the wetlands data in the NWI were of 1980s vintage (FWS 2002), and it is not compiled regionally or by state. Hefner et al. (1994) provides the only regional compilation of wetland data for the Southeast, though these data do not correspond entirely to the Plan's area and were collected only through the 1980s. Development of additional data sources through the NFHI aquatic habitat assessment may provide additional avenues for development of targets following initial results of the assessment in 2010.24 Southeast Aquatic Habitat Plan 2008

Target 6A. Reduction in acreage of freshwater wetlands drained or converted.

•By 2022 reduce the number of acres of altered freshwater wetlands drained or converted through development annually in the Southeast by 30%.

Target 6B. Reduction in number of stream miles destroyed or converted to unnatural or managed drainage systems

•By 2022 decrease miles of streams destroyed or converted by permitted construction into unnatural drainage systems annually in the Southeast by 30%.

SARP is working through the Southern Division of the American Fisheries Society Reservoir Committee to establish methods of tracking reservoir structural enhancements commonly installed by state fisheries professionals and local fishermen. Beginning in 2008, SARP partners will report all stream and river restoration or enhancement projects to measure accomplishments for achieving Targets 6C and 6D.

Target 6C. Increase number of lakes and reservoirs with adequate physical habitat structure.

•By 2022 improve the physical habitat for fisheries in an increased number of affected reservoirs and lakes in the Southeast.

Target 6D. Increase in the number of miles of streams with improved instream physical habitat.

•By 2022 improve the physical habitat of reaches in streams and rivers containing structural improvements in the Southeast. (This would not include downstream affected areas.)

Objective 7: ***Restore or improve the ecological balance in habitats negatively affected by nonindigenous invasive or problem species***

Habitats and diverse populations of biota thrive in balanced, interdependent, natural and human-created systems. Occasionally, the addition of one or more non-native species to biotic communities within a habitat can alter systems and degrade habitats. These changes in the biotic communities of habitats have altered water quality characteristics, energy, nutrient, and sediment flow, and species composition. In addition to the damage to natural resources, such habitat degradation often negatively affects food and water resources, recreation, and economics for people (ISAC, 2006; Pimentel et al 2005). The absence or overabundance of a species or functional guild, especially invasive species, parasites or pathogens, can be major causes of such changes or imbalance (Sarakinos 1999). Pathogens can weaken or destroy whole populations. Invasive species, not native to the habitat, may have no natural enemies present to limit rapid population expansion. Their fecundity, early and rapid development, ability to thrive on available nutrition and tolerance of a broad range of conditions help them to out-compete, and often destroy native populations and disrupt interdependent systems (Williams &

Meffe 2005). Problem species can be introduced by natural occurrences such as storms and floods, and/or by human activities such as shipping, aquaculture, fishing, agriculture, horticulture, landscaping, exotic pet and aquarium trade, and stocking. Biota that improve the health of a system can be introduced in a similar manner. The objective is to encourage appropriate abundance of species or functional guilds within a watershed to establish or restore healthy ecological systems while supporting public use of resources. This will be achieved by controlling or preventing the introduction of new nonindigenous invasive or problem species.

Targets

Progress in meeting this objective will be assessed by using various state, regional, and national databases and management plans, as well as indices of population dynamics, aquatic community species composition, architecture function, and structure to identify problem species that threaten habitat health and establish baselines of habitat health in target watersheds. These changes may be expressed by an increase in the numbers of healthy essential species within a system, an increase in number or percentage of native animals or in acreage of native plants fitting unfilled niches, and/or a reduction in or eventual absence of populations of identified problem species within the target habitat. However, data on which to base such assessments are not yet available or compiled in a manner that can be readily analyzed, particularly for the SARP states as a whole. A suite of targets and strategies has been developed using available data. Development of additional data following initial results of the NFHI aquatic habitat assessment in 2010 may provide avenues for creation of more specific targets.

According to data from 1999 (Benson et al. 2001) for the FWS Southeast Region, the states in the FWS Southeast Region collectively reported, by individual state, a total of 564 nonindigenous aquatic species as having been introduced. However, some species are represented more than once in this total, as they have been introduced into more than one state. Based upon current (June 2007) data from the USGS Nonindigenous Aquatic Species (NAS) website (http://nas.er.usgs.gov/) for the 14 SARP states, comparable totals were 915 for the FWS Southeast Region states and 1,352 for the SARP states. Therefore, between 1999 and 2007 the numbers of introduced species increased in the FWS Southeast Region states by an average of 7.2% per year.

However, not all NAS that are introduced into a state become established and survive year to year, develop reproducing populations or cause problems. Those that do are the most problematic and are the ones referred to in the objective. Using the same data sources as described above, a total of 349 NAS were collectively reported by the FWS Southeast Region states, by individual state, as having become established in 1999. The 2007 comparable totals are 499 for the FWS Southeast Region states and 736 for the SARP states. Thus, between 1999 and 2007 the numbers of introduced species that had become established increased in the FWS Southeast Region states by an average of 5.3% per year. This figure was used as a proxy for the whole region when developing Target 7A since, at present, there is no regional baseline.

Target 7A. Reduce the average annual rate of increase for established NAS in states in the FWS Southeast Region to 3%.

•By 2012 reduce the average annual rate of increase for established NAS in states in the FWS Southeast Region to 5%.

•By 2017 reduce the average annual rate of increase for established NAS in states in the FWS Southeast Region to 4.5%.

•By 2022 reduce the average annual rate of increase for established NAS in states in the FWS Southeast Region to 3%.

Because some non-native species can cause habitat degradation while others may fill an unfilled niche or cause no apparent change to habitat health, additional targets might be set on the basis of certain watersheds or habitat types. These additional targets may be possible at a later date, when all of the SARP states have completed Aquatic Invasive Species Management Plans.

Objective 8: *Conserve, restore, and create coastal estuarine and marine habitats*

The southeastern region's watersheds are critical to the biological productivity and sustainability of coastal estuaries and nearshore waters, and to the economic and sociological health of the coastal communities that depend on them. Actions taken to achieve Objectives 1 through 7 above will have direct and indirect impacts on the overall health of coastal habitats. In a very real way, management actions adopted upstream affect ecosystem health and community resilience along the coast.

As evidence of their value, vital estuarine and marine habitats in the Southeast have been identified as essential fish habitat for federally managed species by the South Atlantic Fishery Management Council, the Gulf of Mexico Fishery Management Council, and the National Marine Fisheries Service. These habitats, also considered important to fisheries managed by the Gulf States Marine Fisheries Commission and the Atlantic States Marine Fisheries Commission, provide food, cover, shelter, spawning sites and nursery areas for marine and estuarine fish and other species. Essential fish habitats in the Southeast include oyster reefs, seagrasses and other submerged aquatic vegetation, estuarine wetlands, mangroves, coral reefs, intertidal flats, estuarine and marine water column, and their underlying sand, mud, and shell bottom substrates.

Coastal habitats, especially in the Southeast, have suffered significant historic losses and degradation due to coastal development, erosion and subsidence, and upstream changes in watersheds. Without well-coordinated, ecosystem-based habitat protection and restoration, these coastal wetland systems will suffer irreparable losses. The challenge is to stop and reverse the loss and degradation of coastal and marine fish habitats in order to maintain fish populations in healthy ecosystems supported by healthy coastal habitats while meeting the needs of all sectors of the U.S. population.

Targets

Achievement of this objective will be measured by percentage of positive change to specific aquatic systems from a baseline condition. Ideally, targets for this objective would be expressed in terms of numbers of acres or percent increases in acreages of specific habitat types, such as oyster reefs, seagrasses, mangroves, and emergent wetlands. Although data on the extent of such areas on a regional basis are incomplete or not compiled in a manner to allow efficient and timely analyses, the EPA has evaluated all estuarine areas on a regional basis nationwide and assigned condition ratings using a standardized format that has been utilized in three coastal condition reports (USEPA 2001, 2004, 2006). These data have been utilized in developing several targets for this objective.

The National Coastal Condition Report II (NCCR II) (USEPA 2004) utilized data from the EPA's National Coastal Assessment (NCA), which gathers data on biota and environmental stressors; NOAA's National Standards and Trends Program, which utilizes site-specific data on toxic contaminants and their ecological effects; and the Fish and Wildlife Service's National Wetlands inventory (NWI), which provides information on the status of the nation's wetlands. In the NCCR II, five primary indices were developed using these data sources for (1) water quality, (2) sediment quality, (3) benthic habitat quality, (4) coastal wetlands and (5) fish tissue contaminants. Although these indices do not address all characteristics of estuaries and coastal waters, they do provide information on ecological conditions. Characterizing coastal conditions was a two-step process. The first step was to assess conditions at individual sites for each indicator. In the second step a regional rating for each indicator using a scale of five (1= poor, 2-4 = fair, 5 = good) was determined, based on the percentage of the area of each region in a given condition. The mean of the indices for the five indicators was then calculated to yield an overall condition index for each region. Using these indices, the NCCR II found that the overall condition for the Southeast Coast estuaries (North Carolina, South Carolina, Georgia and east Florida coasts) was 3.8, and for the Gulf Coast estuaries, 2.4. Although the more recent National Estuary Program Coastal Condition Report (USEPA 2006) also assessed estuarine condition for these same regions using this process, only four of the five indicators were used. For this reason, the data from the NCCR II were used in developing Target 8A.

Target 8A. Increase the overall coastal condition indices for the Southeast Coast and Gulf Coast to 4.2 and 2.8, respectively.

•By 2012 increase the overall coastal condition indices for the Southeast coast and the Gulf coast to 3.9 and 2.5, respectively.

•By 2017 increase the overall coastal condition indices for the Southeast coast and the Gulf coast to 4.0 and 2.6, respectively.

•By 2022 increase the overall coastal condition indices for the Southeast coast and the Gulf coast to 4.2 and 2.8, respectively.

Targets 8B-8F are related to target 8A, but are identified for use in monitoring specific project performance.

The NCCR II found that 5% of the Southeast coast estuaries and 9% of the Gulf coast estuarine areas were in poor condition with respect to water quality. The water quality index was determined using dissolved oxygen, chlorophyll *a*, nitrogen, and phosphorus concentrations and water clarity as indicators. The Gulf coastal area that was rated did not include the large, seasonal hypoxic zone offshore of the Louisiana coast. These indices were used in developing Target 8B.

Target 8B. Reduce the percentage of Southeast coast and Gulf coast estuarine areas rated as being in poor condition with respect to water quality to 4% and 5%, respectively.

•By 2012 maintain the percentage of the Southeast Coast and reduce the percentage of Gulf Coast estuarine areas rated as being in poor condition with respect to water quality at/to 5% and 8%, respectively.

•By 2017 maintain the percentage of the Southeast Coast and reduce the percentage of Gulf Coast estuarine areas rated as being in poor condition with respect to water quality at/to 5% and 7%, respectively.

•By 2022 reduce the percentage of the Southeast Coast and Gulf Coast estuarine areas rated as being in poor condition with respect to water quality to 4% and 5%, respectively.

The NCCR II found that 8% of the Southeast coast estuaries and 12% of the Gulf coast estuarine areas were in poor condition with respect to sediment quality. The sediment quality index was determined using sediment toxicity, sediment contaminants, and sediment total organic carbon as indicators. These indices were used in developing Target 8C.

Target 8C. Reduce the percentage of Southeast Coast and Gulf Coast estuarine areas rated as being in poor condition with respect to sediment quality to 5% and 9%, respectively.

•By 2012 maintain the percentage of Southeast and Gulf Coast estuarine areas rated as being in poor condition with respect to sediment quality at 8% and 12%, respectively.

•By 2017 reduce the percentage of the Southeast and Gulf Coast estuarine areas rated as being in poor condition with respect to sediment quality to 7% and 11%, respectively.

•By 2022 reduce the percentage of the Southeast and Gulf Coast estuarine areas rated as being in poor condition with respect to sediment quality to 5% and 9%, respectively.

The NCCR II found that 11% of the Southeast coast estuaries and 17% of the Gulf coast estuarine areas were in poor condition with respect to benthic habitat quality. The benthic habitat quality index was determined using measures of benthic community diversity, the presence and abundance of pollution-tolerant species, and the presence and abundance of pollution-sensitive species. These indices were used in developing Target 8D.

Target 8D. Reduce the percentage of Southeast Coast and Gulf Coast estuarine areas rated as being in poor condition with respect to benthic habitat quality to 8% and 14%, respectively.

•By 2012 reduce the percentage of Southeast and Gulf Coast estuarine areas rated as being in poor condition with respect to benthic habitat quality to 10% and 16%, respectively.

•By 2017 reduce the percentage of Southeast and Gulf Coast estuarine areas rated as being in poor condition with respect to benthic habitat quality to 9% and 15%, respectively.

•By 2022 reduce the percentage of Southeast and Gulf Coast estuarine areas rated as being in poor condition with respect to benthic habitat quality to 8% and 14%, respectively.

The NCCR II found that indices for coastal wetland loss in the Southeast coast and Gulf coast estuarine areas were 1.06 and 1.30, respectively. These indices were calculated as the average of the mean long-term, decadal wetland loss (1780–1990) and the present decadal (1990–2000) wetland loss rate. These indices were used in developing Target 8E.

Target 8E. Reduce the wetland loss indices for the Southeast Coast and Gulf Coast estuarine areas, to 1.03 and 1.28, respectively.

•By 2012 reduce the wetland loss indices for the Southeast and Gulf coast estuarine areas to 1.05 and 1.29, respectively.

•By 2022 reduce the wetland loss indices for the Southeast and Gulf coast estuarine areas to 1.03 and 1.28, respectively.

The NCCR II found that 5% of the Southeast coast estuaries and 14% of the Gulf coast estuarine areas were in poor condition with respect to fish tissue contaminants. These indices were based on whole fish contaminants analyses and were used in developing Target 8F. Note that fish tissue contamination due to mercury is excluded from Target 8F as the element's presence is widespread and its sources range from historical to natural (including atmospheric deposition from inside and outside the focus area), and control is not currently included through any of the Clean Water Act programs.

Target 8F. Reduce the percentage of Southeast Coast and Gulf Coast estuarine areas rated as being in poor condition with respect to fish tissue contaminants to 4% and 11%, respectively.

•By 2012 maintain the percentage of the Southeast Coast and reduce the percentage of Gulf Coast estuarine areas rated as being in poor condition with respect to fish tissue contaminants at/to 5% and 13%, respectively.

•By 2017 maintain the percentage of the Southeast Coast and reduce the percentage of Gulf Coast estuarine areas rated as being in poor condition with respect to fish tissue contaminants at/to 5% and 12%, respectively.

•By 2022 reduce the percentage of the Southeast Coast and Gulf Coast estuarine areas rated as being in poor condition with respect to fish tissue contaminants to 4% and 11%, respectively.

A combination of these available data can be used to set regional targets that focus on specific wildlife or plants common to the Southeast coasts that respond rapidly, directly and similarly to environmental changes and support habitat health and human needs. Target 8G is an example.

Target 8G. Reduce the percentage of closures of Southeast Coast and Gulf Coast oyster reefs due to contamination of water/tissues to 3% and 11%, respectively

•By 2012 maintain the percentage of closures of oyster reefs due to contaminated water/tissues in the Southeast Coast and Gulf Coast to 5% and 13%, respectively

•By 2017 maintain the percentage of closures of oyster reefs due to contaminated water/tissues in the Southeast Coast and Gulf Coast to 4% and 12%, respectively

•By 2022 maintain the percentage of closures of oyster reefs due to contaminated water/tissues in the Southeast Coast and Gulf Coast to 3% and 11%, respectively.

Data on coastal conditions from many studies may be used to set regional targets as well. Survey data by USGS shows coastal erosion effects in every state. Long-term loss rates range from three to over 60 feet annually. In *Our Living Resources,* a report to the nation on the distribution, abundance, and health of U.S. plants, animals and ecosystems (LaRoe et al. 1995), coastal erosion was classified as severely eroding, moderately eroding or relatively stable. Approximately 40% of the southeast region's shorelines were classified as severely eroding, and only 20% as relatively stable. Target 8H utilizes this baseline.

Target 8H. Prevent additional coastal erosion along 10% of coastlines classified as "severely eroding by 2050.

There are many data resources that can be used on the project level to achieve Objective 8. For example, the USGS' and USEPA's *Seagrass Status and Trends in the Northern Gulf of Mexico: 1940-2002* (Handley et al. 2007), provides an update to their 1995 status and trends report. The World summit on sustainable development committed to reverse the trend of seagrass losses by 2010. Seagrass is valuable fisheries habitat, and some regional states have taken action on this issue. Similarly, an action plan for reducing, mitigating, and controlling hypoxia in the Northern Gulf of Mexico has been developed by the Mississippi River/Gulf of Mexico Watershed Nutrient Task Force.

Where in the Southeast will this Plan be implemented?

Plan Prioritization

The eight objectives in Section 2 of this Plan define the conditions to be addressed through the implementation of the Plan. Because of the size and variety of habitats in the southeastern region, these objectives can guide restoration projects in many areas simultaneously with a broad range of outcomes. However, to most effectively use limited resources to reverse current trends and conserve the region's aquatic habitats, geographic priorities must be set. Careful, periodic selection is required for this Plan's landscape approach to maximize the direct outcomes of every project and sustain the effects at the watershed and regional levels.

In the long term, GIS analysis, incorporating data that are only partially available at the present time, will be used to identify and prioritize aquatic habitats where conservation and restoration actions are most needed and, hopefully, will have the greatest opportunity for local and regional success. In the short term, a less comprehensive prioritization method will provide geographic guidance.

Long-term

The implementation of the National Fish Habitat Science and Data Committee's assessment tool will eventually allow a standardized approach for prioritizing aquatic habitat conservation and restoration projects nationwide. As noted in the Committee's draft science and data report of December 2006, *A Framework for Assessing the Nation's Fish Habitat* (NFHISDC 2006), projects "should be prioritized in the following order: 1) protection of fully functioning aquatic systems to include those that are "untouched" to those that have "manipulated," but fully working aquatic processes; 2) rehabilitation of aquatic systems that have only a minor number of problems that impair one or more of the key processes that sustain them; 3) rehabilitation of aquatic systems that have a number of problems impairing one or more of the key processes; and 4) re-engineering modified systems to improve them for fisheries and aquatic production" (NFHI SDC, p.7). SARP is working directly with the Committee to coordinate the aquatic habitat condition assessment for the southeastern U.S.; and this assessment will enable SARP to enrich its GIS analysis, as described above, and refine its geographic priorities.

Because healthy habitats also affect the ecology, economy and sociology of human communities in the region, data on economic and social elements in the region will also be considered, when available, for objective analysis; consistent with the Plan's goal for restoration undertaken "for the benefit of all in the southeastern region and the entire U.S."

Interim

The need to stem the decline in fisheries habitats throughout the SARP states is urgent. Rather than wait until 2010 to begin this vital work, the year that the aquatic habitat condition assessments are scheduled for completion, SARP is developing a geo-referenced database populated with currently available aquatic system condition data to provide interim geographic priorities for the Plan. This prioritization process – to be used by SARP until the aforementioned condition assessments and an operational priorities database are in place – has provides a less-than-perfect, but acceptable and immediately useful, graphic depiction of the Southeast's most at-risk geographic areas, as identified by one or more of four existing and reliable sources. These sources are:

1. Information on priority geographies from the State Wildlife Action Plans (SWAPs), wherein individual states have identified **priority habitats and habitats supporting species with the greatest conservation needs**. These data have been consolidated by SARP during the development of this Plan.

2. Information on priority watersheds from a 2006 USGS workshop, wherein recognized experts ranked and prioritized by **extant rareness of species and species richness** those southeastern watersheds most in need of protection and restoration. The process involved expert focus on critical areas in the Southeast. Rivers and drainages with the highest number of imperiled and/or at risk species (according to NatureServe), federally listed threatened and endangered species for each faunal group (fishes, crayfishes, mussels, snails, amphibians, turtles), and total richness of each major group were confirmed. Using this information and a set of agreed upon criteria, the workshop developed a list of the top freshwater biodiversity watersheds in the Southeast and the three highest priority watersheds for each state. (NatureServe represents an international network of biological inventories known as natural heritage programs or conservation centers. The objective scientific information about species and ecosystems developed by NatureServe is used by all sectors of the biological scientific community. Data are online at http://services.natureserve.org.)

3. Information on **freshwater, recreational fisheries, and identification of the specific waterbodies** supporting these fisheries, that would benefit the most from habitat enhancement, restoration or conservation activities has been provided by each SARP member state's fisheries management agency.

4. Information on the Southeast's most important estuarine and coastal habitats was also gathered. Each SARP member state with a coastline provided the names and locations of their **most important estuarine and coastal habitats** that could benefit the most from habitat restoration and conservation.

How can SARP facilitate and implement this Plan?

This Plan aims to conserve, protect and restore freshwater, estuarine, and marine habitats in the southeast region to preserve and restore healthy and diverse aquatic resources. Because habitat health depends upon the integration of geographical, geological, biological, sociological and economic systems, recovering and conserving aquatic habitats and communities is biologically complex and sociologically difficult. Watersheds are nested and cross political boundaries; lakes, reservoirs, rivers and estuaries are connected throughout the region. Therefore conservation strategies to accomplish the Plan's aims will be applied on multiple levels.

Habitat restoration, preservation or maintenance in a given geographic area will involve assessing the aquatic habitat's strengths and weaknesses, analyzing threats or problems, formulating partnership-driven action based upon the Plan's overall objectives, completing identified tasks, as well as monitoring and evaluating outputs at the project level and objectives at the Plan's regional level. Although implementation strategies will vary by conditions and time, all projects will utilize best management practices and the best available science of the time.

Science-based conservation strategies responding to causal effects addressed in the Plan's eight objectives are well known among aquatic habitat conservation leaders. These will be applied appropriately to achieve objectives and targets on a project level. As noted in Section 2, the targets will be redefined by new baseline data from research and lessons from individual projects. Through adaptive management, conservation strategies and actions on multiple levels will follow.

Conservation Strategies and Actions – SARP's Role

Although the individual members of SARP will be engaged in local conservation and restoration projects in partnership with other entities, effective implementation of the Plan depends upon SARP's collective management and facilitation at an integrated systems level as well. In this unique role, SARP must initiate, coordinate and lead partnership-driven actions toward the regional achievement of the Plan's goal and objectives.

The objectives and targets in the Plan were selected on the basis of SARP's earlier research in selected river basins, scientific literature, and reported conditions in the SARP states. A review of the SARP member states' SWAP identified common problems and strategies shared by the states in the region. SARP and stakeholders representing diverse habitat conservation and restoration experiences and expertise met and discussed conservation strategies, objectives and outputs. As the basis for these stakeholder discussions, a synthesis of the strategies and actions identified from SWAPs revealed six commonly applied strategic approaches that cross all levels: (1) information collection and distribution, (2) capacity building, (3) law and policy, (4) habitat acquisition, (5) commercial incentives, and (6) habitat management and restoration. The stakeholders advised that two of these strategies, commercial incentives and habitat acquisition, are most often applied on a local (i.e., project) level rather than on the broader, coordination level envisaged as SARP's role in the management and facilitation of this Plan. Therefore these two strategies have been incorporated into one or more of the other strategic approaches as they apply on the integrated systems level of Plan implementation. The strategy of commercial incentives has been incorporated primarily into Integrated Conservation Strategy 2 (capacity building), and the strategy of habitat acquisition into Integrated Conservation Strategies 1 (information collection and distribution) and 4 (law and policy).

The description of each integrated conservation strategy below includes a number of specific actions that SARP and other landscape-level conservation groups can undertake to achieve the goal and objectives of this Plan. These actions, formed by input from stakeholders during Plan development, should be viewed as prospective and contingent on sufficient funds and staff resources, either corporate or through partners. Although actions for SARP are identified for some of the integrated conservation strategies, they are not otherwise prioritized. They are numbered only for convenience. Also, the actions are neither definitive nor inclusive of all actions that SARP and its partners might do, over time, to support the Plan and its implementing partnerships. Rather, they illustrate the forms of integration, management and facilitation that are considered necessary at this point in time. This Plan should be viewed as a work in progress, and specific tasks being undertaken or initiated at any point will, in all likelihood, change in response to environmental, fiscal, and system-level factors, many of which currently cannot be known or predicted.

Integrated Conservation Strategy 1: *Information collection and dispersal*

Through the collection, availability and use of information, SARP can facilitate habitat conservation, restoration and maintenance in several important ways:

Data collection. Verified current and historical data about an area is used in research, and in planning project activities, monitoring projects and post project evaluation to determine the efficacy of achieving the Plan's goal and objectives. By facilitating information collection, developing guidelines to increase data integration, establishing archives, and making information accessible, SARP and its aquatic habitat partners can help project planners secure and integrate scientific data from educational institutions, federal and state databases and archives, as well as private and corporate records. In this way, SARP can enhance GIS analysis and various types of modeling. Such well organized and easily accessed data facilitates multiple-scale habitat planning and coordination. In addition, information about specific habitat conservation and restoration techniques facilitates regional consistency in their application and leads to a more effective use of tools, people, and funding while increasing compatibility between individual projects.

Information distribution. Broadly distributed information provides the basis for public support of a habitat project's actions – from land acquisition to limited use – and public enthusiasm for the general concept of habitat conservation. Information distribution is also an educational strategy. Individuals, corporate officers, and public officials can learn about and participate in a range of activities from planning active restoration of a habitat to applying project guidelines to policymaking. School curricula can evolve from project success stories, as well as from guidelines for particular restoration processes.

The following actions will be ***undertaken by the SARP Steering Committee*** in the first year to implement **ICS 1:**

> **ICS Action 1A.** Establish a Science and Data Committee to identify existing information and data gaps associated with the freshwater, estuarine, and marine aquatic habitat types in the Southeast for purposes of Plan implementation. Thereafter, this SARP committee will encourage data collection, and broad distribution and integrated use through ICS action items 1C and 1D to achieve the Plan's objectives.
>
> **ICS Action 1B.** Establish an Education and Outreach Committee to distribute and explain this Plan broadly among elected officials at all levels, government agency managers, NGOs, industry, stakeholders and the public throughout the Southeast. Thereafter, this SARP committee will integrate information distribution with efforts of project partners to accomplish ICS action items 1E, 1F, and 1G (below).

The following action items will be ***undertaken by the SARP Steering Committee, its committees and partners*** to implement **ICS1**:

> **ICS Action 1C.** Develop an Internet web site to serve as a portal for a variety of information and databases on aquatic habitat conservation in the Southeast, to encourage data sharing among partners, and to inform and educate stakeholders.
>
> **ICS Action 1D.** Support the National Fish Habitat Science and Data Committee in developing science-based tools for on-going assessment of fish habitats nationwide through the coordinated development of a process to better assess fish habitat conditions in the Southeast.

ICS Action 1E. Identify guidelines and guideline sources where needed, on specific aquatic habitat management tools and practices such as stream corridor restoration, fee-title land acquisition, easements, project permitting and monitoring.

ICS Action 1F. Develop educational and outreach tools for specific purposes such as facilitating establishment of conservation easements, or sharing and coordinating best management practices (BMP) in accomplishing aquatic habitat conservation in the Southeast.

ICS Action 1G. Develop general outreach and education tools to be used throughout the region regarding the protection of watersheds, importance of aquatic habitats, and methods for their protection and restoration.

The following action will be ***undertaken by the SARP Aquatic Habitat Plan Committee*** to implement **ICS1**:

ICS Action 1H. Assess progress at five-year intervals, using available information as identified in each objective's targets in the Plan, and report to agency and elected officials, partners, stakeholders and the public. This action will be supported by the Education and Outreach Committee and the Science and Data Committee, both created in the Plan's first year.

Integrated Conservation Strategy 2: *Capacity building*

Habitat conservation, maintenance and restoration projects require tactical alliances among public and private stakeholder groups, solid leadership and adequate funding. By building alliances, encouraging leadership and seeking funding, SARP can facilitate capacity building in the following ways:

Alliances. To build alliances, SARP will facilitate recruitment of new, project-specific partners by integrating groups with specific jurisdictional responsibilities (e.g., states, the EPA, U.S. Army Corps of Engineers and Natural Resource Conservation Service) with local landowners, municipal and county officials, and a variety of NGOs of all sizes, especially those with a Plan-related purpose.

Leadership. Responsible leadership doesn't just happen. A major part of SARP's strategic capacity building aims to identify and support (with funds and information) responsible leadership among project partners. Coordination and integration of these individuals builds leadership capacity. As one project leads to and/or affects another, good leaders can see such connections and, with support, integrate activities to make best use of available dollars and labor.

Funding. Restoration capacity depends heavily on available funds. Identification of funding resources includes encouraging use of federal incentives and stimulating private, state and local incentives. With SARP's coordination, it will be possible to leverage existing funds on a broad basis and possibly to integrate commercial with environmental goals. Sometimes bringing various groups to one table can create the resources needed for a project.

SARP itself is a strong partnership, and its members can contribute leadership, funding capacity, and in-kind resources for various habitat restoration projects and their coordination. Importantly, SARP and the Plan's stakeholders collectively understand that the specific actions needed to successfully support capacity building must be persistent and ongoing.

The following actions will be ***undertaken by the SARP Steering Committee*** to implement **ICS 2:**

ICS Action 2A. Maintain close coordination with existing partnerships, initiatives, and organizations (such as, but not limited to, the Upper and Lower Mississippi River Conservation Committees, the Gulf of Mexico Program, National Estuary Programs, Restore America's Estuaries, the Gulf of Mexico Alliance, the Mississippi River/Gulf of Mexico Watershed Nutrient Task Force, Chesapeake Bay Program, the Comprehensive Everglades Restoration Plan, migratory bird joint ventures, and all NFHAP-recognized partnerships) and identify new groups focused on specific aquatic habitat issues or southeastern geographic areas.

ICS Action 2B. Support the development and efforts of NFHAP implementation units in the Southeast to encourage participation by diverse partners, including groups that have not been directly involved with SARP in the past.

ICS Action 2C. Continue coordination with individual southeastern states, the Southeastern Association of Fish and Wildlife Agencies (SEAFWA) and other partners to assure that aquatic habitat conservation efforts are consistent and coordinated with each state's CWCS (SWAP).

ICS Action 2D. Serve as a catalyst to coalesce NGOs, professional societies and fisheries groups to develop projects, secure funding and build partnerships for aquatic habitat conservation in the Southeast.

ICS Action 2E. Develop and share tools to facilitate partner capacity building, such as templates for memoranda of agreement, grant proposals, bylaws, and operational procedures.

ICS Action 2F: Support and encourage opportunities for communication and coordination among leaders of implementation units to maximize outcomes of aquatic habitat conservation projects.

ICS Action 2G. Serve as a clearinghouse for public and private funding sources for aquatic habitat restoration and conservation.

ICS Action 2H. Work with state, regional, corporate and private partners to facilitate development of economic and other incentives for aquatic habitat restoration.

ICS Action 2J. Stimulate an increase in the level of funding for fish habitat conservation efforts throughout the Southeast from federal, state, and private sources using all appropriate approaches, including initiatives seeking public funds in order to leverage corporate and other private sources.

ICS Action 2K. Stimulate cooperative and integrated use of existing resources, especially habitat conservation funding programs by federal, state, tribal and local agencies, NGOs, landowners, and other stakeholders towards achieving the Plan's objectives.

Integrated Conservation Strategy 3: ***Management and restoration***

Multiple-scale coordination and integration of Plan and project objectives are necessary roles for SARP. Because changes made in one part of a watershed often affect other portions, regional integration on a higher level maximizes the effectiveness of all conservation efforts.

Thus, besides coordinating partnership-driven aquatic habitat restoration projects – which represent joint ventures on many different scales – SARP will take the lead in supporting and enhancing regional habitat management activities wherein all southeastern states can plan and participate together in the compatible uses of resources, integrating activities to protect threatened and endangered species, and control and prevent domination by invasive and problem species. Central to this process, regional priorities will be explored and agreed upon and various project approaches – such as integration by problem, objective, or habitat – investigated so as to maximize available leadership and resources.

The following actions will be ***undertaken by the SARP Steering Committee*** to implement **ICS 3:**

ICS Action 3A. In the first year, identify priority areas and habitats to best achieve the Plan's objectives, sharing conclusions with other aquatic habitat partnerships, organizations and programs throughout the Southeast to encourage compatibility in resource management decisions. Thereafter, the Science and Data Committee will use best available information to review and revise these priorities.

ICS Action 3B. In the first year, develop project prioritization and selection guidelines for specific projects to be implemented with funding from NFHI or similar initiatives or programs in which SARP is a direct participant or serving as a grantor. Thereafter, these guidelines will be revised by adaptive management.

ICS Action 3C. Continue to support SARP states, and the Gulf & South Atlantic and the Mississippi River Basin regional ANS panels in the development and implementation of state and regional ANS management plans. In conjunction with those plans, facilitate integration of early detection and rapid response plans and coordination of management activities to address the issues associated with invasive or problem species affecting watersheds of the Southeast.

ICS Action 3D. Coordinate the development and implementation of uniform standards for mitigating damages to wetlands and other aquatic habitats across the Southeast.

ICS Action 3E. Develop a comprehensive regional approach to reservoir habitat management, restoration, and enhancement.

ICS Action 3F. Facilitate implementation of appropriate activities to address the problematic habitat structure issues affecting watersheds of the Southeast.

ICS Action 3G. Collaborate with other fish habitat partnerships, state, federal, tribal and local agencies, NGOs, and other natural resource partnerships to protect through fee title acquisition, easement, or other arrangements the high quality freshwater, estuarine, and marine aquatic habitats in the Southeast.

The following actions will be ***undertaken by the SARP Education and Outreach Committee*** to implement **ICS 3**:

ICS Action 3H. Encourage use of quality, 'smart' or sustainable growth standards in local and regional land use planning and regulations associated with aquatic habitats.

ICS Action 3J. Facilitate the development and use of standardized aquatic habitat restoration best management practices (BMPs) in projects, including use in requests for proposals, restoration and management activities, and project evaluation criteria.

The following actions will be ***undertaken by the SARP Science and Data Committee*** to implement **ICS3:**

ICS Action 3K. Encourage and facilitate integration of relevant data from state and federal water quality agencies, NGOs and grassroots watershed organizations in the Southeast to address the problematic water quality issues affecting watersheds in the Southeast.

ICS Action 3L. Encourage and facilitate integration of relevant data from state, regional and federal groups concerning identification, introduction, and control of invasive species in the region.

Integrated Conservation Strategy 4: *Law and policy*

Although laws and policy to protect aquatic habitats in the Southeast exist on federal, state and local levels, they are neither universally compatible nor universally applied. Some are enforced throughout the region; others are enforced only in certain areas or under certain conditions. These differences can reduce the effectiveness of landscape-level habitat conservation and restoration throughout a watershed or the region.

Sometimes interjurisdictional overlaps or differences are not noticed until attention is brought when initiating a project or through litigation. Through education on law and policy, such differences could be accommodated early on, prior to implementation of a joint venture. For example, a universal understanding of land use and zoning ordinances throughout a watershed or the region would be an appropriate step in coordinating projects located in several different areas addressing the same problem or focusing on the same watershed. Likewise, support for coordination of instream-flow policies would ensure watershed or regional conservation outcomes and facilitate monitoring activities.

When necessary, tools such as cooperative agreements can be developed to integrate state and local policies, facilitating acceptance and perhaps even universal standards. In addition, policy-related procedures or new legislation can maximize aquatic habitat restoration outcomes. For example, land acquisition may be a necessary part of certain conservation or restoration projects. A streamlined, regionally agreed-upon process for aquatic habitat-related land acquisition or easement acquisition would be an important step in securing broad support and cooperation in a watershed or the region.

SARP's role under the law and policy integrated conservation strategy is to gather and make available relevant data, tools and protocols that can be used by appropriate government bodies to enact or change legislation and policy. SARP does not advocate specific changes in law and policy. It coordinates and shares information about existing laws and policies (and gaps in them) so that appropriate government bodies can enable aquatic habitat protection, conservation and restoration to meet the Plan's objectives.

The following actions will be ***undertaken by the SARP Steering Committee*** to implement **ICS 4**:

> **ICS Action 4A.** In the first three years, work with the Instream Flow Council, state water agencies, state legislators and conservation NGOs to develop adequately staffed instream flow programs in each of the southeastern states and a network to integrate stream flow and mitigation standards in the region. This process will create a procedural template for additional law and policy actions to meet the Plan's objectives.
>
> **ICS Action 4B.** Opportunistically, develop tools, guidelines and protocols to facilitate law and policy focusing on uniform regional water quality standards, TMDLs for sediment and stormwater issues, and the habitat needs of at-risk aquatic species.
>
> **ICS Action 4C.** Using the procedural template from action item 4A, identify and convene as needed networks of experts to assist in developing region- or watershed-wide policies or legislation to facilitate coordinated projects to achieve the Plan's objectives.

The following action will be ***undertaken by the SARP Education and Outreach Committee*** to implement **ICS 4:**

> **ICS Action 4D.** Support workshops for user groups such as city and county planners, describing laws, policies, potential conflicts, jurisdictional overlaps and information gaps relevant to aquatic resources and habitats.

How can SARP and project partners measure success?

Monitoring Habitat Conservation and Recovery

This Plan suggests the pathway to conserve and restore the inland, coastal and estuarine habitats of the 14 member states of the Southeast Aquatic Resources Partnership (SARP). As SARP facilitates and manages the implementation of the Plan, it is vital to understand and document the Plan's conservation and restoration performance and, in view of that performance, adapt the Plan's program and project approaches to improve future conservation and restoration practices and projects.

Monitoring will contribute to an understanding of the complex ecological systems within which the Plan's conservation and restoration projects are implemented, and result in identifying habitat improvement. It can warn of environmental decline, establish a record of conditions or trends, and identify gaps in existing scientific knowledge. It will also provide the basis for a rigorous review of habitat project planning and implementation to determine whether project results are being achieved and if mid-course corrections are necessary. This will allow for design improvements in future projects, provide tools for planning additional habitat management strategies, and provide essential information on whether project results are good measures for anticipating progress on Plan objectives.

The Plan's monitoring approach has a two-tier structure that corresponds to program-level performance measurement of the Plan's objectives at ecosystem and regional scales and, at local scales, project-level monitoring of the performance of specific projects against their purposes and objectives.

Tier 1 – Monitoring the Plan's performance

Because the resource targets in the current version of the Plan rely on existing databases and analyses as described under each objective, program-level monitoring under Tier 1 will use those databases and analyses as further developed in future years. Certain limitations will be inherent in this monitoring approach because these databases and analyses are managed independent of SARP. Where possible, SARP will attempt to secure and use the underlying data from these sources to independently develop assessments of progress in cases where analysis or assessment may not be completed by the source organization.

SARP has begun development of GIS-referenced analysis tools that will allow it to conduct regional aquatic habitat condition assessments using methodology described by the NFHAP Science and Data report. The first phase of this project, focused on the Tennessee-Cumberland watershed, will yield a GIS-referenced database that can eventually be developed for Tier 1 analysis. SARP's long-term plan, as funds can be secured, is to collect and analyze data and conduct habitat condition assessments for all major watersheds in the region in a manner compatible with the NFHAP. GIS analysis of various combinations of these data can provide graphic description to better assess achievement of the objectives' targets as well as assist in future habitat restoration project planning and prioritization. The tool(s) will be compatible with the NFHAP National Habitat Condition Assessments.

When fully developed, such tools can be used for effectively monitoring and evaluating aquatic habitat health in the Southeast. Once sufficient data have been developed, compatible data set formats identified and NFHAP National Habitat Condition Assessments are available, the status and trends of the aquatic habitats in the region will be assessed at the Tier 1 level every five years. A variety of data can be used, based upon the targets identified for the objectives. For NFHI projects, these evaluations will be guided by the NFHAP condition assessment processes and protocols. Conditions in SARP's priority watersheds will be examined in particular detail, and compared to Plan targets and conditions generally throughout the SARP states as an indicator of the effectiveness of the Plan's efforts at ecosystem and regional scales.

Tier 2 – Monitoring project performance

Through the Plan, large-scale habitat conservation and restoration in the SARP states will be achieved by managing aquatic habitat projects implemented through new and existing partnerships, and facilitating project funding. However, many, if not all, of these projects will be completed at local, project level (i.e., watershed, sub-watershed and municipal) scales. While monitoring at the input and output levels for project management purposes is expected, monitoring those Plan objectives associated with the project is also necessary. The former provides SARP and project managers with information on whether the project is doing what it promised to do; and the latter gives information on whether or not the project is contributing to achievement of the Plan's objectives.

To ensure that data is accumulated on these scales, every project proposal will be required to include a monitoring plan. An example will be provided in the request for proposals. The data gathered in this process can then be in forms that can be analyzed on several levels, such as written reports, photographic documentation, information on survival rates or anticipated life spans of physical and biological changes, and hydrologic data. It is expected that monitoring efforts will be periodic in the first year and annually thereafter. This type of monitoring plan can improve the project's success by including contingency measures specifying remediation procedures to be followed if success criteria or scheduled performance criteria are not fully satisfied. Adaptive management activities can then be used to adjust to unforeseen or changing circumstances.

Sharing monitoring data and analyses

To be useful, monitoring findings, conclusions and "lessons learned" have to be shared. Information resulting from a well-designed and conducted monitoring program supports the timely and successful management of on-going habitat conservation and restoration projects, and the success of the Plan itself. Project and Plan managers can use results in adaptive management to make mid-course corrections in specific project features. Additionally, monitoring information regarding the performance of both a project overall and its constituent features is highly useful to individuals designing current and future projects with similar features and goals or in similar habitats. Monitoring data, results analysis, and a discussion of lessons learned will be made available by SARP in many ways, especially on the SARP web site.

Where in the Southeast will this Plan be implemented?

Glossary

Algae – A variety of single-celled to complex multicellular plants that are common in aquatic ecosystems.

Amphibian – A class of cold-blooded vertebrate, such as a frog or salamander, with gilled aquatic larvae (e.g. tadpole) that develop air-breathing lungs as an adult (e.g. frog).

Anadromous – A type of migration in which adult fish spend their lives at sea and return to freshwater to spawn.

Anthropogenic – Effects, processes, objects, or materials derived from human activities.

Aquatic – Growing, living in, or frequenting water. Taking place in or on water.

Aquatic habitats – All bodies of flowing and standing water such as streams, rivers, reservoirs, lakes and ponds; estuarine, palustrine, lacustrine and forested wetlands; riparian areas along streams, rivers, lakes and reservoirs; karsts; coastal freshwater dune swales; coral reefs, oyster reefs, sand and algal flats.

Aquifer – An underground layer of water-bearing permeable rock or unconsolidated materials such as gravel, sand, silt or clay from which water can be usefully extracted.

Armored Shoreline – Areas along a waterbody where the land has been structurally reinforced.

At risk – A description of populations that are likely to become severely reduced or extinct due to imminent threats.

Backwater – A waterbody created by a flood or tide or by being held or forced back by a dam.

Benthic; benthonic – On the bottom, under a body of water.

Benthos – Organisms and habitats under a body of water, on the floor of fresh and salt waterbodies.

Biocide – a chemical substance capable of killing living organisms.

Biodiversity – The variety of life and its processes, including the variety of living organisms, the genetic differences among them, and the communities and ecosystems in which they occur.

Biotic integrity – A healthy balance of biota in a habitat. It is measured by one of a number of multi-metric indices (IBI) that have been developed by study of aquatic ecology. The metrics reflect the richness and composition of biota in a habitat as well as the trophic organization and function, reproductive behavior and condition of all individual species.

Bog – A palustrine wetland with poorly drained, wet spongy soil full of plant residue, frequently surrounding open water.

Buffer – Land located immediately adjacent to a waterbody that has sufficient size and vegetative composition to perform the function of filtering surface and soil water as it finds its way to the stream channel.

Canopy – A layer or multiple layers of branches and foliage at the top or crown of a forest's trees.

Channel – The natural or man-made bed in which a stream of water runs; the area between two stream banks at bank-full elevation.

Channelization – The process of reconstructing the natural course of a stream in order to make it flow into a restricted path.

Clear cut – A harvesting and regeneration method that removes all trees within a given area. Clear-cutting is most commonly used in pine and hardwood forests, which require full sunlight to regenerate and grow efficiently.

Community – A group of species that share an ecosystem.

Connectivity – The ability of water, nutrients and organisms to move unobstructed along water courses to include movement upstream and downstream, lateral movement to floodplains, and vertical movement to recharge aquifers.

Conservation – Planned management of the use of the biosphere to benefit the present generation in a way that ensures continuing availability for future generations; careful use of natural resources for sustainability. Also, the
use of methods and procedures necessary to bring any endangered or threatened species to a point at which the measures provided under the Endangered Species Act are no longer necessary.

Contaminants – substances that are harmful or toxic to aquatic life.

Cubic feet per second (cfs) – Measurement unit to describe how much water is flowing in a stream or river. Flow (or discharge) is measured as the volume (cubic feet) of water that passes a given point each second.

Culvert – A conduit used to enclose a flowing body of water. Culverts can be made of many different materials such as steel, polyvinyl chloride, and concrete.

Dam – A barrier across flowing water that obstructs, directs or retards the flow, often creating a reservoir, lake or impoundment.

Denitrification – The process of reducing nitrate and nitrite, highly oxidized forms of nitrogen available for consumption by many groups of organisms, into gaseous nitrogen, which is far less accessible to life forms.

Detritus – Non-living particulate organic material, such a decaying plant and animal matter.

Development – New construction projects that convert land from green space to buildings and impermeable surfaces.

Discharge – The amount of water that is flowing in a stream channel. Measured as volume per unit of time such as cubic feet per second (cfs).

Dissolved oxygen – The amount of gaseous oxygen molecules (O_2) found in water. Water molecules also contain oxygen, but only this gaseous form is readily available for respiration by aquatic plants and animals.

48 Southeast Aquatic Habitat Plan 2008

Dredging – The removal of material from the bottom of a waterbody, typically done to make the area deeper for navigation, or to harvest gravel or sand for building materials.

Easement – A contractual agreement between a landowner and another party, or government agency on behalf of the public, that allows specific uses of the property for a specified time period, but does not release the ownership of the land.

Ecology – Science concerned with the interrelationships of organisms and their environments.

Ecosystem – Any dynamic and interrelated community of living things interacting with nonliving chemical and physical components that form and function as a natural environmental unit.

Emergent wetlands – Marshes dominated by grass-like plants, rooted in bottom sediments, and emerging or appearing above the surface of the water.

Endangered species – An animal or plant species in danger of extinction throughout all or a significant portion of its range.

Endemic – Restricted in distribution to a particular geographic area or drainage. Term used with reference to any plant or animal taxon.

Ephemeral – Living or lasting for only one or a few days.

Erosion – Process of weathering or wearing away stream banks and adjacent land slopes by water, ice, wind, or other factors. Removal of rock and soil from the land surface by a variety of processes including gravitational stress, mass wasting, or movement in a medium.

Estuary – A semi-enclosed coastal body of water which has a free connection with the open sea and within which sea water is measurably diluted or mixed with fresh water from land drainage.

Estuarine – Of, relating to, or formed in an estuary.

Fauna – Collectively, the animal life of a particular area region, or special environment. A list of animal species and descriptions for a particular area or time period.

Fecundity – Reproductive fruitfulness. Relative number of eggs, sperm, or young produced by an animal.

Fen – Bog with alkaline, mineral rich water.

Floodplain – Palustrine wetland adjacent to a river. When a river's water exceeds its banks, it enters the floodplain and is forced to spread out, losing most if its velocity and capacity to rise.

Flora – The plant life of a particular area, region, or special environment. A list of plant species characteristic of a specific place or time period.

Flow – To move or movement in a continual change of place.

Forested wetland – Wetland dominated by trees, similar to a true swamp but lacking continuously standing water, although repeated flooding is common.

49 Southeast Aquatic Habitat Plan 2008

Freshwater – Water that contains less than 1,000 milligrams per liter (mg/L) of dissolved solids. Water that is not salty.

Freshwater marsh – A wet meadow with saturated soil and dominated by grasses and sedges adjacent to a bog or marsh with persistent emergent plants and open water.

Functional guild – A group of organisms that are considered influential in providing particular ecosystems services. For instance, freshwater mussel species as well as net-spinning caddis flies may improve water quality by filtering a wide array of suspended particles and nutrients such as ammonia and nitrates from the water column, and converting it to animal biomass.

GIS – Acronym for Geographic Information System. An integrated collection of computer software and data used to view and manage information about geographic places, analyze spatial relationships, and model spatial processes. Provides a framework for gathering and organizing spatial data and related information for display and analysis.

Groundwater – Water located beneath the ground surface in soil pore spaces and in the fractures of geologic formations.

Guild – An association of animals with similar food and reproductive habits, and habitat use.

Habitat – Area in which natural functions provide the necessary food, water, shelter and space for a system of plants, animals, and other organisms to live.

Habitat enhancement – Manipulation of the physical, chemical, or biological characteristics of a site to heighten, intensify, or improve specific functions.

Habitat establishment – Manipulation of the physical, chemical, or biological characteristics present to create and maintain habitat that did not previously exist on the site.

Habitat improvement – On-the-ground restoration, enhancement, establishment or protective action to restore or artificially provide physiographic, hydrological, or disturbance conditions necessary to establish or maintain native plant and animal communities.

Habitat maintenance – Manipulation of the physical, chemical, or biological characteristics of an existing, functioning habitat to preserve or continue the efficacy of specific functions.

Habitat restoration – Manipulation of the physical, chemical, or biological characteristics of a site to return some or all of its natural and historic functions.

Horticulture – The science and art of growing fruits, vegetables, flowers, or other plants.

Hydrologic – Having to do with the properties, distribution, and circulation of water on the surface of the land, in soil and underlying rocks, and in the atmosphere.

Hydrology – The science of dealing with the properties, distribution, and circulation of water on the surface of land, in soil and underlying rocks, and in the atmosphere.

Hypoxic – State of having too little oxygen in the tissues or water for normal metabolism or a healthy ecosystem.

Impaired – Made worse or diminished in some respect. Relative to aquatic systems, a particular waterbody has been negatively impacted so that it does not meet its designated use of fishable, swimmable, or some other criterion.

Imperiled species – Species of concern, species of greatest conservation need, a population of a species that is in danger of disappearing due to a variety of circumstances.

Impervious – Refers to material through which water cannot pass or passes with great difficulty.

Impoundment – A natural or artificial body of water that is confined by a structure such as a dam to retain water, sediment or wastes.

Integrated – Incorporated or melding various parts into a cohesive, larger unit. Unified.

Integrity – The unimpaired condition of a habitat or environment.

Interim – An intervening period of time, not final.

Interjurisdictional – Between political jurisdictions. A species, area, or responsibility shared among various state, federal or other public entities.

Intertidal flats – That portion of the sea bottom between high and low tide lines with a very slight gradient. Depending on tidal amplitude and slope of the bottom, intertidal flats may be narrow or wide.

Invasive species – Any nonindigenous species, including its seeds, eggs, spores, or other biological material, propagating or able to propagate in a specific ecosystem, whose introduction does or is likely to cause economic or environmental harm or harm to human health.

Karst –Terrain usually formed on carbonate rock where groundwater has made openings to form a subsurface drainage system. Caves with standing or moving water.

Lacustrine habitat – All habitats situated in a lake, depression or dammed channel, lacking trees, shrubs, persistent emergent plants, emergent mosses or lichens with greater than 30% aerial coverage. Total area usually exceeds 20 acres. Waters may be tidal or nontidal, but always less than .05% salinity.

Lentic – An aquatic system with standing or slow flowing water such as a lake, pond, reservoir or wetland, with a nondirectional net flow of water.

Levee – A natural or artificial embankment or earthen dike, which parallels the course of a river.

Lotic – An aquatic system with flowing water such as a brook, stream or river, with unidirectional net flow of water from headwater to mouth.

Marine – Of or relating to the sea and saltwater.

Marsh – A wetland with emergent vegetation, and located in zones progressing from terrestrial habitat to open water. May be dominated by either salt or freshwater.

Metrics – Standard units of measure for certain characteristics of habitat, biota, organization or function.

Morphology – Physical attributes of a waterbody.

Native – Plant or animal species that occur naturally in aquatic or terrestrial habitats.

Niche – Ecological position of an organism within its community or ecosystem that results from the organism's structural adaptations, physiological responses, and specific behavior.

Nitrification – The process of binding gaseous atmospheric nitrogen to soil or water, usually by conversion into ammonia or nitrate. Nitrification is an important step in the nitrogen cycle.

Nonindigenous – An organisms that is not native to a particular waterbody, basin, or region. Non-native.

Nutrient – Element or compound essential for growth, development, and life for living organisms.

Organic – Of biological origin.

Palustrine habitat –Any inland wetland which lacks flowing water and contains ocean-derived salts in concentrations of less than .05%. Inland marsh, swamp, bog, fen, tundra or floodplain.

Parasites – An animal or plant that lives in or on a host (another animal or plant) and obtains nourishment from the host without benefiting or killing it.

Partner – Any entity that voluntarily participates with another on a project.

Parts per million (ppm) – A unit of concentration equal to a number of parts of one substance in one million parts of the solution. One ppm equals 0.283 gallons/cubic foot, 0.0038 grams/gallon, 2.72 pounds/acre foot, and one milligram/liter.

Pathogens – An organism that causes disease in another organism.

Pesticide – any chemical used to control populations or organisms that are undesirable to humans.

Pollutant – a chemical or waste product contaminating the air, soil, or water.

Preservation – Protection of ecologically important aquatic resources in perpetuity through the implementation of appropriate legal and physical mechanisms.

Priorities – Most critical geographic and or habitat areas, sometimes described in species-related terms.

Productivity – (1) Capacity or ability of an environmental unit to produce organic materials. (2) Rate of formation of new tissue or energy use by one or more organisms.

Reservoir – Anything used to store water with easy access for addition or removal. Most often, it is an artificial lake, created by a dam.

Resource – (1) A living or non-living substance of value to humans. Often classified as renewable (fish, forest, water, etc.) or nonrenewable (minerals, fossil fuels, etc., that cannot sustain a rate of formation relative to human use).

Riparian – Pertaining to, situated or dwelling on the margin of a river or other waterbody.

Riparian corridor – Area between the topographic floodplain banks of a flowing waterbody, excluding the stream channel.

Runoff – surface water from rain, snow melt and other sources that flows overland and into waterbodies.

Saltwater – Water containing dissolved salts, especially salts of alkali metals or magnesium.

Saline – Consisting of or containing salt, especially relating to the salts of alkali metals or magnesium.

Sediment – Particulate matter, especially loose pieces of mineral and rock that may be carried by flowing water, settled in benthic areas, or suspended in a water column.

Siltation – Settling of fine, suspended sediments in water where water velocity is reduced.

Species – A classification of individual organisms with common attributes, which actually or potentially interbreed.

Species of concern –A species that might be in need of conservation action.

Sprawl – Growth of an urban area that is unplanned and uncontrolled.

Stakeholder – A person or group of people having direct interest, involvement, or investment in an issue or resource.

Subsidence – Lowering of surface elevations caused by loss of support and subsequent settling or caving of subsurface materials.

Substrate – Mineral and organic material forming the bottom of a waterway or waterbody.

Sustainability – The continuity of economic, social, institutional and environmental aspects of human society to meet their needs and express their greatest potential in the present, while preserving biodiversity and natural ecosystems, and planning and acting for their maintenance in the long term.

Swamp – A wetland dominated by woody plants.

Target – Desired quantitative and/or qualitative result of restoration, conservation, or maintenance actions.

Terrestrial – Belonging to, or living on, land, the ground or earth.

Threatened species – Any animal or plant species likely to become endangered within the foreseeable future throughout all or a significant portion of its range.

Toxicity – Quality, state, or degree of a harmful effect in organisms that results from alteration of natural environmental conditions.

Urbanization – Increase over time of the population and extent of cities and towns.

Water – A binary compound that occurs at room temperature as a clear, colorless, odorless, tasteless liquid, freezing into ice below 0 degrees C. and boiling above 100 degrees C.

Water quality – Description of the chemical, physical and biological characteristics of water in an aquatic area or waterbody, usually in relation to its uses or suitability for a particular purpose.

Waterbody – Any area with water flowing or standing above ground to the extent that evidence of an ordinary high water mark is established in any normal year. It can be a stream, river, lake, spring, backwater, bayou, creek, ocean, bay, pond, or wetland.

Watershed –The catchment basin bounded by ridges, from which the waters of a stream, marsh, river, lake or groundwater system are drawn.

Watershed connectivity – Spatial and temporal connections for aquatic and riparian species within and between watersheds that provide physically, chemically and biologically unobstructed movement for their survival, migration and reproduction.

Wetland – Land areas containing much soil moisture, usually poorly drained, and characterized by hydrophytic vegetation, and hydric soils. The land area may have permanent or periodic inundation by water or prolonged soil saturation generally resulting in anaerobic soil conditions.

FISHERY ECOSYSTEM PLAN
OF THE SOUTH ATLANTIC REGION

THIS IS A PUBLICATION OF THE SOUTH ATLANTIC FISHERY MANAGEMENT COUNCIL PURSUANT TO National Oceanic and Atmospheric Administration Award No. NA05NMF4410004

ABBREVIATIONS AND ACRONYMS

ABC	Acceptable Biological Catch
ACCSP	Atlantic Coastal Cooperative Statistics Program
APA	Administrative Procedures Act
AUV	Autonomous Underwater Vehicle
B	A measure of stock biomass either in weight or other appropriate unit
B_{MSY}	The stock biomass expected to exist under equilibrium conditions when fishing at F_{MSY}
B_{OY}	The stock biomass expected to exist under equilibrium conditions when fishing at F_{OY}
B_{CURR}	The current stock biomass
CEA	Cumulative Effects Analysis
CEQ	Council on Environmental Quality
CFMC	Caribbean Fishery Management Council
CPUE	Catch per unit effort
CRP	Cooperative Research Program
CZMA	Coastal Zone Management Act
DEIS	Draft Environmental Impact Statement
EA	Environmental Assessment
EBM	Ecosystem-Based Management
EEZ	Exclusive Economic Zone
EFH	Essential Fish Habitat
EFH-HAPC	Essential Fish Habitat - Habitat Area of Particular Concern
EIS	Environmental Impact Statement
EPAP	Ecosystem Principles Advisory Panel
ESA	Endangered Species Act of 1973
F	A measure of the instantaneous rate of fishing mortality
$F_{30\%SPR}$	Fishing mortality that will produce a static SPR = 30%.
$F_{45\%SPR}$	Fishing mortality that will produce a static SPR = 45%.
F_{CURR}	The current instantaneous rate of fishing mortality
FMP	Fishery management plan
F_{MSY}	The rate of fishing mortality expected to achieve MSY under equilibrium conditions and a corresponding biomass of B_{MSY}
F_{OY}	The rate of fishing mortality expected to achieve OY under equilibrium conditions and a corresponding biomass of B_{OY}
FEIS	Final Environmental Impact Statement
FMU	Fishery Management Unit
FONSI	Finding Of No Significant Impact
GOOS	Global Ocean Observing System
GFMC	Gulf of Mexico Fishery Management Council
IFQ	Individual fishing quota
IMS	Internet Mapping Server
IOOS	Integrated Ocean Observing System
M	Natural mortality rate

MARMAP	Marine Resources Monitoring Assessment and Prediction Program
MARFIN	Marine Fisheries Initiative
MBTA	Migratory Bird Treaty Act
MFMT	Maximum Fishing Mortality Threshold
MMPA	Marine Mammal Protection Act of 1973
MRFSS	Marine Recreational Fisheries Statistics Survey
MSA	Magnuson-Stevens Act
MSST	Minimum Stock Size Threshold
MSY	Maximum Sustainable Yield
NEPA	National Environmental Policy Act of 1969
NMFS	National Marine Fisheries Service
NMSA	National Marine Sanctuary Act
NOAA	National Oceanic and Atmospheric Administration
NRC	National Research Council
OY	Optimum Yield
POC	Pew Oceans Commission
R	Recruitment
RFA	Regulatory Flexibility Act
RIR	Regulatory Impact Review
SAFE	Stock Assessment and Fishery Evaluation Report
SAFMC	South Atlantic Fishery Management Council
SEDAR	Southeast Data, Assessment, and Review
SEFSC	Southeast Fisheries Science Center
SERO	Southeast Regional Office
SDDP	Supplementary Discard Data Program
SFA	Sustainable Fisheries Act
SIA	Social Impact Assessment
SSC	Scientific and Statistical Committee
TAC	Total allowable catch
T_{MIN}	The length of time in which a stock could rebuild to B_{MSY} in the absence of fishing mortality
USCG	U.S. Coast Guard
USCOP	U.S. Commission on Ocean Policy
VMS	Vessel Monitoring System
